This is a comparatively rare affection in this country. It seems, however, to be on the increase; within the last two years the writer has seen six cases, and knows it to have been more common in the experience of others. In children it is even more rare than in adults. With the exception of a child under twelve at the University clinic, no cases have come under the writer's observation. In the literature of the disease few if any cases are reported under two years of age. The liver is one of the organs most frequently affected. In childhood it appears to be the organ selected in 70 per cent. of the cases. In the recent exhaustive work of Graham a few cases only are recorded. He states that within a period of one year he observed hydatids in ten children, their ages varying from five to eight years. The youngest case that he refers to is one operated on by Thomas, a boy aged two years and one month. This disproves the statement of Leuckart, who at the time of his publication believed the youngest cases recorded to have been four and six years of age respectively.

There is, therefore, no immunity for children if their associations are such as to cause infection. The infection may occur very early in life, but the slow growth of the cyst makes it possible that they are not recognized for years. Moreover, in childhood, as Graham remarks, "the organs in which the cysts are situated are less likely to be so completely affected as is the case in the adult subject where the pressure changes are more permanent."

Space will not permit a discussion of the mode of development or infection of the human species. The growth in the child and the manner of its infec-

tion do not differ from the same in adults (for description of which recent text-books on pathology contain sufficient information).

Symptoms.—The cyst in the liver may develop and reach a large size without recognition. Attention is first called to its presence by the occurrence of mechanical symptoms; the abdomen enlarges or there are enlargement and swelling of the liver region. On examination, if the liver be the seat of the disease, it is found to be enlarged. The enlargement may be uniform; usually, however, it takes place in a particular direction. If the growth springs from the convex surface of the liver, the area of dulness extends higher in the axillary region and behind in the scapular line. If it begins in the right lobe, and the lower portion thereof particularly, the extent of dulness is increased downward toward the umbilicus. Sometimes the tumor is confined to the left lobe of the liver, and hence is recognized in the epigastric region. The prominence in the epigastric region or below the ribs in the mammary line is smooth and tense on palpation; sometimes fluctuation can be detected. In a moderate proportion of cases the so-called hydatid fremitus is elicited, if the left hand be placed over the tumor and another portion tapped quickly and forcibly with the right.

The tumor is painless, and there is no tenderness on pressure. The patient suffers from distention. There is interference with respiration, so that frequently he is compelled to sit up in bed in order to alleviate the dyspnoea. The general health is usually unaffected.

In some cases the cyst is in such relation to the hepatic duct as to cause compression jaundice. The jaundice usually develops gradually. In rare cases the cyst breaks into the hepatic duct; some pain follows this accident, and on account of the obstruction by the cystic contents jaundice develops. If the patient comes under observation after rupture of the cyst has taken place, the diagnosis is rendered more obscure. The enlarged cyst has been dispersed, and therefore most of the signs of tumor disappear.

Suppuration of the cyst sometimes takes place, and in addition to the symptoms due to hepatic pressure those of pyæmia arise,—rigors, periodical elevations of temperature, sweats, and great prostration. Jaundice occurs either because of the pyæmia, or, if it be intense, because of obstruction of the ducts and probably suppurative cholangitis.

The outcome of cases of hydatid disease varies. The liability to rupture is the same at all periods of life; perforation may take place into the stomach, the colon, the pleura and bronchi, or in some cases externally. It has been said that in a few cases where this accident has occurred recovery has taken place. The perforation may also take place into the pericardium or the vena cava; when this accident occurs death takes place suddenly.

Diagnosis.—A diagnosis is not usually difficult. Irregular enlargement of the liver, the surface of which is smooth and painless, or the presence of a tumor of the same character connected with the liver, probably fluctuating, in an individual otherwise in good health, usually indicates the presence of this disease. If the cysts are multiple, and the surface of the tumor, therefore, irregular, the diagnosis is more difficult. The health is usually retained, and the benign nature of the enlargement thus inferred. Syphilitic disease of the liver and carcinoma must be excluded in adults. The rarity of the latter affection in childhood and the absence of a primary focus of malignant disease, with retention of health and strength, exclude cancer. In syphilis the enlargement of the liver may be irregular and a distinct boss recognizable. This usually occurs in tertiary syphilis, a form not seen in childhood. In congenital syphilis involving the liver large prominences are not seen. Nevertheless, in both

instances it is well to resort to exploratory puncture, and, if syphilis be suspected, to the treatment as a test in diagnosis. If suppuration takes place in the cyst, it cannot be distinguished from abscess unless it be known before the accident that there was a painless enlargement of the liver without fever. In adults dilatation of the gall-bladder has been mistaken for hydatid. This condition does not occur in childhood, and hence need not be considered. Hydro-nephrosis has also been mistaken for hydatid disease. The condition is not common in children, but can be distinguished by the results of exploratory puncture. When the cyst extends upward, it is often difficult to distinguish it from a pleural effusion. The same physical signs in the lower part of the right chest may be present as in effusion. Frehriehs believed that the direction of the upper line of dulness is significant in hydatid disease of the liver. It does not take the S curve, as in effusions, but reaches the highest point at the angle of the scapula. Sometimes empyema complicates a hydatid cyst, as in cases reported by Murchison. The cases that are most difficult of diagnosis are those which have ruptured into the lungs before coming under observation. The appearance of hooklets in the sputum is characteristic.

Reference has been made in the beginning of this article to results of exploratory puncture in cases of suspected hydatid disease. The fluid withdrawn has special properties which render the recognition of the disease absolute.

Prognosis.—From results of observation at the post-mortem table we see that a number of cases of hydatid disease of the liver undergo spontaneous cure. These cases, of course, are not recognized during life. If the disease is recognized and the tumor is accessible, the prognosis is very good. The results of treatment are generally quite favorable.

Treatment.—Internal medication is of no avail and need not be discussed. Surgical procedures are necessary. Electrolysis has been used, but since the advent of antiseptic surgery has fallen into disuse. Medicated injections are not in high favor. Iodine, carbolic acid, solution of bichloride of mercury, and permanganate of potassium have been used, but the treatment is open to objections. Indeed, at the present time all methods except free incision are discarded as more or less dangerous. The uncertainty that attends the introduction of the trocar and the possibility of infection render such methods more or less hazardous, while the difficulty of completely emptying the cyst renders it liable to recur after the fluid is withdrawn. Recamier's method of opening into the cyst by caustics or the thermo-cautery has been employed. The method is tedious and painful, and not without danger.

The treatment by direct incision and evacuation of the contents of the cyst has been rendered possible by the developments of abdominal surgery. Incision should be made over the most prominent part of the tumor in the manner of performance of a laparotomy. After the cyst is exposed it should be attached to the edges of the abdominal incision; it is then opened by the knife and its contents evacuated. The daughter-cysts may be evacuated by forceps. Too much force must not be used. In order to secure complete evacuation irrigation of the cyst-cavity must be employed. A drainage-tube is then inserted and the patient dressed as in an abdominal operation. If the cyst grows from the upper surface of the liver, it must be evacuated by passing through the diaphragm. One or two ribs should be resected, the pleura stitched to the diaphragm, and evacuation then brought about by the previous method.

In cases that have been operated upon a form of urticaria known as the *hydatid rash* is sometimes seen. It is said that the fluid of a hydatid cyst

will not cause peritonitis. Any portions of the cyst-wall that are left behind or any of the daughter-cysts will cause suppuration.

CIRRHOSIS OF THE LIVER.

Through the writings of Palmer Howard, of Edwards, of Hatfield, and others we have learned that in its etiology, clinical course, and mode of termination cirrhosis of the liver in childhood does not differ from that in adult life.

Etiology.—Alcoholism is a very constant factor in its causation. The habit is usually fostered because of the delicate state of the child in early infancy, coupled with the belief of ignorant parents that rum contributes to its development. It is true some children from their swaddling-clothes have an appetite for liquor, and when not discouraged are likely to develop all the lesions of alcoholism. Syphilis, as already mentioned, is another prominent cause. In Howard's cases an adhesive pyelephlebitis took place primarily, followed by secondary cirrhosis. In some of the recorded cases chronic heart disease was the causal factor. The infectious fevers, as scarlatina and measles, play an important part. Tuberculosis is attended by a form of cirrhosis both when the liver is involved in the tuberculous disease and independently of it. Howard and others believe that ptomaines and products of imperfect digestion may be productive of this affection. In rickets there is often found enlargement of the liver which is due to an overgrowth of connective tissue.

Hypertrophic or biliary cirrhosis is rarely seen in childhood. It is due to chronic obstruction of the biliary passages, and hence is present in congenital obliteration of the ducts.

From the recorded cases collected by the above-mentioned authors, cirrhosis of the liver has been found to occur more frequently in males than in females in the proportion of two to one. The largest number of cases occur between the ninth and thirteenth years. It is found, however, at birth, and may occur at any period subsequently.

Symptoms.—In the early stages of the disease capillary congestion is noted in the face. This may increase. As the disease advances the face becomes drawn, the parts free from stigmata are pale, or a sallow, muddy complexion is seen. The symptoms due to obstruction are usually most prominent. Gastro-intestinal catarrh is observed. Morning nausea and retching with discharge of mucus take place, the appetite is poor, the bowels irregular, alternating attacks of diarrhoea and constipation take place, and the bowel movements usually contain considerable mucus. Hæmorrhages from the lower end of the œsophagus, the stomach, or the intestinal tract may occur, and are very characteristic symptoms of cirrhosis. In gastric hæmorrhage the vomiting has no relation to food, and is not associated with symptoms of gastric ulcer. In the later stages of the disease hæmorrhages occur from the nose or the mouth, and purpuric spots develop. They are due to the state of the blood. Hæmorrhoids are frequently present.

Jaundice occurs in about the same degree of frequency as in the cases of adults. It is usually slight, and may disappear and recur two or three times in the course of the disease. Slight fever is seen in many cases. The temperature rises to 101° and 102° in the evening. It may be present for a long period of time, and as the end approaches disappear entirely.

The urine is high-colored, of high specific gravity, and contains an excess of urates and uric acid. Frequently nephritis develops in the course of the affection. Albumin is then found, and the urine contains hyaline and granular casts. The specific gravity always remains high, and there is an excess of

lithates. From time to time sugar may be detected, but a persistent glycosuria is not likely to arise.

On physical examination, when the disease is somewhat advanced, further evidences of portal obstruction and attempts at compensatory circulation are seen. The venules along the base of the thorax, extending across the chest in an arc, following the attachment of the diaphragm, are very distinct. The external veins, particularly the epigastric and mammary, are particularly distinct. If compensation does not take place, ascites develops, and after its development the feet may swell. The spleen is frequently enlarged, but its size often cannot be determined when ascites is present. The liver is found to be enlarged if the case is seen in the early stage, and it may be slightly tender on palpation. Subsequently it diminishes in size, or the small size is at once noted. The diminution of the left lobe is particularly noticeable. With the walls relaxed the edge and surface can sometimes be felt rough and granular. Some cases are not attended by atrophy. Thus there may be much fat in the liver, and, notwithstanding the connective-tissue overgrowth, the organ remains enlarged. Fatty atrophy of the liver is the name applied to this form. In "biliary cirrhosis" the liver is enlarged and smooth. Jaundice is permanent, and the other symptoms of cirrhosis are present.

On account of the organic disease of the liver auto-intoxication takes place with ptomaines or products of imperfect digestion. Low delirium, deepening into stupor, with the occurrence of frequent convulsions, or noisy delirium followed by convulsions, show the effect of the toxine on the nervous system. Jaundice is not necessarily present when these symptoms develop.

Diagnosis.—The disease may be far advanced, and not recognized because of the absence of symptoms or signs. A boy aged fifteen years died in the Presbyterian Hospital of typhoid fever. He had been under the observation of the writer for nine years. Acute rheumatic fever with endopericarditis was the reason of the first consultation; valvular disease continued. The patient had been in poor health, and the parents were wont to give him spirits. This had been continued more or less until the fatal illness occurred. At the autopsy cirrhosis of the liver in an advanced degree was discovered.

The appearance of the face, the symptoms of portal obstruction, and the physical signs of atrophied liver are points on which the diagnosis is based.

The occurrence of subacute gastritis with morning vomiting, of hæmatemesis, and of malæna, without the physical signs of a small liver, are nevertheless most suggestive, particularly if the patient be poorly nourished, with a drawn, pallid countenance, and especially congestion of the cheeks—venous stigmata. If ascites, enlargement of the spleen, and jaundice supervene, the diagnosis is absolute.

Treatment.—We can never tell whether the enlarged liver of the early stage of cirrhosis is one in which congestion predominates, or, on the other hand, one in which the overgrowth of connective tissue is in excess. If the former, we know that there are measures which markedly influence the engorgement. If the latter, it is possible a further increase may be averted by proper hygienic and prophylactic measures. It is our duty, notwithstanding the uncertainty, to relieve engorgement. External depletion by cups and leeches, purgatives in quantity to ensure three to six liquid stools a day, Rochelle salts, citrate of magnesium, and saline waters, are to be used. The waters of such springs as Saratoga and Bedford in this country, and Carlsbad in Germany, are beneficial. Counter-irritation in mild degree is likewise of value. If leeches or cups are inadvisable, stimulating liniments may be employed. The diet is to be carefully selected. A milk diet is for a time the most satisfactory.

Stimulants and rich, stimulating articles of food, fats, sugars, and starches are to be avoided. Waters are to be used abundantly; they may be taken hot in large bulk (a glassful) when the patient is fasting to flush the liver.

Phosphate of sodium may be advantageously added to waters to produce a depurative effect. At first small doses of calomel or mercury with chalk should be given for a few days. A furred tongue, nausea, constipation, with pasty stools, indicate its use. From time to time it should be repeated. Iodide of potassium has been said to relieve the engorged liver in the early stage of cirrhosis, but the chloride of ammonium is a better drug, in doses of five to ten grains in syrup of licorice or in emulsion, given every four hours.

The treatment of the second stage is entirely symptomatic. Gastro-intestinal catarrh, hæmorrhages, ascites, jaundice with its resulting phenomena, and finally the distressing symptoms of the cirrhotic cachexia, require in turn, or too frequently at the same time, careful therapeutic and dietetic management.

Whatever the symptoms may be, the diet plays a most important part. The class of food referred to above is to be selected; from time to time a strict course of milk diet may be instituted. Again, with the ascites most prominent, a dry diet should be advised. The condition of the stomach and bowels very largely determines the character of diet. If there be much intestinal dyspepsia, albuminoid food should be administered. Meats chopped fine and made into a pulp can be given for a long period of time. In order to create free discharge of the products of digestion, large quantities of water should be taken once or twice a day. The disadvantage of a continuous meat diet arises in the possible development of scurvy. This may be counteracted by the use of lemon-juice once or twice in twenty-four hours. The gastro-intestinal catarrh is treated by the same class of remedies as are indicated and have already been detailed in the management of catarrhal jaundice.

Hæmorrhage from the stomach is to be treated by rest, the use of cracked ice, the external application of the ice-bag, the administration of food by the rectum, and the use of astringents. An opiate should always be given to quiet the agitated patient. Morphine hypodermatically or dry on the tongue may be selected, or the deodorized tincture of opium combined with the chosen astringents used. Gallic acid is one of the preferable astringents; aromatic sulphuric acid may also be employed. Both should be given well diluted in iced water:

R̄. Tr. opii deodorat.

Acid. sulphuric. aromat. āā f̄j. —M.

Sig. Eight to ten drops every two, three, or four hours, well diluted.

The acetate of lead alone or with bismuth is a valuable astringent. Hamamelis may be given in the form of the fluid extract well diluted; twenty drops is a sufficient dose, and may be given every one or two hours to a child of ten. Astringent preparations of iron usually are advised—the sulphate, the chloride, and the penitrate. They should be given in small doses frequently repeated. If nausea and vomiting are not present, ergot might be used; the writer, however, has never had any benefit from its use; indeed, gallic acid and the aromatic sulphuric acid have been sufficient to control the bleeding. Intestinal hæmorrhage may be treated by astringents by the mouth or by enemata. If bleeding be from the rectum or the lower portion of the colon, weak solutions of alum or of salts of iron by enema are of special value. The solution should be cold if the bleeding is from hæmorrhoids. One-half drachm of Monsel's solution to three ounces of water are the proper propor-

tions for enemata of this character. Ice may be used in the rectum, as well as ice-water. By the mouth the astringents advised for gastric hæmorrhage can be used. It is best to administer them in such form that they will be dissolved in the intestine; a one-grain pill of Monsel's salt may be given every half hour or hour. The pill should be hard. Acetate of lead in pill may also be given. In this class of cases aromatic sulphuric acid has been sufficient in the writer's experience. Turpentine has been advised by competent authorities, and may be given in capsule in doses of two or three drops every two hours. The oil of erigeron is also considered to be a valuable styptic.

If the ascites be not too great or of too long standing, it may be removed by dry diet and diuretics. Alkaline diuretics are particularly of service. Cream-of-tartar lemonade and infusion of scoparius are excellent diuretics. Saline waters which act on the kidneys and the bowels are of great service. Gentle catharsis may be maintained without fear of exhaustion if salines be used. On account of the tendency to intestinal catarrh, irritating cathartics should not be employed. At times the effusion seems to come to a standstill; the bowels have been sluggish, and the internal viscera apparently loaded with stagnated blood from passive congestion. A brisk cathartic often relieves engorgement and starts up absorption of the exuded fluid. In children the compound jalap powder is the best of the class. It should be given in doses of twenty grains; the amount may be increased if necessary. If the simple diuretics and cathartics are of no avail, four measures are to be considered and may be tried:

1st. The use of calomel with diuretics, as in the well-known pill of calomel, digitalis, and squills. It may be given in accordance with the following formula:

℞. Hydrarg. chlorid. mit.	gr. $\frac{1}{16}$.
Pulv. digitalis	gr. $\frac{1}{4}$.
Pulv. scillæ	gr. $\frac{1}{4}$.—M.

Ft. pil. No. i.

Sig. To be taken every three hours.

After this combination is administered for ten days it should be withdrawn and squills and digitalis given alone. It then may be resorted to again, the frequency of its use depending upon the effect of calomel on the bowels.

2d. Caffeine is a valuable diuretic, particularly if stimulating effects are desirable. Dose 1 to 3 grains to a child under ten. The hydrochlorate of cocaine is another drug of the same class, and seems to have been of service.

3d. Copaiba. This is a most valuable drug in ascites. Its diuretic effect is decisive and usually permanent; it is to be given in capsule; three minims is sufficient for a child, to be taken every four hours.

4th. Paracentesis. Paracentesis should be employed early and frequently, if after a short trial the remedies above indicated do not lessen the amount of effusion. No hesitancy should arise on account of danger, as no accidents or complications are likely to occur. A number of cases have been reported in which frequent tapping has cured the ascites, and thereby arrested for a time at least the progress of the hepatic disease.

The treatment of jaundice need not require further consideration, for it has been discussed fully in a previous portion of this article. The symptoms of the cirrhotic cachexia which ensue in the latter stages of this malady are alleviated by careful nursing, attention in detail to diet, and the administra-

tion of remedies which secure full functional activity of the various organs of the economy. This particularly applies to the circulation. Cardiac tonics are indicated. Stimulants should not be withheld, and now are of service to counteract prostration, aid digestion, and increase the strength of the heart and circulation. All measures that can be invoked to relieve exhaustion, improve anæmia, and aid nutrition should be resorted to. The administration of concentrated food—animal broths, meat extracts, etc.; the inhalation of oxygen; the use of stimulating baths and lotions; measures to prevent the development of bed-sores,—each or all may be used as indications demand. Proper clothing, in order that the extremities and abdomen may be kept warm, must be insisted upon. At this stage multiple hæmorrhages and purpura are liable to ensue. The internal administration of astringents, but more particularly of turpentine, or the oil of erigeron, appears to check their development.

PERITONITIS; TUMORS OF THE PERITONEUM AND OMENTUM; AND ASCITES.

BY J. HENRY FRUITNIGHT, A. M., M. D.,

NEW YORK.

I. ACUTE PERITONITIS.

THIS affection is an acute inflammation of the serous membrane lining the abdominal cavity and covering the abdominal viscera. It is characterized by a tendency to effusion, by adhesions through coagulable lymph, and by the deposition of purulent or sero-purulent fluid. Such an inflammation may be confined to a portion of the membrane, when it is said to be circumscribed or local, or it may involve the whole surface of the peritoneum, and thus become general. At the onset only will it be circumscribed or limited, for, unless checked, it quickly manifests a disposition to extend over the whole of the inner surface of the peritoneal sac.

Etiology.—Peritonitis may occur during intra-uterine life, in the new-born, and during infancy and childhood. In early life idiopathic peritonitis is not a very frequent disease, since at this period the peritoneum is not so susceptible to inflammation as the serous membranes of the thoracic and cranial cavities. When it occurs during intra-uterine life, it is always traceable to syphilis in the parents. It may cause the death of the fœtus in utero, or the child may be born suffering from the disease or its consequences. So far as is known, no symptoms in the mother serve to indicate the existence of peritonitis in the fœtus. If it be not fatal before birth, the resulting adhesions are very apt to interfere with the development of the intestines or to cause a constriction of a portion of the bowel.

In the new-born, acute peritonitis is most frequently the result of septic or pyæmic processes. It is usually caused by an unhealthy inflammation of the umbilicus or by the absorption of septic matter at that point. (See Diseases of the New-born.)

In infancy and childhood an attack may be traced to exposure to wet and cold. Thus, wetting and chilling of the feet, damp beds, chilly winds, sudden alterations of temperature, rapid cooling of the heated body, and excessive fatigue may be enumerated under this head as causes of acute peritonitis, just as they may act in the production of inflammation in other structures. Very often traumatism may serve as the exciting cause, and here may be enumerated contusions, direct blows upon the abdomen, and the wounds of cutting or blunt instruments produced accidentally or surgically, as in paracentesis abdominis. Again, various mechanical causes (which are in reality traumatic in their nature) may operate in its production, such as intestinal invagination, strangulated hernia, displacements of some of the internal organs, or laceration or unusual stretching of the peritoneal membrane. In like manner, peritonitis

may be caused by the extrusion of foreign matters into the serous cavity, as in ruptured hepatic or splenic abscess, rupture or perforation of the stomach, bile-ducts, spleen, uterus, urinary bladder, ureters, or some part of the intestines. It may follow or accompany acute disease of some organ by contiguity of structure; and here may be mentioned gastritis, splenitis, hepatitis, dysentery, ulcerations in typhoid fever, and ulcerations of the vermiform appendix, appendicitis, and the like. Numerous instances have been encountered where an empyema perforating the diaphragm has set up acute peritonitis; and this result has been observed even in the absence of perforation, the lymphatics acting as the channel of communication. In girls purulent vulvo-vaginitis has frequently caused acute peritonitis by an extension of the inflammation through the uterus and Fallopian tubes. At times also it may result from pressure and ulcerative absorption caused by tumors and malignant growths. The sudden retrocession of a cutaneous eruption has sometimes been closely followed by an attack of peritonitis, and it is on record that lumbricoid worms have penetrated the bowel and thus acted as an exciting cause.

Finally, it may occur as a complication of, or a sequel to, rheumatism, erysipelas, pernicious intermittent fever, and the various exanthemata.

It has been quite well established that in the development of peritonitis micro-organisms, rendered operative by any of the before-mentioned local disturbances, must be regarded as the essential causes. When, experimentally, non-pathogenic microbes, even when combined with small amounts of chemical irritants, are injected into the peritoneal sac, purulent peritonitis is not produced, but only a serous inflammation. On the other hand, when pathogenic micro-organisms are introduced even in very small quantities, severe fibrino-purulent peritonitis ensues. The micro-organisms which produce peritonitis are those found in pus, the staphylococcus, and the streptococcus. Before they can increase in number a preceding or accompanying change in the peritonium is necessary. If the absorptive powers of the peritoneum be greatly changed, the microbes will effect a putrefaction of the intraperitoneal fluids, and as a consequence will produce a general putrid infection of the whole system.

Pathological Anatomy.—The transparent and shining appearance of the membrane is lost. This is accompanied by a diminution of the lubricating secretion, rendering the serous membrane less moist. The subperitoneal vessels become turgid with blood, are visible through the thin membrane as an interlacing network, and when they are greatly distended the peritoneum presents a velvety appearance. At times the blood exudes through the coats of the vessels, when puncta or plaques of sanguineous effusion are seen. Later, if the disease progresses, the serous secretion is increased in quantity and altered in character, being composed of liquid serum and a more solid or glutinous material known as coagulable lymph. It may happen, however, that the effusion is entirely composed of serum; or, on the other hand, serum may be altogether absent. In metastatic peritonitis or in attacks of asthenic character the effusion may be puriform or distinctly purulent, while in sthenic cases the deposit of lymph may vary from a very thin layer to a thickness of several lines, and it is usually of a yellowish color. When abundant, it may be found in layers, smooth or corrugated, or it may exist as bands of adhesion uniting the viscera with each other or with the parietal peritoneum. At first villous in appearance, it afterward becomes smooth and denser, and finally assumes a structure similar to true peritoneal membrane. When once formed, plastic lymph acts as an irritant to the serous surfaces with which it may come in contact—a fact which serves to explain how inflammation is so apt to be diffused over the entire

peritoneal surface. When health is restored these bands of adhesion may partly or entirely disappear. If they continue they may cause little inconvenience, though it may happen that, by their topographical relations, they may interfere with the functions of the organs to which they adhere. In children the effusion is most commonly purulent; it may be merely puriform, decidedly purulent, or simply sanious. Ulceration may occur through the abdominal walls or through the diaphragm into the lung or bronchi, or again through the digestive tract, the bladder, the vagina, or through the psoas muscle, permitting pus to escape from the peritoneal cavity by one of these various channels.

When peritonitis exists as a sequel to scarlet fever, measles, rheumatism, or other fever, the serous fluid is in excess, whilst the plastic lymph is inconsiderable in amount or nearly absent. The results of an attack, while at times causative of further disease, may in other cases be protective against more serious accidents: adhesions may supervene which will seriously interfere with the functions of the organs or parts which are bound down or united by these bands; on the other hand, as in some cases of perforation, this same inclination to plastic exudation may be conservative of life, the deposit being a means by which nature seeks to effect reparation.

Symptoms.—The earliest and most pronounced symptom of peritonitis is pain. At first the area of pain may be limited; afterward it will extend over the whole abdomen. The pain is accompanied by high fever and decided constitutional disturbances, such as rigors and general malaise. Pressure over the abdomen and augmented action of the abdominal muscles, as in deep inspirations, coughing, sneezing, expectoration, and the like, will aggravate the pain. The lightest weight cannot be borne upon the abdomen; hence the little patient assumes a position which will relax the abdominal walls as much as possible, and lies quietly on his back with his knees bent and thighs flexed. The belly is hot, rounded, and tense, almost invariably swollen and tympanitic from accumulation of flatus due to paralysis of the muscular coat of the intestines. Sometimes flatus may be readily passed per anum, at others not; and in this case symptoms of intestinal obstruction are simulated. The bowels are usually constipated, though diarrhœa is occasionally met with. Vomiting is nearly always present from beginning to end, and is aggravated whenever food is taken, until the presence of bile and fecal matter in the ejecta may be almost suggestive of some mechanical bowel obstruction.

The skin is hot and dry; the temperature, as a rule, is elevated, ranging from 101° to 105° F., but it becomes subnormal if the attack terminates in collapse. Inflammation of the peritoneum, however, may coexist with a normal or subnormal temperature, and this very frequently happens in the purulent cases. The pulse is small, feeble, rapid, and wiry. The respirations are accelerated, short, incomplete, and jerky, and are costal in type, the abdominal wall remaining motionless. The tongue is coated and the breath is foul. The face is expressive of great suffering and anxiety, and when the attack is very severe, the alæ of the nose are drawn upward, the nostrils are dilated, and the lips are parted, so as to expose the teeth, producing the expression known as risus sardonius. The urine is scanty and high-colored, and often contains albumin.

When the attack is to terminate in recovery all these symptoms gradually diminish in intensity, whilst the countenance, which has been so truthful an exponent of the patient's condition, once more becomes placid and natural. If the attack is to eventuate in death, the pulse becomes quicker and more thready, the general surface cold and clammy, the extremities chilled, and the breathing

shallower and more rapid, until life goes out from failure of the general vital forces. In a few cases incoherency of speech or active delirium is present toward the end, but most generally the mind remains clear and logical to the last. The fatal issue of an attack may take place in two or three days, though frequently the patient may live until the sixth, seventh, or eighth day.

Diagnosis.—Peritonitis in its severer forms is readily recognized, but when subacute or circumscribed, or when it is secondary or exists as a complication, it is not so easy of diagnosis. In young children it is especially difficult to determine its presence because of the uncertainty of exact localization of pain. In erratic cases also pain may be absent, and thus we will be hampered in diagnosis. The diseases simulating acute peritonitis are gastritis, enteritis, colic, rheumatism, neuralgia, renal calculus, and lead-poisoning. The diagnosis must depend upon the severity of the symptoms, special attention having been paid to the history of the case. If there be persistent vomiting of all fluids and solids, with the presence of sharp paroxysmal pain, accompanied by tenderness on pressure upon the abdomen, with cessation of the abdominal respiratory movements, a frequent, wiry pulse, and fever, the diagnosis of acute peritonitis may be made with reasonable certainty.

Prognosis.—In the generalized form prognosis is always grave. It has been said that there is no more fatal disease, recovery taking place in rare cases only. The more pronounced the symptoms are, the more doubtful will be the prospect of recovery; and if the patient shall have passed into the stage of collapse, a fatal termination is usually to be expected. An acute peritonitis which is metastatic in origin or which is due to perforation is generally fatal. Diarrhoea is of evil portent, and constant vomiting with complete obstruction of the bowels is a very grave symptom.

Although the general prospects of recovery are so slight, yet patients apparently moribund have been known to get well. The attack may last but a few days, or even only from thirty-six to forty-eight hours, and very rarely indeed longer than a week.

Treatment.—The cause of the attack will determine the treatment to be followed in a given case. Unfortunately, however, the physician will not always be in a position to know accurately what this may be or what exact anatomical lesions may exist. The patient must be confined absolutely to bed. All food and drink must be stopped, only cracked ice or iced water to moisten the mouth being permitted. This interdiction of all ingesta must be imperative, in order to avoid the harassing and painful vomiting. Nutrition can be maintained until the cessation of vomiting by the use of enemata or suppositories containing appropriate substances, as broth, milk, egg-albumin, stimulants; later, when the vomiting shall have been overcome, the food should be limited to twelve or fifteen ounces (best predigested) per diem. Ice pills may be given to control the vomiting, also iced champagne in small doses frequently repeated, as well to soothe the feeble stomach as for its stimulating effects. Locally, various remedies have been employed. Soft flannel cloths saturated in a solution of tincture of iodine in castor oil and applied over the belly have been highly recommended. Local bloodletting by the application of from four to twelve leeches to the surface of the abdomen is often very valuable in the initial stage. The inunction of mercurial ointment to the abdomen was formerly much in vogue. Stupes, made by steeping flannels in a pint of hot water containing ten to twenty drops of spirits of turpentine and sprinkled with laudanum, are often of great service. Light flaxseed-meal poultices, dashed with oil of turpentine or laudanum and laid upon the abdomen, have in my hands been of great value. Care should be taken that the poultices be

not too hot, lest the integument be burned. By some physicians cold applications, such as the ice-bag or cold-water coil, are preferred, but children almost always resist their use.

As to the methods of internal treatment—whether by saline purgatives or by opium—a difference of opinion still exists among physicians of equal skill and eminence. It will be safe to abide by the following conclusion: When an attack of acute peritonitis is recognized almost at the moment of its inception, salines by their rapid and complete depletion may abort an attack. The peritoneum will be drained of the products of inflammation, the formation of bands and adhesions will be prevented in consequence of the increased peristaltic action of the bowels, whilst, clinically, pain will be relieved as quickly as by the administration of opium. On the other hand, if the case is not seen by the physician until some hours after the commencement of the attack, and especially if grave doubts exist as to the cause of the disease, opium and external methods of depletion must be used. It need scarcely be said that in perforative peritonitis the purgative treatment must not be thought of at all.

In case it has been decided to administer a purgative, either a seidlitz powder or some other mild saline or calomel is to be preferred for children. When opium is to be given—which should always be the case when there is intense pain, tenderness, constant vomiting, and a distended and paralyzed condition of the bowels—it should be given in quantity sufficient to relieve pain, to reduce the frequency of the pulse and respiration (the latter to about twelve movements per minute), and to make the little patient slightly drowsy. Two to five minims of the deodorized tincture of opium, or one to four grains of Dover's powder, may be given every four hours, according to indications, at the age of six years. The effects of the opium must, of course, be narrowly watched, for, as is well known, children are very susceptible to its action. In older children morphine may be given either *per orem* or by hypodermatic injection in doses of from one-twelfth to one-sixth of a grain. The tincture of belladonna is frequently combined with the opium. Excessive tympany can be relieved by the use of laxative enemata in which spirits of turpentine or tincture of asafetida has been suspended; or, in case of their failure, the long rectal tube may be used. Free stimulation must be resorted to early, and such alcoholics as brandy, whiskey, and champagne are to be preferred. To these may be added, to assist in keeping active a flagging circulation, such cardiac stimulants as sparteine, strophanthus, and digitalis; these, if vomited, must be given by the rectum or under the skin. Later, when the attack promises to terminate favorably, every effort must be made to build up the system and to increase nutrition by the exhibition of tonics and easily-assimilated, nourishing food.

As soon as the diagnosis of acute peritonitis has been made, the question of opening and draining the peritoneal cavity will present itself. Here, again, differences of opinion are encountered. Some advocate an early and immediate operation, whilst others claim that, as cases recover without operation, it is better not to risk the added dangers of surgical interference. It may be considered proper to operate in the following forms of peritonitis: First, in the fulminating forms of the disease, which are characterized by a rapid advance of the symptoms, excessive vomiting and tympanites, feeble pulse, and great restlessness. Secondly, in cases in which collapse seems imminent in spite of treatment, and which present a decreasing temperature and a rapid pulse constantly growing feebler. Thirdly, in cases in which pus is present in the abdominal cavity, or in which a tumor is located in, or adjacent to, the abdomen. Fourthly, in cases in which the peritonitis is the result of perforation or ulceration of any of the abdominal viscera. And fifthly, when the peritonitis is

due to intestinal obstruction. In older children the chances of success are greater than in the younger ones. A certain number of cases will be met with in which the diagnosis will be questionable. It will, at times, be doubtful whether the exudation be purulent or composed only of lymph, and whether the inflammation has been general from the first, or has spread from the cæcum or other localized inflammatory area. In such cases it is held to be justifiable to perform an exploratory operation, which may, under some circumstances, be the means of saving the patient's life. To discuss the method of operation and the questions of drainage and irrigation is not embraced in the scope of this article, and for such details the reader is referred to the works on operative surgery.

II. CHRONIC PERITONITIS.

As a chronic affection peritonitis, with the exception of the tubercular variety, is rare. As early as 1838, Wolff published a study upon chronic peritonitis, and stated it to be an extremely common affection in children; but as all of his one hundred cases were reported cured, it seems likely that a large proportion were incorrectly diagnosed. Since then until quite lately the subject has received but little consideration at the hands of medical writers, and the opinion has gained ground that all chronic peritonitis, almost without exception, is tubercular (West). This view, however, has been considerably modified by the more recent studies of Baginsky, Vierordt, Henoch, and others, and it is now accepted that the peritoneum, just as well as the pleura, may be the seat of a simple chronic inflammation with serous exudation.

Chronic peritonitis may sometimes be the sequel of an acute attack of the disease, but it is more frequently an independent affection.

Etiology.—Most of the patients are females—a fact that suggests a possible connection in some cases between the peritoneal inflammation and a vulvovaginitis, which is by no means uncommon in little girls. Rarely a history of traumatism may be elicited, as in a case reported by Henoch, confirmed by post-mortem after a course of six weeks. In another group of cases a preceding exanthem may be the apparent etiological factor, as seemed to be likely in two cases—one observed by Fiedler, and the other by Henoch—both occurring after measles. The complete cure, after several tapplings, in Henoch's case leaves little doubt of its true character.

Symptoms.—The symptoms of non-tubercular chronic peritonitis are rather obscure. The abdominal pain is apt to be slight, whilst the constitutional symptoms are variable. Usually the health fails gradually; the appetite becomes capricious; there is alternate diarrhœa and constipation, the former of which may or may not be accompanied by pain; sleep is disturbed, and the skin is hot and dry at night. Subsequently, pain or a sensation of tightness in the abdomen is complained of, and after a time effusion of fluid takes place, fluctuation may be discovered on examination, and the cutaneous veins are turgid and well defined. The pain now becomes more marked; it is usually not localized, but shifts about from one spot to another; generally there is tenderness on pressure over the abdomen; still, the appetite may be fairly good, the tongue tolerably clean, and the bowels not particularly irregular. As the effusion accumulates dyspnoea appears; the pulse is accelerated; evening and morning exacerbations of temperature are observed; the child rapidly loses strength, becomes much emaciated from profuse diarrhœa, and eventually dies of exhaustion. Yet cases presenting all the symptoms of chronic peritonitis have been known to recover, the effused fluid and other products of inflammation being gradually removed by absorption.

Diagnosis.—When ascites is the only symptom, it will be necessary to differentiate between an effusion due to simple chronic peritonitis and one caused by obstruction to the portal circulation. The latter condition is comparatively rare in childhood, whether it be due to cirrhosis of the liver or adherent pericardium and mediastinitis; and the chances are immensely in favor of the presence of a chronic peritonitis. The ascites due to cardiac disease can be eliminated by careful examination of the heart. Since, in the beginning of the disease, the symptoms simulate those of chronic intestinal catarrh, one must be careful to distinguish between this affection and chronic peritonitis.

The differential diagnosis between chronic and tubercular peritonitis will very often be impossible. The point of greatest value, however, is the general state of the patient: in the simple form the general nutrition and well-being of the child suffer but little as long as digestion is not greatly disturbed nor the effusion overwhelming; while in the tubercular variety the early emaciation is striking. Search for bacilli in the effusion, even in tubercular cases, is often disappointing, and hence a negative finding does not exclude the more serious disease.

Prognosis.—This must be guarded, for, while most cases are decidedly unpromising, a certain proportion recover. The history and progress of a given case must give us the cue.

Treatment.—As the disease usually begins with an intestinal catarrh, our treatment must be directed toward that condition. The child must be placed under the best hygienic surroundings. Plenty of sunlight and, when possible, country air or a sojourn at the seashore, are to be insisted upon. The clothing should be carefully regulated to meet the exigencies of the case, the weather, and other external conditions; and a flannel bandage must be constantly worn about the abdomen. The patient should be kept at rest, and it is a good plan, in the warm weather, to wheel his couch into the open air as often as possible.

The diet should be bland, but nutritious. Moderate quantities of underdone chops or steak, fish, fowl, and eggs are all allowable; so also are milk and cream if they do not disagree, but starchy foods are better avoided.

Abdominal pain may be relieved by hot opium fomentations or inunctions of belladonna ointment; when these fail or in protracted cases, blisters or stimulating liniments, tincture of iodine, compound iodine ointment, and iodide of potassium ointment are useful applications. Frequently in these cases the application to the abdomen of a mild mercurial preparation, such as an ointment of the yellow oxide of mercury, about twenty grains to the ounce, will do good service.

In the way of medicines the mineral acids and preparations of pepsin are useful as aids to gastric digestion; and to combat the intestinal catarrh, bismuth, sulpho-carbolate of zinc, the bitter vegetable tonics, and alkalies should be administered.

The internal use of iodine is also beneficial. This may be administered in the form of iodide of potassium in guarded doses, which must be discontinued on the first indication of disordered digestion; but a preferable form is the syrup of the iodide of iron, in doses of from five to thirty drops, according to the age and tolerance of the patient, several times daily. I usually order it to be given in cod-liver oil, which is convenient and efficacious.

If the ascitic effusion shows no tendency to disappear by absorption, tapping by means of a very small trocar and canula should be resorted to, the fluid being allowed to drain away very slowly. It has been advised that during the first few weeks the fluid be drawn off once in twenty-four hours, the amount varying in quantity from one to two pints; then every two, every three days,

and, finally, once a week. Gradual improvement, it is said, usually takes place under this treatment. When the disease has defied every method of treatment, especially if the fluid returns quickly after repeated tapplings, permanent drainage of the peritoneal cavity has been recommended. If pus be present, incision and drainage should be practised. Recently coeliotomy and washing out of the peritoneal cavity have been advocated by some surgeons as a routine treatment. In some instances it may even be justifiable to perform an exploratory operation. However, in those chronic cases in which the symptoms are not urgent and the child is not failing, it will be the part of wisdom and prudence not to interfere surgically, but to wait on nature's efforts, supplemented by medical measures, to effect a restoration to health.

III. TUMORS OF THE PERITONEUM AND OMENTUM.

Tumors of the peritoneum and omentum, though rare in children, are occasionally met with.

Carcinoma of the peritoneum has been encountered in early childhood and even in foetal life. It may be primary, and then is often congenital, but it is much more commonly secondary. Scirrhus is the usual variety, and generally occurs in diffused nodules. The primary form is difficult to detect; the secondary, much less so, because its presence will be suspected when symptoms referable to the peritoneal cavity occur in the course of cancerous invasion of some other portion of the body.

Sarcoma of the peritoneum has also been met with in childhood, but it is of very rare occurrence. This variety of neoplasm may grow to such an extent as to involve the omentum, mesentery, and other parts in addition to the peritoneum; in fact, both carcinomatous and sarcomatous growths are apt to involve both peritoneum and omentum.

Lipomata may also grow from the peritoneum. They are encapsulated, and have no connection with any other organ.

Serous cystic tumors of the peritoneum also occur. These cysts are composed of pseudo-membrane, which during their evolution and organization includes a portion of the fluid exudation and receives an internal serous investment; they are attached to the peritoneum either by means of a thin neck or by a broad base. Cystic tumors of the peritoneum are difficult to detect, and must be differentiated from cysts of the omentum, from cysts of the various abdominal viscera, and from ascites.

Tumors of the omentum are quite rare in early life. Omental cancer is usually of the colloid variety, and it may grow to an enormous size. Carcinoma, however, is seldom limited to the omentum, the peritoneum being usually involved simultaneously. Again, when scirrhus invades the peritoneum the omentum usually suffers from the same disease. Cysts and hydatid tumors of the omentum are met with in children, the former not infrequently. The cysts are usually dermoid in nature, though simple serous cysts are encountered. Both varieties, but especially the dermoid, may suppurate.

Symptoms of all varieties of tumors, whether involving the omentum or the peritoneum, or both, are rather vague, particularly in their incipiency. Later, when they have grown larger, the so-called pressure-symptoms develop and aid us in making a diagnosis. Even then it is very difficult to make a correct differential diagnosis, the pressure-symptoms chiefly aiding in locating the site of the tumor, without throwing light upon its character.

Cancer of the peritoneum and omentum produces the signs of a diffuse, more or less acute peritonitis with effusion, the so-called cancerous peritonitis.

In the earlier stages of the disease the patient will complain of paroxysmal pain, which later will be more persistent. Lipomata are attended by no special symptoms beyond the growth of a painless tumor. Growths confined to the omentum are movable and occasion no functional disturbance of the intestines. In cystic tumors, either of the omentum or peritoneum, the abdomen is apt to be enlarged; if the tumor be superficial, it will be movable on palpation and give signs of fluctuation, which must be distinguished from the fluctuation of ascites. If the patient live long enough and the growth attain the proper size, true ascites will supervene. Pain, of course, will be most prominent in the cases of cancerous tumors. In time, whatever may be the nature of the tumor, but particularly in the cases of carcinoma, the general system suffers, nutrition is impaired, the patient is easily fatigued, his appetite fails, and, if the growth cannot be removed, a cachectic condition develops which at last terminates in death.

Prognosis is most favorable in cystic tumors, less so in lipomatous and hydatid growths, and fatal in the carcinomatous.

Treatment of cancerous tumors consists mainly of palliation of symptoms. Anodynes and opiates to control the pain are indicated, and, if the ascites become burdensome, paracentesis is to be performed. Attention to the general condition of the patient, sustaining his strength with good food and tonics, together with the observance of well-established hygienic principles, will embrace all that can be done for these unfortunate sufferers. Operative measures are not to be advised in these cases.

Operation, cœliotomy, has been more successful in cases of sarcoma, lipoma, hydatid growths, and particularly in cystic tumors. Cystic tumors may be excised or they may be aspirated and drained. As drained cysts are apt to refill, the radical operation, excision, is to be preferred, and it must always be resorted to when suppuration takes place.

The proper treatment for pressure-symptoms will be suggested by their characters in individual cases.

IV. ASCITES.

Ascites is an accumulation of fluid—usually serous—within the peritoneal cavity; occasionally chylous ascites occurs, but in children this variety is extremely rare. Essentially considered, ascites is not a disease. It is a symptom of either general dropsy or some local disease of the abdominal viscera, and consists of a transudation of liquid into the peritoneal cavity in consequence of disturbed circulation in the liver or of pressure exerted upon some portion of the portal circulatory system.

Etiology.—The most common cause of ascites in children is cirrhosis of the liver, which, in turn, is most frequently due to syphilis. It may also arise from a simple osmosis of the watery constituents of the blood, in which case it is but a local expression of a general hydræmia superinduced by some cachexia, and it is then often associated with hydrothorax or general anasarca. Again, it may result mechanically from an obstruction to the venous circulation caused by cardiac, pulmonary, or peritoneal disease. Neoplasms of the abdominal cavity, whether malignant or benign, and particularly lymphatic tumors situated in the hilum of the liver, will also cause it by mechanical interference with the circulation in the viscera.

Bright's disease and acute nephritis; organic heart disease; atelectasis pulmonum and emphysema; enlargement of the spleen and profound anæmia caused by malarial poisoning; the pressure of lardaceous lymph-glands upon

the portal vein and inferior cava; and occasionally chronic tubercular peritonitis, which interferes with the circulation in the peritoneum,—are other etiological factors. Interstitial nephritis is not so apt to cause an ascites as a general anasarca. Benign tumors in the abdominal cavity are exceptionally accompanied by ascites, malignant tumors constantly.

Pathology.—The pathology of ascites is comprehended in the lesions involved in the primary affection. The changes in the peritoneum itself are slight and inconstant. Sometimes this membrane has simply a reddened appearance, but not infrequently it is pale and devoid of any signs of inflammation.

Symptoms.—The constitutional disturbance attending the formation of an abdominal effusion usually passes unnoticed, but it may be ushered in with chilliness, nausea, headache, vomiting, colicky pain, or a brief, intermitting diarrhoea. Pain is absent unless the effusion is caused by peritonitis. When effusion has reached a certain point, the tenseness of the abdominal walls is apt to cause indigestion and irregularity of the bowels; the skin becomes dry and has an ashen or clayey look; and the navel protrudes and may be encircled by a plexus of dilated veins, termed “caput Medusæ.” In very large effusions the skin of the abdomen becomes stretched and glistening, and at times fine white striæ, similar to those which are observed upon the abdomen of a pregnant woman, make their appearance. The character of the pulse depends upon the primary disease; still, it is generally feeble and easily compressed. Provided no inflammatory disease coexists, the temperature is normal. The urine is variable in quantity, though usually diminished; then it is high in color, and may contain albumin and fibrinous casts. As a result of mechanical interference with the return circulation from the lower extremities ascites is very frequently attended by œdema of the feet and ankles. Large effusions, crowding against the liver, spleen, and kidneys, and forcing the diaphragm up to the second and third ribs, cause anæmia of these organs and collapse of the base of the lungs, with consequent general anasarca.

Finally, painful and difficult micturition or incontinence of urine, together with difficulty in evacuating the bowels, will ensue. The constant crowding upward of the diaphragm and liver causes dyspnœa, hydrothorax supervenes, and at last the child, unable longer to assume a horizontal position, dies either from asthenia or asphyxia.

Physical Examination.—Palpation and percussion reveal fluctuation indicative of the presence of fluid, which varies in position according to the posture assumed by the patient. Thus, whilst standing, the abdomen is largest in its lowest part; when prone it spreads laterally, and if the patient be turned on either side it falls toward the more dependent. In any of these positions percussion practised over the uppermost part of the abdomen, to which the gas-containing intestines always float if entirely free to move, gives a clear tympanitic note, and by successively altering the patient’s posture the tympany readily moves from point to point, while the dulness due to the fluid also changes its place. Wave-like fluctuation is another valuable sign.

Diagnosis.—The diagnosis of ascites is comparatively easy, yet it must not be forgotten that in children other conditions are often encountered which produce an enlargement of the abdomen. Naturally, the smaller the effusion the more difficult is it to make a diagnosis. When the abdomen is distended by a sufficiently large amount of fluid, wave-like fluctuation and movable dulness can readily be obtained, and leave no doubt of the diagnosis. Small effusions, although always obscure, are most readily detected when the patient sits or lies on one side.

In addition to detecting the presence of ascites, it is necessary to determine

the nature of the antecedent disease, as upon this prognosis depends. When the fluid is large in amount and movable, atrophic cirrhosis of the liver may be suspected. If the effusion be small and immovable and loculated, the cause is most probably tubercular peritonitis. This disease is characterized by the presence of disseminated nodules, and its symptoms are tenderness upon pressure, pain, and fever, possibly conjoined with indications of tubercular disease in some other organ.

Prognosis.—Though not always a hopeless condition, the prognosis is not very encouraging. Provided the primary cause upon which the ascites depends be removable, as in malaria or alcoholism, and the liver is not completely invaded by the disease, we may hope, by removal of that cause and by proper treatment and hygiene, to effect a cure of the abdominal dropsy.

Treatment.—In the milder degrees of ascites treatment consists in the administration of diuretics, diaphoretics, and hydragogue cathartics. Acetate of potassium, combined with digitalis and compound spirit of juniper, acts favorably. A very efficient combination is the following :

℞. Magnesii sulphat.
 Potassii bitartrat. āā ʒss.
 Aquæ cinnamomi fʒiii.—M.

Sig. A tablespoonful every three or four hours, according to its effect upon the bowels.

When great general anasarca coexists with the ascites, threatening interference with respiration and circulation, in addition to the free purgation hot vapor baths are to be recommended. These may be applied in the following manner: The patient, completely divested of clothing, is laid upon a blanket, and immediately several bricks, which have been in the mean time thoroughly heated by immersion in pails of hot water, and then enveloped in flannel cloths, are placed at the shoulders and feet. Care must be taken that they be neither too hot nor put too near the body, lest the skin be scorched. Another blanket is then thrown over the patient. The upper corners of the superimposed blanket are brought over and tucked under the opposite shoulders, while the other end of the upper blanket, with the lower end of the underlying one, are lapped together under the heels of the patient, and the head alone is left to protrude from this improvised sack. This hot pack is maintained for at least twenty minutes, producing profuse diaphoresis and usually greatly ameliorating the symptoms. The patient and his friends are apt to complain loudly of this heroic treatment, but I can recollect several instances where by its use the child was saved from imminent death; and often it will accomplish the end sought when all other measures have failed.

A strict milk diet is to be enjoined as a rule. When, however, hydræmia is prominent, iron, tonics, nutritious food, and good air, with a proper observance of all recognized hygienic rules, are indicated. In ascites depending upon atrophic hepatic cirrhosis squills, digitalis, calomel, and iodide of potassium will be of service. In this variety, however, the ordinary diuretics usually have but little effect. Here Basham's iron mixture is highly spoken of—viz.:

℞. Tinct. ferri chlorid.
 Acid. acetic. dil. āā fʒj.
 Liq. ammonii acetat. fʒvi.
 Aquæ q. s. ad fʒvj.—M.

Sig. Tablespoonful three times daily for a child of six years.

If, despite this treatment, the fluid continues to accumulate, paracentesis abdominis must be practised. This operation should not be performed too soon, nor should we delay it to the last moment. The proper time is when remedies fail after a fair trial and when, in spite of treatment, the patient's general health daily deteriorates. Ordinarily this operation is simple and free from danger. Either an aspirator or fine trocar and canula may be used, but I prefer the latter. This tapping can be repeated as often as the exigencies of each particular case may require. If fluid reaccumulates within three or four days, a retapping should be postponed as long as possible; if, however, a number of weeks elapse before the peritoneal cavity is refilled, the operation may be correspondingly deferred to that time.

Permanent drainage by means of a rubber tube under proper antiseptic precautions has been highly commended by Dr. A. Caillé, whenever, after one or two tappings, the ascitic fluid rapidly reaccumulates. When all other measures of treatment are futile, this method of permanent drainage should be utilized.

While the operation of paracentesis is very trifling, every antiseptic precaution should be employed. In order to produce local anæsthesia a hypodermatic injection of three to five minims of a 2 to 4 per cent. solution of cocaine may be made at the proposed point of operation, or the same result may be obtained by the rhigolene spray or the application of ice and salt. The *linea alba*, below the umbilicus, is the usual point of election except for loculated effusions. In the latter case, as distended veins ramify extensively over the abdominal wall, caution must be used not to wound any of them with the trocar. As the fluid escapes pressure is kept up by means of a many-tailed bandage: this lessens the risk of syncope and secures a thorough evacuation of the fluid. If the puncture has been made at the side of the abdomen, the patient must lie on the opposite side for some little time, so that the wound may cicatrize properly. This will obviate the occurrence of a fistula, a sequel which will prove a source of great annoyance to the patient, inasmuch as leakage soils the clothing and provokes cutaneous inflammation.

CONGENITAL INTESTINAL MALFORMATIONS

AND

DISEASES OF THE ANUS AND RECTUM.

BY HENRY R. WHARTON, M. D.,

PHILADELPHIA.

I. CONGENITAL MALFORMATIONS OF THE INTESTINES.

CONGENITAL MALFORMATIONS of the small intestine are met with much less frequently than those of the rectum and anus; in the Vienna Foundling Hospital only 9 anomalies of this nature were found among 150,000 infants. The malformation may consist of a stenosis or atresia of the gut; or the bowel may terminate in a cul-de-sac at the point of obstruction, and beyond this point again begin in a cul-de-sac, the remaining portion of the intestine being well developed; or the bowel may have a diverticulum given off which attaches it to the abdominal walls, and this may contain a fistula opening upon some portion of the body; or, finally, the defect may consist in an abnormal shortness of the intestinal canal. Holmes mentions two cases of congenital occlusion of the small intestine in which the diagnosis was satisfactorily established, and Dr. W. Craig reports a case of congenital malformation of the small intestine in a child who lived seventy-two hours, and in whom the autopsy showed an obstruction of the small intestine at the upper fifth of the ileum. The intestine in this case was distended above the point of obstruction, and upon opening the bowel it was found that it ended in a cul-de-sac; further examination of the gut beyond the point of obstruction showed that the intestine began in a cul-de-sac, and the intervening space between these two pouches was occupied by a band of fibrous tissue. The most frequent position of congenital occlusion of the small intestine is the duodenum near the point at which the biliary duct and pancreatic duct open, or at the point where the duodenum becomes jejunum under the transverse mesocolon. Malformations of the ileum are most common near the ileo-cæcal valve, or a short distance above it, where the ductus omphalo-mesentericus is given off. Among the congenital malformations of the small intestine may be mentioned that condition known as Meckel's diverticulum, which consists in a cylindrical or flask-shaped appendage attached to the ileum a metre or more above the ileo-cæcal valve, and is a remnant of the omphalo-mesenteric duct. Another form of this defect consists in the presence at the umbilicus of a reddish tumor covered with mucous membrane, which has been described as a *warty tumor of the umbilicus*, *congenital mucous polypus of the umbilicus*, and as *adenoma of the umbilicus*.

Congenital malformations of the large intestine are also of infrequent occurrence, but may involve the colon, the sigmoid flexure, or the rectum. The malformations of the large intestine may consist of an occlusion of the

gut at any portion of its length; or the gut may exist in a rudimentary condition. The latter defect is most apt to be associated with Meckel's diverticulum, with a fecal fistula between the ileum and the fissure above the umbilicus, or with a fecal fistula between the small intestine and some portion of the abdominal walls. Atkin reports the case of a child who died two days after birth, and in whom, upon autopsy, the rectum and colon were found to be in a rudimentary state, smaller than an ordinary quill; in this case the parts had remained in the condition in which they exist in the early embryo.

The various congenital malformations of the small and large intestine are probably largely to be attributed to accidents in development due to a complicated disposition of the intestinal tract of the embryo; and it is also likely that fetal peritonitis plays an important part in the production of these deformities. Therein is of the opinion that many of these anomalies are due to changes in the peritoneum which have taken place early in foetal life.

Symptoms.—The symptoms arising from congenital malformations of the large or small intestine are simply those of intestinal obstruction in a more or less marked degree, which depends upon the completeness of the occlusion; and all observers are agreed as to the absence of any definite symptoms accurately localizing the seat of the lesion. The vomiting of whitish mucus, with obstruction of the bowels, in the case of a new-born infant, points to an occlusion high up in the small intestine, and if the obstruction exists in the jejunum or ileum, this may be replaced by the vomiting of meconium. In such a case the symptoms would in no wise differ from those consequent upon the presence of an occlusion situated in the region of the rectum or anus. If a fecal fistula is present, the symptoms of obstruction will not be so marked, and the position of the fistula may serve as a guide to the situation of an intestinal malformation.

Diagnosis.—As before stated, the localization of the lesion is often most difficult. In a newly-born child who presents swelling of the belly with vomiting and obstruction of the bowels, the anus and rectum should first be examined to exclude the possibility of malformation of these parts; a soft catheter should be passed into the rectum, and if, upon injecting water, meconium is brought away, it can be inferred that the obstruction exists at a higher point of the intestinal canal.

Prognosis.—The prognosis is always unfavorable: complete occlusions of the duodenum or of the high portion of the jejunum must necessarily prove fatal in a short time; but when the obstruction is incomplete or occupies a position low down in the small intestine, or if associated with a fecal fistula, the patient may survive for some time, even for years. Complete occlusions are usually fatal within a few days unless relieved by operative treatment.

Treatment.—In cases of complete obstruction operative treatment must be resorted to promptly. Up to the present time the results obtained have not been encouraging; but with the improved technique of abdominal operations more favorable results may be looked for in these cases. As before stated, the diagnosis of the seat of the lesion is often impossible; but as in cases of complete occlusion the result is necessarily speedily fatal, it seems wise to attempt an exploratory operation with the hope of affording relief or bringing about a cure. A median laparotomy, unless there is some definite symptom present which points to the exact seat of the obstruction, should be the operation selected. If upon opening the abdomen the occlusion is found situated in the duodenum or high up in the jejunum, the case must be abandoned as hopeless, unless it be found possible to excise the occluded portion of the bowel and bring the ends together by sutures (circular enterorrhaphy), or to make

an attempt to establish the continuity by the procedure known as lateral intestinal anastomosis. If the occlusion is due to a membranous septum, this may be exposed by incising the gut, and after it has been perforated or cut away the intestinal wound should be united by Lembert's sutures and the abdominal incision closed in the usual manner. If the occlusion exists low down in the small intestine or in the large intestine, circular enterorrhaphy or lateral anastomosis may be employed, or an artificial anus may be made by bringing the gut to the abdominal wound, securing it there, and opening it. This latter procedure would seem to be the wiser one, as it requires much less time to accomplish it, and if the patient survives, after he has attained some age an attempt may be made to establish the continuity of the intestinal canal by lateral anastomosis. If a fecal fistula is present and there are no marked symptoms of intestinal obstruction, no operative treatment should be instituted; but if the patient exhibits symptoms of intestinal obstruction, the fistula should be dilated or incised, and, if relief be obtained, further operative treatment should be postponed until a later period.

II. CONGENITAL MALFORMATIONS OF THE RECTUM AND ANUS.

Congenital malformations of the rectum or anus occur, according to various observers, in the proportion of 1 case in 10,000 births.

Pathology.—These malformations result from arrested development of the parts in early foetal life. At its earliest commencement the alimentary canal consists of a simple sac or bag developed from the innermost layer of the blastoderm, partly within and partly without the body; and as development proceeds this communication between the two portions of the sac is shut off, and the portion within the abdomen consists of a simple tube, the *mesenteron*, which terminates at the anterior extremity of the embryo in a blind pouch, while at the posterior extremity a similar pouch is formed. The cul-de-sac at the anterior extremity of the embryo comes in contact and communicates with an invagination of the epiblast, which is called the *stomodæum*, while a similar depression of the epiblast at the posterior extremity of the embryo, named the *proctodæum*, forms the anal orifice and communicates with the mesenteron. The majority of malformations of the rectum and anus are due to an interruption in the latter stages of the process just described, or, in other words, to an arrested or irregular development of the proctodæum or mesenteron. The termination of the rectum in the genito-urinary tract is due, in addition to the arrested development just mentioned, to a similar arrested development in the perineal septum, which separates the rectum from the genito-urinary tract, both, in the early life of the embryo, having a common orifice. The failure of development of the perineal septum explains the frequency of cases of imperforate rectum and anus in which there is a communication between the intestinal tube and the genito-urinary tract.

The best classification of the malformations of the rectum and anus is that adopted by Bodenhamer, and is as follows: 1. Congenital narrowing of the rectum or anus without complete occlusion; 2. Complete occlusion of the anus by a membranous diaphragm or well-formed skin; 3. The anus is absent, and the rectum ends in a blind pouch at a point more or less distant from the perineum; 4. The anus is normal in appearance, but ends in a cul-de-sac, and the rectum ends in a blind pouch at a variable distance above this point; 5. The anus is absent, and the rectum ends by a fistula at any point of the perineum or sacral region; 6. The anus is absent, and the rectum ends in the vagina, the bladder, or the urethra; 7. The anus and rectum are normal, but the

ureter, vagina, or urethra opens into the rectal cavity; 8. The rectum is totally absent.

1. CONGENITAL NARROWING OF THE RECTUM OR ANUS, WITHOUT COMPLETE OCCLUSION.—This variety of malformation is probably more common

FIG. 1.

Congenital Narrowing of the Rectum and Anus.

than is generally supposed, as it escapes notice if the narrowing is not sufficient to produce marked symptoms of obstruction; and probably in many cases of this nature, in which the stenosis is not extreme, the efforts of the child in passing the feces bring about the necessary amount of dilatation. As the stenosis may not be sufficient to prevent the escape of the semifluid feces of infant life, the condition may not be detected for some time, and it is only as the child becomes older and the feces become more consistent that accumulation takes place in the rectum and attention is directed to the malformation (Fig. 1).

Treatment.—The treatment of this variety of congenital stenosis is best conducted by gradual dilatation, which may be carried out by the daily introduction into the bowel of graduated bougies, or by the introduction of the oiled index finger of the mother or the nurse, which is by far the best of all bougies for this purpose.

2. COMPLETE OCCLUSION OF THE ANUS BY MEMBRANOUS DIAPHRAGM OR BY WELL-FORMED SKIN.—In this form of malformation closure of the anus may be caused by a diaphragm of mucous membrane or skin, which appears to be due to the adhesion or skinning over of the surface of the anus, the rest of the proctodæum being normally formed (Fig. 2).

Treatment.—The treatment consists in making a crucial incision at the position of the anus, opening the rectal pouch, and evacuating the feces and trimming off the edges of the mucous membrane and skin. The wound should be dusted with iodoform and dressed with a pad of antiseptic gauze, and the subsequent management of the case consists in keeping the anus well dilated for some time to prevent cicatricial contraction.

FIG. 3.

The Anus is absent, and the Rectum ends in a Blind Pouch (after Ball).

3. THE ANUS IS ABSENT, AND THE RECTUM ENDS IN A BLIND POUCH AT A POINT MORE OR LESS DISTANT FROM THE PERINEUM.—In this variety of malformation the rectal pouch may terminate near the skin, or it may end high up in the pelvis and the space between it and the perineum be filled with cellular tissue, or in other cases a distinct fibrous cord can be traced from the termination of the rectum to the skin (Fig. 3).

Treatment.—In the treatment of this malformation—and, in fact, of all forms of imperforate rectum in which complete occlusion exists—the duty of the surgeon is very clear; he should, as soon as possible, attempt to reach the rectal pouch by a perineal incision. The earlier this is attempted the better, for delay in operating certainly conduces largely to a fatal result. I cannot subscribe to the opinion of those who advise delay until the rectum is distended with feces and gas, which may make

FIG. 2.

Complete Occlusion of the Anus by Membranous Diaphragm or Skin (after Ball).

the position of the rectal pouch more apparent, but which is not unattended with the risk of rupture of the intestine and exhaustion of the patient; and it has also been shown that by delay the meconium becomes reduced in bulk through the absorption of the fluids. It should be remembered that the rectum in infants descends in the hollow of the sacrum and is close to the bone, and except at its upper portion is uncovered by peritoneum posteriorly; in front its peritoneal investment descends to a much lower level, and its close relation in this aspect to the genito-urinary tract is an additional reason for the selection of the posterior region for exploratory operation. Various operative measures have been recommended and resorted to in cases of imperforate rectum.

Puncture with a Trocar Canula.—The introduction through the perineum of a trocar and canula was formerly advised, and by its use I have seen the rectum reached and meconium evacuated; but subsequently it is usually found necessary to enlarge the wound made by the instrument to secure free exit of fecal matter, so that the procedure possesses no advantage over the perineal incision, and has the disadvantage that the rectal pouch may be entirely missed by the trocar and important structures injured by its blind introduction.

Perineal Operation.—This is considered the best operation to undertake in these cases, since, if successful, it leaves the patient with an anus in the normal position, and often with fair control of the bowels, for the anal sphincter is frequently well developed in spite of the malformation of the rectum. In performing this operation the child should be placed in the lithotomy position, and the incision should be made in the median line of the perineum from the root of the scrotum to the coccyx. The tissues should be divided slowly, any bleeding vessels being secured as they are met with. The surgeon should explore the wound with the finger during the operation, to discover, if possible, the bulging of the rectal pouch, and should be careful to make the deepest incisions posteriorly. In a female infant the finger introduced into the vagina during the operation may give the surgeon some information as to the position of the rectum; or if the mass of fibrous tissue in which the rectum sometimes terminates is seen or felt, it may serve as a guide to the position of the rectal pouch. Nearness of the tuberosities of the ischium is a sign of absence of the rectum; and if it is found that the vagina or bladder fills up the concavity of the sacrum, it is an indication of a high termination of the rectal pouch. The incisions may be carried with safety to the depth of an inch and a half or two inches, and when the rectal pouch is reached it should be incised. After the meconium has escaped the wound in the rectum should be sufficiently enlarged, and, if possible, its edges should be brought down and sutured to the skin of the perineal wound, care being taken in passing the sutures and in introducing a drainage-tube to leave no pocket around the bowel for the accumulation of discharges. The suturing of the edges of the bowel to the skin is a most important procedure, and one which diminishes largely the amount of contraction in the newly-formed anus; it may, however, be found impossible to bring down the edges of the rectal wound to the skin in cases where the rectum terminates high up in the pelvis. In such cases a large flexible catheter or a metallic tube may be introduced and held in place by tapes; but it is difficult to keep it in position, as it is apt to be displaced by the straining efforts of the child. Verneuil has suggested excision of the coccyx in the early part of the operation, which facilitates the search for the gut, and in case it is found this procedure enables the surgeon more readily to attach the edges of the rectal pouch to the skin. The dressing of the wound should consist in dusting the parts with iodoform and applying a pad of antiseptic cotton, to be held in position by means of a T bandage.

When the surgeon has carried his dissection up into the pelvis as far as he considers it is safe, an inch and a half or two inches, and has failed to reach the rectal pouch, he should then consider the advisability of abandoning the attempt to reach the gut through the perineum, and should endeavor to open the intestine either in the left groin (Littre's operation), or in the left loin behind the peritoneum (Amussat's operation), or in the right groin (Huguier's operation). Of these operations, that in the left groin is to be recommended, as it opens the bowel near its natural termination. If the surgeon decides upon this operation, he should make an incision from one and a half to two inches in length, half an inch above and parallel with Poupart's ligament, beginning at a point opposite the junction of the middle with the outer third of this structure. Or an incision suggested by Ball, following the line of the *linea semilunaris*, stopping just short of Poupart's ligament, may be substituted for the former incision. The skin and muscular layers being cut through, the fascia transversalis and peritoneum may be pinched up together, and a small opening made in them, through which a director should be passed, and the two can then be divided with one incision. It is sometimes difficult to determine whether the bowel presenting in the wound is the small or large intestine; this can be ascertained by gently drawing out a coil: if it be the small intestine, it can be drawn out with ease, and the mesentery will show that it is not the portion of the bowel sought for, and it should be replaced. On the other hand, the large intestine cannot be so readily drawn out, and its mesocolon, if it have one, would be found attached to the left side. The bowel should next be secured to the edges of the wound by several sutures of fine silk or catgut, which should be introduced by passing a curved needle through the skin and parietal peritoneum near the edge of the wound, and then transfixing a portion of the bowel; after which the needle should be made to transfix the peritoneum and skin again, being brought out a short distance from the point of insertion; the stitches should then be secured. Sutures should be applied in this manner on each side and at the extremities of the incision, after which the gut should be incised to a sufficient extent and the meconium allowed to escape. After the escape of the latter the wound should be carefully cleansed, and the edges of the gut incision may be attached to the skin by a few silk sutures. The surgeon may introduce the finger or a flexible rubber catheter into the opening in the gut to ascertain, if possible, the point of termination of the rectal pouch; and if it is found to be near the upper portion of the perineal incision, he may deepen the latter on a guide introduced through the artificial anus. It has, however, been found better to rest satisfied with the relief afforded by colotomy, and to postpone for a time the attempt to form an anus in the perineal region, for the majority of cases in which this has been attempted have been followed by a fatal result. Attempts to accomplish this result some months after the performance of colotomy have been more satisfactory, as is seen in cases reported by Byrd and Krönlein. When the patient has attained some age, and an examination through the artificial anus in the left groin shows that the rectal pouch terminates well down in the pelvis, a director or rubber catheter may be introduced through the colotomy wound and made to enter the pouch, and project at the anus, if it be present, or at some point of the perineum. This may then be cut down upon as a guide, and the gut may be opened and sutured to the skin if the edges can be drawn down to that point.

If the surgeon should prefer to make an attempt to open the bowel in the left lumbar region, the best guide to the position of the colon is a line half an inch posterior to a point midway between the two superior spinous processes of the ilium; if he fails to find the large intestine, and distended small intestine

shows itself in the wound, it is better to open this and stitch it to the wound, rather than to abandon the case and allow the patient to perish by intestinal obstruction.

The results obtained by the various operations for the relief of the symptoms due to imperforate rectum show that, in point of safety and as a matter of comfort to the patient, the perineal operation is to be preferred. Cripps has collected 100 cases of the various operations for the relief of imperforate rectum; his table, although exhibiting a high rate of mortality, 50 per cent., shows that the largest number of recoveries followed the perineal operation, and the next in number were those cases in which the colon was opened in the iliac region. The expediency of an operation for the establishment of an artificial anus, either in the perineum or in the groin, in young children with imperforate rectum, is evidenced by a number of well-attested cases in which the patient lived for years afterward in comfort.

4. THE ANUS IS NORMAL IN APPEARANCE, BUT ENDS IN A CUL-DE-SAC, AND THE RECTUM ENDS IN A BLIND POUCH AT A VERY LITTLE DISTANCE ABOVE THIS POINT.—In this form the anus and rectum may be separated by a membranous partition of greater or less thickness, or a portion of the bowel may be impervious, or there may be multiple obstructions, or the anal portion may communicate with the vagina and the rectum end in a cul-de-sac (Fig. 4). The variety of malformation in which the anus is normal, but is separated from the rectum by a membranous partition of greater or less thickness, is not uncommon. It is apt to escape notice for some time, as the anus is normal in appearance, and it is only when the nurse or mother notices that the child passes no feces and the belly becomes swollen, or vomiting begins, that the nature of the trouble is suspected. The introduction of the finger or probe into the anus will soon reveal the nature of the trouble. An attempt should at once be made to reach the rectal pouch by an incision through the anus backward toward the coccyx, and if the gut be found it should be brought down and sutured to the edges of the anal wound. This procedure is much safer than puncture through the anus, which the surgeon might feel tempted to employ if the partition between the two cavities did not seem very thick. If it be found impossible, after a careful dissection in the perineal region, to find the rectal pouch, the surgeon should abandon this operation, and attempt to reach the gut by an incision in the left iliac region.

5. THE ANUS IS ABSENT, AND THE RECTUM ENDS BY A FISTULA AT ANY POINT OF THE PERINEUM OR SACRAL REGION.—The rectum may open at some portion of the perineum or sacral region, or it may terminate in a narrow channel under the raphé of the perineum and open at the prepuce or at the symphysis pubis, or may end in several fistulæ at different points (Fig. 5). Such patients may have satisfactory evacuations through the fistulæ, and may live for months or years without suffering much inconvenience from the deformity.

Treatment.—If a child so suffering shows evidence of discomfort by reason of the feces not passing sufficiently freely through the fistula, this should first be dilated or increased in size by incision, and if relief

FIG. 4.

Anus ends in a Cul-de-sac, the Rectum ends in a Blind Pouch (after Molière).

FIG. 5.

Anus is absent; Rectum ends by a fistula at the prepuce (after Ball).

from the symptoms be obtained, no further operation should be attempted as long as the child remains in comfort. When the patient has attained an age when a more radical operation can be undertaken, the fistula may be explored with a probe or director, and the position of the rectal pouch ascertained if possible; if it be in a favorable position, a perineal opening should be made to reach the rectum, and when it has been found the bowel should be opened and its edges brought down and sutured to the edges of the perineal wound. The fistulous tract should be laid open or touched with the actual cautery, and allowed to heal by granulation.

6. THE ANUS IS ABSENT, AND THE RECTUM ENDS IN THE VAGINA, BLADDER, OR URETHRA.—These malformations, according to the point of termination of the rectum, are classified as *atresia ani vaginalis*, *atresia ani vesicalis*, and *atresia ani urethralis*. Leichtenstern's statistics show that 40 per cent. of rectal malformations are of this nature. This tendency of the rectum to terminate in the genito-urinary tract is remarkable when we consider the definite separation which exists between the rectum and the genito-urinary tract in the adult: it is attributed by Ball to the method of development of the proctodæum, or a tendency to reversion to the cloacal type of birds and lower animals.

Atresia Ani Vaginalis.—In this form the rectum terminates in the posterior walls of the vagina, either by a small or large aperture. The opening may be situated immediately within the fourchette, or may be located high up in the canal (Fig. 6). If the rectal opening is sufficiently large, the patient does not exhibit any symptoms of intestinal obstruction, and the nature of the deformity is only ascertained upon inspection of the parts, when it is found that the anus is absent, and that fæcal matter escapes from the vulva.

FIG. 6.

Anus is absent; Rectum ends in the vagina. (After Ball.)

Treatment.—If the patient suffers no inconvenience, operative treatment may be postponed until she has attained some age, when the greater development of the parts will conduce to a favorable result. Operations for the relief of this variety are the most satisfactory in their results of all those that have been devised for the cure of congenital malformations of the rectum. When an operation is decided upon, the one which is followed by the best results is performed in the following manner: A director is passed through the vaginal opening into the rectum and is pushed backward, its point being made to project as near as possible to the normal position of the anus; this is cut down upon from the perineum and the rectum is exposed and incised. The rectal wound being then sufficiently enlarged, the gut is dissected loose and its edges are brought down and secured to the skin by sutures. By this dissection of the rectum and bringing down of its edges, the opening into the vagina, if it be a low one, is obliterated. If a high opening into the vagina remain after the anus has been established in its normal position, an operation may be undertaken later to close this recto-vaginal fistula. An ingenious operation, devised by Rizzoli, for the relief of this malformation is performed as follows: An incision is carried from the lower margin of the vaginal anus backward through the perineum toward the coccyx, care being taken not to open the intestine; the termination of the rectum with its vaginal orifice is now carefully dissected out, and the abnormal anus is transplanted to its natural situation and secured in that position by a few sutures, after which the perineal and vaginal wounds are brought together by deep sutures.

Atresia Ani Vesicalis.—In this variety the rectum communicates with the

bladder, either by a narrow orifice near the base of the organ or by an opening near its fundus (Fig. 7). The absence of the anus and the escape of fecal matter intimately mixed with urine at the time of urination would point to the nature of this very serious malformation.

FIG. 7.

Anus absent; the Rectum ends in the Bladder. (After Ball.)

Treatment.—In the treatment a staff may be introduced through the urethra into the bladder, and an incision made through the perineum into the neck of the bladder, as in lithotomy, and continued into the rectum. As the result of this operation the immediate symptoms of obstruction may be relieved, but the patient is left with a urinary and fecal fistula. Ball suggests a laparo-colotomy, and, when the colon has been found, its complete division, with closure of the lower portion and the bringing out of the upper portion at the wound, and securing it in that position to establish an artificial anus. This

operation, although attended with greater immediate risk, has the advantage of leaving the patient with control over his urinary excretion.

Atresia Ani Urethralis.—In this form the rectum communicates with some portion of the urethra, allowing the escape of a small amount of fecal matter, which passes more or less in the intervals between urination. The urethral opening is usually so small that feces cannot escape in sufficient quantity, and the symptoms of intestinal obstruction are soon developed (Fig. 8).

Treatment.—The treatment consists in attempting to find the rectum by means of perineal incision, opening it, and bringing down the edges of the gut and suturing them to the skin.

7. THE ANUS AND RECTUM ARE NORMAL, BUT THE URETERS, VAGINA, AND UTERUS OPEN INTO THE RECTAL CAVITY.—As this is a malformation in which occlusion of the bowel does not exist and life is not endangered by its presence, no immediate operation is called for. Where the ureters open into the rectum, no operative interference could be of any avail, but in that form in which the vagina or uterus opens into the rectum, and the child has attained some age, an operation to close the fistula and replace the organs may be attempted.

8. THE RECTUM IS TOTALLY ABSENT.—This differs from the third variety of malformation only in the amount of rectum which is wanting, and its existence may be suspected in those cases in which an exploration of the pelvis by perineal incision fails to reveal the presence of the rectal pouch. This condition is to be treated by laparo-colotomy, in the left inguinal region, and the formation of an artificial anus.

9. THE LARGE INTESTINE IS TOTALLY ABSENT.—This condition is often associated with a fecal fistula at the umbilicus or some other portion of the body, and its treatment consists in securing a free exit of feces from this fistula by dilatation or careful incision, or by the formation of an artificial anus if no fistula be present.

FIG. 8.

The Anus is absent; the Rectum ends in the Urethra. (After Ball.)

III. DISEASES OF THE ANUS.

PRURITUS ANI.

This affection is occasionally seen in childhood, and is characterized by a painful itching in the region of the anus, which causes the child constantly to scratch the part, so that the skin in the vicinity becomes thickened, eczematous, and moist from exudation as a result of the constant irritation. Pruritus ani may result from various causes—from the presence of oxyuris vermicularis in the rectum, from eczema of the anus, from pediculi or scabies, or from the presence of a vegetable parasite, as is the case in eczema marginatum. In other cases in which the itching is not attributable to any of the above-named causes it can often be traced to improper diet or chronic constipation.

Treatment.—Where the condition can be traced to the presence of eczema, the parts should be frequently bathed with hot water and washed carefully with green soap, and one of the following lotions may be used:

R̄. Acidi carbolici ℥xx.
Liquor. calcis f̄ʒvj.—M.

Or,

R̄. Acidi carbolici f̄ʒss.
Glycerini f̄ʒj.
Aquæ q. s. ad f̄ʒvj.—M.

Or the following ointment may be applied:

R̄. Ung. picis liquidæ ʒj.
Ung. zinci oxidi ʒiij.
Ung. aquæ rosæ ʒiv.—M.

When the itching can be traced to the presence of parasites, either animal or vegetable, the use of some of the antiparasitic lotions or ointments appropriate for the individual case will rapidly effect a cure. Where the condition is dependent upon errors in diet, a change of diet will often be followed by satisfactory results. Where the trouble arises from chronic constipation, a change of diet should be made and laxatives should be administered, or enemata or suppositories of glycerin should be employed.

SYPHILITIC AFFECTIONS OF THE ANUS.

Mucous patches and moist papules occur with comparative frequency in the region of the anus as the result of congenital syphilis. Allingham speaks of numerous cracks or fissures of the mucous membrane of the anus in children suffering from hereditary syphilis. Condylomata may appear upon these syphilitic lesions: they are acuminated and spring from previously existing papules or mucous patches, and are accompanied by discharges of a characteristic fetid odor. These growths are to be distinguished from the simple forms of vegetation which frequently occur in this region, and are not dependent upon the presence of inherited syphilis.

Treatment.—The treatment should be both constitutional and local. The constitutional effects of mercury can best be obtained in young children by the use of a binder spread with mercurial ointment applied around the abdomen. The local treatment of the anal lesions consists in the application of the

solid stick of nitrate of silver, or, better, the acid nitrate of mercury, or in dusting them with a powder consisting of equal parts of calomel and oxide of zinc.

VEGETATIONS OR WARTS OF THE ANUS.

Vegetations of the anus are not infrequent in childhood, and the growths may attain great size. They are similar in structure to warts situated in other parts of the body, and are papillary overgrowths covered with squamous epithelium. From their situation they are apt to be kept in a moist condition, and as a result there is often present a certain amount of offensive discharge.

Treatment.—If the parts can be kept perfectly dry, a cure will usually rapidly result: with this end in view, when the growths are not large, dusting with lycopodium or powdered oxide of zinc will often be followed by their disappearance. If the growths are large, they may be touched with the solid stick of nitrate of silver or a saturated solution of chromic acid; or they may be destroyed by the application of the actual cautery, or trimmed away with scissors. The objection to the latter mode of removing them is the profuse hæmorrhage which may result, but this can generally be controlled by the application of a firm compress to the bleeding surface.

FISTULA IN ANO.

Fistula in ano is an affection in which there is a communication between the mucous surface of the rectum or anus and the skin in its immediate neighborhood. A complete rectal fistula is one in which there is a sinus leading from the rectum to some point of the skin in the region of the anus; an incomplete fistula or an internal rectal sinus is one in which there is a sinus passing from the rectum into the perirectal cellular tissue; another form of incomplete fistula is known as the external rectal sinus, and is one in which there is an opening on the skin passing into the cellular tissue around the rectum, but not perforating the wall of the gut. Fistula in ano is certainly a rare affection in infants and children. Allingham mentions the fact of its occurrence in children of a very tender age. I have myself seen a few cases in children, and recall a case of complete fistula in a child a few months of age. The affection may result from perforating ulceration of the mucous membrane of the rectum, or from an ischio-rectal abscess opening into the rectum or through the skin in the vicinity of the anus, and also from wounds involving the rectum or anus.

Diagnosis.—This affection is usually not difficult to diagnose if the finger be introduced into the rectum and a probe passed into the external opening, when, by a little careful manipulation, the probe may be made to enter the bowel if the fistula be a complete one. In the incomplete form of fistula known as internal rectal sinus, careful palpation of the tissues surrounding the anus will often reveal an indurated mass of tissue which indicates the position of the internal fistula, and the finger introduced into the rectum may also feel the orifice of the internal opening; while the discharge of pus with the stool points to the existence of this affection. In the form of incomplete fistula known as external rectal sinus, if the finger be introduced into the rectum and a probe passed into the external opening, it can be felt at some point to come near the wall of the bowel. In children it should be remembered that, in certain cases of disease of the bones of the spine, of the sacrum, or of the pelvis, the purulent matter passing through the connective tissue about the rectum may find its way to the surface and perforate the skin in the neighborhood of the anus; or it may open into the rectum and escape by the

anus. A careful examination of the patient, however, will reveal the origin of the pus and show that it is not a case of ordinary fistula in ano.

Treatment.—The treatment of this affection consists in the free division of all the tissues between the internal and external opening of the fistula, and is accomplished as follows: A director having been passed into the external opening of the fistula, the finger is introduced into the rectum, and when the point of the director is felt it is passed through the internal opening and brought out at the anus; the superimposed tissues are then divided with a bistoury. The track of the fistula should next be carefully explored to discover the presence of any branching sinuses running off from it, and if these be found they should be freely laid open. The wound resulting should next be touched with the solid stick of nitrate of silver, or curetted, irrigated with a solution of bichloride of mercury, and packed with strips of iodoform gauze; this dressing should be changed at intervals of a few days, and the wound is to be allowed to heal by granulation. In cases of incomplete external fistula the director should be introduced into the external opening, and where its point comes in contact with the gut, guided by the finger in the rectum, it should be made to perforate, and its point brought out at the anus. The superimposed tissues are then divided, as in the operation for complete fistula. In the variety of incomplete fistula known as internal rectal sinus, the position of the fistula being located as before described, an incision should be made through the skin at this point, and a director introduced and made to enter the rectum, its end being brought out of the anus. The subsequent treatment of the case differs in no wise from that of the complete fistula. Another method of treatment in incomplete fistula of either variety is to lay the sinus freely open down to the bowel without dividing the sphincter, and to pack the wound with iodoform gauze: in this way a cure may often be brought about. In any case of fistula in which the internal communication is very high up in the rectum, and its division by the knife is considered unsafe by reason of the hæmorrhage which may result, an elastic ligature may be introduced through the external opening by means of an eyed probe and brought out at the anus, after which the ligature is tied and allowed to cut its way out, and the wound resulting is treated like that following division of the tissues by the knife.

FISSURE OF THE ANUS.

Fissure of the anus is an affection in which there exists at some portion of the mucous membrane of the anus a small linear ulcer, which causes great pain at stool or after the bowels have been moved. This affection is considered infrequent in childhood, but I am of the opinion that its presence is not so unusual as is generally supposed, and feel sure that a careful inspection of the anal region in children who complain of pain at or after stool will often show its presence. Allingham and Curling mention cases which they have met with in quite young patients, and I have myself seen cases of this affection in children. Kjellberg of Stockholm among 9098 children found 128 cases of fissure of the anus. The majority of these children were less than one year of age, and in 73 cases the patients were less than four months old. Jacobi thinks fissure of the anus a much more common affection in children than is generally supposed, and believes that many of the fretful children who sleep badly and cry constantly, and often present symptoms similar to those of vesical calculus, suffer from fissure of the anus.

Diagnosis.—Fissure of the anus should be suspected in cases where pain is experienced during or after stool and where the stool contains a few drops of

blood. In such cases a careful inspection of the part will usually reveal the presence of a fissure. The rectum should at the same time be examined with the finger for the presence of polypus, which frequently coexists with fissure of the anus.

Treatment.—The treatment of this affection in children can generally be successfully accomplished by an application of a 20-grain solution of nitrate of silver to the ulcer, or by lightly touching the surface with the solid stick of nitrate of silver, and afterward keeping the parts well covered with an ointment composed of thirty grains of iodoform or aristol to the ounce of vaseline, the bowels being kept in a soluble condition. In cases which are found intractable division or stretching of the sphincter may be resorted to.

STRICTURE OF THE ANUS.

This affection may be congenital or may result from an operation in the vicinity of the anus. The treatment of stricture of the anus consists largely in gradual dilatation of the contracted orifice, either instrumental or digital; if this fails to relieve the condition, a careful incision of the contracted parts should be practised, and subsequent dilatation should be employed for some time.

MARGINAL ABSCESS.

This affection consists in circumscribed suppuration starting in the mucous follicles of the anus, or from a fissure of the anal margin, and is a much more common and less serious affection in childhood than ischio-rectal abscess. Although painful, it is not apt to result in the formation of a fistula in ano.

The treatment consists in making a free opening with a bistoury, and to accomplish this the tip of the finger should be passed into the rectum to steady the abscess-cavity and make it more prominent before it is incised; the wound should then be dressed with iodoform gauze or with lint saturated with carbolyzed oil, and usually heals promptly.

DIPHTHERIA OF THE ANUS.

This affection is occasionally seen in children suffering from diphtheria of the pharynx, and usually develops late in the disease and in cases in which the system has been profoundly impressed. The deposit of diphtheritic membrane may involve the anus and extend on to the buttocks, and to the mucous membrane of the vulva in female children.

The prognosis is extremely unfavorable, and the cases which have come under my personal observation have all terminated fatally in spite of treatment.

The treatment consists in the employment of such constitutional remedies as are appropriate for diphtheria, and the local application to the affected surface of a solution of bichloride of mercury, 1:2000 or 1:4000, followed by the use of an ointment of iodoform.

IV. DISEASES OF THE RECTUM.

PROCTITIS.

Inflammation of the rectum, or proctitis, is an affection frequently seen in childhood. It may result from injury to the mucous membrane by the fæces or by materials contained in the fæces, or it may follow from traumatism received

from without. It is recognized in two forms—acute catarrhal and chronic catarrhal proctitis.

Acute Catarrhal Proctitis.—In this affection the inflammatory symptoms are limited to the rectum, and the disease is characterized by great tenesmus and the frequent passing of bloody mucus, at first mixed with fæces. In addition to these symptoms there are usually present œdema of the mucous membrane of the anus and of the lower portion of the rectum, and vesical irritation; and as a result of this condition and the constant straining there is often observed a partial prolapsus of the rectum. Many of the symptoms presented are those of acute dysentery, but the abdominal pain and the constitutional features of the latter affection are generally wanting.

Treatment.—The patient should be kept in a recumbent posture, and small doses of castor oil or one of the saline cathartics, either sulphate of sodium or of magnesium, or one of the natural mineral waters, should be administered to secure free evacuation of the bowels. The diet should be restricted to milk, animal broth, and eggs. If, after the bowels have moved, tenesmus continues, an enema consisting of a few drops of tincture of opium and starch-water should be injected into the rectum; or a rectal suppository containing powdered opium grain $\frac{1}{8}$, extract of belladonna grain $\frac{1}{8}$, iodoform grain 1, should be administered, and if the patient shows signs of exhaustion stimulants should be employed. The disease is usually of short duration, and under treatment the symptoms generally subside in a few days.

Chronic Catarrhal Proctitis.—This disease usually results from the acute affection, and is characterized by the absence of pain and tenesmus, although in some cases in which ulceration of the mucous membrane of the rectum exists there may be discharged a small quantity of blood and muco-purulent matter.

Treatment.—The diet should be regulated as in acute proctitis, and if the evacuations are not sufficiently free the bowels should be moved by the administration of a saline cathartic. The local treatment should consist in the use of enemata of nitrate of silver, $\frac{1}{4}$ to 1 grain to an ounce of water, which should be gradually increased in strength until they begin to cause pain; suppositories of iodoform and extract of belladonna may also be employed with advantage.

PERIPROCTITIS.

Periproctitis is an inflammatory condition involving the connective tissue surrounding the rectum. It may result from septic causes or direct injury, or may arise from the introduction of foreign matter through ulceration or perforation of the rectum. Abscess or gangrene of the cellular tissue may result, with subsequent involvement of the skin; erysipelas also may attack this region, giving rise to erysipelatous periproctitis.

Treatment.—In this affection, as soon as the swelling and induration can be detected, free incision should be made through the skin and into the cellular tissue outside of the margin of the anus, and the wounds thus produced irrigated with a solution of bichloride of mercury, 1:1000 or 1:4000, or touched with a solution of chloride of zinc, 15 grains to the ounce. The surfaces then should be dusted with iodoform, and covered with a bichloride-gauze and cotton dressing. If the parts are found to be gangrenous, a charcoal or an antiseptic poultice should be applied, and the patient should be given alcohol and tonics with a liberal diet.

ISCHIO-RECTAL ABSCESS.

Ischio-rectal abscess consists of a purulent collection in the loose cellular tissue surrounding the rectum. It is a most painful and serious affection, and

is the most frequent cause of fistula in ano. It may arise from injuries of the rectum, either from within or from without, from phlebitis or periphlebitis of the hæmorrhoidal veins, or from the escape of fæcal matter into the cellular tissue through ulcers perforating the rectum. The most characteristic symptom of ischio-rectal abscess is a sense of fulness in the lower portion of the rectum, with throbbing pain, which is increased at the time of stool. Where this affection is suspected a careful examination of the rectum with the finger will often disclose a bulging of the rectal wall at some point, and this is often accompanied by swelling and œdema of the skin near the anus; the presence of fluctuation in this region will often be revealed upon palpation.

Treatment.—This form of abscess demands prompt and free opening, and by this treatment alone is the pain relieved and the risk of the formation of a fistula in ano avoided. In opening these abscesses I usually follow the practice of Allingham, who recommends that the patient should be etherized and placed in the lithotomy position. An incision should be made at a little distance from the anus parallel with the sphincter, the abscess-cavity laid freely open, and the finger introduced into the wound to break down any secondary cavities or loculi. If it is found that there has been much undermining of the tissues, incisions should be made at right angles to lay all cavities freely open. The abscess-cavity should then be irrigated with a solution of bichloride of mercury, 1 : 2000 or 1 : 4000, or with a 1 : 40 solution of carbolic acid; and the wound should next be carefully packed with lint saturated with carbolized oil, 1 : 30, or, as I prefer, with iodoform gauze. An external dressing of iodoform or bichloride gauze and a pad of bichloride cotton is then applied to the wound and held in position by a T bandage. This dressing need not be disturbed, unless it become loose or soiled, for several days, when the cavity should be irrigated and a few strips of gauze laid lightly in it. The wound should be allowed to heal by granulation. If the bowels do not move in one or two days, a gentle laxative may be administered. By this method of treatment the cavity of the abscess rapidly heals, and a cure results without the formation of a fistula in ano.

ULCERATION OF THE RECTUM.

Ulceration of the rectum is not a common affection in childhood, but it sometimes results from chronic dysentery or chronic catarrhal proctitis.

The treatment consists in the local use of injections of nitrate of silver, grain $\frac{1}{4}$ to 1 to the ounce of water, and in the use of suppositories of iodoform. A restricted diet should also be enjoined, and the bowels should be regulated.

STRICTURE OF THE RECTUM.

This affection may result from the presence of new growths, from the contraction following wounds of this organ, the result either of accident or operation, and also from congenital malformations of the rectum; inherited syphilis is mentioned as occasionally causing congenital stricture of the rectum.

The treatment consists in gradual dilatation of the rectum, either instrumental or digital; if the condition be due to the presence of growths, their removal should be accomplished if possible; and if due to inherited syphilis, antisyphilitic treatment is indicated, in addition to the local measures.

SYPHILIS OF THE RECTUM.

Lesions of the rectum, due to inherited syphilis, are occasionally seen in childhood. A case of gummatous infiltration of the coats of the rectum in a child ten years of age, at the same time exhibiting well-marked symptoms of

inherited syphilis, has been described by Ball; and Oser of Cracow has reported two cases of gummatous infiltration of the intestines in children suffering from congenital syphilis.

The treatment of syphilitic lesions of the rectum consists in the administration of mercury or iodide of potassium, as in the treatment of corresponding syphilitic lesions in other parts of the body.

PROLAPSUS OF THE RECTUM.

Prolapsus of the rectum consists in the protrusion of a portion of the rectum through the anus, and occurs in three varieties: 1. A portion of mucous membrane protrudes from the anus (partial prolapsus); 2. The entire thickness of the walls of the rectum is included in the prolapse (complete prolapsus); 3. There exists an invagination as well as a prolapsus of the rectum. This affection in some one of its varieties is very common in childhood, and the frequency of its occurrence may be accounted for on both anatomical and pathological grounds. The looseness of the attachment of the submucous connective tissues of the walls of the rectum is a well-recognized anatomical fact; and this condition is an important factor in the production of prolapsus. The straightness of the coccyx in children is also said to favor its production. In infants and young children the great amount of straining that seems to be required to bring about satisfactory evacuations is also productive of this affection; this straining

FIG. 9.

Prolapsus of the Rectum. (After Bryant.)

has been ascribed by Jacobi to the anatomical fact that in children it is not uncommon to find two or three angular flexures in the lower part of the colon. The habit so common with mothers and nurses of placing children upon the chamber utensil and allowing them to spend a large portion of time in that position is certainly, to my mind, a frequent cause of the development of prolapsus, and is a custom which cannot be too severely condemned. In many cases the constant straining due to the presence of vesical calculus or rectal polypus, or to a contracted prepuce, may be an important factor in the production of this affection. Improper diet, or the custom of allowing children to eat at all hours during the day—and as a result of this over-feeding the production of a large number of passages—may also be mentioned as a cause. That improper diet and over-feeding produce prolapsus of the rectum is, in my mind, very clearly proved by the fact that at the Children's Hospital of Philadelphia we often have children admitted to the wards for operation who have suffered from this affection for months: under the use of tonics, proper diet, and regulation of the bowels they fail to further present prolapsus, and are thus soon relieved of the condition without operative interference. Mr. Holmes of London makes a similar observation as to his experience in this affection.

Symptoms.—The characteristic symptom is the protrusion, during defecation, of a reddish-purple mass covered with mucous membrane: it is unaccompanied by pain, and usually undergoes spontaneous reduction as soon as the straining efforts cease. In the partial variety of prolapsus of the rectum little inconvenience is experienced, unless the prolapsed portion of the bowel is allowed to remain out for some time, when it may become congested or ulcerated; the latter condition is more likely to occur in cases of complete pro-

lapsus. When the prolapsus is of the third variety and is accompanied by invagination of the rectum, the symptoms of obstruction of the bowel exist, and gangrene of the protruded mass may occur. Death has resulted in such cases from obstruction as well as from peritonitis.

Diagnosis.—Prolapsus of the rectum is likely to be confounded only with hæmorrhoids, which is an extremely rare affection in childhood, or with polypus of the rectum. The appearance of the prolapse is very characteristic: the annular fold of tissue surrounding the whole anus with its depressed central orifice, and the fact that after reduction of the mass no tumor can be found in the rectum, would exclude the presence of polypus. The cases most likely to give rise to error are those of intussusception in children where the intussusceptum protrudes from the rectum, and resembles in appearance a prolapsus. Such cases have been found with prolapsus of the rectum; but if the surgeon makes a careful examination of the protruded mass, and takes into consideration the previous history of the case, such as sudden pain and collapse or the occurrence of more or less obstruction of the bowels, with the passing of blood and mucus preceding the appearance of the tumor through the anus, he will not be likely to confound the two affections.

Treatment.—The palliative treatment of this condition consists in returning the mass through the anus as soon as possible. This is best accomplished by placing the patient across the knees and making gentle pressure with the fingers over the whole mass of the tumor for a few moments, to return the contents of the bowels and the fluids effused in the tunics, and then pushing up the central portion first with the finger. Little difficulty is experienced in effecting this reduction in recent cases, but where the prolapsus has been down for some time and inflammatory effusion has taken place, it may be necessary to administer an anæsthetic before the reduction can be satisfactorily accomplished. The preventive treatment consists in not allowing the child to make prolonged straining efforts on the chamber-utensil or to have the bowels moved in a sitting posture. A child who is subject to prolapsus of the rectum should have the bowels moved while in the recumbent position on the bed-pan, or on the side, or in a standing posture; and the nurse should support the perineum and anus by two fingers placed one on each side of the anus, or by forcibly drawing the skin of the buttock to one side while the child is passing the stool. When the affection depends upon the presence of a vesical calculus, a contracted prepuce, or a rectal polypus or parasites, producing great straining efforts, the removal of the cause will usually effect a cure promptly. The importance of carefully regulating the diet has been previously mentioned, and care in this respect alone may bring about a cure. Enemata of astringent solutions, such as decoction of oak bark, a solution of alum, or cold water, or suppositories containing extract of nux vomica and ergot, have been employed; and of these the enemata of decoction of oak bark, or of cold water, are most satisfactory. In cases where these various palliative measures have failed to relieve the condition, I think the safest and, in my experience, the surest method of treatment is that recommended by Allingham. This consists in the application of nitric acid to the mucous membrane of the protruded gut. The child's bowels having been previously opened by the administration of a small dose of castor oil or by the use of an enema, he is etherized, and the surface of the prolapsed bowel is carefully cleansed and dried of mucus by wiping it with absorbent cotton; the whole surface of the mucous membrane is next painted with nitric acid applied with a swab, care being taken not to allow the acid to come in contact with the adjacent skin. A pledget of oiled cotton or lint is next introduced into the central depression

of the prolapsed mass, and by pressing it upward with the finger the mass is reduced. Finally, a pad is placed over the anus and held in position by bringing the buttocks together over it by means of broad strips of adhesive plaster. The bowels should be kept quiet for two or three days by the administration of a small amount of opium; and at the end of that time they should be opened by a laxative. The introduction of the oiled cotton or lint I have found in practice unnecessary, as it is apt to be passed by straining when the patient recovers from the anæsthetic; hence I generally omit its use, and merely coat the cauterized surface of the bowel with olive oil or vaseline before reducing it. The recurrence of the prolapsus may take place with the first few passages, but a permanent cure generally results from one application of the nitric acid. Should this, however, not be the case, cauterization may be repeated in a few weeks. The ligature and the clamp and cautery or actual cautery have been employed in the treatment of this affection, but as their use is attended with danger in cases of complete prolapsus of the rectum, and as I have never seen a case in a child in which the simpler and safer procedure, cauterization by nitric acid, has failed to give satisfactory results, I do not think their employment is to be recommended. In cases of prolapsus of the rectum in which invagination has occurred and the patient is suffering from obstruction of the bowels, if the mass cannot be returned under ether an artificial anus should be made in the left inguinal region; and if the child survives after the invaginated portion of the gut has been removed by sloughing or other means, an attempt may be made to close the fæcal fistula in the inguinal region, and thus allow the fæces to escape through their natural channel.

HÆMORRHOIDS.

Hæmorrhoids are vascular tumors which occupy the lower portion of the rectum, and arise from dilatation or proliferation of the blood-vessels. They may be either internal or external, and are covered either by mucous membrane or skin. Hæmorrhoids are uncommon in childhood, but are occasionally seen, and may consist either of dilated veins or well-marked venous tumors. Allingham records a case of well-marked hæmorrhoids which he saw in a child three years of age. I have myself seen several cases in quite young children, and have seen recently with Dr. Starr a child three years of age who suffered from well-marked venous hæmorrhoids, which protruded and bled at stool, and presented symptoms severe enough to call for operative interference. Ball also has observed several cases in young children. The symptoms presented by hæmorrhoids in children are similar to those in adults, and consist in protrusion of the tumors and bleeding at the time of defecation.

Treatment.—As hæmorrhoids are apt to occur in strumous children, the administration of iron and cod-liver oil is often followed by decided benefit, and locally the use of astringent ointments and the regulation of the action of the bowels may be followed by marked amelioration in the condition. If, however, the tumors continue to bleed and to be protruded at stool, operative treatment is indicated, and the masses may be removed either by the use of the ligature or, as I prefer, by the clamp and cautery.

POLYPUS OF THE RECTUM.

Polypus of the rectum is a much more common disease in childhood than hæmorrhoids, and is characterized by the presence of a follicular tumor springing from the mucous membrane of the rectum at a point an inch or an inch and a half above the anus; it is attached by a pedicle. The form of

polypus most commonly seen in childhood is of the follicular or adenoid variety, and resembles in structure the normal mucous membrane of the rectum, from which it originates; but fibrous and cystic polypi have also been observed. Mr. Thomas Smith has recorded three cases of disseminated polypi of the adenoid variety occurring in young persons, and Cripps also reports cases of multiple polypi springing from the surface of the rectum and colon.

A rectal polypus is of a bright-red color when first extruded, but becomes darker and more venous in appearance after it has been protruded for some time and its circulation has been interfered with by constriction of the sphincter. The growths may be either single or multiple, and have pedicles varying from $\frac{1}{2}$ to 2 or 3 inches in length. Polypus of the rectum is comparatively rare in children: Bokai found 25 cases of this growth in 65,970 patients, and Jacobi says that he sees from 1 to 3 cases annually among 500 children. A rectal polypus is apt to produce expulsive efforts with tenesmus, and give rise to a sense of fulness or distress in the lower part of the rectum, and to be accompanied by the escape of glairy or bloody mucus or of blood.

Diagnosis.—The diagnosis is usually not difficult, as the growth is apt to present at the anus or to protrude from it during defecation, and a careful examination with the finger will disclose the presence of a pedicle to which the growth is attached. Polypus of the rectum is likely to be confounded with hæmorrhoids or prolapsus of the rectum, but a careful inspection and examination of the parts will disclose the nature of the trouble. Before examining a case of suspected polypus of the rectum it is well to give an enema, and when this is passed the growth is apt to be brought to the lower portion of the rectum or may present at the anus. In examining for polypus it is well to introduce the finger as far as possible into the rectum, and, as it is withdrawn, to make the examination of the walls with a sweeping motion, by which manipulation the pedicle of the polypus may be hooked upon the finger.

Treatment.—A polypus of the rectum may be seized with the fingers or forceps and twisted off, and the stump may be touched with nitrate of silver or with nitric acid; but I think the better method of treatment is to grasp the polypus and draw it out of the anus, so as to expose its pedicle, and to surround this with a ligature close to the mucous membrane, care being taken not to make sufficient traction to invert the wall of the rectum, which might thus be included in the grasp of the ligature. The ligature should next be firmly tied, and the tumor removed by dividing the pedicle in advance of the ligature. If a number of polypi exist, the same procedure should be repeated for each growth.

ANGEIOMA OR NÆVUS OF THE RECTUM.

This is also a rare affection. Mr. Howard Marsh has reported the case of a girl ten years of age who suffered from rectal hæmorrhage, in whom an examination revealed a nævoid growth in the lower portion of the rectum; and Mr. Barker has also published a case of this nature.

Treatment.—The treatment of nævus of the rectum consists in the use of

FIG. 10.

Polypi of Rectum with Prolapsus.
(After Ball.)

the ligature to strangulate the growth, or the application of nitric acid or Paque lin's cautery.

MALIGNANT DISEASE OF THE RECTUM.

Malignant disease of the rectum is very rarely met with in childhood, but may occur either in the form of cylindrical-celled carcinoma or of sarcoma. Allingham, Quain, Cripps, and other observers have reported a few cases occurring in childhood.

Treatment.—The treatment consists in the excision of the growth if its situation be favorable for such a procedure; or linear rectotomy, which consists in freely dividing the growth together with the lower portion of the rectum, including the sphincter, may be practised with benefit, if obstructive symptoms are present. If the growth involves the high portion of the rectum and excision is not possible, colotomy should be performed.

WOUNDS OF THE RECTUM.

Wounds of the rectum may be caused by substances which reach the rectum through the alimentary canal, or by bodies introduced through the perineum or the anus; these wounds may be lacerated, incised, or punctured. Lacerated or punctured wounds may result from patients falling upon sharp bodies which enter through the perineum or anus, or from fragments of broken bones of the pelvis, causing in many cases extensive laceration of the parts about the rectum as well as of the rectum itself; they may be complicated by injuries of the bladder, vagina, or peritoneum. Lacerated wounds of the rectum may also result from the careless or forcible introduction of the nozzle of an enema-syringe; and laceration of this organ in children who have been subjected to unnatural intercourse should also be mentioned. Incised wounds of the rectum may result from operations upon this organ or from its accidental incision in the operation of lithotomy.

Treatment.—The treatment of incised or external lacerated wounds which involve only the lower portion of the rectum consists in controlling bleeding by the application of ligatures to the bleeding vessels; in washing the wound thoroughly with a solution of bichloride of mercury, 1:4000; in dusting the wound with powdered iodoform; and in providing for the escape of discharge by the introduction of a drainage-tube or catgut drain, and in bringing the edges together with catgut sutures. A gauze dressing should then be applied, and the bowels kept quiet for a few days.

In punctured or internal lacerated wounds of the rectum which do not extend high enough to involve the bladder or peritoneum it is better, in order to secure free drainage, to convert the internal punctured or lacerated wound into an open wound by the division of all the tissues, including the external sphincter and the skin. The wounds should then be washed with a solution of bichloride of mercury, packed lightly with iodoform gauze, and allowed to heal by granulation, the dressing being changed as often as it becomes soiled.

In a case of lacerated wound of the rectum complicated by wound of the bladder, perineal cystotomy should be performed to provide for the free escape of urine, and free drainage secured by division of the anal sphincter and the introduction of drainage-tubes if necessary. If a punctured wound of the rectum involves the peritoneum, with injury to the contained viscera, laparotomy should be performed, the wounds of the viscera should be sutured, and the peritoneal cavity irrigated, drained, and closed.

FOREIGN BODIES IN THE RECTUM.

Foreign bodies may enter the rectum from the alimentary canal or may be introduced through the anus. A great variety of foreign bodies have been thus introduced either by accident or design. Patients suffering from foreign body impacted in the rectum will have ineffectual attempts at defecation, with the passage of mucus, which is often blood-stained. In a case presenting these symptoms a careful exploration with the finger will enable the surgeon to ascertain the presence, the exact location, and the character of the foreign body.

Treatment.—The removal of the foreign body should be accomplished with the least possible injury to the walls of the rectum. It is well first to anaesthetize the patient, and then inject into the rectum a few ounces of olive oil. When the character and position of the foreign body have been ascertained, it may be dislodged with the finger and removed by forceps. Where the body is irregular in shape or possesses sharp edges or angles which may cause injury to the surrounding parts, retractors or a bivalve speculum should be introduced to secure free dilatation of the anus and lower portion of the rectum and facilitate removal without injury to the rectal walls. Where the foreign body consists of a large mass of inspissated material, fragmentation should be resorted to in order to secure its satisfactory removal. If the foreign body has remained in position for some time and ulceration has resulted from its presence, a solution of nitrate of silver, 10 grains to the ounce of water, should be applied to the ulcerated surface, and suppositories of iodoform should also be introduced into the rectum. Extensive ulceration of the rectum following the long-continued presence of a foreign body may be followed by stricture, and the possibility of this condition should be guarded against by judicious dilatation by the finger or bougies.

PART VII.

DISEASES OF THE NERVOUS SYSTEM.

SIMPLE CEREBRAL MENINGITIS.

BY THOMAS S. LATIMER, M. D.,

BALTIMORE.

BY simple meningitis, leptomeningitis, or purulent meningitis, is usually meant inflammation of the arachnoid and pia mater. Writers distinguish an arachnitis, but as this probably never occurs apart from inflammation of the pia or dura it may be considered an unnecessary refinement. Varieties are mentioned dependent on the situation, grade, or nature of the inflammation, and whether primary or secondary, or according to the character of the exciting cause. All practical purposes are subserved by dividing simple meningitis into acute, subacute, and chronic forms, whilst considering in their appropriate places those peculiarities in each form incident to locality and origin.

All forms of meningitis have much in common, and a description of any one form is in great part a description of all; more especially is this the case in the clinical history and in the treatment; it is therefore expedient, to avoid needless repetition, which the space allotted to this article does not permit, to discuss the pathology and etiology of the different forms, and subsequently the clinical history and treatment, which are essentially the same in all.

Simple cerebral meningitis may be defined as inflammation of the arachnoid and pia mater of non-tubercular origin.

Etiology.—Simple meningitis is said to occur in utero (Guersant) and to be quite frequent in the new-born. According to Ramskill, its period of greatest frequency is prior to the second year, becoming less so from that time until after fourteen, when it again becomes more common, especially between sixteen and forty-five. Gowers places the period of greatest frequency between the ages of one and ten years, including, however the tubercular form. It is essentially a disease of early childhood, and is more common than is admitted by those who refer all basilar inflammations to a tubercular origin. In the post-mortem observations of Drs. Gee and Barlow, recorded in *St. Bartholomew's Hospital Reports* for 1878, are 6 cases of non-tubercular meningitis, and in 41 post-mortem examinations by Dr. Goodhart, in cases which he says without examination would have been set down as tuberculous, 8 were non-tubercular.

Sex may be admitted among the predisposing causes, since Parent-Duchatelet and Martinet found it to be three times as frequent in males as in females. The occupations peculiar to men and the sports of boys, involving exposure to vicissitudes of weather and to mechanical violence, may account in great part

for this difference, without assuming that there exists any liability or immunity due to sex *per se*.

Injuries to the head, extension of middle-ear inflammation or of any adjacent disease, the special cause of many specific diseases, like pneumonia, scarlatina, erysipelas, and measles, ordinary pus-producing organisms, emboli and thrombi—may all be exciting causes. An inherited or acquired predisposition is perhaps not uncommonly present, but less often than in the tubercular form. Rheumatism has been supposed to be a frequent cause, but its importance has doubtless been over-estimated. Symptoms closely simulating those of meningitis often arise in the course of acute rheumatism when post-mortem examination reveals no trace of inflammation. Trousseau absolutely denied the inflammatory nature of these cases, which he called neuroses. Two of the most characteristic symptoms of meningitis, vomiting and headache, are also commonly absent. Doubtless rheumatism is sometimes a cause of true simple meningitis, but all the symptoms may arise from hyperpyrexia alone. Suppurative endocarditis or any other septic trouble may occasion it, as in the cases following operation for imperforate anus referred to under Pathological Anatomy. Those cases arising from adjacent disease may be limited to the convexity, while those occurring in the course of acute specific diseases may affect the base also, though a preference for the convexity is recognized in all non-tubercular forms.

Pneumonia is frequently associated with simple meningitis and the pneumococcus is found in the inflammatory exudate. Huguenin states that at Zurich it is a frequent complication of pneumonia, and Chvostek found it four times in 220 cases in Vienna.

The most common cause of this affection is extension from some local adjacent disease; middle-ear inflammation is a frequent antecedent. Cases have occurred in which suppuration of the eyeball was primary, the inflammation extending along the sheath of the optic nerve. In some instances no immediately exciting cause is apparent. Fagge relates several cases occurring in Guy's Hospital in which a diseased temporal bone was found post-mortem, but the meningeal inflammation appeared to start in one instance from a blow with a bolster, and in another an attack of sunstroke preceded the cerebral symptoms about seven days. Moxon gives a prominent place to syphilis as causative of meningitis, and Fagge says 5 cases, in which it occurred without other syphilitic lesions within the calvaria, were found among the records of Guy's Hospital. This writer appears to approve the notion that the direct rays of the sun may produce simple meningitis, or that even its reflection from the pages of a book while reading is a sufficient cause; but this is scarcely credible.

Pathological Anatomy.—When death occurs in the early stage of leptomeningitis, intense hyperæmia with extreme dryness and opacity of the membranes—from distention of the lymphatic sheaths of the vessels—over the whole or part of the brain may be the only lesion. If death occur after a few days' duration, effusion of fluid admixed with cellular elements will be found on the arachnoid, in its sac and infiltrating the pia mater. Abercrombie relates a case in which it was so abundant between the dura and arachnoid as to distend the anterior fontanelle. Usually, however, the quantity of fluid exudate is not large. When life has been prolonged to the fifth or sixth day, the quantity of fluid is sensibly diminished, and a little later disappears. A membrane-like deposit of yellowish hue is found on the arachnoid; the pia in greater or less part is covered and infiltrated with "concrete pus," which is also found around the vessels and in the sulci of the convolutions (Ramskill). The nerve-

sheaths may be reddened and bathed in semi-purulent lymph, which at times is punctiform and resembles tubercular granulations. In long-standing cases this may undergo caseation or induration. The nerve-trunks may be in different stages of hyperæmia, softening, and disintegration. The dura and arachnoid may be firmly adherent, the arachnoid and pia almost always.

The ventricles may be invaded, their lining membrane inflamed, the orifices of communication occluded, and the chambers distended with serum or pus, sometimes to the extent of producing a true hydrocephalus. In rare cases they may contain false membrane. More frequently they contain a flocculent fluid of variable quantity, sometimes sufficient to distend the ventricle and compress the cortex. The subjacent brain-substance may be œdematous and softened. This condition is not always associated with unmistakable evidence of inflammation of their lining membrane; indeed, the inflammatory changes in the ventricles are rarely, if ever, well marked. In those cases where inflammation is most pronounced the effusion is seldom limited to the ventricles, but may invade the cord and escape into the brain-space. Great distention of all the ventricles may occur without inflammation, from simple occlusion of the channels of communication with the space around the brain (Gowers). Rilliet relates a case in which the convexity of one side was covered with false membrane, whilst the pia of the opposite side was simply œdematous.

Cases of pneumonic origin are usually bilateral and limited to the cortex; those extending from local foci—purulent otitis, caries, etc.—are unilateral, and may be associated with thrombi of the sinuses or with abscess (Osler). Septic cases and those associated with specific diseases are apt to be bilateral. The base is often involved in the inflammatory process. An interesting case of basilar meningitis following an operation for imperforate anus, reported by W. T. Howard, Jr., in a child of three months, is related in Osler's *Practice of Medicine*, in which the ventricles were distended with pus containing a coccus and the bacterium coli commune; the ependyma was softened and infiltrated with pus. Dr. Hilton Fagge also reports a case, occurring in Guy's Hospital, of a meningeal inflammation following six days after an operation for imperforate anus, attributed to sepsis, though the meningitis was the only evidence of pyæmia. Dr. Fagge says the presence of subdural pus may usually be taken as an evidence of extension from without, though in many cases no subdural pus is found. The pia is usually swollen and œdematous, filling the sulci; the inflammation may extend along the vessels to the cortex, which becomes infiltrated, softened, and so adherent at times that the pia cannot be removed without cortical laceration. The whole surface of the cortex may be bathed in pus or deeply infiltrated with leucocytes, and Huguenin says "suppuration of the brain-substance may reach such a point as to give rise to a diffused yellow-gray maceration visible to the naked eye" (quoted from Fagge's *Practice*). The amount of blood in the vessels may be greatly diminished from pressure of the exudate and thickening of their walls.

Symptoms.—Simple meningitis of childhood usually begins abruptly with well-marked rigors. Prodromic symptoms are much less frequent than in the tubercular form. The patient is petulant and irritable when disturbed, but inclined to apathy at other times, more especially in later stages and when the convexity is especially involved. Violent delirium with or without convulsions may be an early symptom. When convulsions occur early, they are apt to recur often during the progress of the trouble. The delirium may be quiet and the convulsions slight or absent. Pyrexia quickly supervenes, and is usually high: a temperature of 103°–105° F. is not uncommon in the first week. It is sometimes very slight, occasionally scarcely appreciable, and in the last stage

the temperature may be subnormal. The pre-mortal temperature is sometimes as high as 106°–108° F.

The pulse may be frequent and tense, usually so in the beginning, or slow and irregular, sometimes as slow as 60, 50, or 40 per minute, or just before death it may rise to 160–180 per minute. Henoch considers an intermittent pulse characteristic of meningitis. It is of more significance in childhood than in infancy, but at no time has it the diagnostic value imputed to it. The extreme variation in frequency and quality of the pulse is probably its most significant character.

Respiration is usually but little disturbed, but is sometimes sighing, may be quickened at first and subsequently irregular and slow, and toward the close the Cheyne-Stokes rhythm may be present. When the lesion is in the posterior fossa, respiration is slow, labored, accompanied by cyanosis, and may stop suddenly.

Headache is perhaps the most constant symptom, and is seldom lacking. It is often associated with great tenderness of the scalp and subjacent region, and is sometimes circumscribed, but the localization bears no constant relation to the site of the inflammation. The meninges of one side may be inflamed and the pain and tenderness be on the other; but when the pain persists in a circumscribed area it commonly indicates the site of the inflammation. Cases of simple meningitis sometimes run their entire course without pain, and when pain is present it seems to have no constant relation to the intensity or extent of the inflammation.

Hyperæsthesia of the nerves of the special senses of sight and hearing, indicated by extreme aversion to light and noise, is almost invariably present. This may be associated with acute general hyperæsthesia. The pupils are at first contracted; as the photophobia diminishes they become irregular; one may be contracted and the other dilated, or at times contracted, at times dilated; finally, both become dilated and vision is impaired or lost; optic neuritis is present in many cases, especially when the base is involved. Noises at first greatly disturb the patient. This sensitiveness to sound is at times so great that the most softly modulated speech occasions signs of petulance and distress. As the end approaches this gradually passes away, and deafness may ensue.

The intelligence is sooner or later affected; the patient is irritable and petulant when questioned or otherwise annoyed; incoherent speech and delirium are often early symptoms. Other nervous symptoms present at this time are subsultus, carphologia, inco-ordinate efforts at locomotion if this be attempted, and projectile vomiting.

The tache cérébrale is well marked, but is without diagnostic significance. Occasionally the patient emits short, sharp cries that do not always appear to be due to pain, though in older children they often seem to increase the headache.

General convulsions may occur independently of the site (Gowers), and eventually give place to coma. Rigidity of the muscles of the neck, with retraction of the head, is an early symptom of diagnostic value; it is more frequent in inflammation of the base than of the convexity. When the base is the site of the lesion, local spasm may occur in simple as well as in tubercular meningitis. Rolling up of the eyes, oscillations of the globes, strabismus, most marked when the eyes are moved, are frequently present in the first stage; later they may give place to paralysis, sometimes limited to the face or a small part of it, sometimes to a single extremity; or complete hemiplegia is present.

Vomiting is so commonly present and of such distinctive character as to possess diagnostic significance. It is projectile, unaccompanied by gastric pain or tenderness, nausea, or retching. It may persist throughout the disease, but is most characteristic in the early stage. It occurs independently of the site, but is more common in inflammation of the base. It is not present in all cases. The tongue is usually somewhat furred, but presents nothing characteristic. The bowels are constipated in a large proportion of cases, and the abdomen is retracted or boat-shaped.

Finally, all the active symptoms subside; the headache, photophobia, acoustic sensibility, general and local hyperæsthesia, and active delirium, all give place to coma and general collapse. The pupils are dilated, the pulse weak and irregular and the skin cold and clammy. Cheyne-Stokes respiration is established, the sphincters are relaxed, the fæces and urine are voided involuntarily, and death speedily ensues.

SUBACUTE LEPTOMENINGITIS is peculiar only in the relative mildness of the lesions and the slowness with which it develops. It sometimes, though rarely, succeeds to the acute form, but more commonly is subacute from the beginning. The same lesions of milder grade are present, and are due to the same exciting and predisposing causes.

Hydrocephalus is perhaps more frequent and extensive; active delirium is frequently substituted by a more quiet form and a condition of mental torpor. The patient is less irritable, the photophobia and acoustic sensibility is less, and paralyses are slower to appear. There is but little propriety, however, in recognizing a subacute form; it is merged by such insensible gradations, on the one hand, into the acute, and on the other, into the chronic form, that there is little to distinguish it.

A latent form is also described, but in the judgment of the writer it has no well-established claim to recognition, and will not therefore receive further consideration.

CHRONIC LEPTOMENINGITIS.—Chronic leptomeningitis may succeed the acute form, but is of extreme rarity except as a result of syphilis or chronic alcoholism, causes not likely to occasion it in childhood except through inheritance.

The symptoms are less clearly distinctive, and the difficulty in diagnosis therefore greater, than in the acute form; consequently it may often be overlooked and the frequency of its occurrence underestimated. If, as Goodhart has remarked, we accept cervical opisthotonos as evidence of meningitis, it may not only be very chronic, but also intermittent, and, we may add, more frequent than commonly supposed.

Its clinical history is not to be separated by sharply-drawn lines from that of the acute disease. It is essentially the same in character, but of slower development and more protracted stay, and all the more characteristic symptoms are of less intensity. An apathetic condition with headache and a disposition to vomit, a pulse at first slow, soon becoming quick and irregular, double vision, strabismus, and irregularity of pupils, may usually be found if sought for. The favorite site of chronic infantile meningitis is the posterior fossa, and the most characteristic symptoms are local and dependent on the seat of the inflammation. Drs. Gee and Barlow observed cervical opisthotonos in most cases. In some cases of rapid development it may be attended or preceded by convulsions, vomiting, pain, and fever; in others the retraction of the head is slowly induced, unattended by these phenomena. Rigidity of the limbs and epileptic convulsions may occur later, together with oscillations of the globe or strabismus, and occasionally hydrocephalus (Gowers). When the orifices of

the fourth ventricle are closed with lymph, paralyses, facial and hemiplegic, may complicate the later period. The pia is usually thickened from increase in its connective tissue; a similar condition is found in the walls of its vessels, and from them may extend to the cortex, inducing such changes as may lead to insanity and idiocy. The pia and arachnoid may be glued together, œdematous and opaque, and the sulci be filled with serum or sero-purulent fluid or œdematous membrane. The Pachionian bodies are increased in number and size.

Chronic lepto-meningitis is much more frequently associated with syphilis than is the acute form. A swollen and œdematous optic disk, or optic neuritis, may aid the diagnosis, but cannot confirm it.

One is a little at a loss to understand why the cause of the meningitis should be supposed to determine a difference in the symptoms, except in so far as these are due to associated disease. The extent, intensity, and locality of the meningeal inflammation, with the nervous susceptibility of the individual, will determine the symptoms, which will be much the same whatever the cause.

Diagnosis.—The positive indications of simple meningitis are found in the symptoms already mentioned, though they may any or all of them occur without meningeal lesion of any kind whatever. The general cerebral symptoms are valuable according to their degree and combination, rather than by their mere presence. "The significance of the headache depends on its intensity; of the delirium, on its coexistence with headache: of vomiting, on its causeless character and persistence; of general convulsions, on their association with other symptoms; of infrequency of pulse, on its combination with pyrexia that usually accelerates the heart" (Gowers). It is not to be distinguished by its symptoms from tubercular meningitis, though in general it may be said to be more frequently dependent on some pre-existing local disease, to be more abrupt in its invasion and rapid in its progress in acute cases, and to be more frequently associated with active delirium. It is probably more dependent on some local lesion or association with specific disease than is the tubercular form. In the latter the presence of the tubercle bacilli or of septic materials from degenerating tubercles, with peculiar susceptibility, is alone sufficient for its development. The presence, therefore, of tubercle in other organs, the detection of tubercle bacilli, and a tubercular family history are of greater value in the differential diagnosis than any supposed difference in symptoms directly due to the meningitis. Though clear evidence of tubercle elsewhere may be wanting, slow invasion, early childhood, and the absence of distinct local cause make for a tuberculous origin. When the base alone is the site of the inflammation, the probabilities are strongly in favor of the tubercular form. Inflammation of the middle ear or labyrinth, with or without suppuration, may give rise to symptoms that cannot be distinguished, except by their duration, from meningitis. The detection of an otitis, therefore, may lead us to believe in the existence of meningitis originating from it, or to hope that the symptoms are solely due to it and will end in recovery under proper treatment. And in cases that recover under such circumstances, the diagnosis must remain permanently in doubt, since many cases of simple meningitis have been thought to recover.

It is also not altogether unlikely that the characteristic symptoms may arise as a reflex result of lesions of the most varied character in remote parts of the body. From the cerebral form of pneumonia simple meningitis may be distinguished by the physical signs of the former and the detection of the pneumococcus. But it must be remembered that although pneumonia may exist without meningitis, with analogous cerebral symptoms, yet pneumonitis and true meningitis may coexist and be due to the same cause. I know of no way to

distinguish cerebral symptoms occurring in pneumonia without meningitis and those occurring under like circumstances with it, except by their duration; and even this in many cases is the same, since pneumonia with marked cerebral symptoms often runs a speedily fatal course. Perhaps, instead of trying to differentiate them, it would be best to consider both as local expressions of the same constitutional state.

Pyæmia may present symptoms closely resembling meningitis, especially when associated with thrombus of the lateral sinus and jugular vein, as in a case reported by Dr. Frederick Taylor. Dr. Wilson Fox also relates a similar case, and Dr. Andrew two instances of pyæmia with cerebral symptoms not distinguishable from meningitis; both of these recovered, however, so it cannot be said they were not cases of true meningitis, unless it be assumed that acute simple meningitis never recovers.

Those cases of typhoid fever likely to occasion difficulty in diagnosis are characterized by the predominance of cerebral symptoms and the absence or slight nature of those peculiar to the alimentary canal; but in typhoid fever headache precedes delirium, usually ceases with its advent, and is sufficiently accounted for by the pyrexia—not so in leptomeningitis. Photophobia and auditory hypersensibility may occur in either, but they are far more acute in meningitis. In typhoid fever vomiting seldom has the distinctive cerebral character, and rigidity of the neck and local paralysees seldom occur. The invasion of typhoid fever is rarely so abrupt; the pulse is not so irregular.

Prognosis.—In all cases of leptomeningitis but little hope can be reasonably entertained of recovery when no error in diagnosis has been made; but errors of this kind happen in the experience of the most astute and well-informed physicians. Moreover, cases apparently free from doubt have recovered in sufficient number to warrant hope, but hope only, for nothing in the condition of the patient serves as a reasonable basis for expectation of recovery. The cases which do best are those having their origin in injuries, necrosis, caries, suppurative otitis, and other removable causes, and those that arise in the progress of syphilis. The majority even of these will terminate fatally after the inflammation is well established, but much may be done, by the early removal or correction of such causes, to prevent the establishment of meningitis. Those in which the indications are that both the convexity and base are affected run a rapidly fatal course. Patients in whom no reasonable cause exists may be expected to succumb, more especially if the pulse soon becomes irregular and weak, accompanied by nausea, with convulsive seizures followed by profound hebetude.

When light and noise no longer disturb; when the pupils become persistently dilated; the skin cold, pale, and bathed in perspiration; when involuntary evacuations occur; paralysis local or general becomes established, and coma or a semicomatose condition supervenes,—all hope may be abandoned.

Treatment.—The treatment in simple cerebral meningitis and in simple cerebro-spinal meningitis is essentially the same. A much larger proportion of cerebral cases are due to local conditions that may be treated by surgical measures, and whenever they do arise from removable causes surgical treatment should be instituted without delay. Suppurative otitis, with or without necrosis or caries of the temporal bone, is so often causally related to meningeal inflammation that these lesions should always receive efficient attention before the induction of the graver evil. It has happened to the writer to witness two cases of supposed leptomeningitis in adults, with fatal terminations, supervening on chronic suppurative otitis that had followed scarlatina many years before. Had the aural trouble been efficiently treated, the meningeal inflammation

would in all probability have been averted. Doubtless many similar cases have existed, and, in view of the great fatality of the secondary affection and the impunity with which surgeons of the present day invade the meninges, and even the substance of the brain, they should in future disappear from our records. All cases of injury to the skull that carry with them even a reasonable suspicion of injury to the meninges or brain should, in the judgment of the writer, be trephined, bone-fragments elevated or extracted, blood-clots removed though the membranes have to be incised for that purpose, and all the parts thoroughly cleansed. Analogous procedures are no less imperatively called for in diseased conditions than after injury.

Cases of syphilitic origin should receive the specific treatment proper to that disease, with a not unreasonable hope of recovery if the treatment be begun early.

Apart from these special indications for treatment, there is but little to be expected from any means at our disposal beyond the alleviation of suffering. Drugs appear to exert no influence on the course of the disease, and it may be doubted, even in those cases of supposed leptomeningitis that have recovered, whether the remedies administered have contributed to this result.

Bleeding, local or general, and blisters are still strongly advocated by German writers and by many others. Apart from relief of hyperæmia of the cerebral vessels, one sees but little benefit to be derived from them, and it would seem that this might be better accomplished by such remedies as amyl nitrite, which increase the vascular area and so lower blood-pressure without the same impairment of strength as follows bloodletting. Mercury and the iodide of potassium have been warmly and ably advocated as efficient therapeutic agents in this disease, but they so often appear to be entirely without effect that the writer is sceptical of their value except in cases of syphilitic origin. Nevertheless, excellent results of treatment with these agents have been reported by most competent observers. Ramskill in Reynolds's *System of Medicine* thus summarizes the treatment: "It resolves itself into three great remedial measures: first, bloodletting; second, hard purging; third, applications of cold water or ice to the head."

Abercrombie's cases also give strong support to the efficiency of these measures. Case 69, aged eleven, after an illness of five or six days was in a comatose condition, notwithstanding free purging, blistering, and the use of mercury to salivation; was immediately relieved and made a good recovery after one bleeding from the arm. Case 72, aged twenty-one years, was reduced to a condition of stupor from which he could scarcely be roused, and continued in this way for eight or ten days notwithstanding repeated bleeding, blisters, and cold applications. But, after taking full doses of castor oil every three hours until purgation was induced, he was on the same evening relieved and made a good recovery (quoted in Fagge's *Practice*).

A brisk purge in the beginning and from time to time during the progress of the trouble will do much to alleviate suffering, and at times seems to have a decidedly beneficial effect. Cases, not a few, are recorded, especially by the earlier writers, which seem to date improvement, rapidly progressing to recovery, from such measures as free catharsis, bleeding, local or general, blisters applied to head or back of neck. Whilst it is difficult wholly to discredit such statements or to deny to the agents employed the remedial potency claimed for them, yet it is equally difficult to conceive how with such means such ends could be attained. When remedies of this class are serviceable at all, it must be in the early stage before inflammatory exudation, infiltration, or degenerative changes have occurred to any notable extent; and one cannot wholly

shake off the doubt that they were cases of erroneous diagnosis, or at least belong to that rare class of cases that would have recovered without medical interference.

An entirely different class of remedies is found in those drugs of anodyne and hypnotic properties which allay vomiting, soothe pain, subdue or lessen active delirium, procure sleep, and contribute in many ways to make tolerable for patients and friends the last days of those for whom in a large majority of cases we can hope to do no more. And, in the opinion of the writer, relief in these particulars is the extent of the power of drugs to be useful in this disease. First rank in this group of remedies may still be boldly claimed for opium and its derivatives, and especially for morphine, which, because of the small dose required, the facility with which it may be administered hypodermatically, and its almost uniform strength and efficiency, takes precedence of all other drugs. The bromides of sodium and potassium, antipyrin, antifebrin, sulphonal, and many other similar remedies are at times of great usefulness. The occasional use of chloroform by inhalation when convulsions occur gives prompt relief to some of the most distressing symptoms, and is, I believe, as free from danger as any other remedy when judiciously employed; but nothing can be so confidently relied on to relieve pain, to procure sleep, to quiet delirium, and to arrest vomiting as morphine; and this it does at as little cost to a feeble heart as any other drug that may be used; nor do I think is the tendency to coma materially, if at all, increased by its judicious administration. But more valuable than any of the remedies yet mentioned is repose of body and mind as perfect as may be had by the mere exclusion of disturbing causes. The room should be darkened; no one not indispensable to the comfort of the patient should be admitted; no loud talking or other noises should be allowed within hearing; and no needless questioning by anxious friends. In cerebral cases the head should be shaved as soon as the nature of the trouble is clear. Ice or ice-cold water should be almost continuously applied to the head and—in cerebro-spinal cases—to the back. It should be begun early and continued steadily, and in cases of active delirium this may be supplemented by iced applications to the large arteries—brachials and carotids.

When coma appears, all depressing remedies should cease, although occasional recoveries are recorded even in this stage, as in Abercrombie's cases, already quoted, and in Sir Thomas Watson's case of recovery on the application of a blister to the entire shaven scalp after the appearance of coma. It is certainly more reasonable to expect good from the judicious use of stimulants in this stage or at any time when the heart-beat is feeble or intermittent. Throughout the disease, as far as practicable, the strength of the patient should be maintained with the most nutritious diet.

SIMPLE CEREBRO-SPINAL MENINGITIS.

BY THOMAS S. LATIMER, M. D.,

BALTIMORE.

SIMPLE OR SPORADIC CEREBRO-SPINAL MENINGITIS occurs under precisely the same circumstances as simple cerebral meningitis, and is attended by the same lesions, except in so far as the anatomical and physiological characteristics of the part invaded necessitate a difference. Nor can it be maintained in the present state of knowledge that any essential difference exists between this and other forms of cerebro-spinal meningitis. The tendency of recent observations and opinion is to the conclusion that epidemic cerebro-spinal meningitis (cerebro-spinal fever) has its origin in a specific germ, probably the diplococcus lanceolatus, and observations have not yet sufficiently multiplied to enable us to say whether or not this organism is also present in all sporadic cases. However this may be, it is clear that the two forms arise under somewhat different circumstances, and present such clinical differences as may be seen in other diseases, such as dysentery, that prevail at times epidemically and at times sporadically—differences chiefly of intensity in the symptoms and in the extent of the lesions, the epidemic prevalence implying a concurrence of suitable conditions in the individual and in the auxiliary associated conditions by which he is surrounded, and not necessarily any difference in the immediate exciting cause. In this restricted sense, then, we may still speak of simple cerebro-spinal meningitis as distinguished from cerebro-spinal fever. There are also cases occurring from injury, from sepsis, from local extension, from tuberculosis or syphilis, that probably have no causal connection with the pneumococcus, and may with more propriety be designated “simple” than may sporadic cases that appear to be closely connected with this particular organism.

Etiology.—The causes of simple cerebro-spinal meningitis are precisely the same as those of simple cerebral meningitis, and need not be again considered. They are injuries, extension from adjacent disease, pyæmia, specific diseases, childhood, sex, season, vicissitudes of temperature, and those general malhygienic conditions that predispose to inflammations in general. Meningitis is not, however, limited to any class, and may occur among the rich and poor alike. Efforts have been made to connect it with particular articles of food, but without much success. Fatigue from over-exertion seems to be a favoring condition observed most frequently in the adult.

Pathological Anatomy.—This disease may be an extension from simple cerebral meningitis, in which case the anatomical changes heretofore described in basilar inflammation will be present, and to them must be added those due to invasion of the meninges of the cord; or it may originate in the cord and extend up to the cerebral meninges, which would not of course alter the nature of the lesion, only the order of occurrence of its symptoms; or it may occur simultaneously in both regions, the anatomical characters remaining the same. These characters are—great hyperæmia in the first stage, to which soon suc-

ceed swelling and hypertrophy of the walls of the vessels of the pia mater sometimes also of the brain and cord, and with this oedema and cellular infiltration of adjacent parts may coexist. Sometimes the exudate may be small in amount and consist of serum, white corpuscles, and plastic material, by which in the last stage, if the patient survives, the membranes may be bound together, or the pia and surface of the brain or cord; or it may be of large quantity and purulent, filling the canal and bathing the pia and underlying structures in a grayish-yellow or distinctly purulent fluid, which may fill the entire space between the dura and arachnoid. The infiltration may occasion opacity of both pia and arachnoid. The spinal meninges are usually extensively involved, owing probably to the readiness with which septic elements are diffused in the spinal fluid. The spinal fluid is more or less flocculent from the presence of exudation elements, or it may be, as before said, distinctly purulent. A true myelitis may, and not unfrequently does, coexist, in which case paralysis occur of a more permanent character than when the meninges alone are involved. The arachnoid is probably never affected alone, but it is always involved in the inflammation, which may also extend to the dura and to the spinal nerves, to which latter circumstances some of the most characteristic spinal symptoms are due; but they by no means always share in the inflammation. According to J. Simon, the meningeal inflammation may usually be looked upon as an index to the more important changes that occur in the cerebral and spinal tissue, "and hence it is that the essential phenomena of the disease during life consist in disturbances, more or less grave, of the functions of these all-important organs."

Other organs and tissues present little or no pathological change, except perhaps the skin, and the lesions here found are commonly limited to the fulminant cases, which are found almost exclusively in the epidemic form of meningitis, and have therefore been fully described in another section.

Symptoms.—In this affection the convexity is seldom involved, and the symptoms are for the most part those characteristic of inflammation of the base and of the cord, more especially of the cervical region of the latter. The special senses are not affected to the same extent as in cerebral meningitis, although vision is sometimes impaired; irregularities of the pupil and strabismus, with oscillation of the globe, are usually present in minor degree, but intense photophobia is rarely a marked symptom. Deafness is quite common, and may be permanent; in many cases it is due rather to inflammation extending to the labyrinth and middle ear than to direct lesion of the auditory nerve.

Optic neuritis is present in most instances when vision is affected, and may terminate in permanent blindness in cases that recover. Keratitis, retinitis, opacity and ulcerations of the cornea, and opacity of the lens may all occur, but are not characteristic. Pain is invariably present, especially in the occipital and cervical regions, and is associated with general cutaneous hyperæsthesia; all movements of the patient occasion suffering, associated with rigidity of the spinal extensor muscles, sometimes affecting also the muscles of the chest, abdomen, and jaws, producing a sense of constriction and slight trismus. This hyperæsthesia and muscular contraction is probably due to the involvement of the roots of the spinal nerves in the inflammatory process.

The retracted neck and back, at times amounting to decided opisthotonos, is in part voluntary, due to a disposition to relax, as far as may be, irritable muscles (Radcliffe); in part reflex, from irritation of the sensitive fibres of the posterior roots distributed to the pia; and in part from direct irritation of the anterior nerve-roots, or to all these combined. When the patient is perfectly

at rest, considerable intervals of almost complete relaxation exist, but all efforts to restore the normal decubitus are commonly attended with recurrence of the abnormal position and rigidity. Most intense pain in the head and cervical region is an early and continuous symptom; it seldom entirely intermits, but severe exacerbations are of frequent occurrence. Pain in the back and loins is often present—always when the lower segment of the cord is invaded. The thighs are flexed upon the pelvis and the legs upon the thighs. Firm pressure over the spinal column does not occasion pain, a point of distinction between meningitis and spinal irritation. Local paralysis with facial distortion is not infrequently present, and in the later stage the patient may become hemiplegic, which usually implies the extension of the trouble to the substance of the brain or cord. Active delirium generally exists, sometimes as an early symptom, occasionally associated with convulsions, frequently ending in coma. Reflex irritability is always present in the early stage, but is less marked than in tetanus.

Vomiting is a troublesome symptom in most cases, and is difficult to control. The vomit consists of ingesta, bile, or a glairy greenish fluid. The bowels are usually constipated and the abdomen retracted, but diarrhoea not infrequently occurs, with tympany. Whilst this paper is in progress the writer is attending a case of well-marked sporadic meningitis in which diarrhoea induced by purgation continues, together with decided tympanites. The tongue presents nothing characteristic. It may be unchanged, slightly furred, or covered with sordes in the last stage. Appetite is no doubt impaired, but the desire for food is controlled in a measure, owing to the trismus and cervical contracture which efforts at swallowing, together with the necessary movements, induce. Thirst is an invariable symptom and is with difficulty appeased.

Pyrexia is present to a very variable extent; it may be scarcely appreciable, or it may range as high as 105° and 106° F., and in the last stage is usually highest.

With pyrexia the usually febrile pulse and respiration are associated, but marked dyspnoea may be superadded from paralysis or rigidity of respiratory muscles when the dorsal region of the cord is included in the inflammation. In cases complicated with pneumonia additional respiratory difficulty may be due to this cause; this is, however, a rare complication except in the epidemic form. The pulse is almost always quickened, ranging from 80 or 90 to 120, and in the first stage may have considerable tension, which is lost at an early period, a diminished arterial tension being one of the characteristic features of the disease. Very much more frequent pulse is recorded, and at times it falls as low as 50, but these instances are altogether exceptional. The kidneys rarely show any distinct lesion, but the urine is often increased in quantity, and occasionally contains a small amount of albumin. Retention of urine from spasm of the sphincters or paralysis of the detrusor muscles is sometimes associated with reflex spasm and irritable attempts to urinate. Involuntary, not necessarily unconscious, voiding of urine and faeces also happens.

Diagnosis.—The positive indications of simple cerebro-spinal meningitis have already been mentioned. Briefly stated, they are headache, pain in neck, back, and loins, with general cutaneous hyperaesthesia, exaggerated sensibility to light and sound, irregular pupils, oscillations and distortions of the eyeball, followed at times by blindness and deafness, paralysis of cranial or spinal nerves, delirium, convulsions, and coma; vomiting without apparent gastric cause, obstinately persisting; trismus and cervical contractures which may extend to nearly all the muscles of the body; pyrexia of inconstant degree,

and respiratory labor of varying and uncertain extent. From the epidemic form it is to be distinguished by its sporadic occurrence, its less rapid progress, its perhaps more extensive involvement of the spinal membranes, its usually less acute course, and the comparatively infrequent cutaneous lesions, especially of purpuric or hæmorrhagic character. It probably is more frequently causally related to local troubles of eye and ear, bone lesions, trauma, and sepsis. Perhaps if a clear distinction is to be permanently maintained between the simple and epidemic forms, it will come to rest on the absence of the diplococcus lanceolatus in the former and its presence in the latter.

With typhoid fever it may be confounded, but the distinction is not difficult. The severe persistent headache and spinal pain, the cutaneous hyperæsthesia, the exaggerated sensibility of special senses, trismus, muscular contractures, uncontrollable vomiting, constipation,—all early symptoms,—are sufficient for diagnosis before the later symptoms of each make error impossible.

With tetanus it has little in common but retraction of the head and slight opisthotonos, trismus, and thoracic constriction. In meningitis the back is less bowed, less rigid, and the contracture less easily induced; the trismus is seldom severe, often wanting, and rarely persists, whilst in tetanus a touch or a breath of air induces rigid opisthotonos, and trismus is an early, severe, and persistent symptom. In doubtful cases, if any such occur, the detection of the micro-organism of tetanus will resolve the doubt.

Cases of tubercular origin are to be distinguished alone by the invasion of other organs and by the family history, a more protracted course and an initial period of latency, with a less acute career.

Prognosis.—This is always grave, but a fair proportion of sporadic cases recover under judicious treatment. When the symptoms relate chiefly to the cord, a reasonable hope may be entertained, but when paralysis of cranial nerves, stupor, Cheyne-Stokes respiration, coma, and collapse occur, the issue is no longer uncertain. In some instances death has ensued in five hours, in from twenty-four to thirty-six hours not infrequently, but this has always been in fulminant cases, which are rare in the simple form. In sporadic cases life may be protracted several weeks, and in subacute cases sometimes many months; the usual period is about from ten to twenty days. Cases that recover are of longer duration than those that terminate fatally, but even in favorable cases the patient may be maimed for life, blind, deaf, paralytic, or with intelligence permanently impaired. In young children and in adults near middle age the mortality is greater than in youth.

Death may be due to asthenia from continued suffering, bed-sores, and inability to partake of food; or it may be more rapidly induced by respiratory difficulty from involvement of the respiratory centre, or by associated pneumonia; or convulsions may be followed by coma, collapse, and speedy death.

Treatment.—The same treatment advised in cerebral meningitis is advisable in cerebro-spinal meningitis—*i. e.* perfect rest, exclusion of light and noise, of visitors, and all causes of disturbance; removal of the cause when known and practicable; the occasional use of a brisk mercurial or other purge; liquid food and stimulants administered per rectum if not retained by the stomach; free and continued use of cold to the shaven head and back—ice preferred; the careful but efficient use of anodynes, of which opium and its derivatives are best, and in the early stage such remedies as the iodide and bromide of potassium with ergot. When the affection is chiefly or wholly spinal, Bramwell speaks in terms of high commendation of the iodide, and of ergot in the second stage, and also of the use of blisters and of tincture of iodine applied along the spine in the region implicated. Pain, cutaneous hyperæsthesia, and muscular

contractures indicate sufficiently clearly the site of the inflammation by the correspondence of these symptoms with the distribution of the nerves whose roots are affected; attention to the bladder and rectum is of course always requisite. Paralyzes may require special measures in accordance with the common rules of treatment, but Bramwell suggests caution in the use of electrical stimulation during the period of meningeal irritability.

TUBERCULAR MENINGITIS AND HYDROCEPHALUS.

By LANDON CARTER GRAY, M. D.,
NEW YORK.

I. TUBERCULAR MENINGITIS.

TUBERCULAR MENINGITIS—sometimes also designated *basilar meningitis* from the frequency of its occurrence at the base of the brain, and sometimes *acute hydrocephalus* on far less sound grounds—is characterized by marked cerebral symptoms, due to the deposit of tubercular granulations in the pia mater: this usually consists of inflammation of the membrane, central cerebral softening, effusion into the ventricles, and, often, of more or less general tuberculosis.

Etiology.—The etiological factors of tubercular meningitis are heredity, tubercular infection, age, and erythema nodosum.

A tubercular heredity produces of course the tubercular manifestations in the different organs of the body, but there has never been produced any proof that tubercular meningitis is hereditary except in this general sense. Jacobi states that its origin can often be traced to the bronchial glands, in which tubercular degeneration may remain dormant for years, and through them whooping-cough or measles may act as an exciting cause of a general tuberculosis after years have elapsed from the time of the original infection.

Most cases are observed between the second and seventh years, but, nevertheless, it may occur at almost any period of life, and I have myself seen a case in a man of sixty, the diagnosis having been verified by an autopsy. Several cases have been reported as connected with erythema nodosum.

Pathology.—In tubercular meningitis the pia mater is the structure affected, so that the lesion may be said to be an inflammation of the pia, with deposit of tubercle, and this is to be distinguished from the simple non-inflammatory tuberculosis of the pia that is a frequent complement of general miliary tuberculosis affecting the different organs of the body. In children the pia at the base of the cerebrum is alone affected, whilst in adults there is a tendency to implication of the same membrane at the vertex. The favorite nesting-place of the affection is in that portion of the pia which extends over the olfactory, the optic, and the third nerve, as well as the crura cerebri. Changes, however, may be found throughout the pia at the base of the brain, and also as it extends into the choroid plexus and the third ventricle, as well as in that portion extending from the vermis cerebelli forward over the region of the corpora quadrigemina. This last site is of especial importance, as it contains the largest portion of the vessels which nourish the walls of the ventricles and the ependyma, thus explaining the constancy with which cloudy fluid is found in the ventricles, with softening of their walls. The branches of the Sylvian artery are also very prone to be affected, sometimes through the pressure of exudations surrounding these capillaries, sometimes through tuberculous

disease of a capillary wall, but most frequently by an obliterating arteritis. Over the quadrangle at the base the pia looks like wet blotting-paper, very much as it does in syphilitic meningitis. Elsewhere it is opaque and thickened, but it can usually be detached without tearing the cerebral substance. The exudation is abundant, gray, transparent, and gelatinous. In it are imbedded the tubercles, small grayish white masses, some scarcely visible to the naked eye, some the size of the head of a pin, and also of intermediate dimensions, and some so isolated as to form genuine tumors, which are usually, however, of small size. The cortex is in a condition of red softening, this extending to a variable depth, sometimes even through the whole extent of the white matter of a convolution; but occasionally white softening alone is seen. In this softened tissue caseous masses are occasionally studded; indeed, the usual cerebral tubercle is not much else than a conglomeration of widespread cheesy deposits. The tuberculous infiltration implicates the cranial nerves in varying degree. A section of the pia mater and the underlying tissue will demonstrate that the membrane is thickened, this increase in density often extending like a wedge into the cerebral substance; there is frequently thrombosis of the arterioles and of the venules of the pia, obliterating the lumen, and thickening of the capillary walls, which are often hyaline, surrounded by connective tissue and infiltrated with small round cells that have distinct nuclei; whilst farther away from the vessels, areas of reticulated tissue will often be seen. Many bacilli and granulations will be observed. Giant-cells are sometimes, though rarely, seen in the internal wall of the vessel and in the surrounding cerebral tissue, and the tuberculous bacilli are strewn throughout the vascular walls. The perivascular sheath is often dilated and filled with lymphatic cells.

Robert Koch first discovered the bacterium of tuberculosis. In tuberculous lesions in many organs, in sections of miliary tubercles, and in the sputa of tuberculosis he found certain fine and elongated bacilli which colored in a peculiar manner. In the giant-cells they were especially frequent. The observations of Koch have received confirmation by Gibbes, Lichtheim, Frenzel, Balmer, Charnley Smith, Heron, Ransom, Ernst, Shakespeare, Prudden, and many others. Koch's observations have been attacked by Spina of Vienna and other experimenters, but have not been materially weakened. Other bacteria have been found in tuberculous meningitis besides those of Koch. Babes examined twelve cases, and in seven discovered different microbes, this variety explaining, in his opinion, the purulent and acute nature of some cases. There were tuberculous lesions of the mediastinal ganglia in all these, and also often pulmonary lesions of the same nature. In two cases a lanceolated microbe was found; in another the ordinary streptococcus of pus; a staphylococcus aureus in a fourth; in the fifth a streptococcus of pus; and peculiar pathogenic bacilli in the two remaining cases. In one of these cases, a culture from which produced acute meningitis and death when introduced by trephining into the meninges of a rabbit, there was a fine bacillus closely resembling that of tuberculosis. Another microbe, resembling that of Friedländer, was found, and meningitis was also produced by it in the rabbit. Still another case showed a tetrahedric microbe in the pus, in groups like the staphylococci, but negative results followed its inoculation. A peculiar microbe which developed a colony in agar-agar was found in another case. Babes examined some other cases in which no microbe except that described by Koch was found. The same observer has also found a few tubercular bacilli in two cases of meningitis caused by purulent otitis.

Symptoms.—The prodromal symptoms, which may last one week or

several, consist of pallor, peevishness, listlessness, interrupted sleep, occasionally headache (which may awaken the child and be localized), coated tongue, occasional vomiting (which may be either propulsive or regurgitative), constipation, sometimes diminution of urine, occasionally slight hyperæsthesia of the abdomen, photophobia, and a tendency to emaciate. In the majority of cases the prodromal symptoms are present, but the number of them varies exceedingly from case to case, and the onset may sometimes be acute. As a rule, however, the continuance of these symptoms is significant, especially when it is coupled with a constant temperature somewhat above the normal and showing a tendency to rise slowly from 100° to $101\frac{1}{2}^{\circ}$ F. It may be said that, on the whole, the febrile curve is that of the varieties of pulmonary phthisis; that is, ascending, with or without remissions. Thus a child may have a temperature a little above 99° in the morning, and in the evening somewhat above 101° , or the morning temperature may be a little above 100° and the evening $101\frac{1}{2}^{\circ}$ to $103\frac{1}{2}^{\circ}$, or the morning temperature may be as high as 102° and in the evening $102\frac{1}{2}^{\circ}$. In this respect the febrile curve of tubercular meningitis does not have the remittency or the sharp curves characteristic of typhoid fever, and it is not apt to run so high. The pulse is at first slightly irregular, and gradually becomes much more so. Slowly more pronounced symptoms appear. The respiration becomes irregular, and the patient sighs deeply and long, the abdomen is retracted, the eyes half closed as in dying, and the eyeballs occasionally move slowly in a lateral direction. One or both pupils may dilate. The face flushes in patches, and the Trousseau mark may be observed—*i. e.* a red mark left upon the skin when the finger is pressed over it or when it is dented by the pillow—and friction causes a blush corresponding to the area rubbed. These general symptoms of cerebral implication are followed, usually somewhat suddenly, by such evidences of localized organic implication as slight twitchings around the mouth and eyelids, or a convulsion, usually generalized, succeeded by ptosis, amaurosis, strabismus, or paralysis of the face or extremities. When the extremities are involved, the type is usually a hemiplegia, although occasionally one extremity alone may be affected. The temperature now mounts to 102° or 103° , or even more, the head is drawn back, the pulse increases in frequency, and the symptoms may grow in intensity until death supervenes after a period of three or four weeks, the fatal event being usually preceded by Cheyne-Stokes respiration. In milder cases convulsions may not be observed until a few days before death, but in these types vomiting, headache, delirium, and convulsions are marked, and the abdomen may be tumid instead of retracted. In some cases, too, somnolence may be marked from the onset. Occasionally retinal hyperæmia or choroidal tubercles are observed.

Prognosis.—Tubercular meningitis usually proves fatal. A few cases of recovery have been reported by different writers, such as Abraham Jacobi and Hahn, the former of whom claims that he has seen two cases, but I have never met with favorable result.

Diagnosis.—When tubercular lesions previously existing in other organs are followed by the symptoms of tubercular meningitis, its diagnosis is easily made. The diagnosis may become difficult, however, when there is no pronounced hereditary history, and when there is no history of personal tuberculosis in the individual. Tubercular meningitis can be diagnosed in cases showing the prodromal symptoms of gradual change, conjoined with paralysis of extremities or cranial nerves, the retraction of the neck, the somnolency, delirium, half-open eyes, temperature rising to 101° and above, other lesions capable of causing similar symptoms being excluded. Such other lesions are:

cerebro-spinal meningitis, syphilitic meningitis, simple meningitis, trauma, typhoid fever, intracranial tumor, ear disease, the hydrocephaloid state, mental disturbances from pulmonary lesions, and uræmia.

When cerebro-spinal meningitis appears as an epidemic, it is of course easily diagnosed. In endemic or solitary cases the characteristic eruption may be present; the prodromal symptoms are usually short, and the vaso-motor disturbances produced by pressure upon the skin take place at an earlier stage.

Syphilitic meningitis in a child with syphilitic heredity will be accompanied by such well-known signs as early enlargement of the spleen, the characteristic rash, chronic snuffling, usually beginning soon after birth, and collapse of the bridge of the nose: it yields readily to mercurial treatment.

In simple meningitis the prodromal symptoms will be lacking, and it is more sudden of onset. There will be no history of predisposition or tuberculous infection, the temperature is higher, and the course of the disease is more quickly run.

In trauma the diagnosis may be easily made by the onset of a meningitis, or hæmorrhage succeeded by a meningitis, providing the trauma be known; or, in case no history of trauma is given, by the quick onset of the symptoms; and the general history will distinguish it from simple meningitis.

The diagnosis from typhoid fever, when non-typical, is almost impossible in the first week or ten days, but when typical the temperature curve will distinguish it.

In intracranial tumor in a child or adult the symptoms will be much more localized, more prolonged, and will not be marked by a rise of temperature.

Ear disease should be carefully searched for in cases of meningitis where the symptoms are not clear, and the diagnosis may be made plain by the discovery of a purulent discharge.

In the hydrocephaloid state so many of the symptoms of meningitis may be present that the diagnosis may be in doubt for a time, but the nature of the case will soon be made evident by the history of some acute disease, particularly some gastro-enteric trouble, having preceded the brain-symptoms.

Pulmonary lesions, especially in a child, may produce brain-symptoms closely simulating a meningitis, but the diagnosis may be made clear by auscultation and percussion of the lungs.

A careful examination of the urine will make the diagnosis in uræmia; the organic symptoms present in a meningitis are also lacking.

Treatment.—Although the prognosis of tubercular meningitis is so unfavorable as to make it doubtful whether any treatment is of avail, it is still our duty to treat it intelligently and carefully, the more so in view of the existence of such a doubt. Absolute rest should be secured to the patient, and any disturbance of the cerebral or peripheral nerves must be avoided. In dealing with a fatal disease the most minute details should be attended to; clockwork regularity should be observed in administering the medicines; the room should be darkened; and a tactful and careful attendant should have charge of the case. The iodide of potassium, quinine, opium, and the bromides should be the medicines administered. The bromide of potassium and the bromide of sodium are the best of the bromides, and, excepting that in some cases the sodium salt will better agree with the stomach, there is really no choice between them. The chosen bromide should be given in doses varying with the amount of convulsive disturbance and the age of the patient. A sufficient dose for children is usually 5 to 10 grains three or four times a day. The physician should increase these doses according to his judgment in cases of

convulsions. Of the iodide of potassium the minimum dose should be 5 grains three times a day, increasing as the exigencies of the case and age of the patient require. It should be given in a glass of water or Vichy, especially when the stomach is irritable. The tannate of quinine should be given to children three or four times a day. The best method of administering the tannate is in chocolates, which most manufacturing chemists are now making; a capsule or tablet triturate may be employed for the sulphate: and when this salt is used, it should never be given in solution with an acid. Although considerable difference of opinion exists as to the efficacy of quinine in any case of meningitis, I am yet firmly convinced that the administration of this drug sustains the strength of the patient. Opium is of great value as a calming agent when the cerebrum is very excitable. In children 5 drops of laudanum should be given from one to three times a day, according to the judgment of the physician. Moderately cold applications seem to afford great relief to some patients, whilst others are irritated by them, and this response to their use should be the guide; but the application of ice-bags or ice-cold compresses upon the patient's head is not advisable; for the purpose of contracting the arterioles may be attained by fairly cold applications, whilst the temperature may be dangerously lowered by ice, and the general strength decreased thereby. The subnitrate of bismuth, 5 to 10 grains, with $\frac{1}{6}$ to $\frac{1}{3}$ grain of codeine, will be found efficacious in cases of persistent vomiting; or pills of ice may be given, or a mustard plaster applied over the epigastrium from time to time. If cardiac weakness be manifested, it should be met by cardiac stimulants, such as camphor, digitalis, and strophanthus. Great care should be bestowed upon the food, which should be suited to the age of the patient, and consist only of the blandest and most nourishing kinds. If persistent vomiting exists to such an extent as to interfere with alimentation, resort should be had to nutritious injections.

II. HYDROCEPHALUS.

THIS condition is known also as water on the brain and dropsy of the brain.

Etiology.—Hydrocephalus may be caused either by organic disease of the cerebrum or by meningitis, although it often occurs without any preceding disease, being then called primary hydrocephalus. In the so-called compensatory form of hydrocephalus, occurring with organic brain disease, the cerebro-spinal fluid flows to fill the intracranial vacuum caused by the loss of substance.

Symptoms.—The distinguishing symptom is an expansion of the skull in a peculiar shape, being flat behind and rounded in front, the orbital plates being obliquely directed and the eyes bulging downward and outward, and partially covered by the eyelids.

The mental defects are usually quite marked, and generally there are such physical symptoms as convulsions, contractures, and paralysis of one or more limbs. Amaurosis is occasionally seen, and the ophthalmoscope shows optic-nerve atrophy. In children there are usually symptoms resembling a mild meningitis—viz. disturbed sleep, restlessness, sharp cries, etc. These symptoms may be entirely lacking in cases occurring late in life, and the mental capacity may be excellent.

Prognosis.—The prognosis is very grave, as no cases of cure are known.

Diagnosis.—In marked cases, rickets and thickening of the cranial bones may sometimes be mistaken for hydrocephalus. But in rickets the form of the the head is somewhat square, with no bulging of the fontanelles; and in thickening of the cranial bones, in the few cases I have seen, there was hypertrophy of the facial bones.

Treatment.—In hydrocephalus treatment avails but little. Sometimes temporary benefit may be obtained by puncturing the anterior fontanelle, or, this being closed, by trephining the skull and piercing the subarachnoid space; but this is a dangerous experiment and sometimes results fatally. The same objection applies to the injection of the tincture of iodine through the fontanelle or through a puncture, inasmuch as it only affords temporary relief and sometimes causes death. Temporary benefit is often derived by compression of the skull by diachylon plaster, which can do no harm if the compression be not allowed to become extreme. It is applied in a very simple method: The plaster should be brought over the head in strips from front to back, from side to side, and diagonally, in such a manner as to obtain the most effective compression. An elastic band may also be used for the same purpose. A much safer method than any of these, in my opinion, and one which cannot fail of as good temporary results, is that of craniectomy. This should be done by the removal of a piece of bone, three or four inches long and about an inch wide, on each side of the median line. The compression of the brain is effectively relieved by this means, and if there be any virtue in the removal of compression, this is certainly an excellent method, whilst if done with the modern antiseptic precautions the operation is a perfectly safe one; but it is highly improbable that it will have more than the effect of temporary relief.

ABSCESS OF THE BRAIN.

BY FREDERICK PETERSON, M. D.,

NEW YORK.

ABSCESS may form in any part of the brain, but is much more common in the cerebrum than in the cerebellum, and is extremely rare in the basal ganglia, pons, and medulla. The white substance is more apt to suffer than the gray. As a rule, there is a single collection of pus, but occasionally there are multiple abscesses.

Etiology.—Abscess is the result of a suppurative encephalitis, due generally to an infectious irritant. The septic material may be derived from many sources, mostly local, but some distant. Of the local causes of brain-abscess, in all cases, ear disease is the most frequent. Next follow, in their order, traumata of the skull and scalp, diseases of the nasal cavity, non-traumatic caries of the cranial bones, and, rarely, orbital disease and intracranial tumors. Metastatic abscesses of the brain from distant sources have been known to follow pulmonary gangrene, empyema, typhoid fever, ulcerative endocarditis, measles, scarlet fever, small-pox, and other general septic diseases. Males are more commonly affected than females. No age is exempt from the disorder, but it is exceedingly rare during the first year of life. In 223 cases collected by Gowers, 24 occurred under ten years of age and 72 under twenty years. In childhood traumatic abscess is rather more frequent than any other form. In some cases no cause of any kind can be discovered.

Pathology.—The close connection of structures about the head, such as the scalp, bones, ear, and nasal cavity, with the brain, by means of vascular and lymphatic channels, accounts for the conveyance of septic material from these parts to that viscus. The first stage of suppurative encephalitis is known as "red softening." There are inflammatory œdema and swelling, with lessening of the consistence of the affected part, and reddening from distention of the minute blood-vessels, together with extravasations of blood into the tissues. There is infiltration of leucocytes. At first there is no strict delimitation of the diseased area. The ganglion-cells, nerve-fibres, and neuroglia are secondarily affected and undergo necrotic degeneration. As the encephalitis progresses, the pus-corpuseles become more numerous, until a greenish-tinted abscess is produced. At first the cavity containing the collection of pus is irregular and not strictly demarcated from surrounding tissues by a capsule. If the process continues long enough, the capsule begins to form in the shape of a delicate pseudo-membrane, which gradually becomes thick and firm, and gives the abscess a more or less spheroidal form. Usually some two months are required for the formation of encapsulated abscess, but often a much longer time. The capsule may be completely closed, or there may be a fistulous connection with the surface of the brain, or communication by rupture with either the outer surface or the ventricles. Inflammatory and degenerative changes may be found immediately about the encapsulated abscess in the neighboring

tissues. These abscesses vary in size from a centimetre to several inches in diameter, though from one to two inches is the usual dimension. Multiple abscesses are generally very small, and are sometimes miliary. There is a disagreeable fetor in a considerable number of brain-abscesses. An abscess may remain for long periods of time, even for years, in a stationary condition, or, as is more frequently the case, it enlarges until death is produced by interference with brain functions or by its bursting into the lateral ventricles or upon the outer surface of the brain, when purulent ependymitis or meningitis is excited.

While blows and falls upon the head are common causes in children, sometimes these traumata leave no traces, and the abscess resulting subsequently may not be considered due to so trifling a source. Even when injuries are visible in the scalp, there may be no hurt of bone apparent, and the abscess may lie deep in the brain. Usually, however, there is actual fracture or necrosis of bone, and the abscess is likely to be superficial and connected with the point of injury, though, even then, it may be isolated deep in the brain. The following case, observed by me in 1884 in a boy of twenty, is an illustration: In a street-row he was struck with a small heavy snuff-box on the forehead a little to the left of the middle line, causing a scalp wound and a small circumscribed depressed fracture of both tables. These pieces of bone were removed. The dura was normal. The parts were antiseptically treated. On the third day the temperature rose to 100° F. The wound looked well. On the thirteenth day he began to grow stupid, and three days later he died in coma. The autopsy showed the wound quite healed. The skull was exceedingly thin. The opening in the bone was $\frac{3}{4}$ by $\frac{1}{3}$ of an inch and contained a trifling amount of pus. The dura mater was perfectly normal, as were also the pia and arachnoid. There was evidence of brain-pressure, but no apparent injury to the superficies. In the white matter of the left frontal lobe an abscess the size of a small hen's egg was found which had no connection whatever with the exterior of the brain. The ventricles and all other parts of the brain were normal.

Sometimes a month or even a year or two may pass without the manifestation of cerebral symptoms. This may be explained by supposing that at first a very small abscess is formed, and that it remains quiescent for a long period before development.

The ear disease giving rise to abscess is usually a chronic disorder that may have existed for years, even as long as twenty-five years, before there is an extension of the trouble and the septic material is conveyed to the brain. The abscess generally forms in the temporo-sphenoidal lobe of the cerebrum or in the cerebellum. Here, too, the common seat of the affection is in the interior of the brain, separated from the point of origin by normal brain-tissues. In some cases it is more or less superficial.

Symptoms.—The symptoms are of two kinds—those which are especially due to the nature of the process, and those which are shared by abscess in common with other new formations, such as tumors, in the brain.

In the first category we have the symptoms of inflammation, more or less severe according to the acuteness or chronicity of the inflammatory change. There may be every grade of inflammation, from a severe, rapid, and quickly-fatal process to the slow, long-continued formation of an abscess, with remissions frequently amounting to complete quiescence and latency. Consequently, symptoms may be furibund or vague and indefinite. Changes of temperature, generally a rise of only one or two degrees, are noted; sometimes the temperature is subnormal. The pulse may at times be rapid, but is apt more commonly to be much reduced in frequency. There are anorexia, constipation,

general malaise, and chilly sensations amounting at times to rigors. Headache is as frequent as in tumor, and similar in its character. Quite frequently it indicates to a certain extent the position of the lesion, especially when the abscess is of traumatic origin. Sometimes there is vomiting. Convulsions are uncommon in the early, but frequent in the later stages. When general, they show the severity and extent of the abscess; when Jacksonian, they reveal its position in or beneath the motor cortical area. As the disease progresses delirium may appear, followed by stupor, gradually passing into coma. During the "latent" period—which is noted in many cases, and which may last for months or years—some of the above symptoms may be manifested in slight degree and with intermissions; but the latent period usually terminates abruptly with all of the indications of acute abscess. Vomiting and giddiness are very common in cerebellar abscess, but may also occur in cerebral forms. Paralysis is present in nearly one-half of the cases. The cranial nerves may be affected. Mental symptoms are more difficult to study in the child than in the adult.

Optic neuritis is often, but not always, present in cerebral abscess. It is inclined to be milder than in the cases of tumor, and more apt to be unilateral. It is very rarely observed in cerebellar abscess. Altogether, choked disk is not so frequently met with in abscess as in tumor.

Focal symptoms are not so common as in tumor, because abscess is more often situated in parts like the temporo-sphenoidal and frontal lobes, where lesions are less apt to give definite objective symptoms, and because the pressure of abscess is often less pronounced and more gradually developed than is the case in tumor.

Rupture of the abscess usually produces sudden evidences of acute purulent meningitis or symptoms resembling those of ventricular hæmorrhage.

Prognosis.—The outlook in all these cases is exceedingly grave. Acute abscess may run its course to a fatal termination in from one week to a month. Chronic abscess with a period of latency runs a very uncertain course, sometimes terminating suddenly, sometimes slowly developing acute symptoms. Even where abscess remains latent for years (in one case twenty years), death is apt to follow from some unexpected renewal of its activity. This may occur even after calcification of its capsule and inspissation of its contents.

Diagnosis.—Usually a diagnosis may be made from the history of an onset after ear or nasal disease or traumatism of the head, and from the symptoms characteristic of a suppurative encephalitis and of a foreign body in the brain. In acute abscess it is necessary to distinguish between it and meningitis, though this is often extremely difficult where the meningitis is of the suppurative form. The two may coexist, and both are often due to the same causes. The stiffness of the neck, tendency to opisthotonos and convulsions, and the more frequent implication of the cranial nerves in meningitis must be our guide. In the chronic form of abscess the distinction from tumor is often difficult; but here, too, the matter of cause is of great importance, though injury may indeed give origin to either. Definitely localizing symptoms, gradually extending and tending to involve the cranial nerves, together with more marked optic neuritis, and the greater frequency of tumor than abscess, are strong indications in favor of the former.

Treatment.—Surgical procedures are advisable in almost all cases, as abscess is almost certainly fatal, even in cases where latency may last for years. Trephining and the removal of pus, either by free opening and drainage or by the aspirating needle where deeply-seated, have been successful in a number of instances, especially in those following injury to the cranial bones and in

ear disease. As prophylactic measures, local bone disease from trauma or aural inflammations should be most thoroughly and conscientiously treated. The mastoid operation should be undertaken at the earliest appearance of a tendency to extension of the inflammatory process to the meninges and brain. Rest, the application of cold, the use of derivatives in the way of counter-irritants, and the improvement of general health by means of tonics and hygienic measures, have at times their importance in these cases, but too much reliance should not be placed upon these illusory measures.

TUMORS OF THE BRAIN AND MENINGES.

BY FREDERICK PETERSON, M. D.,

NEW YORK.

NEOPLASMS within the cavity of the skull are quite as frequent in childhood and youth as in adult life, and are to be met with even in earliest infancy. They occur in any part of the brain, either as metastatic growths from tumors elsewhere, or as primary developments from the neuroglia, vascular channels, membranes, or cranial bones. Sometimes a scalp neoplasm may erode the bones and affect the substance of the brain, as in a case reported by Braun, where a girl of fourteen had a carcinoma of the scalp which partially destroyed some of the cerebral cortex after eroding the bone.

Etiology.—Males are much more frequently affected by tumors than females, the proportion as given by M. Allen Starr being two to one. Up to the age of twenty years cerebral neoplasms are commoner before the age of eight years than after it. There are a few cases in which the cause may be ascribed to blows or falls upon the skull, yet the traumatic factor is probably not so great as is generally believed. Heredity, fright, mental strain, and the like seem to have little to do with their origin. Primary tumors of the brain are not as frequent as secondary growths, and tubercles, sarcomata, and carcinomata are especially, almost always, secondary to neoplasms in other parts of the body.

Pathology.—In Keating's Cyclopædia, M. Allen Starr has collected 300 cases of tumors of the brain in children from current medical journals and including the collections of Bernhardt and Steffan, thus bringing his list up to the beginning of the year 1888. To these I have added some 35 others, obtained from current literature since that date. Upon these cases and those collected by Starr and upon Knapp's monograph (*Intracranial Growths*, Boston, 1891) this study is mainly based.

The comparative frequency of the various kinds of tumor in children may be seen from the following table:

Form of Tumor.	No. of Cases.
Tubercle	166
Glioma	42
Sarcoma	37
Cyst	35
Carcinoma	11
Glio-sarcoma	5
Angio-sarcoma	1
Myxo-sarcoma	1
Papillary epithelioma	1
Gumma	1
Not stated	35
Total	335

It will thus be seen that tubercular tumors are by far the most common in

children, occurring four times as frequently as gliomata and five times as frequently as sarcomata. Another feature of great interest is the rather common development of more than one neoplasm in the same brain. This is particularly noteworthy in the case of tubercle, 43 of the above-mentioned 166 cases having presented multiple tumors. Thus in a case described by West, a boy aged fourteen had twelve tubercular tumors in the brain, although there were symptoms of but one. Moreover, sarcomata and cysts are occasionally multiple, 4 of the 37 cases of sarcomata and 4 of the 35 cases of cysts having been found to be multiple.

TUBERCULAR TUMORS.—Though occasionally primary in the brain, these tumors are usually due to secondary infection from tubercular processes elsewhere, in glands, lungs, or bones. Infection may be carried to the membrane from a tubercular tumor in the brain, thus giving rise to a secondary tubercular meningitis. About a fourth of the cases have multiple brain-tumors, the neoplasms varying from the size of a millet-seed to that of an egg. Usually round or nodular and encapsulated, they are at times very irregular and diffuse without marked delimitation. They nearly always arise from the membranes of the brain, chiefly the pia or its prolongations, though occasionally they are to be found in the interior, and not connected with the meninges. They owe their existence to the entrance of tubercle bacilli by way of the blood-vessels or lymphatics. Like gumma, the tubercular tumor is a form of granuloma, and histologically they are very much alike, the periphery being composed of the round-cells of granulation tissue, giant-cells, and often epithelioid cells, while the centre is caseous. A few tubercle bacilli may be found in the outer parts, and in the tubercle the caseous mass is confluent, while in the gumma there are apt to be several separate caseous masses. Characteristic vascular changes, such as endarteritis obliterans and periarteritis, often aid in the differentiation of the syphiloma. The extreme rarity of gumma in children, as seen in the above table, must be borne in mind. In fact, this one case of gumma was in a youth of eighteen.

GLIOMATA.—These tumors come next after tubercle in point of frequency. They are due to a hyperplasia of the peculiar connective tissue of the nervous system, the glia or neuroglia. As is well known, this connective substance is allied in some respects to mucous tissue. The glioma resembles neuroglia in its histological characters, but the cells are more numerous and vary much in size. This tumor is a peculiarly nervous one, growing especially in the central nervous system, though sometimes developing in the eye from the retina. Some gliomata are hard, from the greater proliferation of fibrous tissue, but the majority are rather soft and cellular, and are prone to undergo secondary changes, such as fatty degeneration and caseation. Often they are rich in delicate blood-vessels which by rupture give rise to hæmorrhages. Such hæmorrhages may terminate a case, as in ordinary apoplexy, or the clot may become caseous or form a cyst. The glioma being essentially a tumor of nervous connective tissue, it is found generally in the interior of the nervous organs, almost never connected with the membranes. It grows slowly, and is not malignant, though it has a tendency to return after removal. It is always solitary. When hard, it is usually easy to distinguish it from surrounding brain-tissue; when soft, its limits are not always readily defined. The development of mucous tissue in the tumor leads to the designation of myxo-glioma, and of numerous round and spindle-shaped cells to that of glio-sarcoma. Glioma varies much in size, but may attain greater proportions than any other tumor.

SARCOMATA.—In children sarcoma is not quite as frequent as glioma. It is a rapidly-growing tumor, developing anywhere in the brain or from its mem-

branes. Usually solitary, it may in rare instances be multiple. It is generally primary, but may be metastatic from sarcoma elsewhere. It may be of any size, but as a rule it is rounded or nodular in shape, and well differentiated from the normal tissues. When fibrous tissue is present in unusual proportion, the tumor is hard; when the cellular elements (round, spindle-shaped, giant, and stellate cells) are more abundant, it is soft. The interior may undergo secondary changes, such as caseation, fatty degeneration, hæmorrhage, and the formation of cysts. The proliferation of particular histological elements gives rise to such designations as myxo-, glio-, fibro-, lympho-, cysto-, angio-, melano-, round-celled, spindle-celled, and endothelial sarcoma. This neoplasm is malignant.

CYSTS.—Cysts may result from secondary changes in old hæmorrhages, and such are frequently found in the brains of children suffering from infantile cerebral palsies and organic idiocy. Newly-formed cysts are generally, however, due to echinococcus or cysticercus cellulosa. These are more common in Europe and Australia, apparently, than in America. The cyst of the former (hydatid) is usually single, but may reach a large size. The cysticercus is commonly small, producing few symptoms, and frequently multiple. The cysts may grow anywhere in the brain, but their development is very slow. Both may be recognized by the peculiar cystic character or by the examination of their hooklets, those of the cysticercus being very much larger than those of the hydatid.

CARCINOMATA.—About one-thirtieth of the brain-tumors in children are carcinomata, and are always secondary to growths developed elsewhere, or extend directly from the scalp, bones, or orbital tissues.

MISCELLANEOUS.—Gumma is apparently so rare in early youth that it may be said not to exist. I have not been able to find in literature any case except the one given in the table, occurring at the age of eighteen years. Aneurism, psammoma, lipoma, papilloma, myxoma, fibroma, osteoma, neuroma, adenoma, cholesteatoma, teratoma, and enchondroma are among the greatest rarities.

Symptoms.—In very young children the head may be enlarged, either generally, as in hydrocephalus, or there may be actual protrusion of certain limited portions of the skull, as in a case I saw some years ago of extreme oxycephalus. The neoplasms at times erode the cranial bones and bulge out beneath the scalp. Displacement of the eyeball has been noted in cases where the tumor has extended into the orbit.

But in most cases there is no outward indication of the presence of an intracranial growth, and we must diagnosticate its presence by certain general manifestations, such as headache, vertigo, vomiting, sleeplessness, visual disorders, mental changes, spasms, fever, and the like, and by localizing symptoms, as paralysis, limited spasm, anæsthesia, disordered locomotion, and disturbances in the functions of cranial nerves. Some or all of the general symptoms may be present in almost every case of intracranial tumor, no matter what may be its situation, but the exact seat of the neoplasm must be determined by a careful study of the motor, sensory, reflex, and psychic symptoms, and based upon an accurate knowledge of the physiological anatomy of the brain. In rare instances tumor of the brain may exist, giving rise to scarcely any symptoms at all.

Headache.—This is found in the majority of cases of brain-tumor, according to Mary Putnam Jacobi in about two-thirds of the cases. It is more frequent and more severe in cerebellar growths hemmed in beneath the tense tentorium. The pain is doubtless chiefly due to pressure upon, or irritation of, the sensitive dura mater. It may be in any part of the head, but is usually

frontal or occipital, without reference to the seat of the tumor. Occasionally the pain is distinctly and constantly localized at one place, and here there may be tenderness of the scalp and head on percussion, this being under such circumstances of value as a localizing symptom. The pain is dull and continuous or intermittent and severe. Infants probably suffer less, owing to the greater distensibility of the skull; and in them pain may be inferred from restlessness, irritability, sharp cries, sleeplessness, and burrowing movements of the head.

Nausea and Vomiting.—These symptoms are noted in from one-fifth to one-fourth of the cases. They are commoner in children than in adults. The vomiting may occur without nausea, irrespective of the taking of food, and intermittently or more or less continuously. It may be associated with vertigo, and frequently accompanies severe headache. It is often brought on by movement of the body. It is most common in cerebellar tumor.

Vertigo.—This symptom is not uncommon, and is particularly frequent with cerebellar neoplasms. As it accompanies so many divers affections outside of the cranial cavity, it cannot be regarded as of great diagnostic value.

Optic Neuritis.—The optic nerves are affected, according to Starr, in 80 per cent. of cases of brain-tumor, and hence this constitutes one of the most significant objective symptoms. It must be always looked for, since neuritis may exist to a very great extent without visual defect. Usually double, it may at first appear in one eye, and generally one disk is more affected than the other. This symptom, too, is more common in tumors of the cerebellum and at the base of the brain. It must be remembered, however, that it occurs in other disorders beside brain-tumor, such as meningitis, hydrocephalus, and abscess. Optic atrophy may follow the neuritis.

Convulsions.—Spasms are of frequent occurrence in the brain-tumors of childhood. They may be slight (*petit mal*) or severe, limited to certain members, or general, infrequent or frequent—twenty to thirty per day. General convulsions have no significance as to the seat of the lesion, nor can partial epilepsy (Jacksonian) always be relied upon to indicate the situation of the tumor.

Mental Changes.—In at least half of the cases some psychological disturbance is manifest. This is naturally much varied according to the amount of brain injury and the age of the child. It may show itself in mere fretfulness and irritability, or there may be dulness, lethargy, hebetude. In some cases there may be delirium, maniacal excitement, or an enfeeblement of the mental processes amounting to dementia. Somnolence is a common symptom in children. As the disease progresses this often deepens into coma.

Tremor, insomnia, fever, neuralgia, slow or rapid pulse, disturbances of respiration, and constipation, are symptoms occasionally observed in certain cases, but from these no significant deductions can be made. Increase of *head-temperature*, local or general, as measured by the surface thermometer, has not yet been sufficiently studied to be practically available as a symptom in brain-tumor.

Localizing Symptoms.—After due and careful consideration of these *general* symptoms, we must examine the *focal* manifestations, which are either irritative or destructive. Localizing symptoms depend altogether upon the seat of the tumor, whether adjacent to the motor area of the cortex (partial epilepsy) or in the motor tract (monoplegia or hemiplegia); in the sensory areas or tracts (anæsthesia, hemianæsthesia, hemianopsia, etc.); in motor or sensory speech-centres or tracts (aphasia in various forms); or, finally, impinging upon cranial nerve nuclei or trunks (paralysis of cranial nerves).

Gradual onset and spread are the rule in brain-tumor. There are occasional exceptions, since a secondary meningitis or a hæmorrhage in the new growth may produce a sudden exacerbation; and there are in rare instances intermissions, remissions, or even retrogressions, in the course of its development.

Usually the symptoms of cerebral or cerebellar tumor are *unilateral*, whereas those of neoplasm at the base affecting the cerebral axis are often *bilateral*.

The relative frequency with which tumors affect the various parts of the brain may be learned from the following table:

Site of Tumor.	Number of Cases.
Cerebellum	105
Pons Varolii	42
Centrum ovale	41
Basal ganglia and lateral ventricles	30
Corpora quadrigemina and crura cerebri	25
Cortex cerebri	23
Medulla oblongata	7
Fourth ventricle	6
Base of brain	8
Total	287

From this it will be seen that tumors of the cerebellum are slightly in excess of those of the cerebrum proper (105 to 94), while the remaining 88 cases were of new growths in the structures about the base of the brain (crura, pons, and medulla).

TUMORS OF CORTICAL AND SUBCORTICAL REGIONS.—These are mostly tubercles, sarcomata, gliomata, and cysts. It is difficult to differentiate cortical from subcortical tumors, the symptoms being about the same, and neoplasms in either portion tending by extension to involve the other. The manifestations will vary according to the functions of cortical centres or descending tracts involved. A study of Figs. 1 and 2 will show what functions will be destroyed by tumors affecting the different portions of cortex there represented, while in Fig. 3 the tracts of fibres which convey impulses to and from these various centres are shown. The chief points to be noted in relation to new growths here may be briefly stated as follows:

Scheme of Localization in Cortex of Convex Surface of Hemisphere.

Tumors of the Frontal Lobe often present no marked symptoms. If they impinge downward upon the olfactory bulb, they may give rise to loss of the sense of smell. There are often mental changes, such as difficulty in concen-

FIG. 2.

Localization on Inner Surface of Hemisphere.

trating attention, of thinking connectedly, of exercising self-control, of comprehending with ease, or of acquiring and retaining new knowledge. Sometimes there is great mental torpor and enfeeblement amounting to imbecility.

FIG. 3.

Scheme of Position of Fibre-tracts descending from the various areas.

But irritation from the frontal cortex may extend backward to the motor areas, and thus produce hemi-epilepsy or general convulsions. If the tumor exerts much pressure backward or extends into the motor area or tracts, paresis or

paralysis of the opposite side of the body, beginning often as a monoplegia, is developed.

Tumors Affecting the Third Frontal Convolution of the left hemisphere in right-handed persons give rise to motor aphasia, and occasionally agraphia, of imperfect type. In a slowly-growing lesion, like tumor, the opposite hemisphere may often gradually compensate for the loss of function in the affected side. This matter of aphasia, however, is not so important a localizing symptom in children as in adults. From studies I have made of hemiplegia in children I have been led to conclude that during the first years of life (perhaps up to eight or ten years or more) the two hemispheres share equally the motor and sensory functions of speech, and that it is only during adolescence that the left hemisphere (in right-handed persons) takes upon itself gradually the greatest part of this burden.

Tumors about the Fissure of Rolando, or Motor Area, cause convulsions or paralysis of the side opposite to the lesion, affecting later the face, arm, or leg, or all together, according to the size and exact position of the growth. These local spasms are known as partial or Jacksonian epilepsy. When the spasm precedes paralysis, the probability is that the cortex is first affected. When the paralysis precedes the onset of spasm, we may reasonably conclude that the neoplasm began to develop in the white matter beneath the cortex. There may be some anaesthesia in connection with the paresis, for it is generally believed that the motor area subserves sensation also to a great extent. In all of these cases it is important to study the character and manner of onset of the spasms, whether partial or general. The aura of the epileptic attack is often of great value in determining the exact seat of the lesion. This aura may be a sensation of numbness or tingling, arising, for instance, in the fingers, hands, or toes. Seguin has given to this phenomenon the name "signal symptom." It indicates the starting-point of the cortical excitation. The order of extension of the spasm after the signal symptom must also be noted, for it indicates the path of extension of the discharge along the cortex. In the paralyzed parts the deep reflexes are of course exaggerated, as in all forms of cerebral palsy, and there is no actual atrophy, though disuse often leads to a diminution in the size of the affected members.

Tumors of the Parietal Lobe, like those of the frontal, often give no localizing symptoms, though the studies of M. Allen Starr and Dana are quite conclusive as to the frequency of sensory disturbances (muscular, tactile, pain, and temperature sense) in lesions at this point. Thus at times paræsthesia and anaesthesia may be found in the opposite limbs. But irritation may extend from the parietal area forward to the motor, and thus produce, as in the case of frontal neoplasms, partial or general convulsions. And by progressive extension the tumor may invade neighboring structures, and thus give rise to focal manifestations (motor symptoms by forward extension, hemianopsia by downward extension to the visual tract). In adults tumor in the inferior parietal lobule of the left side produces word-blindness, but this indication is of doubtful value in children. We do not yet possess sufficient information on this point to make any definite statements. The same is applicable to the matter of affections of the auditory speech-centre indicated in Fig. 1.

Tumors of the Occipital Lobe, in addition to general symptoms, give rise to the very important one of blindness of a half of each eye opposite to the the lesion (homonymous hemianopsia). The blindness is opposite to the lesion, but of course the affected half of the retina of each eye is on the same side as the lesion. From the occipital cortex, also, discharges may extend forward to

the motor area and produce convulsions, as in a case now under the care of Starr and myself, where a lesion (hæmorrhage at birth) in a girl of fifteen has given rise to hemianopsia and genuine epilepsy. A tumor by continued growth may affect parts forward, such as the sensory tract (hemianæsthesia) and even the motor (hemiplegia).

Tumors of the Temporo-sphenoidal Lobe will be apt, especially in children, to cause no definite localizing symptoms. The sense of hearing has its centre in the first and second temporal convolutions, and smell and taste have been assigned to the tip of this lobe. In adults it is probable that the form of sensory aphasia known as word-deafness may be produced by lesion in one part of the left temporo-sphenoidal lobe. We have still much to learn in this connection in the pathology of childhood.

TUMORS OF THE BASAL GANGLIA, LATERAL VENTRICLES AND ISLAND OF REIL, by their encroachment upon the internal capsule, through which so many important tracts pass (see Fig. 3), are prone to give rise to marked and wide-spread symptoms, such as hemiplegia (when anterior part of capsule is affected) and hemianæsthesia and hemianopsia (when the posterior part of the capsule is involved). Other than these no definite localizing symptoms will be noted in children. At times other structures (such as the cranial nerves) may be affected by pressure or distortion by tumors in these regions.

TUMORS ABOUT THE CRURA CEREBRI give rise to a variety of symptoms according to the parts affected and the extent of the lesion. The crus contains the motor and sensory tracts, and the two third nerves (motor oculi) rise from the crura very close together (Fig. 4). Thus if one crus is involved, there will

Structures at Base of Brain, to show topography.

be complete hemiplegia of the opposite side (occasionally hemianæsthesia also), and third-nerve paralysis on the same side (ptosis, etc.). This is called alternate or crossed hemiplegia. The optic tract is near at hand also, and if

affected, which is seldom, will give rise to homonymous hemianopsia (probably with hemiopic pupillary inaction). There may be unilateral incoördination. If the tumor be interpeduncular, some of the symptoms here mentioned will be bilateral. Optic neuritis is apt to develop early in these cases.

TUMORS OF THE QUADRIGEMINAL REGION are among the rarities. Some fibres of the optic nerve enter the corpora quadrigemina, and the centre for the reflex to light lies in them. Contiguous to them lie the nuclei of all of the motor nerves of the two eyes (third and fourth and fibres of sixth). Notknagel has made a study of tumors of this region based upon 10 cases collected by Bernhardt and 4 cases of his own, so that the symptomatology is pretty well established. There is staggering gait, resembling cerebellar titubation, and a progressive double ophthalmoplegia. The ataxia may be the earliest symptom. When this is followed by the condition of immovable bulbi, we may be quite sure of our diagnosis. The ocular paralyzes may be unequal on the two sides. Nystagmus has been observed in but one case. As the tumor develops, hydrocephalus is produced by pressure upon the aqueduct of Sylvius. A hemiparesis and hemianæsthesia, or irregular paralytic and anæsthetic symptoms, may be produced by extension of the growths toward the crus on either or both sides. The optic neuritis and blindness observed are due to the same causes at work in conjunction with neoplasms elsewhere. Three years ago I observed a case of quadrigeminal tumor in a little girl at the New York Polyclinic. Her first symptom was staggering gait. Then there was gradual development of oculomotor paralysis and blindness, and finally slight hemiparesis. At the autopsy I found a tubercle the size of a hazel-nut in the quadrigeminal region. There was also tubercular meningitis, and a few small tubercles in the cerebellum. The case has been reported by Sachs.

TUMORS OF THE PONS VAROLII give generally distinctive localizing symptoms, because of the cranial nerves which arise from or are adjacent to it. Thus the third nerve rises from the crus close to its upper border, the fifth from its lateral aspect; the sixth lies upon it; the seventh and eighth have their superficial origin below its lower border. In the interior of the pons are the motor and sensory tracts for both sides of the body, and the nuclei of several nerves (fifth, sixth, and seventh). If unilateral, the tumor is apt to give rise to crossed paralyzes or alternating hemiplegia and alternating anæsthesia. In the upper half of the pons a tumor involving part of the crus may cause ptosis and external strabismus, and anæsthesia upon one side, hemiplegia upon the other. In the lower part the growth may produce internal strabismus (sixth nerve), facial paralysis, and deafness, associated, possibly, with paralysis of the arm and leg of the opposite side. If the tumor affects the *root* or *trunk* of the sixth nerve, as may be the case in neoplasms growing from the base of the skull, the loss of power is only in the muscle supplied by that nerve. But if the *nucleus* of the sixth nerve be involved, there is a peculiar disorder of *both* eyes; that is, a loss of power in the internal rectus of the opposite eye also, which is only shown in the impossibility of conjugate movement of the two eyes toward the side of the lesion, since the external rectus of one eye and the internal rectus of the other habitually act together. There is in such lesions a conjugate deviation of both eyes to the side opposite to the lesion.

A lesion may be so placed in the pons that none of the cranial nerves are involved, and only a hemiplegia is produced, indistinguishable from a capsular hemiplegia. If both motor paths are involved, we may have a paraplegia. Such a lesion is generally accompanied by cranial nerve involvement on one or possibly both sides.

Both sensory and motor paths may be involved in primitive lesions, but

these paths are rather widely separated by the deep transverse fibres of the pons, and in such cases the lesion must be large.

TUMORS AFFECTING THE MEDULLA OBLONGATA are prone to give rise to striking symptoms, such as dysphagia, disturbances of the respiration and pulse, severe vomiting, polyuria, glycosuria, etc., from involvement of important nerves (glosso-pharyngeal, pneumogastric, hypoglossal, and spinal accessory), and widespread paralyses and anæsthesias from their impinging upon the great motor and sensory tracts contained in the medulla. These symptoms are generally bilateral.

In growths affecting either pons or medulla all sorts of combinations of symptoms may be observed, too numerous to be described here. The general symptoms, such as headache, vertigo, and vomiting, are common, but convulsions are rare.

TUMORS OF THE CEREBELLUM are among the most common of the intracranial growths in children. In the middle lobe they produce cerebellar titubation, a staggering gait much resembling that of a drunken man. Vertigo is also an important symptom, and is more severe and continuous than that caused by growths elsewhere. If the middle peduncle of either side be involved, the staggering is more to one side than the other. Tumors of the hemispheres of the cerebellum give rise to no focal symptoms unless they impinge upon the middle lobe or the peduncles. Cerebellar neoplasms by extension are apt to injure cranial nerves about the pons or medulla. Hydrocephalus is often observed: it is due to pressure upon the fourth ventricle or veins of Galen.

TUMORS AT THE BASE OF THE BRAIN in the anterior, middle, or posterior fossæ are diagnosticated by the symptoms characteristic of pressure upon or destruction of the important structures already mentioned.

Differential Diagnosis.—The presence, site, and nature of a neoplasm must be determined by the facts given in the preceding pages. Brain-abscess is differentiated by its own peculiar symptoms, described in another part of this volume. Tubercular meningitis sometimes presents symptoms similar to those of intracranial neoplasms, particularly when chronic. Ordinary forms are easily distinguished. Chronic hydrocephalus and cerebral hæmorrhage, when unusual in character, may simulate tumor, but careful study of the mode and order of development of their manifestations will generally serve to distinguish them.

Prognosis.—The prognosis is death unless the tumor be removed. M. Allen Starr gives the average duration of life as two years. Death occurs ordinarily by gradually increasing coma, sometimes with convulsions. Occasionally hæmorrhage in or about the tumor (especially in gliomata) may terminate life. At times a sudden meningitis (in tubercular forms) brings about a fatal end. Sudden death from unknown cause may occur.

Treatment.—It is evident that medicinal treatment of intracranial tumor must be in most cases merely palliative. Gumma of the brain being a growth almost never met with in children, the question of antisyphilitic treatment need not be discussed here. While it is always wise to make use of antitubercular treatment in cases suspected to be of this nature, it is doubtful if much can be done to diminish the extent or stop the progress of such neoplasms.

The routine treatment with cod-liver oil, tonics, fresh air, and the like, should certainly be carried out. It is possible that tuberculin or tuberculocidin may after a time be made available for such cases, but as yet the subject is too new to form any pronounced opinion. Klebs's experience with tuberculocidin in tubercular disease of the lungs, skin, bones, and joints is promising.

It is usual in most cases of brain-tumor, of whatever nature, to employ iodide of potassium in 10- to 20-grain doses, three times daily after eating, in an abundance of menstruum (water or milk). Arsenic is occasionally as useful.

In all cases there are symptoms requiring treatment, such as headache, intracranial pressure, insomnia, and convulsions. Antipyrin (2 to 10 grains according to age), cannabis Indica ($\frac{1}{2}$ to 3 minims of the fluid extract), and morphine ($\frac{1}{50}$ to $\frac{1}{12}$ of a grain) are good agents in headache due to this cause. Intracranial pressure may be relieved to some extent by purges, prolonged warm baths, the hot wet pack, and wet leg compresses. These remedies may quiet headache, vertigo, and vomiting, and will relieve insomnia. The bromides are often useful for insomnia, pain, restlessness, and vomiting, and are always indicated, combined with chloral, in cases with a tendency to convulsions.

The question of surgical interference will arise, for in this lies the only hope of effective relief against impending death. The question of the uses and value of cerebral surgery in children is still under consideration. Operations on the brain in children are more dangerous than in adults. The mortality is very great. There is a greater difficulty in diagnosis and localization in children. There is a larger percentage of cases of multiple tumors in childhood. Some 25 per cent. of the tubercular tumors of childhood are multiple. Considerably more than half of the neoplasms of the brain in childhood are situated in structures in the posterior fossa of the skull, and this region deserves the name of the surgical *noli-me-tangere* much more in children than in adults. Infiltrating tumors, of no well-defined limitation, are not uncommon. Thus we are forced to the conclusion that we must be much more conservative in advising surgical procedures in the brain-tumors of children than we need be in those of adults. When we have pretty certain evidence of the presence of a solitary new-growth in the cortex or centrum ovale of the cerebrum, we may attempt removal with a fair hope of accomplishing a good result. The large percentage of tumors with a recedivial tendency must, however, not be forgotten. The whole matter of brain surgery as regards children is still in an experimental stage.

THE AFFECTIONS OF THE NERVOUS SYSTEM DUE TO INHERITED SYPHILIS.

BY CHARLES W. BURR, M. D.,

PHILADELPHIA.

It has long been known that inherited syphilis may lead to disorders of the nervous system, but the matter was little studied until recent years. Many cases have been reported, and a review of the literature shows that as in the acquired disease any part of the nervous system, central or peripheral, may be affected. It is noteworthy, however, that in children born alive the nervous system is much less frequently the seat of disease than are the other organs. The exact percentage cannot for obvious reasons be determined. We have no positive data concerning the proportion of stillborn or aborted syphilitic infants with lesions of the nervous system. Much remains to be learned of the pathology of the disease, and the present paper will be confined, in large measure, to its clinical aspect.

Fournier claims that *persistent headache with nocturnal exacerbations* is one of the most frequent symptoms. Accompanying it, indeed often its only evidence, are extreme irritability, sleeplessness, and spells of screaming. Demme records a case in which the following cycle recurred: headache followed by anger, then torpor, and finally diabetes insipidus. Convulsions are very common, and are probably one of the most frequent immediate causes of death. They are usually bilateral, and with tonic and clonic contractions. Laryngismus and tetany, though most apt to be due to rachitis, sometimes occur. Barlow and Bury record the case of a child who had ten to twelve fits daily from the fourteenth day to the seventh month. In another case which came to autopsy at the fourth month extensive meningeal changes were found; and in a third, there were no cortical changes in the convexity, but symmetrical gumata were present on several cranial nerves. In this last case there were convulsive seizures in which the mouth was widely opened and the child became very dusky.

A few cases of apparently idiopathic *epilepsy* have been recorded in which the only discoverable cause was inherited syphilis. Gowers cites eight, in six of which the fits began after infancy. Abner Post relates an interesting case in which the attacks began with vertigo, the patient feeling as if she were in a boat which was rocking violently. They lasted about half an hour, and were followed by nausea and vomiting. There was never unconsciousness. The attacks occurred as often as three times a week, and disappeared under the use of iodide of potassium. According to Fournier, the condition is apt to be accompanied by pain in the head, noises in the ears, dimness of vision, vertigo, and intellectual failure. In the greater number of cases there are added to the fits, sooner or later, other symptoms of cerebral or spinal mischief.

The differential diagnosis between tubercular meningitis and syphilis is

often impossible unless a history of hereditary taint or evidence of it can be found. According to Horatio C. Wood, a general indefiniteness of symptoms and slowness of progression should arouse suspicion, especially if the absence of the pulse retardation indicates that the vault rather than the base of the cranium is in fault. Stoeber gives the following points in diagnosis: Tubercular meningitis is rare under one year; there is seldom palsy at the beginning; pyrexia is present; and the pulse is slow. Syphilis, on the other hand, may occur soon after birth; palsy is often present from the first; frequently fever is absent, and the pulse is irregular. Stoeber further regards retraction of the abdomen, projectile vomiting, constipation, delirium, contractures, and rapid wasting as characteristic of the former disease. Too often, however, diagnosis can only be made when it is no longer needed. Recovery means syphilis, as it is more probable that an error in diagnosis has been made than that a tuberculous case has recovered.

Hemiplegia is infrequent. In Osler's series of 120 cases only 1 presented a pretty definite history of syphilis. On the other hand, in Abercrombie's series of 50 cases at least 4 were syphilitic. Barlow and Bury report an interesting case in which there was at first loss of speech with right-sided paresis. After about four months of mercurial treatment the patient recovered almost completely, only to be again attacked, this time by left paresis and loss of speech. Finally there was complete recovery. The authors believe that there was endoarteritis of symmetrical branches of the middle cerebral arteries and degeneration of the cortical centres, especially of the third frontal, on both sides. A case of left-sided hemiplegia in a girl ten years old, described by Hughlings-Jackson, is made doubly interesting by the fact that two years before she had had chorea confined to the same side. Marfan relates a case in a child four months old in which recovery followed two weeks' mercurial treatment. Ordinarily, one-sided fits precede the palsy, and quite often convulsions continue in the palsied members; but it may come on without convulsions—without, indeed, warning of any kind. The child simply falls unconscious, and returns to consciousness palsied. In rare cases even consciousness is not disturbed. On the other hand, there may be restlessness, vomiting, and headache. The presence or absence of aphasia depends of course upon the situation of the lesion.

The most common anatomical basis of cerebral syphilis is *endoarteritis* and thrombosis with sclerosis and meningeal thickening. Angel Money, however, showed a specimen to the Pathological Society of London in which there were atrophy and sclerosis of the left hemisphere without disease of the arteries or membranes. Gummata are very rare. Rumpf cites but two, and M. Allan Starr in a table of 299 brain tumors occurring in persons under nineteen years of age records one only, and that in a youth of eighteen. It is very probable, however, that the small, yellow, and indurated foci found in various parts of the brain by Chiari and others are gummatous.

Chronic hydrocephalus is sometimes of syphilitic origin. Ruffer in a careful review of the literature says that it is mentioned as the cause in 20 per cent. of the cases. Mendel regards it as a frequent cause. Lancereaux speaks of a syphilitic woman who gave birth to several hydrocephalic children. The anatomical cause of the condition is, according to Sandoz, inflammation of the ventricular ependyma and plexuses. In some instances, as in a case reported by Negree, instead of the usual thinning of the cranial bones they are much thickened. Heubner reports a case in which the enlargement of the skull was found post-mortem to be due not so much to dilatation of the ventricles as to a pachymeningitis hæmorrhagica.

Paraplegia may result from disease either of the cord and its membranes or of the spinal column. Fournier records a case of hyperostosis affecting several of the dorsal vertebræ and causing symptoms of compression myelitis. Many signs of syphilis were present, and the patient improved under specific treatment. Laschkewitz cured in two months a palsy of all the extremities due to a similar condition in the cervical region. We have no positive knowledge whether distinctly syphilitic lesions occur in the spinal cord in the inherited disease, or whether the inheritance acts only as a strong predisposing cause. So far as we have been able to learn, no autopsy has ever been made in a case of purely cordal inherited syphilis.

Dixon Mann reports a case in a boy fifteen years old who, after two years of progressing weakness in the legs, became completely paraplegic and anæsthetic. Muscular rigidity, increased reflexes, girdle pain, paralysis of the bladder, and a slight bed-sore were present. Fever was absent. The patient recovered after four months' treatment. The author considered the symptoms to be due to thrombosis with circumscribed softening.

In none of the cases of Friedreich's ataxia recorded in Griffith's paper, and in none which we have seen, is there clear evidence of inherited syphilis, while almost all of the few known cases of *locomotor ataxia* occurring in children had distinct hereditary taint. Remak and Fournier detail several such.

Moncorvo relates three cases of *disseminated sclerosis*, two of which improved under specific treatment. Ozenne relates a case of latent infantile syphilis which was treated for some time for infantile palsy, and which presented the symptoms of that disease, except that fever was continuously present. A month's specific treatment resulted in recovery. True acute anterior poliomyelitis rarely occurs in children with such hereditary taint.

Eustace Smith describes a peculiar form of *palsy* which affects the *anterior branches* of the *brachial plexus*. It causes a more or less complete palsy of the arms, sensation and temperature remaining normal. He quotes two cases from Hensch in which the flexor muscles of the fingers alone retained slight traces of contractility. Under specific treatment the palsy disappeared. In some cases a peculiar twisting of the head backward has been noticed when the child has been placed in a sitting position.

Some years ago Sinkler reported cases of *chorea* occurring in syphilitic children, and others have been reported since. The total number is, however, so very small—in Rachford's 61 cases, for example, there being only 1 with a syphilitic family history—that the relation cannot be more than coincidental.

The *peripheral nerves* are quite apt to be affected, the lesion being either gummatous or inflammatory. Nettleship reported to the Pathological Society of London a case of a girl in whom there was palsy of the third, fifth, and sixth nerves on one side. She was under observation for four years, during which time the condition persisted. Hutchinson relates two cases of ophthalmoplegia externa, in one of which optic atrophy was present. Bury and Barlow speak of two cases in which the seventh nerve was involved. In one there was found post-mortem symmetrical gummata on the third, sixth, seventh, and eighth pairs. Lawford reports two cases of ocular palsy, and quotes one from von Graefe in which there was complete palsy of the third nerve.

It is probable that the form of deafness described by Hutchinson as occurring within a few years of puberty, and being bilateral, painless, and without discharge, is often due to disease of the internal ear or the nerve.

The most remarkable case of spinal-nerve disease is that reported by Omerod, in the person of a woman twenty-three years old with a tumor of the median nerve, probably gummatous.

Examination of the cases given above will show conclusively that inherited nervous syphilis is not a disease confined to infancy, but that, on the contrary, the symptoms may first appear at puberty or even later.

Idiocy is rarer than would be expected. The probable explanation is that given by Fournier—namely, that the lesions which would cause it are apt to be fatal. Shuttleworth and Beach found syphilitic taint in only 28 of 2380 cases which they investigated. Ireland regards it as rare. Mental disturbance coming on after infancy is more common. Many cases present the same symptoms as are found in birth-palsy—spastic paralysis, fits, and weak-mindedness. According to Barlow and Bury, juvenile dementia is more often due to syphilis than is usually recognized. Under the title of “general paralysis occurring about the period of puberty” Wiglesworth speaks of eight cases, the two most prominent causative factors being hereditary and congenital syphilis. Mendel reports a case of mania with hallucinations occurring in a child fifteen years old.

Diagnosis depends entirely upon the history and the presence of signs of syphilis. There are no pathognomonic symptoms. There is a form of syphilitic pseudo-paralysis, the so-called Parrot’s disease, which may be supposed to be of nervous origin if careful examination is not made. The apparent palsy, which may be monoplegic or diplegic, comes on spontaneously after birth without fever or convulsions and unaccompanied by any trophic changes. Examination will reveal that there is hyperostosis of the long bones or crepitation at the epiphyses from spontaneous fractures. Parrot believed the condition to be almost always incurable, but this has been disproved in quite a number of cases.

Treatment is the same as in the acquired disease.

INFANTILE CEREBRAL PALSIES.

BY FREDERICK PETERSON, M. D.,

NEW YORK.

THE infantile cerebral palsies are symptoms of a variety of pathological lesions in the brain, just as in adult life such paralyzes depend upon processes of different kinds taking place in various regions at different levels in that organ. We may have a *monoplegia* of the face, arm, or leg, or a *hemiplegia*, or a double hemiplegia (*diplegia*); or we may have the two lower extremities affected (*paraplegia*), for the amount of paralysis depends upon the extent of the lesion. The cerebral palsies of early life, then, are symptoms merely, and our most important duty in connection with them is to discover the nature of the lesion which causes them, and to localize the seat of the pathological process within the brain. But while the paralysis is the paramount symptom of the destructive process occurring in the brain, there are many concomitant clinical conditions which it behooves us to recognize and study. As a basis for this article I shall make use of a paper by Dr. Sachs and myself, published in the *Journal of Mental and Nervous Disease* for May, 1890, in which one hundred and forty cases were analyzed; and, in addition, shall include the results of my personal observations of considerably over one hundred cases studied at the Vanderbilt Clinic, in my nervous wards at Charity Hospital, and in private practice, making a total of about two hundred and fifty cases. There have been added to the literature since 1890 many valuable articles, clinical, pathological, and therapeutic, dealing with these palsies, from which I have drawn liberally such material as has been deemed useful.

The French are the earliest contributors to the study of these palsies. In 1827, Cazauvielh published a paper upon the palsies appearing shortly after birth, and described the pathological conditions which he found in the brain in six autopsies. He speaks of a primary idiopathic agenesis and of a form of agenesis secondary to a variety of cerebral disorders. Dugès, Breschet, and Cruveilhier about the same time and later contributed to the study of the atrophied brains of children, though Cotard did more than other Frenchmen to elucidate the pathology of the infantile cerebral paralyzes. He found cerebral atrophies to be accompanied by yellow plaques, cysts, cicatrices, cell-infiltrations, defects, and primary or secondary diffuse lobar sclerosis. The earliest German writer upon this subject was Henoeh, who in 1842 wrote *De Atrophia Cerebri*; while the earliest English writer to describe these palsies was Little; and the earliest American, Sarah McNutt. While these are mentioned as the pioneers in the unravelling of the mysteries surrounding these disorders, there have been contributions of enormous importance by many authors of different nationalities. Kundrat in 1882 produced an able dissertation on porencephaly, a name given by Heschl to the defects of brain-substance found in many such cases. Kundrat differentiated between congenital and acquired porencephaly,

and ascribed the origin of these defects to anæmic necrosis from circulatory disturbances. Audry added much to our knowledge of porencephaly by the collection of 103 cases, while Bourneville, Richardière, Wuillamier, and Jendrassik and Marie, on the other hand, carefully studied lobar sclerosis. Strümpell endeavored to explain most cases of spastic hemiplegia of children by his theory of an acute porencephalitis, but this theory is now altogether rejected in the light of recent research, especially that of Sachs. Heine, Benedikt, Bernhardt, Wallenberg, Kast, Hoven, Möbius, Feer, P. Marie, Gaudard, Gibotteau, Ross, Hadden, Gowers, Abercrombie, Ashby, and Freud and Rie, in Europe, have all at various times made valuable additions to our clinical and pathological knowledge of these disorders. In America, Weir Mitchell, Hammond, Sinkler, J. Lewis Smith, Knapp, Lovett, Gibney, J. Madison Taylor, and Imogene Bassette have materially increased the literature of the subject, while the monograph of Professor Osler is a rich storehouse of clinical and pathological facts relating thereto.

Statistics.—The relative frequency of the cerebral palsies of early life, as compared with the infantile spinal palsies, is in the proportion of more than one of the former to two of the latter, so that it is a much commoner malady than has generally been supposed. Boys are somewhat more frequently afflicted than girls. In 452 cases collected to determine the relative frequency of the various forms, there were 332 cases of hemiplegia, 73 of diplegia, and 46 of paraplegia. Cerebral monoplegia is extremely rare, there being only 1 in this entire number. In hemiplegia the right and left sides are about equally affected, the difference in favor of the right being very small. Thus, of the 332 cases of infantile hemiplegia, 175 were of the right and 157 of the left side. In bilateral hemiplegia or diplegia usually all four extremities were affected, but occasionally only three (both legs and one arm). As contrasted with the cerebral palsies of adult life, the enormous frequency of diplegias and paraplegias in the cerebral palsies of early life is striking.

As regards the *age at onset*, most cases of diplegia and paraplegia are congenital, while most cases of hemiplegia are acquired after birth. Two-thirds of the acquired palsies have their onset during the first three years of life. But it is worth while to remember that at least 17 per cent. of infantile hemiplegias are congenital. With Sachs, I found 5 cases where the hemiplegia occurred at the age of eight years, and 4 cases between eight and fifteen years of age; while Osler gives 14 cases with an onset between the ages of four and ten years. It is a fact, however, that cerebral palsies are often congenital in origin, though the symptoms may not become apparent until some three or four months after birth, so that doubtless many are ascribed to the first year of life which had their origin during intra-uterine existence or at the time of labor.

Etiology.—The infantile cerebral palsies fall naturally into three groups: I. Those which have their inception during intra-uterine life; II. Those which result from injury at parturition; III. Those which are acquired subsequent to birth.

The *palsies of prenatal origin* are numerous. Trauma to the mother during gestation is a frequent cause of injury to the cerebrum of the foetus. Serious diseases affecting the mother while carrying the child are common causes, particularly such as are septic in character or interfere with the normal circulation. Thus, fevers like typhoid, pneumonia, uræmic conditions, convulsions, and similar affections have in my experience resulted in maldevelopments of the foetal brain. Fright also has seemed, in one or two cases, to have brought about such a catastrophe, and doubtless other psychological strains may

produce like results. Premature birth at the seventh or eighth month was a coincidence in four or five congenital cases. Syphilis is extremely rarely a cause in congenital cases.

The chief cause of the cerebral *paralyses occurring during parturition* is undoubtedly tedious labor. Delivery is especially apt to be slow in primiparæ, and the older the primipara the more tedious is the labor usually. In such cases the long-continued pressure upon the head is apt to work mischief to the child's brain. While instruments are often employed in precisely these conditions, and sometimes themselves cause injury to the cranium, it is quite certain that the effects of compression in tedious labor are more commonly the cause of congenital paralysis and idiocy than the application of forceps—a point that the obstetrician should keep in mind.

The third group of cerebral palsies of children, the *acquired paralyses*, have a great variety of etiological factors, chief among which are the acute infectious diseases of childhood, giving origin to about 20 per cent. of all cases. These palsies may follow measles, scarlatina, small-pox, typhoid fever, whooping-cough, vaccinia, pneumonia, cerebro-spinal meningitis, gastro-enteritis, and tonsillitis. In pneumonia and whooping-cough the strain and engorgement produced by the coughing are probably important factors in the production of the palsy. Other causes of the acquired palsies are simple fright, trauma to the skull, hereditary syphilis, the status epilepticus, and infantile convulsions. There is no evidence of the existence of an acute polio-encephalitis analogous to poliomyelitis.

Symptoms.—Onset with *convulsions* is exceedingly common, the convulsions sometimes being a concomitant symptom of the brain lesion, and sometimes the actual cause. Since so large a proportion of the cerebral palsies of early life are due to lesions affecting the cortex, it is not surprising that convulsions should be so frequently observed. For the same reason *coma* is very common at the onset of the paralysis. The repetition of convulsions as the disorder progresses, especially in the form of epilepsy, is the strongest indication of involvement of the cortex in the pathological process.

The *form of the paralysis* is either monoplegia, hemiplegia, bilateral hemiplegia, diplegia, or paraplegia. The first mentioned is extremely rare. In hemiplegia the leg recovers more rapidly than the arm, as in the adult, but in rare instances the leg is, and remains, more affected than the arm. While the face is frequently included in the paralysis, it rarely continues to be paralyzed, but is among the first parts to recover. Traces, however, of facial paralysis may often be discovered in these cases on close investigation. Strabismus is found at times in all the forms of infantile cerebral palsy.

In children that have learned to talk, *aphasia* may accompany the palsy, probably quite as frequently a left as a right hemiplegia, for the motor speech-centre does not seem to be specialized in the left hemisphere during the early years of life. But a defective development of articulate speech is common in all forms, and particularly in the congenital cases and the earliest acquired cases.

I have observed *hemianopsia* in two or three cases of infantile hemiplegia, and Henschen has noted several such in his great work. Freud has described two. In the great majority of cases the *reflexes* on the affected side (knee-, elbow-, ankle-, and wrist-jerks) are exaggerated, but in about 5 per cent. they may be normal, diminished, or absent in the paralyzed extremities. Sometimes they are difficult to obtain on account of rigidity and contractures. This is especially true of ankle-clonus and the triceps-jerk. Frequently the deep reflexes are exaggerated also, as in the adult, in the normal as well as in the

paralyzed extremities; nevertheless, they are more marked in the parts involved in the palsy.

Morbid movements are remarkably common in the paralyzed muscles of hemiplegic and diplegic children. The most frequently observed of these motor disturbances is *athetosis*, occurring in some 20 per cent. of all cases of hemiplegia, and occasionally in diplegia. Next in point of frequency are *associated movements*; that is, the more or less exact imitation by the paralyzed hand and fingers of voluntary movements made by the normal hand and fingers, and *vice versa*. Such associated movements are to be observed in healthy children, the tendency in childhood being to make use of the two hands simultaneously; but in cerebral palsy this tendency is often so greatly exaggerated that such nicely co-ordinated movements as are required in writing and buttoning, when executed by the sound hand are closely imitated by the affected hand. *Choreiform movements* are found in some 5 or 6 per cent. of the hemiplegics, but are much more rare in diplegia. *Ataxia*, *rhythmical contractions*, *tremor*, and *tetanoid contractions* are occasionally to be noted. *Nystagmus* is found apparently only in cases of diplegia. I have remarked nystagmus in three, and Osler, in two such cases. I have recently described as present in two congenital hemiplegias a hitherto unnoted morbid movement to which I have given the name *post-hemiplegic polymyoclonus*. The movements are neither choreiform nor athetoid, but are constant clonic contractions of most of the muscles in the limbs affected, not occurring synchronously, and the rhythm being about that of paralysis agitans (five per second). All of these movements indicate interference with motor conduction due to lesions in some part of the voluntary and inhibitory tracts.

FIG. 1.

Cross-legged Progression.

Rigidity and contractures are striking symptoms in almost all these palsies, and for this reason they often fall into the hands of the orthopædic surgeons, who are besought to remedy the rigidly-flexed elbows, wrists, knees, and the various deformities that interfere with locomotion. Adductor spasm in the thighs, causing cross-legged progression, is nearly constant in diplegia and paraplegia. Talipes equino-varus is the most frequent pedal deformity in hemiplegia. Double talipes equino-varus is observed at times in both diplegia and paraplegia. Rarely talipes equinus and talipes equino-valgus are to be found in hemiplegia. While rigidity with contracture is the rule in all of these

forms of infantile cerebral palsy, occasionally, but very seldom, cases will be met with in which the muscles are all completely flaccid.

The chief *trophic disturbance* encountered in these cases is retardation in growth of the paralyzed members. The paralyzed limbs do grow, but at a much slower rate than the sound extremities. Hence the disproportion is often very striking. The earlier the onset of the palsy, the greater is this disproportion. Another peculiarity that I have noted is that the growth of the whole organism is to a certain extent interfered with, the injury to the brain seeming to stunt development and to prevent the patient attaining his normal stature. The patients are more or less undersized and dwarfed. This point was particularly made evident to me in a case of hemiplegia. The mother brought to me her two boys, twins, six years of age, for the examination of the

one affected. One was a tall, well-built lad; the hemiplegic boy was small-bodied and fully seven inches shorter than his healthy brother. In all of these cases the muscles of the paralyzed and undeveloped extremities react normally to the faradic current. In many cases the affected limbs may be blue and cold, as in paralysis of the spinal type. A very rare phenomenon in these cases is a hypertrophy of the muscles, usually combined with athetosis.

Epilepsy is undoubtedly the worst feature of these cases, affecting as it does over 45 per cent. of all forms. In the hemiplegic form fully one-half of the

FIG. 2.

Right Hemiplegia, with contracture and retarded growth of arm.

FIG. 3.

Right Hemiplegia, from age of nine months, in a woman thirty-six years; contracture and retarded development of paralyzed side.

cases suffer from epilepsy, in diplegia 30 per cent., and in paraplegia 36 per cent. of all cases. In most of them the epileptic seizures are general, but about 15 per cent. of the cases of infantile cerebral palsy suffering from epilepsy exhibited the Jacksonian type of seizure. I have observed *petit mal* in two or three cases. A very important fact has been brought out in this connection, and that is that many cases that have been diagnosticated as epilepsy alone are, upon close and careful investigation, found to present traces of a palsy often so rudimentary in character that it has escaped attention. In all cases of what appears to be idiopathic epilepsy search should be made for the residua of paralyse. There are undoubtedly cases of genuine epilepsy having its origin in similar pathological processes which beget the palsies of early life, yet in which no vestige of the organic lesion may be discovered at all. It would naturally be expected that as most of the lesions causing cerebral paralyse in early life are cortical, the epilepsy would be Jacksonian rather

than general, but the contrary is the case. The reason for this is that the original focal lesion disappears, and a general atrophy and sclerosis take its place.

Feeble-mindedness, imbecility, and idiocy in connection with these palsies are more frequently observed even than epilepsy. The proportion of mental enfeeblement is in a direct ratio to the extent of the pathological process, and hence in the diplegias and paraplegias a large degree of imbecility and idiocy is

FIG. 4.

Paraplegia: Photographed in Epileptiform Convulsion.

usually encountered, for here both hemispheres are involved. In hemiplegias, on the other hand, idiocy is relatively rare, though the lower degrees of feeble-mindedness and imbecility are to be noted in nearly one-half of all cases.

Among the *physical defects, or stigmata degenerationis*, are often found various cranial deformities, such as asymmetry of face and skull, microcephalus, leptocephalus, macrocephalus, and cranium proganæum. The Gothic palate, imperfectly developed or supernumerary teeth, hirsuteness, and deformed ears are other physical evidences of imbecility and idiocy at times encountered. I have, in a paper with Fisher, called attention to the flattening of the skull often observed on the side opposite the paralysis in infantile spastic hemiplegia.

Pathological Anatomy.—It is seldom that cases of infantile cerebral palsy come to autopsy at the time, or near the time, of their onset, while there are large numbers that have been carefully studied and described after the late secondary pathological changes have become manifest. But it is precisely the initial lesion that it is very important to understand. For a full discussion of the pathology I would refer the reader to the original paper written by Dr. Sachs and myself, and in particular to the chapter on “Cerebral Hæmorrhage, Thrombosis, and Embolism,” by the former, in Keating’s *Cyclopædia of the Diseases of Children*.

At the post-mortem examination the physician usually finds atrophy of a part of the brain, evidences of sclerosis, one or more cysts, or the condition known as porencephalus. All of these are terminal conditions. Cysts are secondary, as a rule, to hæmorrhage. Porencephaly may follow upon hæmorrhage, upon anæmic necrosis, or upon other long-antecedent processes. Atrophy and sclerosis, too, are the results of a variety of initial lesions, such as hæmorrhage, thrombosis, and embolism. While it is barely possible that encephalitis may be a forerunner of some of these terminal conditions, there is not sufficient evidence of the existence of the polioencephalitis of Strümpell to establish it as a fact. We may group the pathological processes, after Sachs, as follows:

Groups.	Pathological Changes.
I. Paralyses of intra-uterine onset	LARGE CEREBRAL DEFECTS (true porencephaly). HEMORRHAGES OF INTRA-UTERINE origin (softening?) AGENESIS CORTICALIS.
II. Paralyses occurring during labor	MENINGEAL HEMORRHAGE (very seldom intracerebral). Resulting conditions: meningo-encephalitis chronica; sclerosis; cysts; atrophies (porencephalies).
III. Paralyses acquired after birth	MENINGEAL HEMORRHAGE (very seldom intracerebral); EMBOLISM; THROMBOSIS (in marantic conditions and occasionally from syphilitic endarteritis). Results of these vascular lesions: cysts; softening; atrophy; sclerosis (diffuse and lobar). CHRONIC MENINGITIS. HYDROCEPHALUS (seldom the sole cause). PRIMARY ENCEPHALITIS (Strümpell) (?)

The pathology of the congenital cases is very clear. In a certain number of cases there is *defective development*, so that often large portions of the brain are wanting. These defects are possibly due to vascular disorders during foetal life. In other cases the defects are circumscribed, and the chief seat of these lesions is the motor areas. That hæmorrhages in the foetal brain during gestation may occur is proven by a case of Cotard. Sometimes the defects are not gross and large, but evident only upon close scrutiny, or are even microscopic. Such instances are the confluence of fissures, simplicity of configuration, exposure of the island of Reil, and the like. In these the chief feature is defect in the highest nerve-elements, the cortical cells, a veritable *agenesis corticalis*. In all such cases of defective development, whether gross or microscopic, idiocy is a marked symptom, while epilepsy is rarely if ever present. The absence of epilepsy may therefore be cautiously considered as an evidence of the nature of the lesion; it seems to prove a simple maldevelopment, an active process being thus excluded.

Meningeal hæmorrhage is the chief cause of all cases of cerebral palsy occurring during labor, although at autopsy the conditions found may be chronic meningo-encephalitis, sclerosis, cysts, atrophy, or porencephaly. These hæmorrhages are produced by the compression which the head undergoes in the pelvis during parturition. In this connection I cannot forbear referring to the recent researches of Herbert R. Spencer. Among 130 stillborn children he found 4 cases of thrombosis of the longitudinal sinus, 1 of intracerebral hæmorrhage, and 53 of hæmorrhage from the pia and arachnoid: 29 times there was bilateral hæmorrhage, 10 times in the right side of the brain only, 10 times in the left, 7 times into the lateral ventricles, and 6 times limited to the base of the brain. He finds the frequency of central hæmorrhage greatest with forceps delivery, next with breech presentation, and least with natural head presentations. He believes that softness of the skull-bones and their increased mobility may be determining factors in the production of hæmorrhage. In 30 cases he found hæmorrhages into the spinal canal and cord, and I cannot but believe that some, though a very small percentage, of the cases of paraplegia especially, and perhaps diplegia, may be due to cord lesions at birth after all, and not to cerebral lesions. Otherwise it is difficult to explain the great intel-

ligence and freedom from epilepsy, athetosis, and the like, of a select few of the palsies of these forms.

As regards the third group, or the acute acquired palsies, *hæmorrhage*, *embolism*, and *thrombosis* are the chief causes of cerebral paralysis in children after their birth, just as they are in the adult. We have apoplexies in childhood as in later life. I have named these causes in the order of their frequency. Sachs and myself collected and analyzed the results of 78 autopsies in infantile hemiplegia as follows:

Lesions Found.	No. of Cases.
Terminal conditions:	
Cysts, atrophy, sclerosis	40
Porencephaly	2
Hæmorrhage	23
Embolism	7
Thrombosis	5
Tubercle	1
Total	<u>78</u>

It would be impossible to determine the initial lesion in the terminal conditions cited in the above table, but doubtless most of these also were vascular in their nature. Hæmorrhage in children and adults differs both as to cause and position. In adults, as is well known, the bursting of miliary aneurisms in atheromatous vessels is the common cause of hæmorrhage. Miliary aneurisms, as well as large ones, are occasionally found in children, but in them fatty degeneration of the vessel-walls, as described by Von Recklinghausen, is more frequent. In adults hæmorrhage generally takes place in the neighborhood of the internal capsule; in children, in the meninges and about the cortex. Exceptionally, intracerebral hæmorrhages do occur in childhood. In the paralyzes following acute rheumatism, endocarditis, and scarlet fever, it would be natural to suspect an embolic process, as in the adult; and in hereditary syphilis and marantic conditions thrombosis would be the lesion most likely to supervene: but as compared with hæmorrhage both embolism and thrombosis must be looked upon as rather infrequent causes.

The pathological process here described as so common in children may occur, it must be remembered, without producing paralysis; for where other parts than the motor areas are involved other symptoms may result, such as epilepsy alone or the various degrees of idiocy. A beautiful case in point was one sent to the Vanderbilt Clinic some two years ago, a young girl with epilepsy and a left homonymous hemianopsia, congenital in origin, showing undoubtedly a cortical lesion over the right occipital region (reported by M. Allen Starr).

Differential Diagnosis.—The hemiplegic, diplegic, or paraplegic form of the paralyzes, the rigidity, the exaggerated reflexes, the normal electric reaction of the muscles, the absence of actual atrophy in the limbs, the presence of epilepsy or idiocy or of morbid movements of one kind or another, usually serve to easily distinguish this disorder from infantile spinal paralysis. It would be only in some of the mildest types of either of these affections, or in the case of a monoplegia, that any difficulty might present itself; and even here some one or two of these indications would suffice for a diagnosis. It is a fact, however, that in many cases of epilepsy, athetosis, chronic chorea (especially hemichorea), and in some of imbecility or idiocy, a hemiparesis is often overlooked.

Prognosis.—Death as a result of infantile apoplexy is very rare. The duration of life in such palsies is generally short. Few cases of diplegia and paraplegia reach the age of twenty years. A certain small number of hemiplegics may attain the age of forty years. In most cases it may be stated that

the face will recover, and that the leg will become sufficiently useful for locomotion. In the bilateral palsies the prognosis as regards walking cannot be quite so favorable. Except in the severest forms speech will be recovered more or less perfectly. After the lapse of a few months an idea can be obtained as to the mental state, and as to whether imbecility or idiocy is to be apprehended. The probability of epilepsy is the feature in prognosis requiring the greatest exercise of judgment. Epilepsy may not appear for a year or two after the onset of the paralysis, and the statistics already given as to the enormous percentage of these cases thus affected must be borne in mind.

Treatment.—In cases seen shortly after birth, showing symptoms of cerebral lesion, quiet and careful handling are the chief indications. Minimal doses of bromide of potassium or chloral, or chloroform inhalation may be employed if convulsions occur. In the initial stages of the acute acquired palsies we treat the infantile apoplexy in much the same manner as we would apoplexy in the adult. Absolute quiet, cold applications to the head, and emptying of the bowel are the first steps in treatment. In a few days the bromides may be used to ensure greater rest to the brain, and subsequently, combined with an iodide, continued for some time, though not so long as to interfere with nutrition. In the chronic stages relief is generally sought for secondary conditions, such as deformities from contractures, and idiocy and epilepsy. Excellent results are achieved by tenotomy and orthopædic apparatus properly applied for the correction of the various deformities, particularly of the lower extremities. In one case in this city athetosis in the right arm was so extreme that the limb was amputated at the shoulder, to the great relief of the patient. Electricity (especially the faradic current) may be used to exercise the paralyzed muscles, and, combined with massage, may go far to prevent and remedy contractures.

The epilepsy is treated with the usual agents, the bromides, chloral, and the like, though, it must be confessed, without much success. To remedy the mental defects very much can be done by careful manual and intellectual training. In fact, surprising results are often achieved in the development of the mind, speech, capabilities, and character of these cases when placed in schools especially adapted for such purpose, as is evidenced by the experience at Bicêtre and some of the private schools in this country.

As regards surgical procedures in any of these cases, either for relief of epilepsy or for the improvement of the mental condition, the most that can be said at the present time is that, upon the whole, little or nothing is to be expected from trephining, craniectomy, and the like. Possibly future experience may justify operative interference in a small percentage; but the great majority of infantile cerebral palsies are better left to the treatment of the family physician, to the orthopædic surgeon, and to the developmental influences of special schools. M. Allen Starr states, in a very recent paper, that he has collected some fifty cases of operations in these and allied conditions (like microcephalus). Many of these he publishes in a list, and an examination of his table showing the results obtained is certainly not very encouraging. In addition to these, Sachs gives notes of three of his own cases operated upon, all hemiplegics with epilepsy, in two of which the seizures returned after operation in three and six months respectively, and the other was not seen after three months, up to which time no attacks had supervened. Wildermuth, however, reports two cases of hemiplegia with epilepsy, in which the seizures seemed to have ceased, one having not been observed for three years and the other ten months subsequent to operation. Besides the apparent futility of cerebral surgery in most of such cases, children do not undergo these operations with as little danger as adults, and the proportion of deaths in the cases thus far published is rather large.

SPEECH DEFECTS AND ANOMALIES.

BY CHARLES K. MILLS, M. D.,

PHILADELPHIA.

PHYSICIANS are frequently consulted with reference to absence, deficiency, or peculiarity of speech in children at different ages from birth to puberty, but particularly in those under six or seven years old. Healthy infants acquire articulate speech at varying ages, according to inherited qualities, the general health, the influence of some acute disease, or the surroundings of the child. The child of deaf and dumb parents, or one placed where it hears or sees but little, or one not much thrown into the company of talking adults or older children, may be delayed in the initial stages of articulate language. Sometimes at the age of nine or ten months unusual precocity is shown. Ordinarily, about the end of the first year or the beginning of the second, parents and physicians look for some decided efforts at speaking, and when eighteen months or two years have been reached without these, anxiety begins to be experienced and inquiries to be made. The problem presented is by no means a simple one. The physician must carefully weigh a number of facts and must investigate from a variety of standpoints. Starting with the peripheral apparatus of speech and proceeding toward the central nervous system, he must examine into the muscles and nerves of articulation, phonation, and respiration; the external and internal apparatus of hearing, the nuclear centres of several of the cranial nerves; and the hearing, speech, and visual centres of the cerebrum and their commissures. He must fully consider the mental status of the child, and if this be settled adversely, the rest may need little attention; but if not so decided, then, step by step, each of the parts and processes concerned directly or indirectly in the mechanism of speech must receive close scrutiny.

Is the child idiotic or imbecile? Is it suffering from aphasia, congenital or acquired at or since the time of birth? Is the speech loss due to brain arrest? Is the child simply backward in speech? Is it suffering from some functional or hysterical affection? Is the child a deaf-mute, and, if so, what is the character of this deaf-mutism? Is it dependent upon periosteal or bone disease? Is it the result of old or recent inflammatory disease of the ear, either primary or the sequel of some acute infection, as scarlet fever or measles? Is the deficiency of speech due to paralysis of any of the nerves or muscles of articulation? Is it a spasmodic affection of these nerves and muscles? What is the shape and size of the oral cavity, and, if deformity of the vault of the palate, of the pharynx, or of any part of the oral cavity be present, is it or is it not associated with true idiocy and imbecility? Is, as mothers so often wrongly imagine, the child tongue-tied, the frænum being so attached as to prevent free movements of this organ? Are adenoids or other growths or enlargements present?

SPEECH DEFECTS DUE TO IDIOCY OR IMBECILITY.

Dysphrasia, a term applied by Kussmaul (*Ziemssen's Cycl. Pract. Med.*) to defective or absent speech due to intellectual impairment, is more frequent in children than any of the varieties of aphasia, but is of course usually then an accompaniment of idiocy or imbecility. The child cannot speak, or talks imperfectly or foolishly because of an absence or deficiency of ideas; it does not speak, as Griesinger has said, because it has nothing to say. It does not know anything that would be ordinarily transmuted into language. Even in idiocy the cortical organs of speech, considered as special areas, are doubtless often arrested or diseased, but in addition other parts of the brain concerned in mentation may be lacking or altered. As is well known to those connected with institutions for the feeble-minded, not a few cases with some intelligence cannot by the greatest perseverance be taught to speak; some can be taught a few words and sentences, but cannot get beyond a certain point, which is limited by their ability to assimilate knowledge. Others perhaps can be taught, parrot fashion, to repeat words or even phrases or sentences of the meaning of which they have no idea. Many interesting observations upon the development of speech have been made in all such institutions. Physicians will be called upon to give opinions not only as to arrest of mental growth, but also as to the capabilities of future development in such children; and such opinions can be only of value when they are based upon a close study of the conditions present at the time of examination, and of the life and family history of the child. Mierzejewsky, cited by Kussmaul, has described in great detail the history of an aphasic idiot who lived to be about fifty years of age, and whose mental powers and speech were about as developed as those of a one or one and a half year old boy. He could only give utterance to a few of the simplest syllables. His brain was examined, and resembled in the shape and the arrangement of the convolutions that of a human fœtus of the ninth month. The methods of diagnosing idiocy and imbecility will be considered in the next section, and it will therefore not be necessary to call further attention to this subject here.

APHASIA.

The term "aphasia" is sometimes carelessly applied to almost any variety of speech disorder, but it is best restricted to the description of complete or incomplete loss of speech from a local cerebral affection. It is conveniently divided into motor or expressive and sensory or receptive aphasia, and these have special forms, some of which need to be borne in mind even in studying the disorders of speech from which children suffer. Sensory aphasia has several varieties, as word-deafness and word-blindness, which define themselves, and apraxia or mind-blindness, in which the ability to recognize the use or meaning of an object is lost. Aphasia may be both sensory and motor, as when the receptive and emissive sides of the brain are both involved in disease. Agraphia is loss of power of writing; amimia, inability to express thought by signs and pantomime. Besides varieties of aphasia resulting from cortical lesions, others may be due to destruction or interference with the commissures or lines of connection between various centres, and these are known in general terms as paraphasias or conduction aphasias. Alexia is abolition of the power of reading, as agraphia is that of writing; dyslexia refers to difficulty or fatigue in reading; paralexia, to the misuse by transposition or substitution of either words or syllables, while paramimia is the misapplication of signs

or pantomime. Whether a child can have alexia, dyslexia, agraphia, or amimia will of course depend on its acquirements—on its ability to read, to write, to talk, or to express itself by gestures or pantomime. Children under six or seven years old would need to be studied from different standpoints from those over this age, and children between six and ten would need a consideration which would differ for those from ten to fourteen.

True aphasia is sometimes congenital: a deficiency of speech not dependent upon lack of general intellectual power may be present, or, in other words, a distinction can sometimes, although perhaps rarely, be made between a dysphasia and an aphasia of prenatal origin. Broadbent (cited by Kussmaul) has reported an interesting case of congenital aphasia in an intelligent boy. When twelve years of age he understood everything that was said to him and did what he was told to do, but could not, as a rule, say anything but "Yes," "No," and "Father" and "Mother," pronouncing the last two words imperfectly. He used also an indirect expression in answer to all questions; occasionally he uttered a few other words, such as "All right!" "Thank you," and he had other interesting peculiarities. A few cases have been reported which seem to show that the arrest of the organs of articulation was the particular condition present, as one in which the idiot could utter only a few scarcely intelligible words, but could express himself well by an animated and intelligible pantomime, and was even able to report on different things that occurred in the asylum.

Aphasia the result of acute lesions occurring after birth is rare in children as compared with adults, as hæmorrhage, embolism, and thrombosis are of infrequent occurrence in childhood. Of the three, embolism as an accompaniment of rheumatism or endocarditis is probably the most common. When a lesion does invade the speech-areas of the brain on the left side, the other hemisphere more quickly assumes the lost function than in adults. Sachs (*Keating's Cycl. Dis. of Children*) records seventeen cases of hemiplegia with aphasia. His experience is in accord with that of Bernhardt, who found that aphasia in children accompanied left as well as right hemiplegia. Other acute causes of aphasia in children are meningitis, tumor, and abscess. Occasionally in tubercular meningitis a form of aphasia or paraphasia may be developed, and this particularly when the tubercular deposits or conglomerates are in and around the Sylvian fossa. Sometimes in basal meningitis in children, owing to inflammation and exudation in the pons-oblongata region, a form of dysarthria or articulatory paralysis will show itself.

The position and size of a neoplasm will determine how far speech or any of its elements or tributaries will be affected. Word-deafness may be present when the first and second left temporal convolutions or the white matter beneath and near these areas are invaded, although such word-deafness may soon in part be recovered from if the right hemisphere be intact. Word-blindness in a child that can read or write may result from a tumor situated in the zone where the left parietal borders the anterior occipital region. Of course a tumor of any description involving the hinder part of the left third frontal will cause more or less motor aphasia in a child that has acquired speech, and may arrest the development of the faculty in one of tenderer years. When the island of Reil is invaded, either aphasia or paraphasia may result.

Intracranial abscess sometimes is the cause of word-deafness or some other variety of aphasia in children. Such cases are usually associated with aural disease, as when purulent disease of the mastoid or of the tympanic cavity leads to meningeal inflammation and abscess of the temporal lobe.

Aphasia usually with, but sometimes without, monoplegia or hemiplegia may be a consequence of hereditary syphilis. These cases may have several attacks of aphasia with partial paralysis, sometimes affecting different sides of the body. The lesions are usually the outcome of endarteritis or chronic meningitis, particularly leptomenigitis, and in some cases they are forms of cortical sclerosis with atrophy. The child will often show some of the other well-known evidences of inherited taint, as notched or pegged teeth, cracking of the corners of the mouth, flattening of the nose and face, or interstitial keratitis. It is important to recognize the syphilitic origin of these cases, and to treat them accordingly with mercurial inunction, calomel, iodide or bichloride of mercury, or the iodides of sodium or potassium.

In children, as in adults, aphasia has been noticed in the course of typhoid and other fevers: probably in most of these cases the affection is not due to a local lesion, such as a clot or the closure of a vessel, but to a toxic influence exerted by the poison of the disease on the brain. Bassette (*Jour. Nerv. and Ment. Dis.*, July, 1892) has reported two cases of this kind, one in a girl nine years of age, who in the second week of typhoid fever became markedly deaf without middle-ear complications, and also had partial hemiplegia. The paralysis passed off, and she began to recover her speech about the sixth week. Another, a girl of five years, ceased to speak for eleven days.

Children, through fright or other cause, sometimes suddenly become speechless. Hysterical children also have attacks of mutism. Langdon Down (cited by Ashby and Wright in *Diseases of Children*) records the case of two brothers, who had spoken well and understood two languages, completely losing the power of speech at the second dentition.

In rare cases children who are not idiotic, and who are not suffering from either central or peripheral disease, are nevertheless exceedingly slow in learning to speak, and in particular for a long time may fail to acquire the proper method of articulating and pronouncing certain letters and sounds. Sometimes such children are otherwise intelligent, and eventually develop up to the full standard of mental health and activity. In some remarkable cases children, even to the age of ten or twelve, have habitually made use of only a few letters. Deferred or retarded speech development must be distinguished from congenital or acquired aphasia of more permanent type. According to Bastian, cases allied to congenital idiocy are observed, in which, owing to some intracranial lesion occurring before, during, or soon after birth, the child's mental condition is greatly degraded as well as his motor power. In some of the less severe examples of this type speech is merely deferred, perhaps until the fourth, fifth, or even sixth year, and may become after a time established in a natural manner. Bateman (*Aphasia, or Loss of Speech*, 2d ed., 1890) mentions a case of this tardy development of the faculty of speech which came under his observation. The child never spoke at all until he was six years old, and it was thought that he would remain dumb. At six years of age he began to talk, and was able to receive an education suitable to his condition in life, but he grew up to manhood a person of feeble intellectual and also of feeble physical power.

ECHOLALIA AND COPROLALIA.

In the affections known as echolalia, coprolalia, and by various other names, convulsive or choreic movements are associated with a sudden explosion of speech. The patient with a grimace, contortion, or violent movement of some kind suddenly bursts into obscene, profane, or absurd expression. This

expression may be the echo of something overheard—hence the name, *echolalia*—or it may be a spontaneous outcry. It is not simply a hysterical affection, controllable and curable, but is a true monomania, the affection of speech being beyond the patient's volition; it could properly be discussed under morbid impulses as well as here. One patient of mine, a boy twelve years old, at times, without warning, would in a street-car or other public place, as well as in private, suddenly give utterance to a filthy expression two or three times, accompanying it with a violent movement of the head, shoulders, and one arm.

DEAF-MUTISM.

Deaf-mutism must be carefully distinguished from aphasia and other affections of speech. While some cases are congenital and associated with more or less profound idiocy, the number of these, according to good authority, does not equal those which can be fairly attributed to disease and accident after birth. Even congenital deafness and dumbness are sometimes due to peripheral causes, as to periostitis, otitis, or imperfect development of the petrous bone. The semicircular canals or other portions of the internal ear may be wanting or altered by intra-uterine disease. Colloid degeneration of the labyrinth is said to be a frequent cause of the absence of hearing, and various diseases of different parts of the auditory apparatus, particularly of the internal and middle ear, may occur before birth. These cases must be separated from those of mutism or deaf-mutism associated with idiocy. A diagnosis may sometimes be made by careful physical examination and a study of the mental condition of the patient. Purulent otitis or, what is more difficult of decision, *Voltolini's* labyrinthine otitis, or some other form of labyrinthine non-purulent inflammation, may cause absolute deafness, and owing to this deprivation the child may be supposed to be mentally deficient. Indeed, such a child may, under unfavorable circumstances, fail to develop to any considerable degree. A process of experimental training of the senses which are left will sometimes enable a decision to be reached in a comparatively short time. The patient who is simply deaf-mute, from whatever peripheral cause, will under proper incitements be able to fix his attention and show intelligent interest in his surroundings.

The exact age under which a child will lose its speech because of loss of hearing cannot be absolutely fixed; but when total deafness is caused by purulent disease of the ear or other destructive affections before the age of six or seven years, the child is likely to become mute as well as deaf unless special training has at once been started, and even in spite of this a certain degree of loss or imperfection of speech will result. The original capacity and the acquirements of the child at the age when deafness occurs will of course have a bearing upon the question of deaf-mutism. Occasionally children who have had scarlet fever, measles, or infectious diseases at the age of two or three years, and have become totally deaf in consequence, are supposed to be idiotic. Such children, if naturally intelligent, will exhibit great interest in everything that comes within the range of the senses that are left. Slow or stupid children deprived of hearing and speech, particularly if treated with neglect or indifference, will sometimes sink into a state of inertia which simulates a true imbecility or fatuity, leaving them with defective mental powers. A physician should be acquainted with the usual time when a child of average mental capacity acquires the ability to respond to general sounds and noises, and then to special sounds, voices, and eventually to definite words, and also when it first gives vent to feelings of pain or pleasure, when it makes special response to particular sounds, when it imitates sounds connected or not connected with

ideas, and when, finally, speech becomes a method of expressing centrally initiated thought, no matter how elementary this may be. It is not as difficult, as at first sight might appear, to learn to follow and analyze such processes of development and to determine as to their retardation or advancement. Mothers acquire great facility in this way by comparison of the progress of their different children.

Preyer (*The Mind of the Child*, part I., transl. by H. W. Brown, 1889) has made a practical study of the development of the different senses and mental faculties, based largely upon the close study of his own child. According to him, the new-born are always deaf, because of temporary local conditions, such as lack of air in the tympanic cavity, collections of liquid or gelatinous substances in the middle ear, and closure by foreign matter of the external auditory canals. Whether this be absolutely true or not, it is certain that all healthy children in a few hours or in a day or two at least react to impressions of sound. Of fifty children who were tested by Mollenhauer, ten, less than twelve hours old, reacted to a brief disagreeable sound. Preyer was not convinced until the first half of the fourth day that his child was not deaf. In the eighth week he showed pleasure at piano-playing, and in the ninth the sound of a repeating watch aroused his attention to the highest pitch, while in the eleventh week he moved his head in the direction of the sound heard; and soon this was always done with great promptitude and certainty. After a half year he enjoyed single notes and military music, and soon he showed evidence of intellectual advance. After the first year the child rapidly advanced in his exhibition of logical activity in connection with hearing. The statement that children from three to four months old possess normally very slight capacity for hearing must be pronounced false, according to Preyer, for long before the third month the human voice is heard by the normal infant, and before the close of the first week normal children react to the stimulus of loud sound.

Kussmaul distinguishes three periods in the development of articulation. Within the first four months, and about the time of the earliest movements of prehension, children give vent to spontaneous sounds indicating their feelings of joy. These are chiefly lip and vowel sounds, but sometimes they are also lingual and palate sounds. In a second period these savage noises, are gradually crowded out by the conventional sounds of the national language, but even these are of a very simple character. Some of them are imitated and some are not. With the commonly used words *ma, ma*, and *pa, pa*, the child at first does not connect any idea, but by degrees learns to do this. At a third stage speech becomes an expression of thought, a child learning to associate certain definite objects with the words acquired by practice. All this may be accomplished in the most elementary way by the end of the first year.

"Sounds such as *m-m, ba-ba, da-da*," say Ashby and Wright, "may be repeated in a meaningless sort of way, but before long are applied to persons and things. During the second year the vocabulary increases fast, and the child quickly imitates and repeats the words it hears, so that by the end of the second year it not only uses a number of words, but can string together a few nouns and adjectives or has learned the meaning of short sentences. At this period, and for the next year or two, words are indistinctly or improperly pronounced, with a tendency to clip them short or to drop consonants. Some consonants present greater difficulty to the young child than others, and are constantly dropped out of words; thus *s*, especially when it precedes another consonant, is omitted, as *cool* for *school*, *kweek* for *squeak*, *no* for *snow*. Difficulties often arise with the aspirate dentals, as *th* and *sh*. *Ruth* becomes *roof*; the vibratory consonant *r* is a great stumbling-block, and the distinct pronun-

ciation of it is perhaps never acquired; *grub* is apt to become *gwub*, and *roof*, *woof*."

AFFECTIONS OF SPEECH DUE TO PERIPHERAL PARALYSIS.

After acute infectious diseases, and particularly after diphtheria, palatal or pharyngeal paralysis may be present. Occasionally an attack of diphtheria is overlooked or supposed to be some other throat affection, and even so-called latent cases sometimes result in forms of paralysis. Facial paralysis in children would be determined by the appearance of the face, and indeed the affection of speech in such cases is usually very slight. Lingual paralysis of peripheral origin is rare both in adults and in children.

STUTTERING AND STAMMERING.

The presence and meaning of stuttering and stammering in children may demand careful consideration. Boys are much more likely to be afflicted with this disorder than girls. Stuttering can be distinguished from stammering, although this distinction is often not made. According to Kussmaul, individual sounds are difficult for the stammerer, but not for the stutterer, with the latter the syllabic combinations offering the greatest obstacles. In stuttering a spasm accompanies the impeded utterance, but not in stammering; and greater nervous embarrassments underlie stuttering. Other differences are given by Kussmaul, but the one which is perhaps of the most practical importance in making a differential diagnosis is that stammering is often accompanied by anomalies of the tongue, lips, and articulating organs in general, while malformations, defects, paralysis, etc. are rarely observed in connection with stuttering. It is important for the practitioner to study the duration, possibility of improvement, and underlying causes of such defects when presented by young children. Usually stuttering does not show itself so as to attract attention before the age of six or seven, although rare cases have been observed in young children. Sometimes stuttering or stammering is a temporary affection, coming on in children who have been overworked or undernourished or both, who have been subjected to unusual strain or excitement, or who have had an attack of fever; and in the last case it may or may not be curable. Some forms of stuttering are distinctly hysterical, and may be relieved by attending to the general nervous health of the patient. The condition of the tongue and mouth of a little patient who has been attacked with a spasmodic chronic disturbance of speech should not be overlooked, as now and then some affection of the tongue, lips, and palate may be the cause of the difficulty. A spasm of the muscles of articulation and deglutition may cause an affection of speech that will simulate ordinary stuttering. Putting aside all these causes of temporary and, it may be, remedial forms of spasmodic utterance, the vast majority of cases will be found to depend upon some original defect in the central nervous apparatus. By prolonged and careful training a few of these cases can be cured, others can be helped, while a large percentage are absolutely beyond remedy.

DEFORMITIES AND DEFECTS IN THE MOUTH AND PHARYNX.

Sometimes in children who are not mentally defective the palate, and even the jaws, may be of some particular shape, interfering to some extent with easy and perfect speech. The possibility of such cases should always be remembered, but, on the other hand, it should be clearly before the physician that

among the commonest somatic evidences of idiocy and imbecility are the shape and condition of the palate and jaws. In some types of congenital idiocy both upper and lower jaw may be narrow, the roof unusually vaulted or gothic, while in others the vault may be unusually low and flat. All varieties of palatal deformity or aberration are present in various types of idiocy. Teeth also are likely to be imperfect in such cases, and the tongue may be disobedient to the behests of the will. A fair judgment of the mental status of such a child and the meaning of its defective speech can often be reached by a study of these peculiarities and deformities of the head, face, mouth, tongue, teeth, jaw, and palate.

Mothers are always much inclined to regard a defect of speech in their children as due to what is popularly called tongue-tie. In rare cases a frænum which reaches too far forward may be present and cause some interference with the pronunciation of a few sounds; in still rarer cases the tongue itself may be congenitally short or deformed, but such conditions are easily determined or dismissed by careful examination.

ADENOID GROWTHS.

Adenoid growths of the vault of the pharynx may be the cause of difficulties and peculiarities of speech, as well as of interference with hearing even to the extent of deafness. It will happen now and then that a child of two, three, or four years of age, supposed to be idiotic or imbecile, will in reality be suffering from adenoid deaf-mutism, the lack of mental development being apparently due to privation of two of the most important channels of communication with others. In all doubtful cases careful examination of the mouth should be made. Even if the deafness be not curable, great relief will be afforded to the parents by the knowledge that the child is not idiotic, and special efforts can be made at training and education in accordance with the principles and methods which bear the most fruit in dealing with deaf-mutes who are not primarily deficient in mind.

Various impediments in enunciation and pronunciation may also result from the peculiar obstruction produced by these papillomata when of large size. The voice is often considerably changed, and in enunciating certain letters muffling may occur; but hasty opinions should not be given as to the future simply because of the discovery of these growths, as they are sometimes present in idiotic children or in stammerers or stutterers.

BAD HABITS OF SPEECH.

In studying cases of imperfect or nervous utterance attention should be given to the subject of bad habits of speech. Children, through carelessness, through the foolish management of those around them, or of their own motion, may acquire certain habits of speech which will cling to them to such an extent as to become serious impediments in the way of development of good methods of speaking. Among these habits are frequently hesitating, unduly repeating, drawling or hurrying, using babyish or foolish expressions. Children should be coaxed or disciplined out of such habits when once acquired, but it is far better not to let them take possession of the child.

TREATMENT OF SPEECH DEFECTS.

The treatment of different forms of defective speech must depend upon the nature and degree. Aphasia from an acute lesion, such as hæmorrhage or

embolism, or as one of the effects of inherited syphilis, may often be benefited by time, medicine, and training. The medicinal treatment, after the first period of rest and care during the apoplectic stage, would be chiefly the use of absorbents and tonics, such as iodides, arsenic, iron, and strychnine. Diligent efforts should be made to train an aphasic child. Even some cases of congenital origin can under appropriate and persistent training be much improved. Here the diagnosis as to the presence or absence of true idiocy, and as to the degree of mental deficiency, is of great importance in deciding as to how far to push the treatment by efforts at education and training. In aphasia coming on gradually with more or less dementia in a child previously bright, or at least ordinarily intelligent, the probability of inherited syphilis should always be considered with the view of judiciously using iodide of potassium, iodide of iron, and similar remedies. The diagnosis of acquired deaf-mutism having been made, institutional or very careful individual treatment should at once be given. The oral system of educating deaf-mutes is particularly valuable for such patients, and much advance in the direction has been made in recent years. Great patience and skill are required even in acquired deaf-mutism. Some congenital cases improve, others make no advance, the former being cases in which the causes, whether prenatal or at the time of birth, have acted upon the organs of hearing or their encasements, and not upon the brain as a whole. It is said to be best to commence the instruction of congenital deaf-mutes at the age of about six years, but neglect of some training even before this age may at times be a great disadvantage. Practically, instruction should be begun as soon as it is possible to engage the attention of the child, but the amount of this instruction should be carefully considered. Where there are special impediments of speech, instruction directed to the relief of these may be successful. Of course all local surgical conditions should be carefully attended to, such as the rare cases of attached frænum, and those conditions which are more common, such as enlarged tonsils and naso-pharyngeal adenoids. Cleft palate and other forms of hard or soft palate must receive the attention of the surgeon and surgical mechanism. Stammering and stuttering can occasionally be greatly benefited by treatment, although in some cases all methods prove to be discouraging failures. The greatest attention should be paid to the maintenance of the best physical health, as by good food, careful hygiene, muscular and respiratory gymnastics. Systems of respiratory and vocal exercises are given in special works on the subject. Such treatment must necessarily be in the hands of one who has specially trained himself to carry it out.

IDIOCY AND IMBECILITY.

By CHARLES K. MILLS, M. D.,

PHILADELPHIA.

IDIOCY.—Three great classes of mental arrest or deficiency are known as *idiocy*, *imbecility*, and *cretinism*. Idiocy is an affection, either congenital or acquired in very early life, characterized by extreme mental deficiency, although it may be of varying grades of severity. Sometimes the idiot scarcely rises in brain power above the level of the lower animals, or he may be able to some extent to take care of himself, or again he may be capable of limited intellectual improvement. The mental deficiencies of idiocy, as a rule, go hand in hand with physical infirmity.

“The term idiocy,” says Langdon Down (*Tuke’s Dict. Psychol. Med.*), “has a very vague significance. It is associated in many minds with one type only of mental and physical condition, very often an imaginary type or one which rarely exists. It will be well to break down such contracted views and to efface the incorrect and distorted image. Looking around a large assemblage of children whose mental condition brings them under this generic term, it is very evident that they can be broken into well-marked groups, and that instructive life-pictures may be drawn of typical representations of this interesting class. Looked at *en masse*, they would give the impression of being heterogeneous to the last degree, but it will be found on closer investigation that it is possible to arrange them into groups with strong natural affinities among the constituents, and that in many cases a very remarkable family likeness may be traced.”

The terms “imbecility” and “feeble-mindedness” may perhaps be regarded as nearly synonymous in common medical usage. Although between idiocy and imbecility no absolute line of demarcation can positively be drawn, a distinction is made for some practical purposes in clinical medicine and medical jurisprudence; but it is not correct to attempt to differentiate idiocy and imbecility by regarding the former as congenital and the latter as due to some cause acting after birth. Imbecility, like idiocy, may be congenital, developmental, or accidental, but true imbecility is nearly as often congenital as idiocy. Imbecility is therefore best defined as an affection congenital or acquired very early, and characterized by mental deficiency less in degree than idiocy. It must be distinguished from dementia, which in rare cases comes on in children who have been born with average capability and intelligence. Under congenital imbecility Clouston (*Clinical Lectures on Mental Diseases*) places cases which show every degree of mental deficiency, from the smallest amount of mental weakness down to idiocy. Such imbeciles may, according to this authority, have attacks of maniacal excitement or of melancholia; they may become dangerous and even homicidal; they may after an attack have secondary stupor, or may become demented as compared with their primitive condition; and they are often terrible masturbators. The clowns and fools of all ages would, as a rule, come under the head of imbeciles.

The medico-legal aspects and bearings of idiocy and imbecility should not be entirely neglected in general medical works, as not infrequently the family physician is the first to be called to give an opinion, which may have present or future importance, with reference to the mental status of the child under his care, although the more difficult and intricate problems associated with questions as to the mental capacity of the idiotic and feeble-minded are generally submitted for final decision to medical and legal experts. Ingenious efforts to frame legal definitions of idiocy which would stand the test of experience and practice have from time to time been made. The idiot, for example, has been designated by judicial authority as one who from his nativity by a perpetual infirmity is non compos mentis; or one who cannot count or number twenty pence, or tell who was his father or mother, or how old he is, so that it may appear that he hath no understanding of reason what shall be for his profit or what shall be for his loss; but if he have sufficient understanding to know and understand his letters, and to read by teaching or information, he is not an idiot. The defects and shortcomings of this ingenious definition are evident even to careless examination, and have often been indicated both in courts of law and by writers. The whole question of the legal relations and consequences of true idiocy can be dismissed with the assertion that if it has once been clearly established by competent mental and physical examination, it deprives the subject of the legal right and capability of performing acts which will stand in law and equity, and also relieves its subject from civil and criminal responsibility. It is simply a matter of careful determination in a given case. It is somewhat different, however, when the issue is that of imbecility or of backwardness.

The elder Seguin and others have erected a class of *backward children*, in whom functional torpidity or backwardness of the nervous apparatus is present, while not sufficiently abnormal to be classed as idiots or even imbeciles. These children are behindhand in mental development, and in some physical development is also retarded. They do not learn to creep or to walk until a much later period than others. Probably most of them could be classed, were it not for the sensitiveness of those to whom they belong, with the highest grades of imbeciles. Such children show a tendency to be behind their fellow-children in school and work, and even at play and in their sportive relations with other children. They become the butts and slaves of their better-equipped companions, by whom they are teased and hazed, and in various ways have their lives made a burden.

MORAL IMBECILITY.—Moral imbecility is an affection sometimes classed under juvenile insanities as moral insanity; but a distinction can be made, although not with the same certainty as in the adult, between moral imbecility and moral insanity in the young. In some instances it would appear that perversion of the moral or affective life is brought about through injury, disease, or vicious habits in children who have been previously of a healthy moral and mental tone; but the subject of true moral imbecility is the victim of heredity; his condition is manifested as soon after birth as it is possible to clearly recognize by conduct deficiencies in the moral sense. Whatever views may be held as to the substrata of conscience and morals, it is convenient to use such terms as moral faculty and moral sense in their commonly understood significance. The moral sense covers that which causes a human being to weigh, consider, approve, or disapprove his own conduct; it includes that which in common language is called conscience. This faculty or sense, like others, should be regarded as a function or effect of organization, although one school contends for its separation from the physical man and would relegate it to some super-

natural sphere. I am not here particularly concerned with discussions of this kind, but as a physician, and in common with others who have seen much of nervous and mental disorder, I have become only too familiar with a class of cases which must be recognized as the subject of disease, and the mental care and treatment of which are forced upon us by every scientific and humane consideration. Maudsley speaks of cases of this kind as a group of persons of unsound mental temperament, "who are born with an entire absence of the moral sense, destitute even of the possibility of moral feeling; they are as truly insensible to the moral relations of life, as deficient in this regard, as a person color-blind is to certain colors, or as one who is without ear for music is to the finest harmonies of sound. Although there is usually combined with this absence of moral sensibility more or less weakness of mind, it does happen in some instances that there is a remarkably acute intellect of the cunning type." Such children are incorrigible to reproof and training. Punishment has no effect upon them, or will only be so heeded as to allow of their escape from immediate difficulty.

Much difference of opinion has arisen among authorities almost equally competent with reference to the exact nature of such cases. One contention is that such a thing as moral insanity or imbecility does not exist, and that close investigation will show in all alleged cases that intellectual disorder is present. It is held that we should not, even by a convenient label, separate these cases from others of accepted or acknowledged intellectual disorder. The difference is probably largely one of terms. In a well-studied class of cases the brunt of whatever defect or disease is present has fallen upon what every one regards as the moral nature of the individual. Recognizing morality and immorality as facts, no reason exists for not regarding these cases as instances of moral arrest or departure; it is as scientifically correct to do this as it is to subdivide the forms of insanity into intellectual, perceptual, emotional, and other well-known psychological varieties.

According to Herbert Spencer, higher feeling is merely the centre of co-ordination by which the less complex aggregations are brought under proper relations. In the process of evolution this centre of co-ordination may never be developed and moral imbecility may result, or great waywardness of moral conduct without marked disorder of intellect. The doctrines of moral imbecility and moral insanity are, then, as Tuke says, in full accord with the mental rules of evolution and dissolution laid down by Spencer.

Ray (*Medical Jurisprudence of Insanity*) gives numerous examples of moral imbecility, some of the most extraordinary character. One of these of historical interest is that of "Count Charolais, brother of the duke of Bourbon-Condé, whose sanguinary character has been commemorated by Lacreteille. He manifested an instinct of cruelty in the very sports of his childhood. He took pleasure in torturing animals and committing the most ferocious acts of violence against his domestics. He would stand at the window and shoot the artisans at work on neighboring buildings, merely for the pleasure of seeing them tumble from roofs and ladders. It is said he loved to stain even his debaucheries with blood, and committed many murders from no motives of interest or anger."

Works on medical jurisprudence and on mental diseases, and periodical literature connected with studies of this character, have furnished many illustrations of what is best classed as moral imbecility. Kerlin (*Med. News*, March 19, 1887) has presented short histories of four children—the first, illustrative of the incipient prostitute whose mental incapacity should be her protection; the second case, that of an incipient burglar; the third, a hereditary religious hyp-

ocrite and egotist, who, if not permanently sequestered, would fill a dramatic if not an awful rôle in crime; the fourth, a confirmed juvenile confidence-man.

Under the head of *idiots savants* has been described a class of idiots a few examples of which are to be found in almost every large institution. They exhibit in some special direction extraordinary or apparently extraordinary mental power. They may, for example, be extremely skilful in some simple handicraft; may have a wonderful ear for music or great skill in playing upon musical instruments; or they may show a remarkable faculty of making difficult calculations. They are usually instances of over-development in some one direction, the individual faculties in general being stunted and imperfect.

Varieties.—A thoroughly scientific classification of idiocy is in the present state of our knowledge impossible. Idiocy and imbecility may with reference to classification be briefly considered together. Kerlin (*Med. and Surg. Reporter*, May 20 and 27, 1882) has made a practically useful classification of these affections into idiocy, idio-imbecility, and imbecility, considering separately, as I shall also, forms of juvenile insanity which cannot properly be included under either idiocy or imbecility. Under idiots are placed groups of the lowest grades of intelligence and possible development; under imbeciles, those of low intelligence and development, but of higher grade than true idiocy and capable of various degrees of improvement; and under idio-imbeciles, those which form a connecting link between the others. Following Griesinger, the same authority divides idiots into the apathetic and the excitable, and imbeciles into a low, middle, and high grade. Various other attempts at classification have been made, but it would serve no good purpose to consider each of these in detail. All are more or less deficient, as standards of classification are commingled and confused. Some classes are founded upon teratological and others upon pathological data; some upon ethnological and others upon anatomical, etiological, psychological, or other features. The best classification eventually will be one based upon a study of groups of clinical phenomena which can be readily referred to teratological and pathological conditions.

A useful general classification of idiocy is one suggested by Langdon Down (*Tuke's Dict. Psychol. Med.*) into congenital, developmental, and accidental. Congenital idiots are born deficient as the result of causes usually unknown, except that bad heredity is commonly present; and the majority of cases of true idiocy belong to this class, although some authorities improperly exclude from it cases whose pathology seems evident, as porencephalic, hydrocephalic, and microcephalic cases.

Congenital idiocy is usually recognized at an early period, within a few months or even a few weeks after birth, although in exceptional instances it is overlooked until the child has reached a year or more.

Developmental idiocy receives its name from the fact that it originates at certain developmental epochs, as at first or second dentition, or perhaps at the beginning of puberty, typical cases being up to a certain age normal and of good, or at least ordinary, physical health. Following a convulsion or a series of spasms, the child may show a marked intellectual change and variation of character, or this deterioration may come on gradually, without any history of spasm or any abrupt attack, in children perfectly normal as to intelligence up to the age of eighteen months or five, six, or even seven years, or perhaps nearly or quite to the age of puberty. In some of the cases which have been reported the mother has been acted upon by malign or depressing influences or has been the subject of disease or deprivation of some kind during pregnancy. Down has advanced the reasonable supposition that, according to the period of embryonic life at which the causative impression is made upon the mother, may

be the time of development of the manifestations of idiocy; occurring at an early period, such disturbances result in congenital idiocy.

Accidental idiocy is a form of mental arrest which is caused, as its name indicates, by some accident at or after birth. In not a few such cases the predisposition to mental weakness may have existed, but even in these it might not have shown itself in so marked a manner or at all. Hæmorrhage or depressed fracture or abscess from aural disease may have been present, and meningitis of either the hard or the soft membranes is sometimes found post-mortem. While recognizing these three etiological varieties as of great importance and value for purposes of study, one cannot get a clear idea of the types of idiocy without a different subdivision, as under the congenital, developmental, and accidental classes idiots differing widely in appearance and in their mental and physical possessions are found, although the differences are greater in congenital idiocy than in the other forms.

Down has also proposed a more elaborate and differentiated classification, giving many different forms, and arranging these into more than twenty subclasses under the general heads already considered. He has paid particular attention to ethnological features, describing such varieties as the Caucasian, Ethiopian, Calmuck or Mongolian, Malayan, and Negroid. The patients bear a real or fancied resemblance, particularly in face and head, to individuals of the different races indicated by the names. The Calmuck or Mongolian appears to be the most clearly recognizable of these varieties. Among its characteristics are short stature, deficiency of the posterior part of the head, sparse hair, obliquely-placed and widely-separated eyes, and depressed nose. Mongolian idiots are grotesque, seeing the humorous side of things; they are all characterized by strong self-will and wonderful imitative power, and they have other physical and mental peculiarities to which our space will not permit us to refer.

Among other varieties of idiocy recognized by Down, Shuttleworth, and others are those the names of which are based upon peculiarities in the size and shape of the head; but this method of classification, like that based upon ethnological marks, is not capable of being carried out over the entire range of cases. Different shapes of head are found in cases of idiocy with the same or similar mental and physical features, or, on the other hand, either different or the same or similar symptoms, syndromes, or conditions are presented by idiots with heads unlike in shape and size. It is true, nevertheless, that some of the varieties present more or less common features, and the terms used are at least convenient for the purpose of investigation and record. Macrocephalic idiocy in such a classification might describe cases due to hydrocephalus or to hypertrophy of the bone or intracranial structures, or to both. Microcephalic is a term applied to idiots with very small heads, technically to those whose heads are less than seventeen inches in circumference; hydrocephalic idiocy is the result or accompaniment of hydrocephalus; brachycephalic means broad and short-headed, and dolichocephalic long-headed—long in proportion to breadth. The term cephalic index is applied to the breadth of the skull multiplied by 100 and divided by its length, and if above 80 the skull is called brachycephalic. In plagiocephalic idiots the skull is out of shape, so that the features lie in an oblique plane; scaphocephalic, from a word meaning the hull of a ship, is a term applied to that form of idiocy in which the head is shaped like the keel of a boat turned upside down.

Ireland, the author of a well-known text book on idiocy and imbecility (*Idiocy and Imbecility*, London, 1887), has proposed a classification which has been much followed and has much to commend it, but it is by no means suffi-

cient to cover all cases. It is a mixed classification, based on pathological, etiological, and semiological features, and has ten classes, as follows: 1, Genetous; 2, Microcephalic; 3, Eclamptic; 4, Epileptic; 5, Hydrocephalic; 6, Paralytic; 7, Cretinism; 8, Traumatic; 9, Inflammatory; 10, Idiocy by deprivation.

The term "genetous idiocy," as used by Ireland, practically means the same as congenital, but other varieties in his classification are just as truly genetous or congenital. Eclamptic and epileptic idiocy are two varieties, in both of which spasm or convulsion plays a prominent part, but in the eclamptic occurs soon after birth, and is supposed to be due to convulsive seizures, these not infrequently stopping, but leaving the mind permanently affected and arrested; while in epileptic idiocy the convulsion and the idiocy may both come on at different ages, and the epilepsy remain as a permanent accompaniment of the idiocy. According to Brush (*Keating's Cycl. Dis. Children*, vol. iv.), an epileptic idiot is one whose mental growth has been arrested by the occurrence of epilepsy in infancy or childhood. From this point of view epileptic idiocy would belong to the etiological variety, while eclamptic might or might not. Microcephalic and hydrocephalic have been already discussed. Paralytic idiots have forms of monoplegia, hemiplegia, paraplegia, and diplegia, as described in this work by Peterson. Very commonly the paralysis is of the spastic variety. Various forms of idiocy might be classed under traumatic. Not a few cases are supposed to result from injuries inflicted during prolonged labor by bruising and squeezing of the child or by instruments in assisting at its delivery. Some, but by no means the majority, of paralytic cases are attributable to traumatism; many are dependent upon sclerosis, arrest of development, neoplasms, meningitis, meningo-cerebritis, or cerebritis, and the pathological process may occur either before or soon after birth. Of course inflammation may be set up by traumatism, when the case might be regarded as either traumatic or inflammatory. Hydrocephalus is sometimes the result of a tubercular or other inflammation of the membranes or ependyma of the ventricle. Confirmed idiocy and forms of juvenile insanity occasionally occur during or after the infectious febrile affections of infancy or early childhood, such as cerebrospinal fever, scarlet fever, measles, whooping-cough, diphtheria, etc., and these are either toxic or inflammatory affections, or both. Sensorial idiocy, or idiocy by deprivation, is the result of the lack or the loss of important senses like sight or hearing. Some, but by no means many, of these cases may by careful education and training be lifted out of this idiotic state; in others the loss of hearing, of sight, or of other senses may, like the mental defects in general, be dependent upon embryonal arrest. Sensorial idiocy and imbecility, therefore, need to be subdivided into at least the two varieties of congenital and acquired or accidental. It may be of great practical importance to be able to decide to which of these two varieties a case belongs. Cretinism will be treated of in a separate article.

Shuttleworth's classification (*British Med. Jour.*, Jan. 30, 1886), which includes the varieties of Ireland with some additional classes, is as follows:

"CLASS A—CONGENITAL.—1, Microcephalic; 2, Hydrocephalic (also non-congenital); 3, Scrofulous (Mongol type); 4, Sensorial (also non-congenital); 5, Primarily neurotic; 6, Paralytic (also non-congenital); 7, Choreic (also non-congenital); 8, Cretinoid; (a) sporadic, (b) endemic. CLASS B—NON-CONGENITAL.—a, *Developmental*.—9, Eclamptic; 10, Epileptic; 11, Syphilitic; 12, Post-febrile (also accidental); b, *Accidental or Acquired*.—13, Toxic; 14, Traumatic; 15, Emotional; 16, From mixed causes."

Strumous or scrofulous forms of idiocy can be clearly placed to the strumous

PLATE XVII.

FIG. 1. Congenital Idiot of Low Grade.

FIG. 2. Epileptic Imbecile.

FIG. 3. Insane Imbecile.

FIG. 4. Congenital Idiot of Low Grade.

or scrofulous diathesis; they belong to the congenital class. The primarily neurotic are those with bodies comparatively well developed and with signs of irregular nervous action.

The term "choreic," as applied to idiocy, has been used in several ways—as descriptive of the motor phenomena presented by the patient; or of idiocy resulting in a child born of a mother choreic during pregnancy; or of cases in which violent or persistent chorea seems to induce idiocy in the developing child.

Congenital idiocy due to inherited syphilis is probably but not certainly rarer than a form of juvenile dementia, which usually develops some years after birth, and is described in another section. Some syphilitic children are idiotic from birth, and in these cases treatment is generally as useless as in cases due to other causes, while in syphilitic juvenile dementia specific treatment may be very efficient. Shuttleworth applies the term "toxic idiocy" to idiots who without bodily deformity suffer from malnutrition of the brain, which he supposes to be due to some unknown toxic influence. Emotional or excitable idiocy is that which shows shrinking, fear, apprehension, excitement as its chief features.

Etiology.—A bad heritage is the great predisposing cause of idiocy. The idiot's ancestor may not have been insane, imbecile, or idiotic, but in the majority of cases some constitutional taint or tendency, as syphilis, struma, or tuberculosis; some toxic affection, as alcoholism; some form of mental disease or defect; some neurosis as epilepsy, hysteria, neuralgia, or neurasthenia, or some organic disease of the brain, as meningitis, sclerosis, softening, or hæmorrhage, will with sufficient investigation be found to have been present in near or remote progenitors. Intemperance, alone or combined with other causes, such as epilepsy or insanity, has been shown by reliable statistics to be one of the commonest predisposing causes. Far too frequently imbeciles of high, or in some cases of comparatively low grade, marry, with degenerate offspring as the result. Numerous studies of heredity in connection with this question of the causation of idiocy have been made. According to Shuttleworth and Beach (*Tuke's Dict. Psychol. Med.*), the most frequent combination of two causes of insanity is that of insanity with epilepsy. Even deaf-mutism, with perhaps in most cases the addition of some other lowering agency, has resulted in idiocy and imbecility in the second and third generation. By the authors above quoted syphilis was found certainly to be the predisposing cause in 17 per cent. of more than two thousand cases. Good authorities place 2 per cent. as covering the cases of syphilitic idiocy, although others would put it much higher. The question of consanguineous marriages has been much discussed in connection with the causation of both insanity and idiocy, and authorities are somewhat at variance; but it may be regarded as certain that the marriage of relatives in one or both of whom mental or neurotic defects or constitutional or toxic conditions are present will predispose to idiocy and imbecility as to other degenerative diseases. It is better, as a rule, that relatives should not intermarry, as few stocks are absolutely without taint or weakness.

Bad health in the mother and impressions made on her during pregnancy, the father's health or condition at the time of procreation, age or premature senility of parents, and acute diseases during pregnancy,—all have some etiological importance.

Among causes acting at the time of birth are prolonged and difficult labor in mothers with small or deformed pelvis; injuries by instruments or other manipulations or by the umbilical cord, and suspended animation from whatever cause. The use of instruments is, however, a much less frequent

cause of idiocy, infantile paralysis, and convulsions than is commonly supposed. They are often used after the injury has been done by long-continued pressure. The prompt and skilful use of forceps sometimes saves life and health for both mother and child, oftener than the reverse. In these pressure and forceps cases skull depressions and hæmorrhages sometimes occur. The causes acting after birth are comparatively few, but among these are injuries from falls or blows, convulsions of unknown origin, fright, febrile diseases, and in rare cases the ingestion of toxic substances.

Symptoms.—To briefly give the symptomatology of idiocy in general is an almost impossible task. The signs and symptoms will vary widely with classes, and to a certain extent, in considering the varieties of idiocy. I have already described its symptomatology; but certain physical and mental characteristics belong to almost any form of idiocy, and from studying these the practitioner of medicine, even without special knowledge of the subject, may be able to come to a conclusion as to the nature of such a case at an early period. Much can be learned as to the physical features of idiocy by mere inspection, and much more by careful and detailed investigation. The size and shape of the head and face and defects of feature may prove serviceable in coming to a decision. I have already spoken of varieties dependent on the shape of the head to which special names have been given, as microcephalic, and brachycephalic. Unusual smallness or largeness of the head, or, what is more common, deformity or asymmetry in its shape, is often the first to attract attention. In some types of idiocy, as the Mongolian, a remarkable deficiency of the posterior part of the cranium is often observed; in others it may be that one side of the head, or even one special region of the cranium, will show marked depression or arrest. In almost every instance of true idiocy some peculiarity of face or feature is present: this may be abnormal position or separation of the eyes; deformity, unusual size, or peculiar implantation of the external ear; depression or flattening of the nose, or general asymmetry of the face. The oral cavity of idiots has been the subject of much investigation, and great varieties in the shape of the mouth and pharynx are found; it is high and gothic; or low and flat; or irregular; or a cleft or partially cleft palate is present; and sometimes the entire buccal and pharyngeal cavities are contracted as well as irregular in shape. The greatest possible variations in the shape, size, and implantation of the teeth are to be observed: they are notched or pegged or serrated; they overlap and are irregularly crowded: frequently they decay at an early period. The jaws may be too narrow or may fail to be properly apposed to each other; occasionally, instead of being small, the lower jaw is prognathian—of unusual size and projection. The tongue may be too large, or even too small, and frequently refuses to obey the behests of the will. The head cannot be held erect or is carried badly.

The control which the patient has over ocular movements and facial expression is often of great value to the diagnostician. Strabismus is common, and this may be of one eye or both, or of an alternating or varying type. Of other simple tangible phenomena, drooling or slavering is an important manifestation. Inability to stand or walk at the usual age may lead to suspicion as to the true condition, and even if the child can walk his carriage and gait may be very significant. Some idiots stoop, some have a lopsided method of progression; many are slouching in station and in walk; some run when they should walk, or walk when they should run; the gait is often ataxic or incoördinate, or, rather than this in a technical sense, it may be simply maladroit or awkward. The hands and arms are not used with the same precision, accuracy, and adaptation of means to ends as by other children.

Below the head and neck defects and peculiarities may be as various as above. Curvatures and twistings of the trunk, asymmetry in the development of the legs and arms; flexures, curvatures, or other deformities of the limbs; knock-knees or bow-legs or parrot-toes, and numerous other deformities, malpositions and arrests, may be present. According to the variety of idiocy there may be paralysis, with or without local spasm or contracture, in limbs or face; sometimes this is one-sided—that is, monoplegic or hemiplegic; sometimes both legs, or both legs and one arm, or all four limbs, may be involved in the parietic-spastic condition.

The skin may be harsh or dry or coarse; it may show evidences of impaired or imperfect circulation in coldness or duskiness of the extremities, in blotches or discolorations, or even in a tendency to trophic affections, such as ulcerations and eruptions. Not seldom the hair is scanty or coarse or badly nourished, and the nails may be of bad shape or abnormal in appearance. The sexual organs may show unusual smallness or deformity or peculiarity of some kind.

Speech may show many varieties of defect and aberration, and these have to some extent been considered in another section. The incapacity to attend to what is said or what should be done is one of the first things to attract attention to an idiotic child. At an age when infants and small children ordinarily attend to many matters of passing interest, such a child cannot be made to fix its attention even by the most strenuous efforts; indeed, a close study of this faculty will perhaps throw more light than anything else upon the degree of mental development in children. Self-will, undue emotionality, lack of ordinary obedience, impetuous and unreasonable behavior, inattention to natural wants and demands, are all points of importance in the mental investigation of supposed idiocy.

While some or many of the physical peculiarities enumerated may be present in cases of idiocy, it must not be forgotten that in some types at least they are nearly all wanting. In the so-called accidental idiocy, for example—that which has resulted from injury at the time of or after birth—there may be a striking absence of the usual physical defects and deviations. Such children are sometimes scarcely to be distinguished in head, face, form, attitude, or movements from those retaining their mental faculties, although the traumatism may have left its mark in depressed skull or paralytic or spastic limbs.

Pathology.—Many facts with reference to the pathology of idiocy will be found discussed under such heads as the cerebral paralysees of childhood, hydrocephalus, brain atrophy or hypertrophy, porencephaly, sclerosis, cortical arrest, cysts, softening, hæmorrhage, embolism, thrombosis, chronic meningitis, meningo-encephalitis, and encephalitis; while many of the symptoms peculiar to idiocy have been or will be considered under such headings as speech defects and anomalies, nystagmus, athetosis and athetoid affections, and epilepsy.

Idiocy has no fixed pathology, but numerous exceedingly interesting pathological appearances and conditions have been reported, as anæmia and hyperæmia of the brain; hypertrophy and atrophy, general and partial; softening, usually local; sclerosis of various forms; hydrocephalus and porencephalus, meningitis, and tumors; thickening of the arteries; thrombosis of the sinuses; asymmetry or unusual simplicity of the hemispheres and convolutions; alterations in the relative amount of white and gray matter of the brain. Disease of other organs than the cerebrum is often associated with cerebral disease, as, for example, atrophy, tumors, and cysts of the cerebellum, or spinal affections,

such as poliomyelitis; congenital arrest of development of the pyramidal tracts; descending sclerosis; chronic myelitis; or pseudo-hypertrophic paralysis.

Wilmarth (*Alienist and Neurologist*, October, 1890), has given the results of the study of one hundred brains, and his condensed statement presents in an unusually interesting and practical form the pathology of most cases of idiocy. I had the opportunity of studying some of the brains and skulls which are included in this list of cases. Sclerosis with atrophy, 12; scleroso-tuberculous, 6; diffuse sclerotic change, 7; degenerative changes in vessels, ganglionic cells, or medullary substance, not constituting the true sclerosis, 15; hydrocephalus, 5; general cerebral atrophy, 2; non-development in various forms, 16; infantile hæmorrhages, 1; extensive adhesions of membranes from old meningitis, 3; angiomatous condition of the cerebral vessels (with degenerative changes), 1; glioma (with sclerosis), 1; porencephalus, 1; and 31 cases where actual disease or imperfect development of the brain proper was not demonstrated; there was hypertrophy of the skull, 6; acute softening (recent), 2; demi-microcephalic, 2; 1 brain was above the usual weight, but the convolutions were large and very simple in their arrangement.

In 75 cases, or in all in which injections of chloride of zinc or extensive destruction had not made weighing valueless, the brain was carefully weighed. The average weight was 38.3 ounces; in 14 cases the weight was below 30 ounces; thickening of the skull to an extent to constitute hypertrophy was found in 8 instances; while in 8 the skull was unusually thin, not including cases in which there was distention from hydrocephalus.

An attempt at a pathological classification of idiocy might be made, although this undoubtedly would contain many imperfections. The classes will be sometimes found to blend and commingle, cases will repeat themselves under different headings, and other objections will appear; but, on the whole, such a classification will indicate in a general way the groups as they would be found in any large institution.

The most important of these classes are as follows:

1. Idiocy due to gross organic lesions, the history of which can be determined with more or less accuracy—lesions such as hæmorrhage, embolism, thrombosis, tumors, meningitis, meningo-encephalitis, and encephalitis.
2. Idiocy due to various forms of sclerosis, as the diffuse, multiple, or disseminated; sclerosis with atrophy, and lobar or tuberculous sclerosis.
3. Idiocy due to arrest of cortical development, a true *agenesis corticalis*, or absence of normal cells, which has been well studied and described by Sachs of New York (*Jour. Nerv. and Ment. Dis.*, August, 1892).
4. Idiocy due to large cerebral deficiencies, but sometimes originating in hæmorrhage, thrombosis, embolism, sclerosis, meningitis, etc.—such conditions as general atrophy or hypertrophy, porencephalus, and hydrocephalus.
5. Idiocy due to inherited or congenital syphilis, which perhaps might be included under some other subdivision, but the cases are supposed by some authorities to have a peculiar history and special appearances, and therefore may be placed for practical purposes in a separate group.
6. Idiocy of toxic origin, under which head would be included cases resulting from acute poisoning or following infectious diseases, such as measles, scarlet fever, etc.

Diagnosis.—The diagnosis of idiocy will only be difficult in early infancy and in a few rare cases. The facts to be learned by observing whether or not the child pursues a regular, or at least an average, method of development have already been considered with reference to the sense of hearing, the

acquisition of speech, and the development of ideas, when discussing anomalies and defects of speech. Different children of the same family or healthy children who are known to the physician can be compared with the one alleged to be idiotic. Careful consideration must be given to the question of normal retardation or mere backwardness, or the existence of a true insanity, such as syphilitic dementia. The diagnosis of idiocy and imbecility is always most assisted by a careful study of the physical conditions presented by the child—the shape and size of the head, which have already been discussed; the condition of the eyes and the ocular muscles; the appearance of the palate, jaw, and tongue; the presence or absence of drooling; ataxic, athetoid, or choreic movements; peculiarities of expression; deformities of the ear, nose, or mouth; ungainly, limping gait; paralysis or contractures, or both in the same case. The more marked and numerous these arrests and aberrations of bodily development, the more likely it will be that the diagnosis of idiocy is correct. In every part of this article mental disturbances and deficiencies are under consideration, and it is only necessary to say here that such faculties as attention, memory, and inhibition should be particularly studied.

Prognosis.—The prognosis of idiocy as to cure is of course altogether bad, but it should be remembered that improvement can be made in the condition of idiots even of comparatively low grade. They can be made more comfortable, happier, less offensive, less destructive, and even, in a limited number of cases, more useful, by care, discipline, education, training, and, to a limited degree, by the use of nutrient and medicinal agencies.

“During the fifty years over which efforts for the amelioration of the imbecile have extended,” says Shuttleworth (*Tuke's Dict. Psych. Med.*), “the sanguine prognostications of early enthusiasts may not have been realized, but nevertheless a large percentage of benefit has been recorded. An imbecile, however well trained, will always need some kindly aid and consideration from those with whom he is associated. It is not to be expected he will be able to manage his own affairs or compete in the labor-markets of the world. Placed in a niche, however, where he can without molestation exercise his acquired talents, he will in many cases turn out more or less remunerative work; and, failing this, he will, in consequence of having some resources within himself, cease to be a nuisance to his friends. Even the improvement of habits by systematic training is not to be despised in relation to the comfort of the family; and it must be borne in mind that the idiot left untrained is sure to deteriorate. A review of twenty years' experience at one of the large English institutions furnishes the following results: Of patients discharged after full training, 10 per cent. are self-supporting, whilst another 10 per cent. would be so if they had obtained suitable positions, and about 20 per cent. were reported as useful to their friends at home.”

Treatment.—In considering treatment the subject might be variously subdivided, as into prophylactic and direct; into hygienic, educational, gymnastic, and medicinal; into measures for the affection itself, and for diseases and conditions that are intercurrent or resultant. Habitation, diet, and clothing should be carefully selected; and in doing this particular attention should be paid to the variety of idiocy and to the diathesis from which it may have resulted. The ventilation of rooms at night and proper beds and clothing should receive attention. Cleanliness must be enforced by bathing, which can also be used as an invigorating and strengthening measure. All idiots should have exercise graded to their physical condition and powers; mistakes may be made in attempting to do too much in this direction or by not duly considering their differences from other children. Systematized gymnastic exercises or calis-

thenics can be used with great advantage, both for physical development and to a limited extent to promote mental power, and to a larger degree to add to the happiness of these defective children.

Whether or not an idiotic child should be removed from its home to an institution is a question that the physician must frequently meet, and in general terms it may be said that a well-conducted institution, as a rule, is the best place, both for him and for other members of the family. The danger of being made worse by contact with others—an argument which is so often used against sending a patient to an insane hospital, and occasionally with force—does not apply, or to an exceedingly limited extent. In institutions of large size the defective children can be so classified that their training can be carried out systematically and without much jarring and strain, or, if incapable of any improvement, so that they can be cared for and their happiness promoted in the best possible manner. The presence of an idiot in a family is often painful and deteriorating both to parents and to other children. Home treatment may be pursued where parents have large means and the care and training of an idiotic child can be managed apart from the rest of the family. For the wealthier classes the institutions which take only a small number of children, if these are conducted on thoroughly scientific as well as humane principles, offer some advantages. Amusements, exercises, and social intercourse are all regulated to excellent purpose in institutions like those at Elwyn, Pennsylvania, at Vineland, New Jersey, and at Barre, Massachusetts.

The educational treatment or training of the feeble-minded has received much attention in recent years. In 1801 the first great incentive was given by Itard to this method of bettering the condition of the idiotic by his interesting account of his own experiences with a child that had been found savage in the woods, but to the elder Seguin (*Idiocy and Its Treatment by the Physiological Method*, 1866), the greatest of credit is due. He was truly the first apostle of the idiot. Volumes have been devoted to this most interesting subject, but to these I can scarcely do more than refer. This training and education should be patiently directed to the development of the deficient senses; to the training of the hands and feet; to the improvement of carriage and gait; to stimulating the slow and to braking the morbidly active; to the development and improvement of speech; to arousing attention, imitation, imagination, comparison and judgment; and to the awakening and cultivation of the moral senses and power of control.

Not much can be said about the medical and surgical treatment of idiocy. Attention should first be directed to the probability of the idiocy being due to such possibly remedial causes as inherited syphilis or traumatism. The iodides of potassium and sodium, hydriodic acid, and various mercurial preparations may be tried in cases presumably due to inherited syphilis, but too much must not be expected, as syphilis in the progenitor has established a condition of arrest rather than an active and removable lesion. It is different in infantile and juvenile dementia due to syphilis, which have been treated of in another article; here the treatment may promise much, and, as the differentiation is sometimes difficult, it may sometimes be employed as a diagnostic measure. Everything should be done to promote the nutrition of the idiot—malt, maltine, cod-liver oil, and nourishing food for the strumous; the same with preparations of iodine, arsenic, and tonics in general for the rachitic; digestants like pepsin, pancreatin, the mineral acids, and stomachics for those of weak digestion; astringents, antifermentatives, and intestinal tonics for those afflicted with diarrhœas and dysenteries; lime-juice, vegetable acids, bitters, quinine, iron, and fresh food for the scorbutic; ointments for the skin, washes for the mouth,

lotions for the eyes,—but these will not be to the working of a cure, but to the relief of annoying and depressing symptoms and conditions. For convulsions, bromides, chloral, sulphonal, antipyrine, and similar inhibitors of cortical excitability, guarded by arsenic and supported by nutrients, may be administered. For excitement trional and tetronal have been found valuable.

What to do with backward children is often a serious problem. They certainly should not be sent to the institutions for the idiotic and feeble-minded, nor can they always with advantage be kept at schools of ordinary or high grade. When their parents can afford the expense, it is best, for a time at least, to have them instructed by tutors or to send them to small schools, with the understanding that special attention shall be paid to them, and that their instruction shall be regulated as far as possible in accordance with their needs and capabilities. The physician should be careful not to be too hasty in his prognosis or prophecies in reference to such children. A practical point worth while to be always borne in mind is that sometimes mental backwardness, like physical backwardness or peculiarity, is due to the rachitic diathesis. Just as in well-defined types of rachitic pseudo-paralysis, the bony and other forms of arrest or deformity will yield to an abundance of good air, good food, and treatment with such preparations as cod-liver oil, arsenic, iron, and iodides in various forms, so some cases of intellectual slowness and torpor will be greatly improved or cured by similar measures.

For evident cranial depression and fracture trephining may be resorted to, though in long-standing cases the outcome is generally doubtful. The surgical treatment of idiocy has recently received an impetus through the operations performed first in France by Lannelongue (*L'Union Médicale*, July 8, 1890), in England by Horsley (*Brit. Med. Jour.*, September 12, 1891), and in this country by Keen (*Med. News*, Nov. 29, 1890, and *Amer. Jour. Med. Sci.*, June, 1891), and others. At the French Surgical Congress in 1891 twenty-eight cases of craniectomy were reported, with but one death, and considerable improvement was claimed in some of the cases, but a careful reading of the reports of cases shows that the real benefit has not been great.

The best method of training moral imbecility must be sometimes considered. In most genuine cases, education or philanthropy, kindness or cruelty, the sugar-plum or the whip, the Sunday-school or the reformatory, the asylum or the penitentiary, will equally fail: or perhaps I should not say equally, as in a few instances some strengthening of the weak and imperfect coördinating centres may be possible. To the typical case, to the vast majority of cases that would come under this designation, belongs the term incorrigible. Some of the most practical and most experienced authorities, as Tuke and Kerlin, believe that education in its ordinary meaning should be largely withheld from this class. The former says of them: "The early detection of these cases is not difficult: they should be subjects for life-long detention; their existence can be made happy and useful, and they will train into comparative facility and harmlessness if kept under a uniform, temperate, and positive restriction. The school-room fosters the ill we would cure: in teaching them to write we give them an illimitable power of mischief: in educating them at all, except to physical work, we are adding to their armament of deception and misdemeanor." As Kerlin puts it, we should refuse them the ordinary routine of education, because "we believe that in educating moral imbecility we are training experts for the later rôle of so-called moral insanity."

CRETINISM.

BY CHARLES K. MILLS, M. D.,

PHILADELPHIA.

CRETINISM is a form of arrested physical and mental development, chronic and usually endemic, characterized by peculiar appearances and malformations, but especially by smallness of stature, distortion or deformity of the face, head, and body, unhealthiness of the skin, enlargement or absence of the thyroid gland, or fatty growths above the clavicle. The derivation of the word "cretin" is involved in curious uncertainty. Its origin has been assigned, for example, to *creta*, chalk; to *cretira*, stupid, silly; and to *Chrétien*, Christian, because cretins are supposed to be as happy as Christians ought to be. In different regions and by different writers cretins have been called by various names, as *cagots*; but the *cagots* are not true cretins, but a proscribed people living in Bearn and Gascony who may at one time have suffered from a form of leprosy. In Germany cretins are called *Kreidlings* and *Kretins*; in Austria, *Gacken* and *Trotteln*; in Italy, *Gavas*, *Totolas*, *Cristiani*; and in South America, *Bovos* and *Tontos* (Tuke).

Cretinism is endemic in various countries, but nearly always in mountainous regions, as in the Pyrenees and Alps, in the Highlands of Scotland, and in the Himalayas. In this country a few cases are occasionally found together, as in the mountains of Vermont and California, but the affection is chiefly of interest to American physicians as a sporadic disease. Probably it is found to some degree all over the world. In a few countries in which it is most prevalent, as in Switzerland, France, Italy, and Spain, it often shows a curious tendency to limit itself to particular spots, even in a region of the same general climatic and geological features—to blight one valley or village, while another close by, and apparently not different in environment, escapes. While pronounced cretinism is rare in this country, cretinoid cases are seen with more frequency; and by cretinoid cases, in this connection, I do not refer to ordinary cases of myxœdema, although Sir William Gull described myxœdema under this term, but rather to cases which I now and then see in which neither myxœdema nor true cretinism is present, but in which the patient in face, head, expression, stature, skin, mental capacity, or other points reminds one of the cretin.

Symptoms.—The symptomatology of cretinism and cretinoid disease can perhaps be best presented by first describing one or two cases. One recently studied by me at the New Jersey Home for the Feeble-minded, a girl aged nine years, was the seventh child, born after difficult labor, but seemed strong until she was sixteen or eighteen months old, and until this time was bright and active and did not seem defective. At this time she had a severe fall. Her mother was a hard-working woman; the father had rheumatism and was unable to work, and at times was a hard drinker. She had one brother

and three sisters living and healthy. She was a well-marked cretinoid case, with flat face and open mouth, the tongue filling it, but not protruding. She had a soft, but not large, swelling above each clavicle. Her mental condition was very low. She never gave a direct answer to any question, and had no words at her command; but she knew her own name, could feed herself, and could walk a short distance with assistance. She was almost as broad as she was long. I have seen a fair number of such cases of cretinoid idiocy, but generally of much higher grade, in private and hospital practice and in the institutions for the feeble-minded both at Elwyn, Pa., and at Vineland, N. J.

In the nervous wards of the Philadelphia Hospital is a typical example of sporadic cretinism, which I have frequently studied and discussed before my classes. Recently a description of this case has been published by Lloyd (*International Clinics*, 1892). The cretin is thirty-two years old, and was born in the outskirts of Philadelphia. He has a myxœdematous face with large lips and hypertrophied, protruding tongue; small limbs, even as compared with his body; protuberant belly; the sexual apparatus of a small child; no hair about the pubes or on the face, and a scanty supply on the head; bad teeth and gums; eyelids red, tumid, and nearly closed; the skin yellowish-white and dry, and sweating only on the forehead and forearms. His height is 35½ inches. He can walk a little, but is very weak on his limbs. Knee-jerks and the reflexes are normal; sensation seems to be everywhere preserved, and sight and hearing likewise appear to be good. The thyroid gland is wanting, but above the clavicles on each side is a soft mass, probably a fatty growth. While his mental capacity is very low, it is more than his appearance and lack of speech, which is confined to a few words, would indicate. He is observant of much that goes on in the wards, understands much that is said to him, recognizes physicians and old friends, and is appreciative of favors. He has lived along with scarcely any change during the many years that he has been in the hospital, escaping intercurrent disease. Lloyd gives the following measurements of his head and limbs:

	Height	35.5	inches.
Head :	Fronto-occipital diameter	7.5	"
	Bitemporal	5.5	"
	Biparietal	5.5	"
	Circumference	22.25	"
	From ear to ear	12.25	"
	From root of nose to occip. protuberance . . .	13.25	"
Limbs :	From ant. sup. spine of the il. to inner mal. . .	14.5	"
	Length of femur	7.	"
	Length of humerus	5.5	"
	Length of radius	5.5	"

His temperature is almost constantly subnormal, and during one week in which it was carefully taken, he being in his usual health, it never reached the normal but once, and most of the time ranged below 97.4° F. (The plate representing this case, is from Lloyd's paper.)

For many years in the neighborhood of the hospital was another example of typical sporadic cretinism, presenting most of the features of the case just described.

In describing the above case I have practically given the symptomatology of cretinism. The word *stunted* describes the conditions, physical and mental, better than any other. The cretin is small in stature except in very rare

cases; thus Lombroso has described a family of cretins of unusual stature. The head is frequently contracted from the front backward or in some way is asymmetrical. In typical cases the features are striking—short, flattened nose; eyes wide apart; puffy, drooping lids; small face and protruding tongue. Not only temperature, but pulse and respiration, and all the vital processes, are sluggish; digestion, secretion, and excretion go on torpidly; menstruation is established late or not at all.

Speech varies much in different cases, and efforts have been made to classify cretins with reference to their possession of this faculty, the lowest grade consisting of those who are deprived entirely of language or have so little as to amount to nothing. Cretins of this class lead little more than a vegetative life, and are not capable of being improved much by education, training, or change of environment. By a study both of their speech and of their mental deficiencies in general they are sometimes placed in two higher classes than the one just described. In one the cretins have some language which is capable of being extended; they improve somewhat by imitation; they have limited powers of reproduction, but they have little spontaneity or real intelligence, and generally their efforts are confined to matters absolutely necessary to their existence and comfort. A higher class of semi-cretins often possess a fair amount of physical and mental development. They can take care of families, which, unfortunately, they sometimes have, and they are capable of considerable intellectual improvement; in a few cases, indeed, they have so little the characteristics of true cretinism that they are only to be recognized as belonging to these people by one or two peculiarities.

A peculiar class of cases of foetal or congenital rachitis has been observed, the children being born with deformed bones, beaded ribs, etc., the bones in some cases being soft. By some the terms infantile osteomalacia and cretinism have been applied to these cases, chiefly because they have failed to present the macroscopic and microscopic appearances of rachitis. They have been described by Bode, Barlow, and Marshall of Preston, who are referred to by Ashby and Wright.

Recently, through the kindness of Dr. D. T. Lainé of Media, Pa., I had the opportunity of seeing an interesting case of this rachitic pseudo-cretinism. The child is now three years and seven months old. The sutures are closed, and the head shows a prominence in the right parietal region, and also a large depression in the frontal bone of the same side. The face is broad, eyes wide apart, nose flattened, eyelids drooping, and she has slight right internal strabismus. The bones of the upper arm are slightly curved; the lower ends of the radius and ulna enlarged and knobbed, these bones being also slightly bent; the ribs are beaded or irregularly knobbed and the chest contracted; the bones of the legs show some bowing and curving. The spine shows a rachitic dorso-lumbar curve, more prominent on the left. Liver and spleen are greatly enlarged. The child can barely sit up and hold up her head, and has never been able to stand alone. In appearance she reminds one at first glance of a cretin, and is probably a case of infantile osteomalacia. She weighed eight pounds when born, sixteen when five months old, ten when one year of age, and thirty now. When born she was very dark-skinned and hairy all over the body. During most of her life her bowels have been much disturbed, and she had one attack of convulsions when about five months old. She cut her first teeth at fifteen months. During the last year she has slept from twelve to fifteen hours out of the twenty-four. As a rule, she is not cross and cries very little. The family history is not good. The maternal great-

PLATE XVIII.

SPORADIC CRETINISM.

grandparents were cousins; the maternal grandmother has paralysis agitans; the paternal grandmother has "bowel consumption."

Etiology.—Cretinism is especially prevalent in high mountain-ranges remote from the coast; wet or undrained soil appears to have some power for its development; and water charged with lime and magnesia is common in the regions in which it is endemic. Practically, the ultimate cause of cretinism is unknown. Bury (*Keating's Cycl. Dis. Children*) suggests the great importance in future investigations of the causation of this disease of reconsidering the question of heredity, and especially to what extent close interbreeding takes place in the affected districts.

Although one may be present and the other absent, it is undoubted that where goitre exists to any large extent cretins are likely to be found. When the goitre is not present, and even in some cases where it is, peculiar soft, fatty growths may be found in various parts of the body, but usually above the clavicle. In the Philadelphia Hospital case goitre is absent, and also apparently the thyroid, but soft movable masses are found in the neck. By some these are regarded as distinguishing the sporadic from the endemic and epidemic forms of the disease, but this is a mistake.

Pathology.—The pathology of cretinism is perhaps as little determined as its etiology, although much work has been done in this direction by a few observers. The theory which has claimed most attention is that of Virchow, according to whom cretinism is the indirect result of premature ossification of the several parts of the spheno-basilar bone, which in foetal life consists of three portions separated by cartilaginous disks. Ordinarily, these bones remain separate until puberty, but, according to Virchow, in cretins synostosis takes place at a very early period, and in consequence of this a necessary arrest of the parts at the base of the brain occurs, and consequently of the brain and body in general. While this osseous peculiarity has been found in many cretin skulls, yet in some instances of undoubted cretinism it has not been present; but no hypothesis better than Virchow's has been established.

The conditions found post-mortem and under the microscope are varying in character. The brain-membrane, and particularly the dura, is sometimes thickened and adherent, as it is in not a few other forms of arrest; great variety in the shape and arrangement of the convolutions is found, the tendency being to undue simplicity and smallness of size in important regions; the important fissures of the brain are ill defined or in unusual positions, and shallowness of the fissures is common. Asymmetry both of the cerebrum and cerebellum has been noted, and a few observations have been made on the relative thickness of the different layers of the cortex, showing great abnormalities in this respect.

Diagnosis.—While cretinism may be, and usually is, regarded as a form of idiocy or imbecility or closely related to these affections, it differs from them in several essential particulars, as has been shown by various authorities. The cretin is not necessarily born to this state, although after several generations the offspring are likely to be cretins or cretinoid cases. For a long time the individual shows no sign of cretinism, although doubtless having within him the potentiality of the disorder. Removal from a given locality to a higher situation, even during the pregnancy of the mother, will sometimes prevent the development of cretinism. It differs from idiocy in being so often endemic, in the comparative improbability of some of its grades, and in its apparent dependence upon conditions of air, water, or soil.

It may be occasionally important, as in the case of Dr. Lainé referred to under Symptomatology, to distinguish between true cretinism and osteomalacia,

as treatment in the latter case may be of very great service if begun sufficiently early. The diagnosis can be made by a close investigation for the well-known signs of rickets, such as soft or deformed bones, enlarged liver, and beaded ribs.

Prognosis.—The prognosis of cretinism is of course bad, but some improvement in the higher grades can be made by training, and something can be done for its prevention by early removal from the localities in which it is endemic.

Treatment.—Cretinism, once fully developed, always leaves its stamp upon the individual, but even a low grade cretin is capable of a surprising degree of mental improvement, as has been demonstrated by the enthusiastic philanthropic efforts of Guggenbuhl and others in Europe. In cretinism the physical and mental arrest or deterioration go hand in hand to a greater degree than in idiocy, although, of course, in the latter the truth of this assertion will be measured somewhat by the peculiar form of idiocy which is under consideration.

Monographs and even treatises have been written, to show that cretinism was due to this or that atmospheric, telluric, or other cause. Perhaps in a work of this kind it is better to dismiss any consideration of this matter, except as it may bear upon the prophylaxis of the disease. It has been found by abundant experience that the tendency to cretinism is combated by making careful selection of drinking waters which are contaminated with peculiar salts, as magnesium, iron, etc.; also, that the removal of the mothers who are pregnant, or of the young children who are born in the neighborhoods where cretinism has a tendency to become endemic, to remote and higher districts will sometimes prevent the development of the affection.

Horsley (*Tuke's Dict. Psychol. Med.*) has conducted valuable experimental investigations on the functions of the thyroid gland which have important bearing both on the pathology and treatment of cretinism and myxœdema. He has removed this gland in monkeys, taking careful aseptic precautions, and when the removal has been complete a myxœdematous condition has resulted. Another phase or modification of this experimentation has been to ameliorate by treatment the myxœdema, and then observe the result. This has been an advancing state of hebetude or torpor coincident with the atrophic condition of the thyroid. Such an animal, according to Horsley, died presenting all the appearances of advanced cretinism. The treatment used in these experiments, and one which may be adopted also for the palliation of the myxœdematous symptoms or cretinoid states of the human being, consist, in the first place, in keeping the patients in a warm room or hot atmosphere, thoroughly clothed; secondly, the internal administration of pilocarpine or the tincture of jaborandi. According to Horsley, if the idiocy and the physical state of cretinism are produced by loss of function of the thyroid body, when any of this gland remains an attempt should be made to restore that function. One method by which this could be done is that suggested by Prof. Schiff—viz. transplantation of the thyroid gland. The possibility of this has lately been shown to be more hopeful than might have been expected, by the researches of Esselberg, and the operation has actually been performed upon individuals with cachexia strumipriva, with promising results. Feeding with sheep's thyroids is another method that might be tried.

MYOTONIA, OR THOMSEN'S DISEASE.

BY CHARLES K. MILLS, M. D.,
PHILADELPHIA.

MYOTONIA, or Thomsen's disease, like other family forms of disease, such as Friedreich's ataxia and several types of dystrophy, should receive attention in a treatise on diseases of children; for, although it may develop after puberty, it is most frequently detected before the age of ten years, and it has been observed and studied even in infants. The name by which it is best known is derived from Dr. J. Thomsen of Schleswig-Holstein (*Arch. f. Psych.*, 1876, vol., vi.), who wrote of the affection as occurring in himself and in numerous members of his own family in different generations, although before his time it had been described by Leyden and had been referred to by Sir Charles Bell. In 1886, Erb published a valuable monograph on this subject and a few other articles of more or less value have appeared during the last ten years, one of the most important of these by G. W. Jacoby (*Jour. Nerv. and Mental Dis.*, March, 1887). I recorded a case under the title of "Myotonia and Inertia on Voluntary Effort" (*Intern. Clinics*, April, 1891), and, although this patient was first seen by me when he had reached the age of nearly forty years, he could trace back some of the symptoms of the affection to childhood. When a boy ten years old his father had taken him to a medical college to get advice about his hands, which were even then in some way afflicted with weakness or with clumsiness and difficulty in using them. His feet were also slightly affected in childhood, and he was somewhat stiff in his movements.

Symptoms.—The special symptom of myotonia, or Thomsen's disease, is a tonic or stiffness of the muscles, with inertia or inhibition of movements coming on with voluntary effort after a long period of rest, the morbid phenomena not being present or not attracting attention during the latter period. The prompt and easy performance of all movements is sooner or later interfered with by the spastic state. After the muscles have been used for a short time the stiffness may pass off, so that the patient who has the greatest difficulty in initiating movements will soon be able to walk with increasing ease, and once fairly afoot may continue to walk without trouble for hours; but after an interval of rest the whole morbid process will be repeated. As a rule, the muscles of the face are not affected, but this is not invariable, and in one of the cases of myotonia reported by me some of the most striking phenomena were exhibited by the muscles of mastication, and in a second case of myotonia and atetoid spasm the facial contortions and snapping of the eyelids were very marked. These cases were adults, although in one of them the affection had originated in childhood, and was probably congenital. Usually the phenomena are most marked in the lower extremities. Sensation is not affected. Trophic changes are not present, but the muscles are bulky, although their strength is not commensurate with their size. Erb and Jacoby have called attention to the peculiar changes in the mechanical and electrical excitability of the muscles.

Erb believes that Thomsen's disease may be diognosticated by a few closures of the galvanic current and a few blows with a percussion hammer, but this is doubtful, except perhaps in absolutely typical cases. The electrical response has been termed the myotonic reaction. In examining patients for this a large electrode is placed upon the sternum or back of the neck, and another of smaller size in the palm of the hand. Using a galvanic current of sixteen or eighteen cells and allowing the current to flow, a tonic spastic condition of the muscles of the arm occurs. In a little while, particularly after changing the poles with the commutator, curious wave-like contractions take place in a serial, rhythmical order. These undulations move upward or downward according to the position of the anode and cathode—downward when the anode is in the hand, upward when the cathode is in the same position. They move inward from the negative to the positive. Erb has compared the single waves to those produced by a stone falling in water. He considers that the best places for the application are the flexors of the forearm, the palm of the hand, or the volar surfaces of the wrist-joint and nape of the neck. The amount of current requisite for the production of the phenomena varies from six to twenty milliampères (Jacoby). Briefly, the peculiarities of the so-called myotonic reaction are increase and change in the faradic muscular response, while the excitability of the nerves to this current remains normal. Similarly, to the galvanic current the muscles show increased excitability and qualitative changes, the nerve-reaction not being affected. With Jacoby, I have not been able to verify the difference between nerve and muscle application. The mechanical as well as the electrical excitability of the muscle is changed, so that in a typical case tapping on the muscles will cause unusual response, a slight blow, for instance, producing a marked grooving or furrowing of the muscles.

Etiology.—Hereditiy is the most important factor in the production of the common types of myotonia. It is pre-eminently a family disease, although not infrequently, instead of a family history of the affection clearly myotonic in character, the ancestors, direct or collateral, may have suffered from some form of neurotic degeneration or may have been the subjects of some constitutional taint or toxic affection, as alcoholism. In one family, that of a patient recorded by Bernhardt, consanguineous marriages were frequent, but these may simply have intensified a pre-existing tendency. It is more often a disease of males than of females. Fright, intense emotion, and injuries, have been assigned as exciting causes. Of the cases occurring after puberty, Gowers records one as having resulted from prolonged and severe exertion continued for two years in a man without hereditary tendency, and the same author cites a lightning stroke as a clearly proved exciting cause.

Pathology.—No autopsy supported by careful microscopical examination, so far as I know, has as yet been made. As a rule, the disease has been regarded as essentially muscular, rather than of central or peripheral nervous origin, but this must be regarded as an unsettled question. The relations between the muscular and the connecting and controlling nervous apparatus are so intimate that in the absence of pathological proof the real nature of this or any similar affection must remain in doubt. The primary change may be in the nerve-cells of the cord, of the basal centres, or even of the cerebral cortex, or it may be at the other extremity of the system, in the end-plates in the muscles. The evidence so far is in favor of the disease being muscular and functional. In several instances pieces of muscles have been excised during life, and have been submitted to a careful microscopical examination, and Erb and Jacoby, among others, have made interesting reports upon the conditions present. Erb found an enormous hypertrophy of all muscular fibres and great proliferation

of nuclei, with alterations of the minute structure and a slight increase of the perineurium. Jacoby demonstrated another characteristic change—the distinct division of the muscle-fibres into angular fields, the threads of connecting protoplasm being broken almost everywhere. The motor-nerves and the motor end-plates show no deviation from the normal.

“In Thomsen's disease,” says Jacoby, “the motor nerves and motor end-plates do not show any deviation from the normal, so that the nerve impulse is transmitted into the muscle-fibre in the same manner as in the normal condition. The result of the reception of impulse will be a contraction, which, especially after a certain rest, will be a hypercontraction, or, rather, tetanus. This tetanus leads to an agglomeration of a certain number of sarcous elements which break into a continuity of the contracted clusters. In consequence of this tetanus the nerve-influence is inhibited for so long as the tetanus lasts. After the lapse of a few seconds the tetanic contraction will subside, the continuity between the hitherto separated groups of sarcous elements will become re-established, and the propagation of nerve influence will be again rendered possible. We can thus understand the peculiar reaction of the muscles to the various stimuli when applied directly to them, but why the muscles should react differently to indirect stimulation is still inexplicable.”

Diagnosis.—Diseases which have some likeness to myotonia are tetany, pseudo-muscular hypertrophy, and some forms of sclerosis. I have also seen a hysteroidal affection which somewhat closely resembles this disease, but the characteristic spastic phenomena and the conditions of electrical and mechanical irritability will prevent mistake on the part of a careful investigator. A form of myotonia, designated paramyotonia, has been described, which differs somewhat from Thomsen's disease, but is also a family affection. One difference which has been noted is that the spasticity is not initiated by voluntary movements, but may be by exposure to cold. Myotonia as a symptomatic affection is observed in several forms of spinal and cerebro-spinal disease; it has been described, for instance, as occurring in connection with ataxia.

Prognosis.—The prognosis of myotonia is unfavorable, although the disease does not particularly shorten life.

Treatment.—No treatment is of any practical avail. The patients may live long lives. Thomsen, speaking from personal experience, believes that active muscular exercise is beneficial. Patients learn by experience to take care of themselves. One of the most serious evils of the disease in one of my cases was the tendency of the patient to have sudden falls, owing apparently to the spastic locking of his muscles. He learned by watching his movements to control the occurrence of these falls. Usually in childhood the disease has not advanced sufficiently to call for special protective measures, unless it be the avoidance of cold and emotional excitement.

ACROMEGALY.

BY CHARLES K. MILLS, M. D.,

PHILADELPHIA.

ACROMEGALY, sometimes termed Marie's disease, was first described by Marie about 1886. As the derivation of the word indicates, it means enlargement of the extremities. Acromegaly, as a rule, occurs between the ages of eighteen and thirty years, and therefore the subject is not of first importance in a work on the diseases of children, but a few cases have been recorded as occurring in early childhood, and even as congenital. Recently Moncorvo of Rio Janeiro (*Revue Mensuelle des Maladies de l'Enfance*, Dec., 1892) reported a well-marked case observed in conjunction with microcephalus in a female infant fourteen months old. The mother was a delicate, nervous woman, who during her pregnancy had been subject to violent emotion. At fourteen months the child exhibited congenital microcephalus, idiocy, aphasia, paraplegia, and contractures, and the fundamental symptoms of acromegaly—namely, the retreating forehead; the vertical elongation of the oval of the face; the great enlargement of the nose; the prominence of the superior maxilla; the thickening and advancement of the lower lip; the cervico-dorsal kyphosis, with lumbar lordosis and projection of the anterior plane of the chest, compensated for by flattening of the abdominal wall; and, finally, the spade-like hands, with prominent thickening of the palmar surfaces, and short fingers of uniform width and sausage-like appearance. In another case, cited by Moncorvo from Freund, the disease commenced as early as puberty.

In a series of cases studied by me at the New Jersey Home for the Education and Care of Feeble-minded Children, at Vineland, one remarkable case was found in a boy who was at the time of examination sixteen years old, but who had suffered for years from the disease then present. This boy was the first-born after difficult labor; his mother was feeble-minded, his father a chronic alcoholic; he could dress and feed himself; his speech was imperfect, but he could read and write a little; he was excitable and inclined to be gluttonous. He attended school with very poor results for seven years.

He exhibits two different conditions according to the time when he is studied. For weeks he will be in fairly good health, happy, lively, and disposed to make himself generally useful. His hands and feet are dusky and cold. When the hands are pendent, the dusky area reaches to at least two inches above the wrists, but when they are held above the head the entire limbs become to a less degree of the same hue. He has a marked tendency to indolent ulceration, particularly in the distal portions of the extremities. At the end of the index finger of the left hand are the remains of a formation similar to one which appears from time to time at the end of any of the fingers. The finger-tip swells, and in a little time contains serum and sometimes pus. The toe-nails are black or brownish and ridged roughly. Both hands and feet are abnormally large (Fig. 1). No

loss of sensation was determined. Knee-jerk and muscle-jerk are about normal. He remains in about the same condition for weeks, when a change comes on, almost acutely. His face, arms, hands, legs, and feet swell perceptibly, increasing sometimes almost one half, and this swollen state will last a month or six

FIG. 1.

An Acromegaloid Case.

weeks, and then gradually disappear, leaving him very weak, his pulse at the end of these periods being scarcely perceptible. During the attacks he is obliged to keep his bed most of the time, and is in a condition of general lassitude and depression.

While this case may not, strictly speaking, be one of acromegaly, it is a most interesting allied vaso-motor and trophic disorder, with permanent enlargement and transient changes in the extremities, these increasing at periods.

Symptoms.—Acromegaly is a trophic disease characterized chiefly by a gradual increase in size of the extremities, and usually also of the face. Acromegaly usually begins with progressive enlargement of the hands, feet, and head. The hands and feet may become of enormous size, the other related parts not increasing proportionately. Marie has suggested the name of battle-dore hands, while the English have sometimes described them as spade-like. Of the parts of the head, the face is usually most strikingly involved, being enlarged particularly from above downward. The hypertrophy attacks both the soft and hard parts. Sometimes the tongue, lips, nose, and lower jaw become enormously increased in size. Rheumatic or neuralgic pains may be present. The skin is often dry. The special senses are sometimes affected; vision, in particular, is likely to suffer. Forms of hemianopsia or sector defects

in vision have been observed. Anæsthesia is not commonly present. The affection as seen in children, so far as reported cases are concerned, has been chiefly in those who exhibit evidences of idiocy or imbecility.

Pathology.—The pathology of acromegaly is practically unsettled. In a number of autopsies which have been made, in almost every case some enlargement of the pituitary body has been present; still, this change is not constant, and some diseases of this organ certainly do not cause acromegaly. A case of pernicious anæmia at the autopsy, in which I took part, revealed a hæmorrhagic tumor of the pituitary body, but the patient had none of the phenomena of acromegaly. In this case, however, as in acromegaly, the fundamental perversion was of nutrition. Efforts have been made to relate the occurrence of the disease to lesions or absence of other organs, as, for instance, of the thymus or thyroid gland. The truth is that the exact pathology of the disease is as yet unknown, although interesting autopsies have been reported. More is known about the peculiarities of the pathological conditions present in various organs and tissues of the body. The bones, particularly the vertebræ, the clavicles, and the long bones of the limbs, are the seat of hypertrophic processes. The bone enlargement is regarded as a true hypertrophy rather than an inflammation, an increase due to surplus of nutritive energy or pabulum, or both. In one case of Virchow's the pituitary body was carefully examined and found to be absolutely normal.

Diagnosis.—The diagnosis of acromegaly is not difficult to make, once on the alert for its occurrence. Other affections in children simulate it to some extent, as, for example, myxœdema and cretinoid disease: true cretinism could not be mistaken for acromegaly. In myxœdema the swelling is not particularly of the extremities, but of the subcutaneous tissues; and the differences in the color and appearance of the skin, and in the condition of the thyroid, will serve to separate it.

What is sometimes spoken of as gigantism might be confounded with acromegaly, but the one differential point is that in gigantism the great disproportion between the extremities and the main portion of the limb is not present. In gigantism the individual may be unusually tall, in accordance with the general increase in all directions, while patients afflicted with acromegaly are as likely to be under as over the average size. The pulmonary osteo-arthropathy described by Marie would be distinguished from ordinary acromegaly by the presence of the pulmonary lesions and the peculiar deformities of the terminal phalanges. Marie has described these deformities as, if observed sideways, having some resemblance to the head and curved beak of a parrot. In acromegaly the nails, if anything, are too small for the parts they cover, while the nails in pulmonary osteo-arthropathy are deformed as well as the fingers. In a disease known as partial acromegaly a considerable hypertrophy of one half of the body, or of a limb on one side, or one side of the face, may be present. In this disease, however, true deformity is always present, and it is usually unilateral and congenital.

Many instances of hypertrophy of the fingers and toes have been reported; they must be separated from true acromegaly, although it is possible that these diseases have something in common, and such cases might be classed under the head of partial acromegaly. Recently a case of this kind was seen by me in consultation, and was presented at the meeting of the Philadelphia Neurological Society by Dr. W. J. Taylor. The first and second toes of the left foot were enormously enlarged, and the third toe was also hypertrophied to a less degree. The hypertrophy was much the greatest in the second toe. This deformity of the foot, according to the mother's statement, was present at

birth, but she thought that the left leg and foot had been growing out of proportion to the right. The nails were thin and imperfect, showing evidences of bad nutrition. Both feet and hands were of good and perhaps of unusual size. Such affections probably have some pathological relationship to the disease here considered, but one which has not yet been clearly determined. Operations are sometimes resorted to for their relief, but the question of the central nature of the affection and its probable progressiveness deserves consideration by the surgeon.

Prognosis.—Acromegaly is essentially an incurable disease, but may make no progress for years.

Treatment.—Some good is reported to have been obtained by the use of remedies like arsenic, the iodides, the alkalies, and special diet. The headache, often present, may be relieved by some of the remedies ordinarily used for congestive or neurotic headaches, as antipyrin, antifebrin, the salicylates, and phenacetin.

ATHETOSIS AND ATHETOID AFFECTIONS.

By CHARLES K. MILLS, M. D.,

PHILADELPHIA.

ATHETOSIS, a word meaning "without fixed position," is a name first given by Dr. W. A. Hammond to a peculiar mobile spasm observed chiefly in the finger and toes. Strictly speaking, it is not a disease, even in the ordinary clinical sense; it is usually part of a symptom-group which indicates the presence of some lesion of the cerebrum. The movements of athetosis are difficult to describe. They are most commonly observed in the upper extremity of one side, being particularly marked in the fingers and hand, but occasionally they are bilateral. Hughes of St. Louis (*Weekly Med. Review*, 1887) has reported a case of bilateral athetosis coming on in a boy about one year after a railroad accident which caused injury both by concussion and direct violence, although the case was not fully developed for several years. This boy had not complete voluntary control over the movements of his muscles; he could not, by direct effort of the will along the regular channels of nerve conduction, restrain either the rhythmical movements or the spasmodic attitude of the fingers, but he could, by strategy, modify both attitude and movement by bringing one limb to bear upon another and by assuming for the affected limbs flexed positions; but, no matter how much he succeeded in managing these movements, grotesque attitudes would always recur in one or more of the fingers. His affliction unfitted him for occupation requiring manual dexterity. He tried a number of things, but had to give them up because of physical incompetency.

Athetosis is most frequently congenital or an affection of early childhood, occurring particularly in connection with some of the forms of cerebral palsy in children which have been described in this work by Peterson. Church (*Review of Insanity and Nervous Disease*, March, 1892), has recorded an interesting case of symmetrical and universally distributed athetosis in a woman thirty years old, who had suffered from the affection since birth. She was lacking in mental development; face and speech were both affected. Many instances of what might be termed athetoid affections are to be found, particularly among idiotic and imbecile children. These differ from typical athetosis in the irregularity and wide diffusion of the mobile spasm. Several cases of this kind are nearly always present in the nervous wards of the Philadelphia Hospital. One, a mentally defective deaf-mute about thirty years old, has been subject, probably from early childhood, as no history can be obtained, to excessive and irregular movements and distortions, particularly of his face and upper extremities.

Symptoms.—Athetosis, as already indicated, is a word descriptive of a series of grotesque, irregular, and yet monotonous, involuntary movements which are persistent, but subject to exacerbations, and are usually confined to an extremity or the extremities of one side. The movements are more or

less rhythmical, and do not seem to cause the patient fatigue, in this respect being like other rhythmical spastic affections of functional or organic origin. By a strong effort of the will the patient can usually control the movement. As a rule, sensation is not impaired. The muscles on the affected side are often hypertrophied. The condition of the reflexes and so-called reflexes vary, but the knee-jerks and other allied phenomena may be increased on the affected side. As the disease is usually cerebral in origin, electrical changes are commonly not present.

Etiology.—The etiology of athetosis is that of the organic affection of which it is a symptom or with which it is associated. It may be caused by accident, as in Hughes's case of bilateral athetosis to which reference has been made, but whether or not athetosis results will depend upon the particular lesion which is inflicted on the nervous system. The disease has been attributed to fright or undue excitement of the mother during pregnancy, and fright has been given as a special exciting cause in a few instances, but on uncertain grounds. It is much more likely to cause chorea or choreoid affections. Many cases of athetosis and of athetoid affections are associated with well-defined idiocy or imbecility, and are dependent upon the same causes, hereditary, developmental, or accidental, which have led to the latter. According to Strümpell, athetosis may be a sequel of poli-encephalitis; and I am inclined to subscribe to this opinion, although the very existence of this disease in children has been denied by authors of ability. Toxic agents by affecting the motor cortex or subcortex may cause this affection.

Pathology.—The lesions in reported cases of athetosis have been largely in the basal ganglia or their immediate neighborhood. In one case a sclerotic nodule was found in the thalamus very near its central upper surface, and in several other instances lesions have been discerned in the same great ganglion; but in nearly all of these cases neighboring parts, as the caudate nucleus, internal capsule, or corona radiata, have also been involved. Undoubtedly, mobile spasm may depend upon lesions either of the thalamus, the striate bodies, the motor cortex, or any part of the cerebral motor tract. In one interesting case of athetoid spasm and myotonia, occurring in an adult, reported by me, and in which an autopsy was obtained, some light was thrown on the character and situation of the lesions which may in some instances produce athetoid spasm. The most striking features were brought out when the patient attempted any voluntary movement, and among other manifestations his fingers were twisted and thrown into a position which illustrated well one of the forms of athetosis of the upper extremity. Many other phenomena, sensory and motor, were present in the case and are detailed in the report (*Intern. Clinics*, April, 1891). The autopsy showed that in both hemispheres, chiefly over the superior and inferior parietal gyri, the dura was adherent to the pia mater, the pia was deeply injected, thickened, and infiltrated with plastic lymph, and in numerous places was more or less firmly fixed to the brain-substance; but the injection, infiltration, exudation, and adhesions were much more marked in the postero-parietal regions than elsewhere. Beneath the area of meningitis both the cortex and the subcortex were softened, giving the appearance on the right side of a sunken, subcortical, or subpial cyst. On the left side of the brain, in a nearly corresponding but somewhat smaller area, was a similar belt of inflammation and softening. Subsequent incisions on both sides showed that the softening included the whole of the gray matter, and involved to a considerable extent the white, but did not invade the ganglia or capsules; it was confined to the supraventricular corona radiata. In cases

unassociated with hemiplegia or diplegia, irritative foci in the motor areas or tracts may give rise to the affection; and Gowers believes that it is sometimes due to impaired nutrition of the growing motor cells.

Diagnosis.—Typical cases of athetosis are not difficult of recognition. Occasionally cases of hemichorea and hemiathetosis in children might be temporarily confused. The movements of athetosis are said to continue during sleep, and this is certainly true of some cases. Post-hemiplegic chorea and athetosis may be confused; and, indeed, chorea secondary to a paralytic attack and this affection differ but little in nature and characteristics. In this work Peterson has described, as occurring in two cases of congenital hemiplegia, an affection to which he has given the name of post-hemiplegic polymyoclonus, in which the movements are neither choreiform nor athetoid, but are chronic, constant contractions of most of the muscles of the limbs affected. The face is seldom affected alone in a disorder which may properly be called athetosis. In athetosis, as contrasted with chorea, the movements, although irregular and bizarre in themselves, have a certain regularity and monotony in their method of repetition, which is not the case with choreic movements.

Prognosis.—The prognosis in the vast majority of cases is bad, as the disease is due to an incurable, often congenital, organic condition. A case of primary athetosis which is quoted by Jacoby from Gnauck (*Keating's Cycl. Dis. Children*, vol. iv.) resulted in complete recovery, and many cases have been reported as improved, but such reports are always of uncertain value. Usually the affection goes on from bad to worse very slowly. Not infrequently, athetosis or athetoid movements are associated with general convulsions, and the latter may be much improved by the treatment employed for epilepsy. Organic athetosis must, of course, from the very nature of the affection, have an exceedingly unfavorable prognosis. A disease which is due to atrophy, sclerosis, neoplastic formations, meningo-encephalitis, or softening, can scarcely be otherwise than incurable. The only point in diagnosis is to separate a few cases of pseudo-athetosis of hysterical or neurotic origin from those of the common type. Hysterical athetosis is possible, has been observed, and has a favorable prognosis.

Treatment.—It follows from what we have already said as to their nature that little can be done in the way of treatment for these interesting but usually hopeless cases. Nerve stretching will temporarily stop the movements, just as it will in cases of histrionic or facial spasm due to organic lesion, but as soon as the nerve has recovered from the traumatism the movements will begin to return, and will soon be present again in their original intensity. Galvanism has been frequently employed, but is of little permanent value. The iodides, bromides, and mercury may be used in cases in which a tumor or meningitis is supposed to be present. Remedies like conium, hyoscine, opium, gelsemium, may be tried, but from the very nature of the cases can only be of temporary value.

INSANITY IN CHILDREN.

BY CHARLES K. MILLS, M. D.,

PHILADELPHIA.

ALTHOUGH juvenile insanity is comparatively rare, it is sufficiently important, both clinically and medico-legally, to demand systematic consideration in a treatise on the diseases of children. It is important not only in itself, but also in its bearings on the mental and physical health of the patient after he has reached adult life. The varieties of insanity which occur in early childhood are largely the same as those of youth and manhood, but they have special characteristics due chiefly to age. These affections are distinct from idiocy, imbecility, and cretinism, although idiotic and imbecile children may have attacks of mental excitement or depression, or other evidences of active insanity. The two conditions of arrest and of acquired disorder must be separately regarded and discussed. Morison, in his *Lectures on Insanity*, speaks of having frequently met with violent and unmanageable idiots of a very tender age.

The mental affections to which particular attention will be directed are those which occur in children presumably born with at least an average degree of intelligent power and possibility. Although it is difficult to separate moral insanity and moral imbecility in children, yet such a distinction can sometimes be made with advantage, and therefore the former will receive brief consideration in this section.

The difference between insanity in the child and in the adult is in harmony with known facts and physiological principles regarding the evolution of the mental faculties. "The insanity met with in children," according to Maudsley (*The Physiology and Pathology of Mind*), "must of necessity be of the simplest kind; where no mental faculty has been organized no disorder of mind can well be manifest." The forms and degrees of insanity exhibited by children according to their stages of mental evolution and their acquired habits have been well discussed by this able psychologist and alienist. Violent and convulsive response to sensorial impressions gives rise to mental disorder of an epileptiform character; or, once the power of definite sensory impression has been acquired, and hallucinations are possible, these may lead to choreic reactions. Some forms of nightmare in children are the result of vivid hallucinations which have arisen in response to such impressions. Hallucinations may occur before the mind is sufficiently organized to make delusion possible; but later, after a varying time, ideas or concepts become organized, so that the child is able to think about absent objects. Ideas which are at first simple and isolated become elaborated and grouped, and as soon as ideas are fully organized, delusion, which is an insistent baseless belief, becomes possible.

True insanity in children has been observed at a very early age: indeed, Greiding has reported one case, cited by Crichton and Maudsley, of a child who is said to have been raving mad when it was born. The mother was about forty years old, was of full plethoric habit, and constantly laughed and did

strange things, but otherwise was in the best of health; she was delivered of a male child who possessed so much strength in his arms and legs that four women could at times with difficulty restrain him. His paroxysms of motor excitement either ended in uncontrollable fits of laughter or else he tore everything or anything near him. Mania has also been reported by Greeding as beginning at nine months in a child who died at eighteen months old; by Rush and others at the age of two years. Sinkler (*Univ. Medical Magazine*, Jan., 1893), has reported two interesting cases in children three years old. Many cases have been reported as occurring between the ages of five and twelve or thirteen years.

Varieties of Insanity in Children.—It would serve no useful purpose to attempt a formal classification of the insanities of childhood, and it is best, therefore, simply to consider the subject under such heads as experience and published records indicate. All forms of insanity may occur before puberty, although some are very rare. According to Cohn (*Arch. f. Kinderheilk.*, Bd. iv.), juvenile insanity should be divided into functional and organic, under the former subdivision placing those neuroses which may be in part, or may develop into, psychoses, as the insanities of chorea, epilepsy, and hysteria, and also what might be termed idiopathic psychoses, such as hallucinatory confusional insanity, hypochondriacal insanity, melancholia, mania, and moral insanity; while the latter are comprised under such forms as exhibit clear manifestations of organic cerebral disease, as, for example, the rare cases of parietic dementia and mental affections due to tumor, abscess, meningitis, or other determinable lesions.

It will be convenient for practical purposes to arrange juvenile insanities under the following heads: 1, Transitory Psychoses; 2, Mania; 3, Melancholia; 4, Circular or Alternating Insanity; 5, Choreic Insanity; 6, Hysterical Insanity; 7, Cataleptic or Cataleptoid Insanity; 8, Epileptic Insanity; 9, Paranoia or Primary Delusional Insanity; 10, Moral Insanity; 11, Instinctive Perversions and Morbid Impulses; 12, Morbid Fears or Phobias; 13, Parietic Dementia.

A favorite method of classifying insanity, and one which has much that is practical in its favor, is on the basis of etiology, but it has disadvantages, and may be scientifically misleading. In some instances, however, both in adults and in children, special causes are so prominent in the production of certain types of insanity that it serves a good purpose to name the affections from the point of view of causation. Understanding that different forms of insanity from the semiological standard may be produced by the same or similar causes, we may have in children such etiological varieties as *dementia due to inherited syphilis*, *febrile and post-febrile insanities*, *reflex insanity*, *masturbational insanity*, and many others, according to the views of the alienist discussing the subject.

TRANSITORY PSYCHOSES.—Although any form of non-organic insanity in a child is likely to be transient, because it has not the soil in which to take firm root, still certain phases or varieties of mental disturbance in the very young can because of their fleeting character be conveniently classed as transitory psychoses. Under this head would be placed a form of delirium arising in young children from special causes. It is well known to mothers as well as to physicians that some children have a greater tendency to attacks of delirium than others. In them the slightest rise in temperature, as of one or one and a half degrees, will always be attended with more or less delirium. Sometimes this delirium, mild in type and without any special features, constitutes the entire case; but an attack of delirium may be prolonged and take the form

of a true although a transient and non-tenacious mania. The child may have frightful hallucinations, especially of sight or hearing.

Speaking of the insanity of young children, Maudsley well says that "the precocious imagination of a child which sometimes delights foolish parents cannot possibly be anything more than lying fancy; and this for exactly the same reason that the insanity of children must be a delirium, and cannot be a mania—the incomplete formation of ideas and absence of definitely organized associations between them."

Pavor nocturnus, or night-terrors, might be classed with the transitory psychoses of children, but this affection is discussed in another article.

These transient psychoses may take the form of an excited or agitated melancholia, as mentioned by Clouston (*Clinical Lectures on Mental Diseases*, 1884), the patients in such cases screaming, sobbing, weeping, and giving evidence of great mental suffering and depression, usually without being able to give any reasons therefor, although they will sometimes speak of seeing or hearing something, or more or less vaguely of being worried or frightened by apprehensions of evil or injury.

The affection variously known as transitory frenzy, mania transitoria, or ephemeral mania, which in the adult has often been the subject of medico-legal dispute, occasionally has been observed in children—an abrupt, rapid disorder, lasting only a few minutes or hours. Morel (*Maladies Mentales*, 1853), speaks of a little girl eleven year old who after the sudden disappearance of a skin eruption exhibited choreic symptoms, and soon after those of a true maniacal fury in which she became homicidal; and other cases of transitory fury, some traceable to special causes and some not, have been reported by various observers.

MANIA.—Mania is the form of insanity of most frequent occurrence in childhood. It usually shows itself by active delirium, great motor excitability, screaming and crying, incoherence, and sometimes by hallucinations, and even delusions of slight tenacity in children old enough to have ideas. Exacerbations of extreme fury or violence come on in the course of the general excitement; convulsions sometimes occur, and speech may be lost, as in a case reported by Morel of a girl ten and a half years old. It was necessary to send her to an asylum, and she never seemed to be happy unless she was destroying something or tormenting somebody. A boy five years old was suddenly frightened, lost the power of speech, was turbulent, and had frequent maniacal paroxysms. These little patients sometimes exhibit great anger and destructive and even homicidal impulses and propensities; but these acute morbid impulses and propensities must be distinguished from those which are due to character, and will be referred to later when speaking of instinctive insanity and morbid impulses.

MELANCHOLIA.—Melancholia is not an uncommon form of insanity in children, but it is not likely to occur before the age of five or six years. It is always necessary to distinguish between monomanias or paranoias and melancholias, but genuine uncomplicated melancholia is sometimes seen in children, and has been reported by numerous observers. Hallucinations may or may not be present with the mental depression. Melancholy in a child seldom assumes the extreme form which is observed so frequently in the adult, but now and then a true agitated melancholic frenzy is observed. Ordinarily a child suffering from melancholia will be sad, anxious, weeping, restless by day and by night, wanting in the liveliness and changeability of children—blue, depressed, worried and worrisome, knowing not why. Delusions so common in adults, as of self-condemnation, of the unpardonable sin, of coming to want,

or of fatal organic disease, are often absent in the melancholia of children. Children brought up in morbidly religious or in distressing surroundings sometimes exhibit a delusional state of a religious or painful character, but this does not obtain the same depth and fixity as in adults. The varieties of melancholia most frequently observed in children are the simple, the hypochondriacal, the excited or agitated. Suicide in children is not commonly due to melancholia, although it is occasionally, when an inherited taint will often be found to be present. Children, like adults, are now and then driven to melancholia and suicide by want of care and ill-treatment. The suicides of children are sometimes dependent upon the most trivial causes or notions, as a trifling chastisement.

CIRCULAR OR ALTERNATING INSANITY.—A well-known and most interesting type of insanity in the adult is that which is characterized by alternating mental states, in which, for example, the patient suffers first from exaltation or mania, then from depression or melancholia, then has a sane or lucid period, and again starts on the vicious circle with an attack of exaltation. Sometimes other forms of alternation appear, or simply depression and exaltation in rotation. This mental disorder, which has been designated *folie circulaire*, or circular insanity, and also alternating insanity, is sometimes observed in children.

CHOREIC INSANITY.—Several varieties of choreic insanity have been described. One form of choreic mania usually does not commence until the motor disorder has lasted two, three, or four weeks. Before the onset of the mental disorder the motor disturbances become more severe and irregular; the movements never cease, even in some cases during the little sleep which is obtained, and insomnia becomes almost as complete as in delirious mania. As a rule, the sufferers preserve more knowledge of themselves and their surroundings than would seem likely from the apparent mental disturbance. They do many things which appear to be purposive or hysterical in character, as struggling, striking, hurling things, breaking furniture or dishes, jumping, rolling or thumping themselves against the floor and walls. These cases have been well described by Meyer (*Tuke's Dict. of Psychological Medicine*), who also briefly details the symptoms of acute choreic delirium, in which great excitement with anguish, vivid hallucinations of vision, hearing, smell, taste, and also with stupor, are reported. Fever and evidences of endocarditis are usually present. Idiots not infrequently exhibit choreic disturbances of limbs and language. The insanity of choreic cases is not to be regarded so much as caused by the disorder as an essential part of it, the peculiar delirium, irregular and incoherent, being comparable to the choreic movements themselves.

HYSTERICAL INSANITY.—Occasionally hysterical mania and chronic forms of hysterical insanity are observed in early life. Even in adults it may be difficult to distinguish between common acute mania and hysterical mania, and it is sometimes even more difficult in children; indeed, these two affections run more together in childhood. The association of other hysterical phenomena, such as ecstasy, catalepsy, trance, mutism, aphonia, fantastical notions, sensational deceptions, or pseudo-palsies, will be aids to diagnosis. Hysterical mania in childhood usually comes and goes, the attacks being short and showing great emotional excitement. Some, at least, of the acts may be purposive, although apparently beyond control. Sometimes, alternating with these maniacal attacks or independently of them, children are caught in sensational deceptions of such outrageous character, and repeated so often, that they can only be regarded as due to mental perversion. "You may be sure that a young girl is on the premises," says Wilks, "when you read of loud rappings in a house at night,

of a room being constantly set on fire, of sheets torn by rats, and of similar extraordinary occurrences."

Hammond (*Treatise on Insanity in Its Medical Relations*, 1883) records the case of a girl whose disposition was always sullen, capricious, and eccentric, and who never exhibited the least feeling of tenderness toward her parents—who laughed and cried without cause, and committed from an early period of her life all kinds of singular and ridiculous acts. She could not be prevented from using obscene and ridiculous language; and soon she exhibited a series of spontaneous and delirious acts, such as are met with in hysterical mania. One day she crowned herself with flowers, took a guitar, and announced that she was going to travel through the world. She got up in the night and washed her clothes in the chamber-pot. She had convulsive seizures, mewed like a cat, tried to climb up a wall, was violent in her acts toward others, and finally fell into a state of stupor. These accessions were periodical, and it became necessary to send her to an asylum.

The dancing manias, child-pilgrimages, and other epidemic and endemic nervous disorders may be regarded as forms of hysterical insanity; at least they are fundamentally psychoses. Occasionally these endemics from imitation are observed in homes and schools. Usually convulsions, speech affections, pseudo-paralyses, contractures, visual hallucinations, or spells of great emotional excitement are among the phenomena exhibited.

CATALEPTIC OR CATALEPTOID INSANITY.—*Katatonía*, a clinical type of insanity first described by Kahlbaum in 1874, has in rare instances been observed in children. It is a cyclical or alternating insanity, sometimes having as many as five stages—beginning, for instance, with mania, and then melancholia, stupor, cataleptoid, and dramatic periods following. The different stages may vary in duration and continuation; thus, depression and exaltation may be present with cataleptoid and histrionic phenomena. Some cases recover, and others pass into a state of chronic dementia. It has been claimed that katatonía cannot be regarded as a distinct clinical entity, as various cataleptoid and convulsive phenomena and histrionism are present in other types of insanity, as mania, melancholia, paranoia, imbecility, while others, again, hold that it is an hysterical disorder. It is certain, at any rate, that in childhood mental disturbance of peculiar character, associated with catalepsy, ecstasy, and trance-like states, is observed; and transient maniacal attacks may be present in these cases. Occasionally seizures of this kind have been observed in undoubted epileptics, although the attacks are not to be regarded as epileptic in their nature. A true epilepsy is occasionally developed in children who begin with cataleptic, hystero-epileptic, and hystero-maniacal spells.

EPILEPTIC INSANITY.—Congenital epileptics are not infrequently idiots or imbeciles or sufferers from some form of paralytic or atrophic disease; in other cases epilepsy appears early in life in children of fair mental health, some of whom develop epileptic insanity; sometimes a true epileptic dementia comes on even before the period of childhood has passed, showing itself by loss of memory, judgment, and general mental enfeeblement. Mania may occur before or after an epileptic paroxysm, or may take the place of such a paroxysm, just as in the adult. When without sufficient apparent cause a child has transitory fury or frenzy, even though no known history of epilepsy be present, the possibility of the attack being epileptic should be borne in mind. Sometimes very young children have maniacal outbreaks, and subsequently develop regular epilepsy; or the epileptic seizures may be nocturnal, and thus be overlooked; or, again, attacks of *petit mal* may be undemonstrative in character, so that their true nature may not be recognized.

Attacks of fury followed by epileptic convulsions, and of epileptic convulsions followed by furious excitement, in children under ten years of age are recorded by many, and have been observed by every one who has had much experience with epileptic children. Epileptic children also show peculiar perversions of character and manners. Post-epileptic conditions of stupor, delirium, or confusion are sometimes present, and a chronic maniacal state may accompany the epilepsy.

PARANOIA OR PRIMARY DELUSIONAL INSANITY.—Paranoia, a Greek word meaning insanity, has been reintroduced into the literature of mental disease. Primary delusional insanity, suggested by Stearns (*Lectures on Mental Diseases*, 1893), is a better term, although even this is open to objection. It is a chronic insanity, in its completest type characterized by recognizable systematized delusions, but showing itself also by general mental instability, insistent ideas, morbid impulses, and perversions of character, the foundation of these being in reality a delusional state. The delusions of paranoiacs may or may not be accompanied by hallucinations. While paranoia is rare under the age of puberty, the children who subsequently develop primary delusional insanity have often such marked peculiarities and eccentricities as to lead physicians experienced in mental diseases to forecast the probable occurrence of this affection later in life. They show oddities of dress and conversation, excess of self-consciousness, a tendency to scheming and dreaming, ambitious and egotistical notions, conceits and misconceptions, and periods of moodiness, depression, anger, or excitement. Recently, Moyer and Lyman (*Med. and Surg. Reporter*, March 25, 1893) have reported paranoia in a boy between twelve and thirteen years old. He imagined that his mother was going to poison him and that he had yellow fever and tape-worms. In a strict sense, he was neither exalted nor depressed. Two maternal grandaunts died insane. This case might be regarded as one beginning at puberty, but now and then a case with definite delusions of a systematized character is seen at an earlier age. According to Spitzka, imperative conceptions, morbid fears, and *folie du doute* are frequent in infantile masturbators, and hypochondriacal and persecutorial paranoia in a crude form is similarly detected at this period.

MORAL INSANITY.—It is difficult, as already stated, to make a distinction between moral imbecility and moral insanity in children, and sometimes the distinction is of little importance. In moral insanity the perversion of the moral or affective life may be brought about by injury, disease, or vicious habits in children who to all appearances have been of healthy moral and mental tone. The moral imbecile is the victim of heredity, his condition being manifested as soon after birth as it is possible to recognize deficiencies in the moral sense. Extraordinary perversions of character have been recorded in considerable number due to acute fevers in children. Psychological phenomena approaching attacks of true insanity sometimes occur during malarial fevers, and sometimes seem to take the place of malarial attacks.

INSTINCTIVE PERVERSIONS AND MORBID IMPULSES.—Instinctive perversions and morbid impulses flow out of the same inherited or constitutional conditions which are at the root of fully-developed monomania or paranoia. Children who show these perversions and impulses sometimes later in life become examples of paranoia. Maudsley prefers to consider these symptoms or conditions under the general head of affective insanity, under which he would also include moral insanity proper. With regard to both adults and children it is important to determine whether such manifestations are symptoms of mania, melancholia, or epilepsy, or whether they are constitutional or paranoiac in type. One must have a clear idea of certain terms now frequently used in

considering these questions, such as concepts, imperative concepts, morbid concepts, imperative acts or movements, insistent ideas, and morbid propensities. *Concepts* are distinct or isolated thoughts, the elements of thought-processes; they become imperative when they dominate or tyrannize the mind. *Imperative acts or movements* or morbid impulses are the results of these imperative conceptions. The term *insistent idea*, suggested by Cowles, describes a habit of thought resulting from the repetition and multiplication of morbid concepts; after a time these insistent ideas hamper and manacle the individual's will and intellect. *Morbid propensities*, like insistent ideas, sometimes steadily hold possession of the mind; they are often simply exaggeration of the normal propensities, but to such a degree as to become a true insanity. They are perversions chiefly of the desire for food and of the sexual appetite.

Under morbid impulses, monomanias, partial ideational insanity, and partial moral mania have been described such affections as moral mania; homicidal mania or the impulse or propensity to kill; suicidal monomania; kleptomania or the propensity to theft; erotomania or the tendency to fall in love with everybody; nymphomania which may be distinct from erotomania and exhibit itself in sexual precocity and salacity; pyromania or the impulse or propensity to incendiarism; and dipsomania or the irresistible periodical craving for drink. It is perhaps better to regard these as designations of the most prominent symptom or symptoms in a case of insanity, rather than to erect them into a special variety of mental disease, although the latter procedure sometimes serves a good practical purpose.

Almost every variety of monomania or morbid impulse has been observed in young children, and many cases might be given. Esquirol speaks of a girl aged five years who repeatedly attempted to kill both her stepmother and her brother. Not a few cases have been reported like that of the boy Pomeroy—children who have shown an insane inclination to cruelty as well as to homicide, this often exhibiting itself in a tendency to give pain, to mutilate, to harm in various ways the lower animals or other children. Such cases usually belong to the inherited paranoiac type, but in others the inclination to injure or kill may be simply one of the violent manifestations of a curable acute mania.

Both thieving and lying can sometimes only be regarded as true mental perversions, although it is certainly difficult in the child as in the adult to separate such forms of monomania from conscious and controllable viciousness. Girls at or approaching puberty are known to exhibit such tendencies to a morbid degree, in many cases recovering from them in a shorter or longer time, but occasionally even younger children show the same monomaniacal inclinations. Such a child will lie without rhyme or reason, and will steal without a desire to gratify appetite or passion.

What is known as erotomania is more frequently exhibited in adults than in children, but rare juvenile cases have been observed. Erotomania and nymphomania are not the same, although often confounded. In erotomania, as a rule, the tendency to indecency and excess is not present. The erotomaniac boy becomes the adorer of most of the girls he meets, or the girl the admiring slave of the boys. Nymphomania or satyriasis exhibited in an insane degree is by no means uncommon in children, and even occasionally in very small children, both boys and girls. Cases have been reported of children two and three years old who have exhibited the most remarkable sexual precocity, as shown by indecency of attitude and act.

Some of the most extraordinary instances of morbid impulses and propensities in children are those which have been reported as cases of pyromania, the child persistently and perversely striving to set fire to anything and everything

that it thinks will burn, and using sometimes great cunning and skill both to succeed and to conceal the act.

Hammond relates the case of a girl less than fifteen years of age, affected with nostalgia, who twice set fire to the house in which she lived. She declared that from the first minute of entering her master's house she had been seized with the desire to destroy it by fire. It seemed to her that a ghost standing before her constantly urged her on to the act. This girl had suffered from pain in the head and disordered menstruation.

MORBID FEARS OR PHOBIAS.—In a philosophical sense, sanity and insanity are relative terms whether applied to conditions in children or in adults; certainly, not a few cases are observed which may be properly regarded as on the borderland between mental health and disease. They are perhaps best regarded as examples of partial or quasi-insanity; that is, forms of mental disease which in a certain manner and degree have the attributes of insanity. They are abortive or imperfectly-developed mental disorders. Sometimes they are as transient in duration as they are limited in phenomena; but in other instances the few elementary deficiencies or disturbances may persist without much change or increase through life. Many of these cases, like the morbid impulses just treated of, belong under the head of paranoia. They have been described as morbid fears or phobias, as morbid doubts, as emotional monomanias, and even as forms of neurasthenia. They are fundamentally dependent upon the domination of the mind by morbid concepts and insistent ideas. They are sometimes observed among young children, although more common after than before the period of puberty. Morbid fear may be the result of functional disturbance or disease in a normally constituted individual, but the cases which afford the most striking instances of morbid fear or phobia occur in those who have not been subjected to any physical or mental strain sufficient to break down a healthy organization. Persistent fear of the monomaniacal type occurring in children is rarely due to overwork or fatigue, as at school, as is frequently supposed. The real cause is generally in a child's progenitor or progenitors. They are cases of the class referred to by Oliver Wendell Holmes, the cure of which should have been begun two hundred years ago.

These quasi-insanities or phobias have been much divided and subdivided; not infrequently several of the so-called varieties are present at the same time in the same case. Among the forms of morbid fear which have been described by particular names are *pathophobia*, or fear of disease; *mysophobia*, the fear of contamination, defilement, or pollution; *agoraphobia*, the fear of open squares or places; *claustrophobia*, the fear of closed or narrow places; *topophobia*, the fear of places in general; *monophobia*, the fear of being alone; *pyrophobia*, the fear of fire; *astrophobia*, the fear of lightning; and *hydrophobophobia*, or fear of hydrophobia. Some cases belong to a class which may be described as *pantophobia*, or fear of everything.

A few cases have been observed in comparatively young children. Hurd (cited by Stearns), reports an interesting case from an account written by the patient herself. When about twelve years old she began to have strange fancies, as fearing the blood flowing from a cut finger would harm those who came near her. Subsequently, dressing, walking out of doors, eating, were all greatly interfered with through the same morbid ideas. She feared contagious diseases because she might communicate them to others. The insistent idea changed from time to time, but seemed to spring always from the emotion of fear. She eventually recovered. Hammond cites from King, of Sedalia, Missouri, an interesting case of pyrophobia in a boy of ten years. Day and night he was infested with fear of this kind. On one occasion, when the morning

was cool, he succeeded, after a contest with his mother, in opening the stove-door and pouring a bucket of water on the fire. He is said to have been cured by quinine, the bromides, and the use of evaporating applications to the head.

A few cases in comparatively young children have been reported and some have come under my notice. A boy eleven years old, developed what was practically a pantophobia, although his disorder exhibited itself chiefly as a pathophobia, or fear of disease. He was kept almost constantly under the care of physicians. Sometimes his morbid ideas revolved round real affections of slight importance; sometimes his fears and suffering were due purely to morbid conceptions and insistent ideas. Now his eyes were the source of morbid dread; soon his limbs were the seat of rheumatic pain; he narrowly escaped laparotomy for typhlitis, probably of psychological origin; to a moderate degree he suffered from mysophobia, spending unusual time at his ablutions, teeth cleaning, in dressing, and in the care and arrangement of his clothes. Anything in the nature of a symptom or a disease mentioned in his presence was likely to take possession of him. His morbid notions and apprehensions were fed and encouraged by the unceasing attentions of members of his family. He was practically cured by taking him from his home-surroundings, disregarding his complaints, forcing him to do things on time and after the manner of others, at the same time carefully but not obtrusively looking after his general health.

Another boy at the age of ten began to develop the scrupulous and mysophobic type of monomania; in fact, he was, as so many of these cases are, an illustration of the admixture of several of the so-called classes of morbid fears. He was constantly worrying about many things he said and did in his intercourse with others. If left alone, he would spend hours in bathing and washing himself, and often imagined he had been polluted or would contaminate others. The symptoms were in many respects like those of the lady described by Hammond, and to whose case he first applied the term mysophobia, who could touch nothing without being irresistibly impelled to wash her hands, and who in many other ways was tormented by the fear of contamination. This boy improved greatly under mental discipline, out-door exercise, and careful tonic medication.

These cases of morbid fear, particularly when they assume the form of pathophobia or dread of disease, are sometimes incorrectly regarded as examples of hypochondria or hypochondriacal melancholia, but they differ from the latter as monomania or paranoia differs from mania or melancholia.

PARETIC DEMENTIA.—From its nature and pathology paretic dementia is essentially a disease of adult life. It usually arises in patients more than thirty years of age, and is most common between the thirtieth and fortieth years; but occasionally it is observed in the aged, and in very rare instances in the young. The youngest paretic dement observed by Spitzka in 346 cases was eighteen years old. Other cases, however, still younger, have been reported, as one by Turnbull (*Jour. Mental Science*, October, 1881) in a boy of twelve years, who was first observed by the reporter at the age of eighteen years. Up to the age of ten he had been healthy and apparently like other boys, but at this age he had an attack of hemiplegia, which passed off in a week and left him with a certain amount of stupidity. He continued to perform his duties as a messenger-boy, but from the age of twelve a mental weakness increased gradually but distinctly. His symptoms, as described, were certainly those of general paralysis, except that he had not delusions of grandeur. The boy died in less than a year after his admission to an asylum, and the post-mortem findings were those usually seen in cases of paretic dementia.

Etiological Varieties, and General Etiology.—A form of juvenile dementia, the result of inherited syphilis, sometimes occurs, and it is necessary to separate this from idiocy and imbecility, whether of syphilitic or other origin, which may be done by remembering that the dementia usually comes on after the child is four or five years old, and therefore when the mental condition has been determined not to be that of idiocy. In rare cases, however, it happens that a juvenile or infantile dementia occurs when the child is two or three years old, so young that its true mental status has not been fully determined. With this word of caution as to the possibility of inherited syphilis showing itself in a child otherwise healthy in the first year or two of life, most of the cases of this form of dementia will be comparatively easy of recognition. A family history of syphilis will often, but not always, be obtained; often the upper incisors will be pegged and notched, while cicatrices at the angle of the mouth and the characteristic physiognomy will be present; and sometimes the child will have attacks of keratitis, choroiditis, or iritis, or a history of snuffles or of a rash, and sometimes epilepsy will have developed.

Febrile and post-febrile insanity is, on the whole, not rare in children. Many cases have been put on record. They have been arranged by Nasse into three classes—those coinciding with the fever, those which are apparent continuations of the fever, and those developing during convalescence. According to Spitzka (*Keating's Cycl. Diseases of Children*), the latter group is more benign in character and prospect than the other two, and is most often found in adults, the first two groups being more frequent in children. Of course delirium is an accompaniment of most fevers, and this is more pronounced and sometimes of a peculiar character in childhood; but, setting aside ordinary febrile delirium, mental disorder sufficiently intense and persistent to be classed as insanity is of comparatively common occurrence. The fevers during which or after which insanity is most likely to develop are typhoid, scarlatina, measles, rheumatism, and diphtheria. Owing to the intensity of the psychical phenomena, the true nature of typhoid fever in the child or adult is sometimes overlooked. Most cases of febrile and post-febrile insanity recover in periods varying from a few days to a few weeks or months. Rarely, however, a true dementia is originated, and when this does result the child is sometimes left weaker in mind and less capable of development than before the attack.

Under the head of *reflex insanities* might be included a large variety of cases, chiefly illustrations of mania, which has been attributed, and apparently with correctness, to splinters in the great toe, to a carious tooth, to ascarides and other varieties of intestinal parasites, to rectal and preputial irritation. In one case seen by me in consultation a tape-worm was the apparent cause, as the symptoms disappeared when the parasite was discharged. Affections of the nose and throat and digestive disturbances are other assigned causes of juvenile insanity; probably such causes simply act as excitants in children who are predisposed by heredity to mental disease. Some of the conditions which are regarded as causes are really due to the mental condition. Spitzka refers in this connection to the functional disturbances of the digestive apparatus in girls about the age of puberty, who go on from slight dyspeptic symptoms until they get an aversion to food, and sometimes even delusions about eating, so that they may actually starve to death, forced feeding being resorted to too late.

Masturbational insanity, as occurring both in children and adults, has been both overrated and underrated, but, on the whole, the tendency has been to the former rather than the latter. Some alienists deny that this vice is ever the true cause of insanity, holding that it like the insanity is due to the neuro-pathic state of the individual, or that at the most, it is merely a concomitant or

aggravating cause. My experience leads me to believe that while, as is known to almost every one, the vice is extremely common, especially among boys, it only in rare instances is the true cause of mental disease, but that these instances must be recognized. Of recent writers, Spitzka has laid the most stress upon the existence of masturbational insanity, and has ably described it from his point of view. According to this writer, the typical masturbational psychosis occurs between the thirteenth and twentieth years, and therefore at a time which just removes the subject from consideration in an article on diseases of childhood proper; but occasionally the same symptoms and conditions are observed before puberty, although before this period Spitzka believes that the dementia is more like a true imbecility, and that infantile insane masturbators are more liable to epileptiform attacks than to outbursts of mania.

Juvenile insanity may be directly inherited, but far more frequently, it is the tendency rather than the psychosis which is inherited. Besides syphilis, which has already been considered, alcoholism exerts its sinister influence in this as in so many other directions. Neurasthenia, hysteria, chorea, epilepsy may be present in the immediate ancestors. Other causes are great heat or cold, exposure to the sun, variations in temperature, and fright which acts unexpectedly, especially to excite the maniacal or hysterical forms. Injuries to the head are of so much importance as to almost warrant the creation for purposes of convenience of a class of traumatic juvenile insanities. In many of these traumatic cases the mental affection is of the maniacal type, and is often associated with epileptic or vertiginous attacks. Sometimes insanity originates in connection with disease of the heart or some form of kidney affection, although these causes, and particularly the latter, act much more frequently in adult life. Poor food, bad ventilation, and bad hygiene generally, may be auxiliary causes.

Diagnosis.—Much that has already been said in the general consideration of the subject, and also in connection with the discussion of special varieties of insanity, will assist in the diagnosis. In the first place, insanity in childhood must be distinguished from idiocy and imbecility, or the existence of both in the same case must be determined. The delirium which ushers in or accompanies a continued or ephemeral fever must not be set down as insanity, the febrile disease being overlooked, although, as has been considered, the occurrence of true febrile insanities must be borne in mind. The distinction between vice and insanity is not always easy to make either in the child or in the adult. I agree with Tuke (*Dict. Psychol. Med.*), that it is difficult to lay down rules to differentiate moral insanity from moral depravity; each case must be decided in relation to the individual himself, his antecedents, education, surroundings, and social status, the nature of certain acts and the mode in which they are performed. Hysterical excitement or mania may be difficult to distinguish from mania of either toxic or unknown origin, but the past history of the child, and the presence of certain hysterical stigmata, such as aphonia, convulsions, or paresis, will be of great assistance in making the diagnosis. The existence of epileptic insanity can often be determined by a close investigation of the history of the case, which will sometimes unexpectedly reveal the fact that the child has had at least serious *petit mal* during the day and probably spasms during the night. Every child who has sudden and unaccountable outbursts of extreme violence should be watched for a time both day and night with the view of determining as to the existence of larvated epilepsy. It is sometimes highly important to decide as to the type of insanity from which a child is suffering. If the symptoms point to paranoia or primary delusional insanity, even if of an imperfectly developed form, the prognosis will not be as favorable as if the child is suffering from true mania or melancholia. The mode of onset, the condition

of the logical faculties, the amount of emotional manifestation, will aid in the diagnosis, and the trained observer will recognize in the paranoic child that the changes are fundamentally those of temperament and character. Transient morbid fears and doubts must not be always regarded with great apprehension. Children, like adults, are subject when neurasthenic to such fears and doubts, but these only arise to the importance of mental disease when persistent, progressive, and of peculiar character. Their importance should be neither overrated nor misunderstood. Paretic dementia is so rare in children that its diagnosis has not much practical importance; the only point of interest would be, in a case which simulated general paralysis, to decide whether it might not be one of juvenile dementia due to inherited syphilis, rather than a true paretic dementia of unknown origin. Much help will be given in the diagnosis of the latter by a study of the physical evidences, such as interstitial keratitis, choroïditis, acute iritis, and optic neuritis. The eye should always be carefully examined in suspected cases. The occurrence of deafness independently of acute aural disease is important. Notching and pegging of the incisor teeth, fissuration of the corners of the mouth, flattening of the bridge of the nose, and changes of the knee-jerks may be other physical evidences.

Prognosis.—On the whole, the prognosis of insanity in childhood is good, but differs somewhat with the varieties. The transitory psychoses, mania, melancholia, circular, choreic, hysterical, and cataleptoid insanities generally recover under appropriate treatment. The rare cases of primary delusional insanity, and the more numerous instances of morbid perversions, impulses, and propensities, while they may be recovered from in whole or in part, are likely to lay the foundation or to be the precursors of serious mental affections later in life. This, however, is not the invariable rule. Young patients suffering from morbid fears or phobias, worried and driven by insistent ideas, may be much benefited, and sometimes permanently relieved, by a treatment which consists more in moral management, discipline, and general hygiene than in the use of medicines. These cases also sometimes become instances of life-long monomania of mild or severe type. Dementia due to inherited syphilis may be arrested if recognized sufficiently early. True paretic dementia is practically hopeless in the child as in the adult. Some cases of masturbational insanity are rescued; others pass into incurable dementia, or at least to a lower plane of mental life.

Treatment.—“Great care,” says Tuke (*Op. cit.*), “has to be given to the surroundings of the patients, especially in acute mania. If the patients have to keep in bed, the quiet of being in a room without noise or without exciting impressions is to be preferred to isolation in a cell, but one scarcely ever can do without the padded room. Lukewarm baths, with cold showers on the head and back if wanted, are very useful, because of the good they do to the skin, which is in many places injured.” In the treatment of mania at home every effort should be made, in the first place, to remove sources of irritation and excitement. The child should be kept in a room away from the rest of the family, and noises and to some extent even light should be excluded. The bowels should be thoroughly opened if they show any tendency to constipation, but sometimes the reverse is the case. Attention should be given to the action of the skin and the kidneys, using diaphoretics and diuretics, either alone or in combination with some of the remedies to be presently mentioned, for the more striking manifestations which are present. Food should be systematically urged upon the patient, although in some cases the tendency may be to eat too much rather than too little. It will rarely be necessary in mania, or even in melancholia, in children, to resort to feeding either with the

nasal or the stomach tube, but this should be done rather than to let the child go for several days with little or no food. The food should be of a digestible character, and should be such as can be easily taken or given to the patient, as milk, broths, milk toast, egg custard, soft boiled eggs, or tender meat.

Sleeplessness and excitement are among the most important indications to be met with in the mania of children by such remedies as chloral, bromides, conium, hyoscine, or other preparations of hyoscyamus, sulphonal, opium, cannabis Indica, acetanilid, antipyrine, chloralamid, amylene hydrate, paraldehyde, somnal, urethan. Of these the most valuable in the treatment of acute mania in children are the bromides, chloral, hyoscine hydrobromate, conium, sulphonal, and opium. The doses should be proportioned to the age of the child, bearing in mind, however, that larger doses can be borne than in children not suffering from extreme mental excitement. It is a good plan to combine bromides and fluid extract of conium, with or without chloral, in one preparation, to be given four or five times daily, and in addition to use one or two doses of about $\frac{1}{200}$ to $\frac{1}{150}$ of a grain of hyoscine hydrobromate twice daily. The combination of bromides with tincture of cannabis Indica will be sometimes found very serviceable.

The melancholia of children is generally of brief duration. It should be treated, in the first place, by rest and change: a trip to the seashore or to the country or mountains will sometimes be quickly efficacious. All the secretory and excretory glands and organs should be kept in good condition. Fruits; laxatives, mineral waters, salines, syrup of figs, and preparations of aloin, strychnine, and belladonna, combined with cascara or podophyllin, will serve a good purpose in regulating the bowels. Opium is of more service in melancholia than in mania, and may be used in small doses combined with bromides. Squibb's deodorized tincture of opium is excellent. Food should be regularly administered, and even in children the very careful use of stimulants may prove advantageous. The preparations of malt will be found preferable. Various combinations of tonics and digestives will prove of service, among the best being nux vomica with liquor pepsin, the compounds of calisaya, iron, and strychnine, and arsenic in the form of Fowler's solution administered with the compound syrup of hypophosphites.

The treatment of choreic insanity is practically the treatment of a bad case of chorea, plus that of mania. In a severe case seen in consultation, a girl eight years old developed chorea shortly after an attack of scarlet fever, and the movements were incessant, violent, and uncontrollable; the patient sleepless and at times semi-delirious. Arsenic, cimicifuga, bromides, and morphine had been used without effect, but the following treatment was successfully adopted: At first she was ordered Squibb's fluid extract of conium and Fowler's arsenical solution, each 5 minims, well diluted, every two hours; and also hydrobromate of hyoscine, grain $\frac{1}{96}$, every two hours until some effect was produced. Clysmic water was ordered to be taken freely, and poultices were used over the kidneys. The choreic movements abated somewhat, but after two doses of hyoscine had been administered she had a hysterical convulsion, the tongue became very dry, and her delirium increased. The hyoscine and arsenical solution were discontinued in about twelve hours, and she was then ordered Squibb's fluid extract of conium and tincture of digitalis, each 5 minims, every two hours, with neutral mixture. This treatment was kept up steadily for forty-eight hours. One dose of chloral, 30 grains, and bromide of potassium, 60 grains, was given by rectal injection. The poultices and clysmic water were continued, and a purgative was also administered. The chorea showed marked

improvement in forty-eight hours. The conium and digitalis were continued, but with gradually decreasing frequency, for a week. Two or three doses of chloral, of 10 or 15 grains, were given in the latter part of the day. Great attention was paid to the administration of nourishment, chiefly in the form of milk.

In epileptic insanity, or when epilepsy is suspected, bromides should be administered, guarded by arsenic, and at the same time nutrients, such as cod-liver oil and the preparations of malt, and also tonics in small doses, should be given.

The remarks made in another chapter about the treatment of moral imbecility will apply with almost equal force, at least in most cases, to the treatment of moral insanity; but the cases which have been referred to as arising from traumas, toxic diseases, and blood-poisoning should be borne in mind when considering the question of treatment. Doubtless some of these may be amenable to surgical or medicinal treatment. When children are found to suffer from instinctive perversions and morbid impulses, they should be watched with the greatest care; they should be kept as far as possible from temptations; their moral training should receive particular attention, and as far as possible they should lead healthful out-door lives, great care being observed as to the choice of their companions. In some cases these perversions and impulses pass away at puberty or adolescence. The treatment of children who are the victims of morbid fears and doubts, of pathophobias, mysophobias, pyrophobias, and the host of other phobias, is worthy of careful thought. While the tendency which has led to these disturbances is usually inherited, much may be done to prevent their full development, and in some instances the affections may pass away under appropriate treatment. Such children often require to be removed from their home-surroundings, as almost invariably mistakes are made by their parents and guardians either in the direction of too much sympathy and coddling or of too much harshness or want of appreciation of the disorder. They should be prevented from constantly thinking about themselves, their aches and ailments, and if any real disease be present, it should receive appropriate but not too anxious consideration. They should be disciplined to act promptly in all cases—to act twice before thinking once.

By no one better than by Clouston has the treatment of masturbational insanity as occurring in youths been discussed, and some of his advice and rules are applicable to the disease in childhood. The paramount indication is to brace up the youth mentally and morally. As soon as the child can be reached by judicious instruction, efforts should be made to strengthen both bodily and mental inhibition. The mistake should not be made of unnecessarily calling the attention of young children to their genital organs and sexual feelings; occasionally parents and physicians err in this direction. A healthy child should be let alone, and too much anxiety and interference should not be shown because of some physiological sexual manifestation. Ordinary attention to health will often suffice to keep a child straight. My own view, as already stated, is that mental disorder in children from masturbation may occur, but is not common, and that the habit sometimes weakens children who are mentally and physically deficient from other causes. The physician or parent should not take for granted, as is done so often, that a large majority of the nervous and mental symptoms and affections of children are attributable to this vice. Some mothers and fathers seem to live in constant worry about this matter, and are always suspecting their children of self-abuse. Clouston's particular suggestions with reference to the treatment of this form of insanity must of course be qualified by considerations of age. "Avoid flesh," he says, "as the

incarnation of rampant, uncontrollable force, sexual and otherwise. Be much in the open air, work hard. Finally, so fill up and systematize the time that none is left for day-dreaming."

Spitzka holds that painful corporal punishment should follow every attempt by infants at touching the privates or executing friction, as to no other argument is so young a child accessible. It is doubtful whether this advice is of universal application, but it is perhaps best followed in some cases. As soon as children are old enough appeal can be made to the sense of shame and of self-respect. Any local source of irritation, such as adherent prepuce, irritative affections of the genito-urinary apparatus, and worms in the alimentary canal, should of course be removed, although this last source of trouble is likely to be overrated.

IMPERATIVE MOVEMENTS IN DEFECTIVE CHILDREN: ALSO HEAD-NODDING, HEAD-SHAKING, HEAD-ROTATING, HEAD-BANGING, AND NYSTAGMUS IN INFANTS.

BY CHARLES K. MILLS, M. D.,

PHILADELPHIA.

UNDER various but similar names, such as head-nodding, head-jerking, head-rotating, and head-banging, certain acute affections in infants and young children have been described. The reports of these cases show that they differ in character, and to such an extent that for the practical purposes of prognosis and treatment distinctions must sometimes be made between different varieties. Among the authors who have contributed to our knowledge of this subject are Henoeh, A. Baginsky, S. Gee, Stephen Mackenzie, and, more than all, W. B. Hadden (*Lancet*, June 14, 1890, and *St. Thomas' Hospital Reports*, 1890) and for most of the facts contained in this brief sketch I am indebted to the valuable papers of the last named.

IMPERATIVE MOVEMENTS IN DEFECTIVE CHILDREN.—Before considering the affections described by Hadden, it should be borne in mind that in well-known organic affections of the nervous system, so-called imperative movements, due to dominating conceptions and insistent ideas, may be present either in children or adults. These may take the form of the salaam or bowing spasm, of snapping the eyes, of contortions of the face, of shrugging of a shoulder or shoulders, or of some repeated movements of the arm, trunk, or leg; or, again, they may be some peculiar combination of movements executed together or in succession. They may in other rare instances be shown as an irresistible tendency to touch some special point or to handle an object in some particular way. Occasionally such imperative movements are associated with explosive expressions which may be of profane or obscene character, and to these I have referred in discussing speech-defects and anomalies. Among the idiotic, interesting instances of imperative and automatic movements are observed. At the New Jersey Home for Feeble-minded Children at Vineland one little epileptic patient has at frequent intervals attacks of head-shaking, nodding, and jerking. Another girl has curious recurring rhythmical movements which can be started by music or by beating monotonously some object, as a fan or desk. Holding one hand open with the little finger of the other, she rapidly vibrates the fingers of the open hand or, standing squarely on her feet, she continues for a long time a semi-rotary movement of the trunk, at the same time tossing the head from right to left and bending the body from side to side.

At the Pennsylvania Training School for Feeble-minded Children at Elwyn is, or was, a little patient familiarly spoken of as "The Dervish." The

boy was of small stature and weight, a demi-microcephalic epileptic and mute idiot. At all times he was subject to certain automatic tricks with his hands, putting them and twisting them into various positions. Periodically, almost every day, he gave exhibitions of the habit which had led him to be called The Dervish. He commenced by tattooing his chin with his left hand; next he deliberately and delicately touched the fingers of his left hand to the wrist of his right, made two or three salaams, and then impulsively gyrated the body from left to right.

Sometimes peculiar movements are associated with ordinary epilepsy in children not imbecile or idiotic. At least some of the cases particularly described in this article may have some alliance with eclampsia nutans of the salaam convulsion form, to which affection the terms nodding spasm, spasmus nutans, and eclampsia rotans have also been applied.

HEAD-NODDING, AND HEAD-JERKING.—The cases particularly described by Hadden in his series of papers on "Head-nodding and Head-jerking in Children, commonly associated with Nystagmus," are, in his own words, "characterized by nodding or lateral movements of the head, either singly or associated with one another or with movements of rotation. Further, these movements of the head may be almost constant, or may occur more especially during efforts at fixation or during excitement, always ceasing during sleep or when lying down. In most cases there is nystagmus of one or both eyes, vertical, horizontal, or rotary, often occurring simultaneously with the onset of the head movements, but sometimes preceding or following them. The nystagmus is much more rapid than the head movements, and has an independent rhythm; it is aggravated by attempts at fixation or by forcibly restraining the head, and may even be induced, when previously absent, by these means."

Hadden's first observations were based on an analysis of twelve cases. His second series included nine cases of which he had kept notes, although in all he had seen fourteen since the publication of his first series. His deductions from an analysis of twenty-one cases can be summarized as follows: Pure nodding, like the movements of a mandarin doll, is rare; in others the movements were lateral, although combined or alternated nodding or rotation was common. He sees no reason for subdividing the cases into nodding and shaking as separate classes, as one of these movements may replace the other. The movements are chiefly seen when the child's attention is attracted to an object, and are increased each time it makes a new effort at fixation. They cease during sleep and when the child is lying down and when the eyes are covered. The associated nystagmus is rapid and of short range, and is not constantly present, the movements of the eyeball being usually horizontal or combined with some rotation. In one case the head-nodding and nystagmus were vertical, and in another the nystagmus was confined to one eye and associated with side-to-side movements of the head.

The pupils were almost always normal. Hippus or oscillation of the pupil was present in some cases. No unhealthy ophthalmoscopic appearances were found. In nearly half of the cases the children had a tendency to cock the head on one side or to hold it in some other unusual position when looking at an object. In a large percentage of cases they had attacks as if consciousness was in abeyance—seizures much resembling in character the descriptions given of *petit mal* or epileptic vertigo. Convulsions were present in a few cases, and attacks of convulsive laughter were observed in one child. Rickets was present in nine out of the twenty-one patients.

HEAD-BANGING.—An affection has been described by Gee (*St. Bartho-*

lowew's Hospital Reports, 1886), as head-banging, in which children have a habit of turning on their faces at night and banging their heads into the pillow. According to Gee, the affection is perhaps a habit. As few of these cases have been recorded, I give Gee's brief account of three cases:

"I.—Gilbert G—, two and a half years old when seen with Dr. Donald Hood, had been affected thus for two or three months past. At night in bed, both when awake (half awake?) and when sound asleep, he would turn over on his face and bang his forehead into the pillow. In this way he sometimes behaved nearly all night long; in which case, it need hardly be said, he awoke very weary. He never had convulsions of any kind; indeed, no disorder, past or present, other than head-banging. A year and a half afterward this disorder continued when he was not tied down in bed. He had never suffered from nightmare or sleep-walking. (Four months after the last notes the patient's mother told me that he continued to bang his head at night when not tied down. Even when tied down he rolls his head from side to side, being asleep. Put asleep with a younger brother, the latter began to bang his head also; separated, he, the younger child, lost the habit. The first boy continued healthy and cheerful.)

"II.—George H—, five years old, a patient of Mr. Patten's, was backward in understanding and speaking, but there were no signs of cretinism. He was a first child, born at full time after a long labor in which no instruments were used. He had knock-knees and splay-feet, but his dentition was very regular. He was restless, but clean in his habits, and never wet the bed. There were no other signs of disease. He never had convulsions of any kind. Head-banging began when he was two and a half years old (that is to say, as soon as he could hold his body up), and it had continued until the time when he was seen. He used to turn over on to his face and bang his forehead into the pillow about six times in succession. The act was seldom repeated in the same night, and seldom occurred more than one night in four. He was fast asleep at the time, but was easily roused.

"III.—Francis C—, two and a half years old, had been subject for six months to banging his head on the pillow at night for two or three hours at a time. He had an inguinal hernia; he had erections of the penis at night; he masturbated, and the foreskin was adherent; otherwise the child seemed well. A year afterward Mr. J. Lucas Worship wrote this about him: 'While he was staying in Sevenoaks, about a month ago, he was better of knocking his head about, but the nurse said that whilst at home it was as bad as ever. He was a great deal in the meadows, and slept well from being in the open air so much, which he was unable to get while living at home in the town. He was operated upon for his phimosis, which is all right now, and he does not masturbate since then.'"

At the meeting of the Pennsylvania State Medical Society in May, 1893, two interesting cases of head movements were reported, the first by Dr. J. C. Gable of York, Pa., to whom I am indebted for notes. The patient was a girl ten months old, well developed and apparently healthy at birth. The family of the child was of more than ordinary intelligence, but had a pronounced neurotic and tubercular taint. The mother suffered from chorea when a young girl. The paternal grandparents died of pulmonary tuberculosis, and an aunt suffered from an attack of tubercular arthritis of the right knee, which eventually necessitated a thigh amputation. When the doctor was first called to see the little patient he found her suffering from singular and seemingly very distressing semi-rotatory, oscillatory bowing or bobbing movements of the head. These were somewhat varied in character and degree, but continued with a monotonous, rhythmical regularity, as long as the child remained awake, during a month, and then gradually began to diminish, and ceased entirely in about eight weeks. There was no nystagmus, nor any other special symptom except a somewhat demented expression of face, which caused the anxious parents to fear that the child was suffering from unsoundness of mind, until assured that its complaint was a special and a rare form of chorea, which yielded to zinc treatment and proper hygienic measures.

The second case was reported by Dr. J. C. McAllister of Driftwood, Pa., who also has kindly furnished me with brief notes. The child was born in April,

1892, with forceps delivery, the labor being the first and quite difficult; but the baby was, however, a strong and well-nourished boy, and no history of nervous trouble in the family could be obtained. In February, 1893, when the child was about ten months old, the doctor was consulted for the relief of choreic movements of the hands and arms, and also for certain nodding and rotatory movements of the head. Aside from this, constipation was the only symptom. Bromide of potassium and Fowler's solution were prescribed for the movements, and the constipation was also treated. After a few weeks the bromide was stopped, but the arsenical solution was increased to two drops four times a day. The infant had a long prepuce, and the doctor performed circumcision, April 26, 1893. The movements of the hands ceased under the use of the arsenic before the operation, but the other movements continued until after the circumcision, when they gradually disappeared.

NYSTAGMUS.—Nystagmus may be described as a constant involuntary movement of the eyeballs, which is usually horizontal, but sometimes vertical, and even in rare cases may be in a slightly oblique direction; and rarely also the vertical and horizontal oscillations may alternate regularly or irregularly, or a vertical movement may be present in one eye and a horizontal in another. The commonest form of nystagmus is that in which the movement is bilateral, horizontal, and consentaneous. Nystagmus is present in several organic affections of the nervous system, as in disseminated sclerosis, and to a less degree in other forms of sclerosis, diseases of the cerebellum, and hereditary ataxia. It is sometimes due to local affections of the eyes which interfere with sight, as opacities of the cornea or of the lens or humors of the eye. It is very common in albinism, and is, as is well known, of frequent occurrence among miners. As an affection of children it is chiefly of interest as it occurs either in rare cases of cerebellar or other form of brain tumor, or as it occurs associated with head-jerking and head-nodding, described in this article. Nystagmus seems to be an essential element in a majority of these cases, and Hadden describes and discusses these movements as follows:

“This is very rapid, about four to six movements per second, and of very short range. One mother said it was ‘like Perry’s pens at the underground stations,’ and this homely description is not inapt. Nystagmus is not usually constant; not infrequently it has to be induced by making the child fix objects here and there, by forcibly restraining the movements of the head, or by placing the child on its back. On two occasions it was especially well marked when the child was put to the breast. I verified this by personal observation.

“The movements of the eyeballs are usually horizontal, combined with some rotation. As a rule, the movements of the head and eyes are in the same direction, but this is by no means invariable. In my solitary case of head-nodding the nystagmus was vertical, whereas in another patient there was vertical nystagmus limited to one eye, associated with side-to-side movements of the head.

“There is occasionally a relation between nystagmus and the position of the eyes or evident ocular state. In one case the nystagmus was exaggerated on extreme conjugate deviation to the right. In two instances the nystagmus was chiefly evident when the eyes were directed upward, and in one of these it was generally horizontal, and tended to become vertical when the eyes were turned upward. The nystagmus may vary in direction apart from this; in two instances the nystagmus was sometimes vertical, sometimes horizontal, and sometimes rotatory.”

Nystagmus may be the only form of movement present in cases exactly similar in nature to those in which the head movements are also present; as Hadden put it, the disorder may be indicated by nystagmus alone just as there may be tabes dorsalis without ataxia or paralysis agitans without shaking. He gives one instance in which nystagmus alone was present for a year, but after this the patient showed occasional slight movements of the head.

Etiology.—In some of the reported cases a decided predisposition to neurotic disorder was present. In six out of the twenty-one cases a history of convulsions in other children of the same family was obtained. Rickets was present in the family in three instances, and decided evidences of rickets were shown in nine out of the twenty-one of Hadden's patients. The affection often appears to be due to reflex irritation from the alimentary canal or from dentition. Henoeh attached great importance to dentition as a cause, but on it Hadden does not lay so much stress. Head-jerking occurs sometimes at an age before the process of teething has begun, and a history of injury to the head, usually by falls, has been present in a large number of cases. The affection is more common in females than in males. In the majority of cases it begins between the ages of six and twelve months. Usually the head movements and nystagmus occur simultaneously at the onset.

Pathology.—The pathology of the cases of imperative movements described is that of the idiocy or imbecility with which they are associated. With reference to the nature of head-nodding cases, Hughlings Jackson has suggested that they are a variety of spinal chorea, a symptomatic condition allied to canine chorea; but Hadden believes that the seizures point to instability of motor-centres above the nuclei in the spinal cord and fourth ventricle, and he would therefore attribute the disorder to a functional or other disturbance of the cerebral cortex. The child has acquired certain voluntary or purposive movements of the head and eyeballs, but these have not as yet become thoroughly organized and fixed in the psycho-motor areas of the brain; hence a dissolution takes place because of the inability of the strained cortical centres to stand the work to which they have been too early subjected. He compares these head movements to the tremors in the head which often occur in aged people and those seen sometimes in adults.

Diagnosis.—The chief point in the diagnosis of these cases is to distinguish between the different varieties of head movements, particularly as to their occurrence in children otherwise healthy or diseased. Imperative or automatic movements suggest the presence of idiocy or imbecility, and should lead to a study for these affections. Knowing that epilepsy is an accompaniment of some forms of repeated head movements, the existence of this disease should be determined or dismissed. Bearing in mind a few important facts of this character, the explicit and careful descriptions afforded by Hadden and Gee will serve to identify these curious cases.

Prognosis.—As a rule, these little patients recover, the disorder lasting for varying periods. Sometimes the movements will pass away in a few weeks, and at others several months or even one to two years may elapse before recovery takes place. Nystagmus is said to persist longer than the head movements, and shows a greater tendency to recurrence. One case was observed by Hadden for two years and a half, nystagmus not being present. In making a prognosis a distinction must be made between the acute and curable cases, such as have been reported by Hadden, Gee, and others mentioned in this chapter, and the patients suffering from idiocy, imbecility, epilepsy, or other serious

forms of mental or nervous disorder, who are the victims of imperative and automatic movements described in the beginning of the chapter.

Treatment.—Any sources of reflex irritation should be carefully attended to, but in this, as in many other cases, reflex irritation has been made a scapegoat for ignorance or imperfect knowledge. The general health of the child should be carefully looked after, although in some of the reported cases this seems to have been very good. The somewhat frequent occurrence of rachitis should give this constitutional condition an importance in connection with therapeutics. Fatty and albuminous foods in easily-digested form should be given; cod-liver oil in some of its various combinations, as with lime or malt; maltine with pepsin and pancreatin; iron, particularly in the form of the powder or the carbonate; glycerin, cream, peptonized milk, and such nutrients as are commonly chosen in rachitic cases, may prove of service in some instances, as are also such medicinal remedies as Lugol's solution of iodine; Donovan's solution of arsenic, mercury, and iodine; Fowler's solution of arsenic, the syrup of the hypophosphites, and similar strengtheners and builders. Iodide of iron, tartrate or malate of iron, and phosphate of sodium may prove useful. Among the remedies which are supposed to have some influence upon the disorder bromides hold the first place, but they should be given with care, and not in the same doses as in undoubted epilepsy. Five to seven grains of bromide of potassium or sodium, with two or three minims of tincture of belladonna, or one minim of the fluid extract of conium, may be used with advantage, and at times this dose may be increased until a decided impression is made. Sulphonal or chloralamid in small doses is worthy of trial. The children are usually not old enough to have their eyes refracted. In view of the theory that the condition is allied to canine chorea, and in the light of the suggestion of H. C. Wood (*Jour. American Med. Assoc.*, February 25, 1893), that in chorea, and particularly canine chorea, the inhibitory apparatus which controls motor power in the spinal cells is weakened to a greater extent than is the discharge power, and also that quinine has a great controlling power over choreic movements in the dog, the importance of at least trying quinine in increasing doses in the treatment of these movements is suggested.

HEADACHE.

BY CHARLES K. MILLS, M. D.,

PHILADELPHIA.

THE term "headache," which defines itself, is used to describe pain due to causes either outside or inside of the cranial cavity. Its general synonyms are cephalalgia and cephalæa, and for one of its most common varieties the synonyms are migraine, megrim, hemicrania, or sick headache. Headaches in children are less frequent in occurrence, fewer in varieties, and less severe in type than in adults. Headache is most frequently a symptom of some recognizable functional or organic disease, and its occurrence in many affections, such as infectious fevers, will not, of course, here receive consideration. The wisdom of discussing headache separately has been questioned, and with good reason; but it may be the ruling feature of a case which is presented to the doctor for diagnosis and treatment, and if it is banished from the picture little is left except to the most critical research, although even in such a case careful study will generally show that it is simply a symptom of some rheumatic, dyspeptic, hysterical, inflammatory, or other morbid state.

The mechanism of pain in the head is worthy of brief attention. It is a well-known fact, although one often overlooked, that the brain substance is practically insensitive, and pain in the head, even when the result or the accompaniment of disease of the brain, is not due directly to lesion of its tissue. The brain of man and of the lower animals can be excised without giving rise to any sensory response, although the gentlest electrical application to a motor centre may excite the liveliest movement. Nerve end-organs, which are an essential portion of the apparatus of sensibility, are wanting in the brain itself. Disorders of sensibility due to disease of the brain tissue are referred to more or less distant parts of the body. The membranes of the brain play an important rôle in intracranial pain, as has been shown by Duret (*Brain*, April, 1878), Ferrier (*Brain*, January, 1879), and others. The dura is highly endowed with nerves of sensation derived from the trigeminus, and in rheumatic or neuritic headaches and in those due to organic disease the pain is frequently dependent upon direct involvement of these nerves. The pia or pia-arachnoid membrane is not so largely supplied with sensory nerves as the dura. The pia is largely an immense network of vessels, whose supply is from the gangliated nervous system, and is concerned in head pain through variations in pressure and tension within the cranial cavity, as well as to a less degree by direct nerve irritation. Inflamed arteries and veins cause pain, probably through their direct or indirect influence upon nerves of sensation. Blood charged with toxic matter also causes pain both by direct and indirect irritation of nerves. In explaining headaches it is necessary, then, to consider neural or membranous inflammation, alterations in pressure or tension, and toxic states of the blood.

The varieties of headache which best deserve to be ranked as special types are (1) migraine, and (2) the headaches of organic intracranial disease. Other so-called varieties are usually based upon etiological considerations, and will be considered under that heading. It is indeed of questionable propriety to class migraine as a headache, and this is only done because it seems to be the most practical method for physicians likely to use a general treatise on diseases of children. The disease is migraine, and headache is only one of a series of important phenomena—visual, gastric, motor, and mental; but it is the symptom which causes the patient the greatest suffering and for which he appeals for help.

MIGRAINE.

Migraine, megrim, hemicrania, or sick headache is by no means uncommon in children. Sometimes very young children have mild attacks of sick headache; these at first come very seldom, and apparently only under special exciting causes, as over-eating, excitement, or exhaustion; and at first the intervals between the paroxysms may be many weeks or months, but gradually they become shorter. At first, also, the attacks can be scarcely recognized as genuine sick headaches, pain not being prominent, but as years progress they become more prolonged and severe; still, under the age of puberty, however clear may be the type, migraine does not usually assume the severity and intensity which it shows after this period. I have seen a few instances of migraine in children under six years of age. A boy, now ten years of age, began to have mild attacks of migraine at the age of three, at first having only two or three attacks a year, but these gradually became more and more frequent, until now he averages a spell about once a month. A history of migraine is present in four generations—in the mother, and in the maternal grandfather and great-grandfather. Three other children in the same family are not affected in the same way. The child in other respects is unusually robust and free from disease.

Symptoms.—Except that the symptoms are less pronounced and severe and have fewer concomitants, the phenomena of migraine in children are practically the same as in adults. It perhaps shows less tendency to recur at regular periods. The child may suddenly or unexpectedly exhibit an indisposition to play, may look pale and troubled, may complain of nausea or of being chilly, or may speak of disturbances of sight; then the pain comes on, and at first is often confined to one temple or at least to one side of the head. Soon it becomes more and more severe, and the little patient, without urging, is glad to go to bed in a quiet room. The pain may last for hours or the better part of a day, or in some instances in young children it is relieved in an hour or two, usually by vomiting, followed by sleep. The migraine of childhood is not so likely to occur early in the morning as in adult life. The visual prodromes are comparatively common in children, although they may be absent. They may take the form of photopsia, as balls or rims of fire or zig-zag colored lines, or hemianopsia, or general obscurity of sight. The more complicated and profound cerebral phenomena sometimes seen in adults, such as amnesic aphasia, hemiparesis, monoanæsthesia, and hallucinations of sight or great mental perturbation, may be present, but are not as common in children as in adults. Putnam (cited by Sinkler, *St. Louis Med. Review*, October 29, 1887), has recorded a case of a patient in whom, in boyhood, migraine was represented by repeated attacks of numbness and tingling in the right side of the face and right half of the body, with aphasia and hemianopsia, followed by a trifling headache or none at all; but later in life he had attacks of pain. The pain of migraine is usually one-sided, and may be confined to the supra-orbital or

temporal region. The attacks are usually much the same, except that they grow in severity as the years advance. Nausea and vomiting are of frequent occurrence, but not invariable.

Etiology.—Hereditv is the most important predisposing cause of migraine, as of some other forms of headache. Of exciting causes, excessive fatigue, mental or nervous exhaustion, and indigestion are the most important. Disorders of digestion are often placed in the front rank of exciting causes, but it may be forgotten that the nausea and vomiting are frequently of central origin. Rheumatic weather seems to have an influence in precipitating attacks of migraine.

Pathology.—The pathology of migraine is practically unknown, as no theory which has been advanced has well withstood the attacks made upon it. It does not explain its true pathology to show that attacks may be induced or excited by eye-strain, or disordered digestion, or intestinal putrefaction. These attacks are certainly sensory explosions, analogous in their methods of exhibition to the spasms which result from discharges of the cortical motor centres. Migraine, as has been claimed, has many of the appearances of sensory epilepsy. Cortical discharges of the visual cerebral centres would best explain the curious and frequent visual prodromes. Whatever may be its pathology, it is, as a rule, a cerebral affection. Anstie regarded migraine as a variety of neuralgia of the first or ophthalmic division of the trigeminus; and in favor of this theory is the occurrence of certain local trophic affections, such as herpes zoster, ulceration of the cornea, and changes in the color of the hair; but cases of neuralgia or neuritis of branches of the fifth nerve, not instances of true migraine, are sometimes confounded with the latter. In the so-called tic-douloureux and in other less severe forms of painful disease of the branches of the trigeminus, trophic disorders are frequent. True migraine and trigeminal neuralgia or neuritis may be present in the same case; indeed, the affections sometimes blend in the same person. Migrainous subjects are vulnerable to the same influences as are neuralgics and neuritics; but these and similar facts do not prove that the disorders are identical. Much stress has been laid upon the exact state of the vessels of the brain during attacks of migraine. According to one view, in one form of hemicrania the blood-vessels of one side of the brain or of a limited area of the brain are in a spastic state, while in another variety a parietic state of the vessels exists. To explain the pain Du Bois-Reymond held that the spasm of the vessels caused pinching of the nerves in their sheaths.

Diagnosis.—A clear understanding of the usual prodromata and of the method of progression of the symptoms is the best key to the diagnosis of migraine. It is perhaps most likely to be confounded with headache of organic origin, particularly with tumor and meningitis. The ophthalmoscope and various localizing symptoms which will be spoken of hereafter will greatly aid. Hysterical or imitative headaches in children may occasionally closely simulate migraine, particularly in children whose parents are victims of the disease.

Prognosis.—The prognosis of migraine as to cure is bad. Usually the attacks become more frequent as the child grows older.

Treatment.—For attacks of migraine in children energetic active treatment does not seem as necessary as in adults. As soon as the prodromes appear the child should be placed in a quiet, darkened room, away from sources of irritation and depression. Phenacetin, antipyrin, antifebrin, and caffeine are among the most useful remedies for the abridgement or the mitigation of the attacks. Four or five grains of antipyrin or antifebrin, with two or three minims of tincture of digitalis or tincture of strophanthus to protect the heart,

may be given every hour or two until three or four doses are taken. Caffeine, or the citrate of caffeine, in doses of one to two grains every half hour, will sometimes abort an attack if given early. Once an attack has fully developed, it is, as a rule, best to let the patient alone or only to use external applications, as of hot water to the head or feet or menthol or chloral-camphor or mild galvanization to the forehead and head. An emetic of ipecacuanha is sometimes efficient, and the administration of a large dose of this drug may afford relief even when it does not produce emesis.

The treatment of migraine during the intervals of the attacks is of considerable importance. Everything should be done to keep the child in the very best general condition. Cannabis Indica has been much praised for adults, giving it in increasing doses, beginning with one-tenth or one-twelfth of a grain three times daily, and continuing the treatment systematically for months; but its use for children, like that of other narcotics, is not to be encouraged. Arsenic, quinine, iron, hydriodic acid, and the hypophosphites are of benefit, particularly in debilitated cases; but it is not my experience, as it seems to have been of others, that migraine in childhood is likely to occur in subjects who are weak, anæmic, and sedentary. The most robust and hearty child of a family may be the sole victim of the disorder, although this is not invariably true. Great attention has been paid in recent years to the relief of eye-strain in the treatment of this affection; and, while the favorable results of ocular treatment have been overstated, measures directed to the eyes should not be neglected. Hypermetropia, myopia, and astigmatism should be corrected if sufficient in degree to clearly cause discomfort or annoyance. The eyes should be examined under atropine, and the correction should be as complete as possible. Tenotomy or partial tenotomy may need to be performed, but too much in a curative way should not be expected from these measures. In particular, children who are going to school and paying close attention to their studies should have their eyes investigated. Imperfectly ventilated and badly-lighted school-rooms and house-rooms probably count for much as exciting causes of migraine.

Some children suffer from forms of headache which have many of the characteristics of migraine, but cannot be said positively to belong to this type. These children, most commonly young girls at school, have attacks of head-pain, accompanied with nausea or with both nausea and vomiting, which compel them to rest and cause them to be irritable and worrisome. These headaches are often associated with constipation. They are sometimes entirely relieved by a change from a sedentary to an open-air life. They recur so frequently that the term "recurrent headache" has been used in describing them, although this expression has been applied also to other forms of headache. They differ from typical migraine in the absence of prodromes and in their lesser severity. They might perhaps be termed migranoid cases. Like typical migraine, such headaches are often observed in children of neurotic heredity.

HEADACHES DUE TO ORGANIC DISEASE.

Intracranial tumor, meningitis, abscess, and, in very rare instances, aneurism, may be the cause of headache in children. Headache is rarely absent in brain tumor, and sometimes causes extreme suffering, but occasionally a growth may be present without this symptom. The tumors which are most likely not to give rise to pain are the gliomata, probably because these neoplasms are not usually connected with the brain membranes, and also because owing to their soft

structure, they exert comparatively little pressure. Much of the horrible pain commonly present in intracranial tumor is dependent upon irritation of branches of the fifth nerve in the dura, and this does not always occur in gliomata, because, as has been stated, they may be unconnected with this membrane. In several instances I have observed cases of gliomata of the cerebellum in which pain was unimportant; but it remains true that in children, as in adults, headache is a very common symptom of an intracranial growth. In infants and very young children, the sutures still remaining open, the pressure within the cranium is not increased to the same extent as in adults by a developing tumor. The location of pain in the head is sometimes, although rarely, a guide to the position of the growth, but at the best it is an uncertain guide. A constant occipital pain may indicate a neoplasm in the posterior fossa, but often this will be deceptive. Patients with cerebellar tumor may complain of severe frontal pain. In tumors pain in the head is usually increased by percussion, and in some instances this pain will be greatest over the seat of the disease.

Tubercular growths or conglomerations are common in tuberculosis in children, and in these cases more or less tubercular meningitis is present, so that the diagnosis of the cause of the headache, as between an isolated growth and a meningitis, becomes difficult. The headache of tubercular meningitis is often of great intensity, and this disease may be accompanied, like other affections of the cerebral membranes, and particularly of the dura, with vertigo, nausea, vomiting, and screaming or crying; but, while this is true, headache is not an invariable accompaniment of cerebral meningitis, and particularly of lepto-meningitis of slow development.

Occasionally the source of a severe headache is a cerebral or cerebellar abscess, which is usually of rapid development, as long-latent abscesses are not likely to occur in children. Such abscesses are commonly found in association with disease of the middle or internal ear, and the pain will be more or less referred to the location or neighborhood of this organ.

The diagnosis of tumor, meningitis, or abscess as the cause of a headache will be made by a careful study of the accompanying conditions. The most common of these will be, first, such general symptoms as optic neuritis, nausea, vomiting, vertigo, monospasm, or convulsions, mental irritability, or depression, apoplectiform attacks, and paralysis of cranial nerves or of the face or limbs, hyperæsthesia, anæsthesia; and, according to the seat of the growth, special phenomena, such as hemianopsia, or cerebellar titubation. As tumors of the cerebellum are somewhat common in children, the particular symptomatology of growths in this location should always be borne in mind. These symptoms, in addition to the headache, vertigo, vomiting, hyperæsthesia, optic neuritis, etc., just described, are, or may be, unsteadiness in station or gait; nystagmus; sometimes internal squint; frequent blindness; sometimes deafness; enlargement of the head from acquired hydrocephalus; rigidity of the muscles of the neck with retraction of the head; loss of knee-jerk, or occasionally striking peculiarities of the knee-jerk. Sometimes pain is marked in the neck and back. These symptoms point particularly to tumor of the middle lobe of the cerebellum.

Among organic headaches may be classed those which are due to inherited syphilitic affections, but which are not necessarily either growths or meningitis. The headache which accompanies the epileptic paroxysm also must not be overlooked in considering this class. As is well known, it may either precede or follow the epileptic fit, or it may be present with slight attacks of petit mal which are scarcely observed. Catarrhal headache of inflammatory origin,

according to Allen (*Med. News*, March 13, 1886), is seen occasionally in acute congestion or inflammation of the frontal sinuses. The pain, which is severe, is usually confined to one side, but it is rare in children.

ETIOLOGICAL VARIETIES OF HEADACHE.

The predisposing causes of headache in children are few, the exciting causes are many, and numerous classes or varieties of headaches have been erected, based chiefly upon etiological considerations. These etiological varieties may be indefinitely extended, and it is chiefly for this reason that authors differ so much in their classifications of headache. Even the headaches of children have been subdivided into numerous classes, as into the so-called school-headaches; the headaches of the period of growth; anæmic, hyperæmic, and neurasthenic headaches; headache of the eye-strain and of genital irritation; and so on through a long list, according to the inclination or views of the classifier. The causes of organic headaches have necessarily been given in the course of their general discussion. The great predisposing cause of migraine, as has been stated, is heredity; the exciting causes are those also of headache of any type, as excessive fatigue, mental or nervous exhaustion, disorders of digestion, changes in the weather, badly heated and ventilated rooms, lack of exercise, impoverished or altered blood (anæmia, hyperæmia, or toxæmia), overwork, excitement, undue exposure to heat or to cold, eye-strain, gastro-intestinal disorders, genital irritation, nasal or pharyngeal catarrhs, or aching teeth. A close consideration of the causes or alleged causes of headache in children will show that in addition to migraine and organic headaches we might conveniently erect the following etiological varieties: 1, anæmic headache; 2, reflex headache; 3, hysterical headache; 4, neuritic headache.

ANÆMIC HEADACHE.—Anæmic headaches sometimes occur in children, although with not nearly the same frequency as in adults, and especially in women. A few children seem to inherit an anæmic diathesis, just as others are congenitally rachitic. These children are pale in skin and mucous membranes, sometimes to the extent of being chlorotic; they lack in strength and in nerve energy; they are neurasthenic as well as anæmic. It is rare, in children, to see a neurasthenic or exhaustion headache not associated with impoverished state of the blood; and therefore the distinction between a neurasthenic and an anæmic headache can be more sharply made in the adult. The diagnosis of an anæmic headache is to be made by a careful investigation for the evidences of anæmia, even to the extent, if necessary, of a blood-count. It is well to remember that every pale-faced child is not anæmic, and also that some children who are well supplied with fat may have poor blood.

REFLEX HEADACHES.—While too much stress is laid upon reflex action as the source of innumerable maladies, it plays an important part in many cases of headache, as in the production of other symptoms. When a child complains of headache after study or use of the eyes at close work, as in drawing, writing, or sewing, the eyes should be investigated. Serious defects of refraction may be present, particularly hypermetropia with astigmatism, and these, if sufficient to cause strain, should be at once corrected. Children who indulge in over-eating or careless eating sometimes suffer in consequence from headaches, which are relieved by spontaneous vomiting or by the use of emetics or cathartics; but it must be remembered that true migraine in children is associated with nausea and vomiting, and that the gastro-intestinal disorder in these cases is a concomitant rather than a cause of the headache. Perhaps too much stress has been laid on sexual irritation as a cause of headaches in children, but that it may be occasionally causative cannot be doubted. Allen

(*loc. cit.*) has presented some points of practical importance in connection with reflex headache, in association with chronic nasal catarrh, which have a bearing on the headaches of childhood. These reflex headaches are said by him to be almost entirely restricted to the temple and the vertex. Sometimes nausea is present, and sometimes if a probe, passed into the nose, is made to touch the middle turbinated bone, vertex pain will instantly follow. The inner wall of the orbit is often peculiarly sensitive, and the nasal mucous membrane is in a state of intense inflammation. The reflex headaches of chronic nasal catarrh are sharply separated from the headaches of cerebral disease by the absence of any symptom referable to cranial sources, the lack of evidence, as furnished by a history of the case, that the complaint is of central origin, and the complete control of the pain by local treatment. Allen distinguishes reflex catarrhal headache from sick headache of gastric origin by the absence of furred tongue, and from the temple pains of eye-strain by its persistence after the correction of errors of refraction. Such headaches may be the cause of nervous prostration. Reflex headache may also have its origin in the pharynx or even in decayed teeth.

HYSTERICAL HEADACHE.—A frequent form of headache, even in children of tender years, is the hysterical headache, or what might perhaps be better termed, in most instances, the imitative headache. Most children, and particularly those of the precocious and affectionate type, are fond of sympathy and coddling. They are very close observers of the sufferings and peculiarities of others. They have slight pains and aches, and these become headaches apparently of very great severity. Often a child who complains of vertical headache, or of headache associated with inability to stand the light, or of great pain over the eyes or in the back of the head or neck, will be found on close inquiry to have a father or mother, and especially a mother, who is subject to similar aches and pains. Just as hysterical and hystero-epileptic convulsions, aphonia, paresis of one or more limbs, and even hysterical blindness, may be simulated or mimicked by the child of a neurotic parent, so headache and other pains and aches in children are even more frequently to be traced to the same source.

NEURITIC HEADACHE.—Some children, usually of neurotic, rheumatic, or arthritic heredity, suffer from pains in the head and face which are accompanied by tenderness and pressure over exposed nerve ends and trunks, and also are commonly increased by pain on movement of the scalp. These mild but annoying head pains are due to forms of subacute or chronic neuritis, which may or may not be associated with slight inflammation of other tissues. Head pains and headaches of this kind are much influenced by the weather. Even when external tenderness is not present, pains in the head may be due to inflammation of the branches of the fifth nerve in the dura, or in the grooves or foramina of the skull, or in the scalp. These cases usually yield rapidly to antirheumatic or antineuritic treatment. Since the occurrence of the recent prolonged epidemic of influenza many cases of chronic headache or of chronic head and face pains have been observed, chiefly in adults, but now and then in children. Most of these have been due to a lingering neuritis or to the want of tone in nerve centres, left wounded or vulnerable by the ravages of this disease.

Diagnosis and Prognosis.—The diagnosis of headache in general relates chiefly to the differential diagnosis of its varieties already considered. When pain in the head is present, the general diagnosis of headache is made, the only point of importance being to distinguish as to whether it is due to intracranial or extracranial causes. The points already given under the general varieties of headache will serve in the main for their differentiation. I would simply lay

stress upon the necessity of separating those forms due to pronounced organic disease from migraine and from functional types, such as the hysterical, the neurasthenic, and the rheumatic. Proper but not undue attention should be given to the question of reflexes. The prognosis of headaches has already been sufficiently considered in speaking of its different varieties.

Treatment.—The treatment of the headaches of children will depend largely upon the special variety. The treatment of migraine has been discussed; that of organic headache will be largely of the underlying disease. For the relief of these headaches two classes of remedies should be employed: first, those for the immediate relief of pain; and, secondly, those to improve the state on which the headache depends. For the immediate relief of pain the best remedies are phenacetin, antipyrin, antifebrin, bromides, chloral, sulphonal, chloralamid, codeine, hyoscine, ether, chloroform, and preparations of opium. These remedies should be used in doses proportioned to the age of the child, although it should be remembered that children suffering from violent pain, wherever located, will stand larger doses of hypnotics and narcotics than those in health or those who are suffering from non-painful diseases. In brain tumor and meningitis phenacetin and antipyrin in combination will sometimes afford great relief.

For the constitutional or the acquired organic conditions on which some headaches depend, mercury, the iodides, hydriodic acid, arsenic, and similar constitutional measures will be found most beneficial. In most cases mercury is best used in the form of minute doses of the bichloride.

As not a few children who suffer from chronic headache are both anæmic and neurasthenic, it is of great importance first, to pay attention to these conditions, and the best treatment for adults will not always answer in these cases. Preparations of iron and arsenic should be given, but care should be taken in their selection. Among the most useful iron preparations are the malate, the citrates of iron and quinine, the ammonio-citrate of iron, the lactate of iron, powdered iron, and dialyzed iron. Palatable preparations can be readily chosen with a little care. Arsenic alone or in some combination will often be found extremely useful. I prefer small doses of Fowler's solution alone or in combination with the compound syrup of the hypophosphites. In these anæmic children most careful attention should be paid to the quality of the food and to the manner of giving it. Much headache in American children and in adults is associated with the dyspeptic troubles which are so common in this country, and which are not infrequently due to the use of the frying-pan and to other evil methods of preparing food. Children with their fresh and vigorous digestive organs do not suffer so much in this way as adults, and particularly those who have reached middle age or who have passed into the decline of life; still, the matter is one of practical importance and should not be overlooked. The diet of children inclined to be dyspeptic and to suffer from headache should be plain, wholesome, nutritious, and easily digested. It is not well to train children to depend upon digestives, such as pepsin and pancreatin, although occasionally their use may be necessary. The stomachs of children are greatly helped sometimes by the administration in small doses, before meals, of bitter tonics, such as chamomile, quassia, columba, gentian, or cascarrilla, which are best given in the form of infusion or small doses of the fluid extract.

The exciting cause of a reflex headache should always be attacked. Eyes, ears, teeth, nose, pharynx, stomach, liver, or genital organs should receive therapeutic attention if necessary. The removal of adenoids has resulted in great benefit to children suffering from headache and inability to study or fix their attention. Some striking instances are also on record of headaches due

to decayed teeth, writers even going so far as to declare that these and visual defects are the most common causes of headache.

For hysterical or imitative headaches moral treatment and the improvement of the general condition of the patient by tonics, nutrients, good food, gymnastics, bathing, and out-door exercise will prove most beneficial.

Neuritic or rheumatic headaches should be treated with the salicylates, which are often usefully combined with small doses of bromides and iodides.

Of local applications for the relief of headache in children, the most important are the use of menthol, chloral and camphor, ointments of aconitia, hot, cold, or ethereal applications, galvanism, and head massage. Sinapisms to the back of the neck and hot or stimulating foot-baths are good old-fashioned remedies which may prove of great service.

HYSTERIA.

BY JAMES HENDRIE LLOYD, A. M., M. D.,

PHILADELPHIA.

HYSTERIA IN CHILDREN has probably existed always. Peugniez tells us that in an old fresco of Dominicaïn the painter represents a saint curing a child possessed of an evil spirit. The patient is not drawn from imagination, but from life, for he is in one of the classical attitudes of the grand attack. With arms extended in the position of the cross, eyes rolled upward, and trunk convulsed in opisthotonos, he exhibits the disease in one of its most common forms. It was only because of the ancient Hippocratic definition of hysteria, which attributed the great neurosis to disorders of the womb, that for such a long period it was not recognized or acknowledged before puberty. For two thousand years this error ruled the medical world, and had for a kindred error the belief that hysteria is not observed in men. Lepois was undoubtedly the first writer to note the frequency of hysteria in children. After his time scattered references to the subject appeared, but still the old pathology prevailed even to the time (1846) of Landouzy's treatise. Briquet's statistics in his classical monograph on hysteria inaugurated the modern epoch of scientific investigation which secured the recognition of this form of the disease. It is, however, to Charcot and the contemporary school of the Salpêtrière that we owe the most light upon this subject. In the masterly demonstration of hysteria in both sexes and at all ages given by this school we recognize for the first time the unity and individuality of this disease. Hysteria is henceforth no longer a vague label, of indeterminate value, for an incongruous mass of phenomena, seen exclusively in women, which most writers have by tacit agreement united to call "protean." Far from being changeable and indeterminable these phenomena are shown to be constant and subject to a strict arrangement: far from being confined to one sex or age or country, they are shown to be distributed well-nigh universally; and far from being typical only in the adult female they are seen probably nowhere to more advantage than in children.

In addition to the writings of Charcot, we may make special mention of the thesis of Peugniez and the treatise of Gilles de la Tourette, to both of which we are indebted for invaluable information. Other notable theses are those of Clopatt d'Helsingfors and Mlle. H. Goldspiegel, quoted by Tourette. The annual contributions of Bourneville on hysteria, epilepsy, and idiocy are of great value. In the English language the most complete paper on hysteria in children is by Dr. Mills (*Keating's Cyclopædia of Diseases of Children*, vol. iv.). All these papers contain copious references and bibliographical lists, which, combined, bring the whole subject easily within the reach of the student.

It is our design in this paper to present a concise arrangement of this subject somewhat after the manner of the French school, and to illustrate it with our own clinical observations. We may premise, also, that while we hold hysteria to be a morbid entity, with a well-defined etiology, symptomatology,

and prognosis, we recognize that, as in the cases of so many other diseases, it is modified to some extent in childhood. It shall be our especial aim to emphasize this fact.

In the statistics of Briquet, hysteria in children occurred as follows in 87 cases :

In childhood (exact age not given)	31 cases,
At 5 years	3 "
From 6 to 7 years	6 "
" 7 to 8 "	11 "
" 8 to 9 "	6 "
" 9 to 10 "	9 "
" 10 to 11 "	4 "
" 11 to 12 "	17 "
	Total, 87 cases.

According to Briquet, this table constitutes one-fifth of his own observations in patients of all ages; hence 20 per cent. of his cases occurred in patients before puberty. This proportion is probably not exceeded in any other general nervous disease, unless it be in chorea. Briquet's patients seem to have been girls.

Cloplatt's statistics are the most complete up to date :

	Girls.	Boys.	Total.
In early childhood (exact age not given)	19	1	20
At 3 years	—	1	1
4 "	1	1	2
5 "	4	2	6
6 "	3	2	5
7 "	15	4	19
8 "	16	6	22
9 "	15	7	22
10 "	18	15	33
11 "	24	17	41
12 "	22	13	35
13 "	27	16	43
14 "	12	8	20
15 "	—	3	3
	176	96	272

According to this table, the disease is almost twice as frequent in girls as in boys. It increases almost steadily in frequency from the third year to the thirteenth.

Etiology.—The most common causes of hysteria in children are heredity, exhaustion and anæmia from acute disease, trauma, disturbing emotions, imitation and defective education.

The subject of heredity has two aspects according as the transmission is between similars or by transformation. By the first is meant transmission of the disease from an hysterical parent to an hysterical child; by the latter, transmission of hysteria from a parent suffering with some grave nervous disease, as epilepsy or insanity, to the child. The latter aspect, although not the more common, is far the more important of the two. This indirect heredity illustrates the kinship of many of the great neuroses, and demonstrates the necessity for a scientific investigation of remote causes. Briquet was the first to give this subject exhaustive treatment. According to his table, 351 hysterical patients had 1103 near relatives whose records were attainable; among these relatives were found 214 cases of hysteria, 13 of epilepsy, 16 of insanity, 1 of delirium tremens, 1 of paraplegia, 3 of somnambulism, 14 of convulsive diseases, and 10 of apoplexy. This is almost 25 per cent. of

cases of grave nervous disease in the immediate families of the patients. A "control" table of statistics based upon the cases of 167 non-hysterical women showed less than 3 per cent. of such nervous affections among 704 near relatives. Hence the percentage in the first class is more than eight times greater than in the latter.

Bourneville claims that alcoholism in the father is a not uncommon cause of hysteria in young children.

Children not infrequently present hysterical symptoms during the progress of, or convalescence from, acute disease. This is so especially in cases of the infectious diseases, and the complication may obscure the diagnosis in some cases not a little. The symptoms then observed are apt to be interparoxysmal. Other toxæmias also, such as those caused by lead, mercury, and alcohol, may produce hysteria, but to these causes children usually are not exposed.

Trauma, next to heredity, is most important as an exciting cause of hysteria, and the symptoms of the grand neuroses which it is especially apt to excite are among the most intractable and simulate most closely organic affections. These symptoms are paralysis, contracture, tremor, and persistent localized pain or tenderness. This cause is often conspicuous in the so-called neuroses following accidents on the railroad and by machinery; but in children very trifling accidents may cause hysterical phenomena.

Exciting or depressing emotions may provoke hysteria in children who are predisposed. Fright is one of the most common of these. Disappointment, chagrin, loss of near relatives have all acted thus. Sometimes vexations of a quite trifling character are sufficient. In former ages, more than at present, religious excitement claimed many victims for the grand neurosis. The chapters of this part of its history were often written in blood. Demonology, witchcraft, and possession were often but phases of hysteria complicated with superstition and fanaticism. The revolting epidemic of Salem witchcraft in this country was begun by some hysterical children in the kitchen of a New England parson. Imitation and suggestion were, and are, the potent factors in these epidemics. Somewhat similar but harmless epidemics, due to these causes, are still seen occasionally in schools and convents.

Finally, a defective or unwise education has much to do with the production of hysteria. The child that is constantly indulged, never corrected or controlled, taught to regard itself and its own wishes as always first, allowed to excite the emotions and imagination with fictitious literature, not disciplined to self-control, to self-denial, to duty and to the cultivation of the higher moral and intellectual faculties, is the child that is most apt to display the symptoms of hysteria. It must not be inferred, however, that hysteria is necessarily perverseness, selfishness, and simulation. This is a too common error, and one which unjustly attaches to hysteria a certain measure of opprobrium and contempt. It is true, rather, that in some of the finest minds a defective education leaves undeveloped the essential qualities of self-knowledge and self-control. This conduces to hysteria. On the other hand, as Briquet has pointed out, excessive severity and cruelty to children, as seen especially among the lower classes, may be the exciting causes of the disease.

Symptoms.—The symptoms of hysteria divide themselves naturally into two groups—(1) the Paroxysmal, and (2) the Interparoxysmal. We shall consider these in turn.

(1) Just as in epilepsy, so in hysteria, the convulsive phenomena too often attract the attention of the medical observer to the exclusion of even more significant symptoms. The hysterical paroxysm is regarded as in some sort

the essential element of the disease, the acme toward which all the other elements tend. Its bizarre character is no doubt the cause of this. As we shall see, however, the more permanent but less conspicuous symptoms of hysteria are often the more trustworthy, and sometimes the only, signs of the disease.

The hysteric fit has several grades, but as the less are included in the greater, being but modifications or abortive attacks, it is best to limit the description to the typical spell. This grand attack of hysteria has, rather unfortunately, been called hystero-epilepsy. This is a misnomer, because the fit has nothing of epilepsy about it. The term seems to signify a union of the two diseases, but such is not its true meaning, because such a union does not exist in the grand attack which we call hystero-epilepsy. It is hysteria—nothing more nor less. If a distinctive term were required, it would be better to speak of the attack as hysteria major, just as in epilepsy we distinguish the grand and the petit mal. The term hystero-epilepsy is unfortunate, moreover, because *both* diseases sometimes occur in the *same* patient. But in these cases the fits are always distinct. The French speak of these as cases of hystero-epilepsy with *separate crises*.

The hysterical paroxysm usually has prodromes. These especially are mental symptoms, and are noted and interpreted rather more easily in children than in adults. The child presents a change in disposition; this change is usually from gay and amiable to moody and choleric. The immediate exciting cause is sometimes evident, but not always. In the latter case the origin or point of departure of the fit may be in some mental state, some auto-suggestion, which we shall study later. In this mental prodrome the child shuns society, appears sad, melancholy, or irritable, and cannot be drawn readily from its self-absorption.

The paroxysm is preceded immediately by an aura. These auræ, as in epilepsy, are either sensory or motor. The most common is the sense of a ball rising in the throat, causing a feeling of suffocation. This may be quite alarming to the child, who clutches wildly at his throat in evident terror, crying that he cannot get his breath. This aura is called the *globus hystericus*. Another, equally characteristic, is the cephalic aura. This consists of loud bruits, or beating, throbbing, and hissing sounds in the ears; of acute pain, sometimes as of a nail driven into the head, hence called *clavus*; and of dimness of vision, and even vertigo. Other common auræ are the ovarian and the testicular. Ovarian tenderness not uncommonly precedes the fits. This may be spontaneous in women rather than in little girls. We have observed one case in which the patient called the physician's attention to ovarian pain, which proved to be only the precursor of an hysterical fit. Most frequently this ovarian tenderness may be elicited by pressure, and thus in confirmed cases the attack may be elicited by simply pressing firmly on the ovary. The aura, once started, seems in these cases to set going the whole associated mechanism of the fit. Similar results are claimed in boys by pressure on the testicles.

Immediately after the aura the fit proper begins. It is customary, for convenience of description, to divide this into periods. The French school observes four of these: first, the epileptoid period; second, the period of grand movements; third, the period of passionate expression; fourth, the period of delirium. We have convinced ourselves in our own clinical observations of the general accuracy of this division, but think, with Peugniez, that the third period is most likely to be wanting in the cases of children.

The first (or epileptoid) period may closely simulate true epilepsy, with which, however, it has no identity in any respect. It begins with a tonic stage, in which the patient usually lies supine with the limbs extended and rigid,

but with fingers and toes flexed. Deviation of the eyes is conspicuous; usually there is lateral conjugate deviation, the eyes being rolled slowly either to the right or left; in some cases, however, as in the one to be reported later in this paper, convergent deviation occurs. The teeth are held forcibly together, the breath is heavy and slow, then rapid, the neck is swollen (more so than in epilepsy), and the face is suffused. The heart's action is already becoming rapid. Sensation is usually blunted, and even abolished in some areas. The conjunctival reflex, however, is usually preserved in this stage. Consciousness is obtunded, and even lost in some cases, but in our observation consciousness is not affected so profoundly as in epilepsy. The tonic phase gives place rapidly to the clonic. The muscles of the face, trunk, and extremities begin to tremble, and then to be agitated with a succession of shocks. During this, or even during the preceding stage, the patient may turn over on his side or even precipitate himself from the bed. This clonic stage ends usually rather abruptly with a long-drawn breath, and is succeeded by a brief period of repose, during which the patient lies with closed eyes as if asleep.

The second and third periods of grand and passionate movements have not been observed so commonly by English and American writers, possibly because they have not studied these cases so methodically as the French. We have no doubt of the importance of the second period, especially in the cases of boys and girls. It explains many bizarre co-ordinate movements in children which exist sometimes as unsuspected abortive or atypical cases of hysteria. This period of grand movements begins abruptly. The patient throws himself into many and curious attitudes. Among the most common of these is the position of extreme opisthotonos, in which he rests upon his head and feet, which are at the ends of an arc of a circle. Other movements, too numerous and complicated to describe here, occur. Some of these have received special names, as the movement of salaam. Some of these movements are quite complex and apparently purposive, and may be elaborately automatic. These are more common in confirmed cases, and are probably the product of suggestion and auto-suggestion. They may persist, we believe, as isolated phenomena sometimes, or as a kind of abortive attack. Charcot calls these phenomena "*clownism*." We shall narrate a case briefly in this paper.

The third, or period of passionate movements, is the least common in children. We do not, in fact, quite see the necessity for this subdivision, because these movements naturally grow out of those of the second period, with which, in fact, they are sometimes blended and confused. They are still more complex movements, or rather expressions of passions, and as such are not common in children, in whom passions are not yet elaborated, and such as do exist receive simple expression. In these passionate moods the patients betray fear, anger, resentment, etc.; and it is notable that if they attack they usually attack some one whom they dislike. We recall the case of a colored girl (in whose race hysteria major is not uncommon) who in this period of the grand attack struck savagely a fellow servant, with whom she had had a quarrel a short time before. These passionate movements, in fact, are always the expression of some pre-existent mental state, which persists as a mental picture—or "hallucination," as the French say.

The fourth and closing period of the convulsive attack is the period of delirium so-called. This delirium, well portrayed in children and young persons, is also the expression of a mental state, which is usually reproduced in every succeeding fit in the same patient. This mental state is one usually of fear and sadness, so that the period of delirium is characterized by tears, sobs,

cries, incoherent pleading, and appeal. These subside gradually and the attack is finished.

These grand attacks may be complicated with somnambulism and catalepsy, and they may present various atypical and abortive forms, such as choreiform movements.

Somnambulism has several traits that ally it to the hysterical status. In it we see a profound unconsciousness and abolition of will-power, leaving the patient under the influence of dreams and hallucinations, and extraordinarily susceptible to suggestions from without. A somnambulist state has been observed sometimes as a complication of the hysterical paroxysm or as a post-paroxysmal phenomenon. Profound lethargy also supervenes sometimes in the fourth period. Catalepsy is another psychosis, which, while not essentially hysterical, has yet something in its nature that affiliates it with hysteria. Cataleptoid symptoms are not uncommonly seen in various periods of the grand attack, for they are not confined to any one period. They may be elicited sometimes by suggestion. We have done this in the tonic stage of the epileptoid period by elevating the patient's arms, and thereby have suspended the fit temporarily or even suggested a new turn in it.

Among the most interesting products of hysteria are the cases of so-called "chorea major." This is another misnomer, for which the Germans especially are responsible. This chorea major has nothing choreic about it; it is entirely hysterical. To understand its true position among the hysterical symptoms we may recall what was said above—viz. that the grand attacks may present various atypical forms. As Peugniez has shown, the attacks are not always complete. One period alone may appear, having an exaggerated development and leaving the other periods in the shade. Sometimes merely an aura, as the globus, is felt, and the attack aborts. In other cases the period of delirium, with tumultuous emotions, has such a large place as to appear to constitute the whole attack. Thus we believe it is in some cases with the period of grand movements. These movements become stereotyped as it were on the child's brain at the moment of the extreme susceptibility or "suggestibility" that characterizes him at this crisis. They become further developed, in successive fits or even between fits, into most extraordinary combinations of movements and cries. These movements are sometimes apparently purposive, sometimes of the nature of an acquired dexterity or trick, or, again, they may be most elaborately automatic, the patient's will and personality seeming to have nothing to do with them. These complex movements may be propagated readily to others, and thus they may give rise to epidemics in schools and religious communities which resemble the dancing manias of the Middle Ages. The writer saw and recorded one such case in a boy, in whom there was an elaborate syndrome of spasm, rotation, and catalepsy, undoubtedly hysterical in origin, and which was cured by a slight operation on the foreskin.¹

(2) The interparoxysmal symptoms of hysteria, which form the second main group, are even more important than those of the paroxysm itself, for upon them must often depend the diagnosis of the disease from grave organic affections. Their study is too often neglected. They are the permanent markings of hysteria, and hence have been called the *stigmata*. These stigmata are sensory, motor, visceral, mental, and nutritional, and may be considered here in the order named.

The changes in sensation are varied in hysteria, but some of them are almost always present. Hyperæsthesia and hyperalgesia are common. The

¹ For a full discussion of the history of this phase of the subject see Richer's *Études Cliniques sur l'Hystero-Epilepsie*, Paris, 1881.

former is usually distributed in a characteristic way, and gives origin to the well-known hysterogenous zones. These zones are points or areas on the skin, pressure on which is usually painful and may excite the manifestation of other hysterical symptoms, especially the convulsion. This acute sensitiveness, however, does not appear to be confined entirely to the skin, but to include the subjacent organs, as for instance, the ovaries. The most common of these hysterogenous points in our observation are over the ovaries and at points along the spine. Others describe them as in the testicles, at the juncture of the ribs to the sternum, and at other points on the trunk. Pressure on a hysterogenous zone is a common means of exciting the convulsion of hysteria major, and when at its height pressure on the same region will often stop it. Hyperalgesia exists as various forms of neuralgia: some of these are the accompaniments especially of traumatic hysteria. We had such a case under observation in which pain at a circumscribed area in the dorsal spine in a girl, following a fall, simulated the early stage of spinal caries. This case occurred in the Home for Crippled Children, and the diagnosis was so uncertain for a time that the child was put in a plaster jacket. This seemed to make a beneficial mental impression, and the patient recovered rapidly. Among these traumatic cases that simulate organic disease are those in which the hyperalgesia becomes fixed in one of the joints, as the hip or knee.

Anæsthesia is one of the most important stigmata of hysteria. So common is it that it is doubtful if it is ever entirely absent in pronounced cases, and yet so little observed is it that even the patient himself is often ignorant of its presence. It may be very profound, and accompanied with coldness and vasomotor changes in the part. During the dancing manias and religious crazes of the Middle Ages and later, it was observed that a pin-stick would not bleed. This was a mark of especially evil augury to superstitious minds during some of the witchcraft plagues. It is now one of the best-recognized marks of hysteria. The distribution of the anæsthesia varies. One of the most common types is hemianæsthesia. This extends from the top of the head to the sole of the foot, and is often accompanied with anæsthesia of the special senses—sight, hearing, taste and smell—and of the mucous membranes. Another type is the distribution in geometrical figures, in which case the patient has areas of anæsthesia of various shapes and sizes scattered over the body. Still another is the monoanæsthetic type, in which an area of anæsthesia covers the arm and hand like a gauntlet or the leg and foot like a stocking. This latter distribution is often accompanied with paralysis of the member. This association with paralysis and the peculiar sharp demarcation of the anæsthesia at right angles to the long diameter of the limb serve to characterize this form very clearly. The hemianæsthesia of hysteria sometimes displays a peculiar phenomenon called transfer. Under the influence of some external agent, as electricity or a magnet, or even by suggestion or auto-suggestion, the anæsthesia passes from one side to the other. This change, however, is usually of short duration, for, as a rule, the affection soon returns to its first seat.

The affection of the special senses is often marked in hysterical hemianæsthesia. There may be hemianopsia toward the anæsthetic side, and deafness and loss of taste and smell on the same side. The most significant changes are in the eyes. First of these in importance is the concentric narrowing of the visual field. In the normal eye the visual field is not extended equally in all directions, being widest toward the temporal side, next toward the lower segment, next toward the higher segment, and least extended toward the nasal side. In the hysterical patient these relative proportions are apt to be maintained, the centre of the normal field being the centre of the abnormal

one, but the field itself is very notably contracted. In some cases, however, the relative proportions are not maintained, the contracted field being a round or oval area around the normal centre. This contracted field may be very small in some patients. Another significant change is in the perception of colors. In the normal eye the fields for colors are not the same. The widest field is for blue, then come the fields for yellow, red, green, and violet in the order named, violet having the smallest field. These fields for color are practically concentric. In the hysteric eye the violet field disappears first, being "squeezed out at the centre," as some one has expressed it. Then the other fields contract gradually and disappear in the order named, with the important exception that the red usurps the place of the blue field—*i. e.* it becomes the widest and the last to disappear. In fact, red is a very persistent color-perception in the hysteric, and is supposed by some French observers to play a part in the hallucinations and mental states of these patients. Other affections of the eye are amblyopia in various grades, and the curious phenomenon known as monocular diplopia or polyopia, in which the patient sees with one eye two or more images of the same object.

The motor symptoms of hysteria are of two orders: those that depend upon the absence of function, and those that characterize its perversion. Paralysis is of the first order, and contracture and tremor of the second. As Richer has pointed out, these disorders of motility are very apt to appear as isolated phenomena in juvenile hysteria, and sometimes at a very early age.

Hysterical paralyses present a variety of forms, but these forms are not as significant as their mode of onset, their clinical history, and their termination. The most common are hemiplegia, paraplegia, and monoplegia. Very frequently the paralyzed part is also anæsthetic—a very uncommon phenomenon in similar paralyses due to central nervous disease. In some cases there is no anæsthesia. Paraplegia is more common in children and young persons than hemiplegia. In hysterical hemiplegia the face often escapes; but if the face be invaded, it is more frequently some of the eye-muscles that are involved, in the form not of a paresis but of a blepharospasm. The paralyzed limbs may be flaccid or spastic. The onset of these paralyses usually is sudden. Their most common causes are trauma, emotion, and the hysterical fit. In the case of a young woman observed by the writer a paraplegia developed brusquely during a highly emotional love scene. In one of Bourneville's cases a paraplegia followed a grand attack of convulsions. During the paralysis the convulsions ceased, but after it disappeared they returned. The duration of these paralyses varies, but not infrequently they disappear as suddenly as they come, and sometimes as a result of mental impression. In the above case observed by the writer the faradic current cured the disease promptly. Sometimes a paralysis suddenly quits one limb or group of muscles and appears in another, as in the transfer scene in hemianæsthesia.

A peculiar form of hysterical paralysis is loss of power of co-ordination—the so-called *astasia-abasia*.

The most common contractures in hysteria in children are as follows: partial or complete contracture of a limb, intermittent torticollis, spasm of the orbicular muscle, and paraplegic contracture. The position assumed by the contracted limb varies according as the contracture occurs in the arm or leg: in the case of the arm the limb is usually flexed, while in the case of the paraplegic form the limb is extended, the foot being in the position of plantar flexion. The hysterical contracture may be very persistent, enduring for years. In childhood, as Richer observes, the contracture may appear, disappear, and

reappear with a sort of periodicity; in other cases it may pass from one seat to another. The causes of contracture are the same as those of paralysis.

Tremor is a rather rare motor disorder in hysteria, and is more common in adults than in children. It may be caused by trauma, but it occurs sometimes spontaneously. It generally presents the type described by Rendu of a rather fine tremor increased by voluntary movement.

The visceral and internal disorders of hysteria are numerous and quite important. We prefer to consider them here as a separate class, although some authorities include them under disorders of motility. Among the most common is aphonia, which as an affection of the larynx may be included here. It is caused most frequently by emotion, and is sometimes an isolated symptom. It may be complete, but more frequently the voice is not entirely lost, but only sinks to a whisper. It may appear and disappear suddenly.

Rapid respiration is seen sometimes in hysteria, and may confuse the diagnosis, because it suggests some affection of the lungs or heart. It is a rather rare symptom, and is probably more common in adults than in children. It presents the superior costal type of breathing, and the respirations may be as rapid as seventy to the minute. Dyspnoea is not present, nor any acceleration of the heart, as a rule. The only typical case of this affection seen by the writer occurred in a young woman during a long convalescence from a serious surgical operation.

Hysterical anorexia and vomiting are occasionally seen, and may constitute the most serious symptoms of the disease. They may bring the patient to the verge of the grave; in fact, in a few cases they have actually caused death. The vomiting is of a peculiar type which may serve to distinguish it. It is caused usually by a spasmodic movement of the œsophagus, by which the food is regurgitated without having entered the stomach. This has been called *œsophagismus*. In extreme cases this spasm continues at intervals without the ingestion of food, as in a case seen by the writer and reported elsewhere, in which the patient regurgitated only a frothy saliva. She kept a napkin constantly under her chin as she lay in bed, to receive the ejecta. She was emaciated to an extreme degree. In her case the symptom was caused by the shock produced by swallowing supposed poison accidentally.

Paresis of the intestine, causing immense dilatation of the tube and consequent distention of the abdomen, is seen occasionally in hysteria.

Affections of the bladder are not uncommon. Hysterical ischuria and painful tenesmus are observed, the latter, especially in women, being associated with a vaginismus. In young girls this is rare.

The consideration of the mental stigmata of hysteria has been reserved for this place, because, while these stigmata are the very first in importance, and constitute really the essentials of the disease, they can best be described after the sensory, motor, and visceral disorders which they serve to interpret. Hysteria is a psychosis. Without a study of the disease from this standpoint it is futile to attempt to understand it. But this subject is deep, complex, and, to some, repellent. Moreover, we have space here only to indicate its outlines.¹ It is necessary first to reject the idea that the hysterical child is a simulator and a liar. It has been a too common error, due to the writings of Legrand du Saull and others, to confuse the mental stigmata of hysteria with those of imbecility, degeneracy, and moral perversity. Hysteria and degeneracy are distinct, and, while the two may coexist in the same patient, just as may hysteria and epilepsy or hysteria and tabes, it is inexcusable to confound

¹ An early paper by the writer on "Hysteria—A Study in Psychology" was an attempt to state this aspect of the subject. (See *Am. Jour. of Nervous and Ment. Dis.*, Oct., 1883).

them. We must expect and search for distinct and characteristic mental stigmata in hysteria, and we believe, with Gilles de la Tourette, that such exist and may be recognized. With this author we recognize a mental impressionability, a proneness to take and act upon suggestions, as the real characteristic of hysteria. But even more than he, we would insist upon the hysterical automatism, in which there seems to be a dissociation of the higher mental faculties, as the will and intellect, from the lower emotional and impulsive states. This dissociation of mental faculties is more apparent than real: a more exact statement would be, that the hysterical child reacts to a morbid association of ideas, which permits it to develop the various physical stigmata. It is of first importance to recognize this, because by the proper use of suggestion—*i. e.*, education—much can be done to counteract the effects of this evil “dislocation” of the mental faculties. Suggestions come to the hysterical child either from without or from within; they doubtless, by the law of association of ideas, tend to form in each successive grand attack a more complicated web. Hence it is that many of the physical stigmata—paralysis, anæsthesia, etc.—either originate in or are aggravated by a seizure. Suggestions from

FIG. 1.

Case of Hysteria—(Harriet B.—). First stage under Hypnotism.

without, as by trauma, moral shock, etc., act often between or independent of the paroxysms. Sometimes in children the paroxysm aborts, and there may be a true “psychical equivalent” (as in epilepsy), in which some of the most astounding of the hysterical combinations may appear. In children, too, the attack may pass off in some of the psychical prodromes, but these prodromes

may be followed by the dreamlike or delirious states of the fourth period. To these dreamlike states and states of reverie, as well as to their congeners, the nightmares and night-terrors not uncommon in hysterical children, Tourette justly attaches great importance. They influence remarkably the mental state between the attacks, as well as the physical stigmata. The auto-suggestion in traumatic cases is often reinforced by these dreams and nightmares.

Changes in nutrition are not marked or characteristic in hysteria. It is commonly said that anæmia is observed, but this is not in any sense characteristic, but only a result of the anorexia which is sometimes present. In other words, it is only an anæmia from malnutrition. The normal hysterical patient between paroxysms, unless anæmic, does not present changes in the blood. The observation of the ancient writers, that the blood would not flow freely from an hysterical patient, was correct, but the fact depended upon alteration in the vessels of an anæsthetic limb, and not upon any alteration in the blood. According to the table prepared by Gilles de la Tourette, the proportion of red blood-corpuseles, of hæmoglobin, and of urea in the blood of hysterical patients is practically normal. During and after the paroxysm it is probable that some transient alteration would be found.

The following case, from the writer's clinic in the Philadelphia Hospital, illustrates some of the foregoing descriptions :

Harriet B—, aged seventeen, English. The patient has a history from early childhood of headaches and fainting-spells. At twelve years she was severely burned

FIG. 2.

FIG. 3.

Anæsthesia in Geometrical Figures. (From author's case of hysteria in a girl, drawn by Dr. Riesman.)

about her body and limbs by her dress catching fire. She had her first fit at about fourteen under the following circumstances: A week before the attack she had slept with a very sick relative who was raving in a wild delirium all night. After returning home she constantly talked of this experience, which had evidently made a deep impression on her mind. On the night on which the fit occurred her father had stayed with the same relative until a very late hour, and then, going home, knocked on his daughter's door and awakened her. The child opened the door, was much frightened, and fell to the floor in a violent fit. Thereafter for a while she had as many as from nine to fourteen seizures a day. A physician who saw her in one of these said she was hysterical, and stopped the fit by slapping her in the face with a wet towel. Some of the seizures were nocturnal.

On admission the patient was observed to be a tall, well-developed girl, with a marked English accent.¹ She had many scars due to extensive burns. (These happened some years before her first convulsion). On the fifth day after admission she had a grand attack, lasting about twenty minutes; it came on spontaneously. She uttered a loud wailing cry for a minute or two, then became motionless in tonic spasm, with the eyes rolled up and respiration suspended. Then there was bilateral squint and extreme dilatation of the pupils. The period of tonic spasm was succeeded suddenly by one of slight clonic movements, complicated with spells of crying, sobbing, and choking. The patient was evidently conscious during part of the attack. During subsequent attacks she exhibited grand and passionate movements, and the fit was sometimes followed by a lethargic state. She can be thrown into one of these seizures by causing her to gaze fixedly at an object held before her, as, for instance, a lead-pencil.

The patient was found to have hysterogenous zones over the ovaries and over the upper dorsal spine. Pressure on these produces an attack as follows: The patient becomes rigid, with some flexion of the elbows and knees. The eyes become suffused, the face

Contraction of the Visual Fields in Hysteria. Field of O. S. (From author's case; drawn by Dr. Riesman.)

¹ This case furnishes a commentary on the claims of some English writers that hysteria, as described in France, does not exist in England. This patient is a typical English girl, born in Birmingham, and drops her *k*'s unmistakably. Yet she exhibits the grand attack as perfectly as though she were in La Salpêtrière.

The Editor of "An American Text-Book of Practice."

"IN announcing the completion of "An American Text-Book of Practice," the publisher asserts that in this work *over 500 pages are from the pen of Dr. William Pepper*. This fact, from a purely mechanical standpoint in these days of enormous literary production, would not appear in itself to be matter for special comment, but when there is taken into account the Editor's busy life, it is a notable instance of the wonderful vitality and executive ability of an exceptionally gifted man."

"Dr. Pepper, who is a native-born Philadelphian, is perhaps no less widely known as a medical practitioner than as Provost of the University of Pennsylvania, and since assuming the administration of this venerable institution its interests have been more rapidly advanced than during any equal period of its history. The words of Governor Hoyt, addressed to Dr. Pepper at the time of his installation as Provost (1881), that "the events of this day will affect your own and the *fortunes of the University of Pennsylvania*," were singularly prophetic. An indefatigable worker, he has conducted the affairs of the University with such remarkable tact that the various educational departments now aggregate thirty huge buildings and the institution commands an international reputation. But it is not alone as the chief administrative officer of the University that Dr. Pepper's influence is all-potent; he is connected with, and is especially active in various capacities in, many learned societies."

"Moreover, in addition to shaping and directing the general policy of the University, Dr. Pepper attends to a very large medical practice. He is recognized as the leading American authority on medical questions, his powers of diagnosis amounting almost to intuition. He was mainly instrumental in securing from the city of Philadelphia the gift of the site on which now stands the University Hospital, and he has always been an ardent supporter and a successful promoter of charitable works deserving public recognition."

"The question naturally arises, How does Dr. Pepper meet the exactions of all these engagements? The answer is, Simply by self-abnegation and by his mental adroitness, no opportunity being lost—whether it be in his office or in his carriage responding to a business, a professional, or a social call—in formulating the duties of any function requiring personal attention. As an Editor and writer, as Provost and practitioner, it may be inferred that the official demands on Dr. Pepper would preclude attention to the enjoyments of society; but in social as in public life he still finds time for interchange of civilities with a wide circle of friends, by whom he is highly esteemed not only for the brilliancy of his literary attainments and his gentlemanly qualities, but also for his congeniality as a friend and a companion."

JUST ISSUED.—Vol. II. Pepper's "American Text-Book of Practice," completing this magnificent work of medical art. Of the 2000 pages of text, over 500 pages are from the pen of Dr. William Pepper. **PRICES:** Two volumes, Cloth, \$10.00; Sheep, \$12.00; Half Russia, \$14.00. Full particulars will be furnished promptly on application to the Publisher, **W. B. SAUNDERS,** 925 Walnut Street, Philadelphia.

From the **NEW YORK MEDICAL JOURNAL** (published by D. APPLETON & Co.)—We reviewed the first volume of this work and said: "It is undoubtedly one of the best text-books on the practice of medicine which we possess." A consideration of the second and last volume leads us to modify that verdict and to say that the complete work is, in our opinion, the best of its kind it has ever been our fortune to see. It is complete, thorough, accurate, and clear. It is well written, well arranged, well printed, well illustrated, and well bound. It is a model of what the modern text-book should be. (*New York, April 7, 1894.*)

FIG. 5.

Contraction of the Visual Fields in Hysteria. Field of O. D. (From author's case.)

flushed, and a rapt expression appears. The breathing is hurried and the pulse rapid. The eyes converge in internal strabismus and the pupils dilate. The arms may be placed in any position, and remain fixed in true cataleptoid rigidity (see Fig. 1). The hysterical symptoms are seemingly interrupted at times by the catalepsy. The tonic stage lasts for a long time. The clonic stage is of rather short duration, and is marked by tremors and clonic movements of not very wide range. Grand movements are observed in some attacks. The seizure ends in a paroxysm of tears and sobs. A lethargic state follows.

Between the paroxysms the patient has marked anæsthesia, both in geometric areas and in islets (see Figs. 2 and 3). Sensation is blunted in the buccal and lingual mucous membranes. There is no thermo-anæsthesia. There is some vasomotor weakness, shown by a bright erythematous flush extending for an inch or two around the mark of the æsthesiometre. The visual fields are narrowed concentrically (see Figs. 4 and 5), but the color fields are not modified in a typical way.

It is to be noted finally that this patient has had a few seizures strikingly like true epilepsy, in which she is unconscious, froths at the mouth, and bites her tongue. These have occurred mostly at night, and their exact nature therefore is difficult to be determined. But it is possible that the patient has "separate crises," *i. e.*, both hysteria and epilepsy.

Diagnosis.—In general terms it may be said that in the diagnosis of doubtful cases of hysteria the main reliance must be placed upon the presence of some of the permanent stigmata. It is frequently said that hysteria simulates all diseases, but the truth is that it simulates none exactly. The stigmata of the disease, if it is present, can usually be found.

Epilepsy is the disease most closely counterfeited by the grand attack. But this resemblance is seen in the first period only, the periods of grand movements and passionate attitudes not being seen in epilepsy. When the attack aborts in the first period, the likeness to epilepsy may be striking, and it may be necessary to base the diagnosis upon the stigmata. The possible asso-

ciation of the two diseases in one patient ("separate crises") must not be forgotten.

Paralysis due to organic disease may be simulated by hysteria. Paraplegia especially may be so simulated. The history of the case and the detection of other hysterical signs can usually determine the diagnosis. The same may be said of hysterical joint-disease.

The so-called "traumatic neuroses" are in large proportion hysterical, as a proper study of the stigmata will usually demonstrate.

The most common error is to confuse hysteria with degeneracy and moral perversity. It is commonly said that the hysterical patient has one or more of such syndromes as *folie du doute*, morbid scruples, mysophobia, agoraphobia, impulse to set fire, to commit suicide, to make murderous assault, or that he is guilty of sexual perversions. It is needless to say that these are the stigmata of degeneracy, not of hysteria. The hysterical child is not a moral imbecile. While hysteria may coexist with degeneracy, as with numerous other morbid states, it is not part of it.

The various internal and visceral disorders, as hysterical breathing, anorexia, vomiting, phantom tumors, etc., may usually be diagnosticated by a process of exclusion, the history of the case, and the presence of one or more hysterical stigmata.

Treatment.—The treatment of hysteria in children must be partly moral and partly physical. Among the first we include especially education, and secondarily isolation. We have not space to discuss the subject of education, but after what we have said already of defective education as a cause of hysteria, and of the peculiar impressibility of the hysterical brain, it is enough simply to indicate the sovereign necessity for a sound moral and intellectual régime for these cases. Unfortunately, it is often difficult to procure it. In some cases, if a good training cannot be obtained permanently, the influence of an evil one may be combated temporarily by isolation. To remove the patient from unwholesome domestic surroundings is the first requisite for a cure.

Among the physical agents the most important for children are gymnastics, hydrotherapy, and vigorous tonic treatment. Gymnastics and hydrotherapy are much used by French practitioners, and with signal success. They probably act partly by their moral effects, both direct and indirect, as, for instance, by substituting wholesome impressions for morbid ones, and by divesting the mind of the unhealthy complexus of ideas which underlies the hysterical state. This vigorous restorative treatment, unless contraindicated by special conditions, is better adapted for hysterical children than is treatment by rest and by measures adapted to pamper and enervate them.

In anæmic states, secondary to anorexia, forced feeding and iron may be indicated. But anæmia, being a secondary condition, will usually improve, even without drugs, on the hygienic plan above suggested. As a rule, few if any drugs are indicated, but as it may be necessary to use some of them for their moral effect, the least injurious ought to be carefully selected. Bromides and sedatives ought to be avoided.

To abort or control the paroxysm a cold douche, pressure on a hysterogenous zone, a hypodermatic injection of morphine, or an emetic, have all been recommended and tried. Morphine, however, is not proper for these cases. In the cases of children suggestion skilfully used will sometimes abort paroxysms and diminish their frequency. The suggestion of an operation will sometimes act thus. Too much solicitude and too persistent holding and controlling the patient should be avoided.

CONVULSIONS.

BY FREDERICK PETERSON, M. D.,

NEW YORK.

ECLAMPSIA is a term often used synonymously with convulsion. Eclampsia is a series of violent contractions of a limited number or of many muscles, clonic generally, sometimes mingled with more or less tonic spasm, paroxysmal in character, and accompanied, when severe and general, by loss of consciousness. Convulsions are to be looked upon not as a separate and distinct disease, but as merely a symptom of a great variety of morbid conditions affecting the most divers portions of the animal economy. The constant repetition of convulsive seizures at irregular intervals is often considered as a distinct disease, but, in the light of recent research, epilepsy too is now regarded merely as symptomatic of many pathological states which give rise to katabolic discharges in epileptogenic centres.

But while eclampsia is only a symptom, it is one of so pronounced a character that it merits, and indeed requires, special consideration as regards its point of origin, etiology, nature, and treatment.

Convulsions occur at all periods of life, but are so common in infancy and childhood as a symptom of disturbance in nervous centres that, as West says, convulsions in children correspond with delirium in adults; and Trousseau goes even farther in saying that there are some children who have convulsions as easily as some persons have delirium or dreams. They are more common under the age of two years than at any other period of early life. Males are more frequently affected than females.

Seat of Origin of Eclampsia.—Convulsions, whether local or general, have their origin in katabolic discharges of nerve-cells, either in the cortex or at the base of the brain. J. Hughlings Jackson has taught that there are three levels from which such discharges may occur: from the cells of the ponto-bulbar region; from the Rolandic area; and from a level (purely speculative on his part) which he conceives to exist in the frontal lobes and to represent the highest control of sensory-motor functions. Whatever may be the merits of his highest-level theory, I believe that from a practical point of view we may consider eclampsia as originating either in the ponto-bulbar region or the Rolandic cortical area, and generally the latter. Jackson thinks laryngismus stridulus is a convulsive discharge from the ponto-bulbar region, while Semon believes it to be cortical. The former would also classify as ponto-bulbar convulsions the respiratory fits induced in animals by asphyxia, the seizures produced by convulsant poisons (such as nitrous oxide, curare, absinthe, camphor, and uræmia), and those resulting from injuries to the cord and sciatic nerve in guinea-pigs. Lately he has been modifying his earlier views, for now he intimates that, though the primary discharge in these cases occurs from the ponto-bulbar level, the higher centres may also at the same time be implicated by intermediation of the ascending sensory fibres. For my own part, I see no

reason why poisons, for instance, circulating in the blood may not discharge cortical centres simultaneously with ponto-bulbar centres. Whatever may be the ultimate idea attained as to the different levels, the seat of the discharge in convulsions is undoubtedly in the ganglion cells of the brain, and the molecular disturbance in these cells necessary to the discharge is determined either by direct irritation at these centres (from morbid states of the blood or vascular apparatus, trauma, neoplasms) or by indirect irritation (reflex).

I submit a diagram of the two chief epileptogenetic centres. (Fig. 1). There is no form of eclampsia generated from the ganglion cells in the spinal cord.

Showing, schematically, the two convulsive centres—one the cortical, the other the ponto-bulbar, and their relations and connections. They may be acted on directly by lesions of the centres themselves, or by vascular or blood states. They are more commonly acted upon reflexly by irritations conveyed along sensory fibres from remote parts.

Etiology.—Infants are always particularly liable to present the convulsive symptom, because of the incomplete state of development of the nervous system. An infant is a bundle of nerves and nerve-centres and reflexes in a state of great activity, prepared to receive, store up, and re-energize a worldful of new

impressions suddenly thrust upon it. While the nervous system of the adult has acquired the steadiness of long habit and has but to repair waste, that of the infant has all the delicacy and instability of newly-formed and highly-impressionable protoplasm, and, besides having to preside over the processes of repair, it must govern the growth of the whole organism. The lower centres at birth are more developed than the higher ones, and control is therefore much more imperfect; yet at the same time the healthy child rarely suffers from eclamptic seizures. It is the child with a hereditary neurotic and unstable nervous system, or with acquired nervous instability, that is prone to fall a victim to convulsions. Most authors are united in the belief that there is an inherited convulsive tendency, that some families are more predisposed to the development of convulsions in infancy than others, and that various neurotic conditions in the parents, such as drunkenness and epilepsy, may give origin to this tendency in their offspring. Rickets is one of the strongest predisposing causes, and the rickety condition is exceedingly common in children that suffer from convulsions, the coincidence occurring in 30 to 40 per cent. (Gee, Morris J. Lewis, and others). Anæmic conditions and exhaustion or general debility from any cause predispose to eclampsia.

The exciting causes are chiefly reflex, either from irritation in the fifth nerve (dentition) or in the visceral sensory distribution (gastro-intestinal disorders). Many of the exciting causes act directly upon the convulsive centres (febrile and toxæmic conditions). These are given as typical exciting causes. Whether the purely physiological condition of dentition is the sole exciting cause in the cases usually ascribed to that period, or whether there may not be other causes operative during this important epoch of early life, cannot always be definitely determined.

Improper feeding, over-feeding, and disturbances of digestion are very frequent causes of convulsions. Instances of improper feeding are not often so remarkable as one that came under my observation lately, where an infant of nine months was given a dinner of corned beef and cabbage. This was promptly followed by convulsions lasting seven hours, and these by a hemiplegia from a meningeal hæmorrhage. Gastro-intestinal disorders of all kinds are frequent precursors of convulsions. Worms no doubt often give rise to eclamptic symptoms, but not so commonly as is popularly believed. Convulsions complicate many of the acute infectious diseases, and are probably due to toxins of bacterial origin circulating in the blood. In the intermittent fever of children convulsions usually take the place of the chill. In certain districts it is common to speak of malarial eclampsia as a very fatal disorder. Convulsions complicate pneumonia occasionally, but rarely after the age of two years (Holt). Fever from any source is a prolific cause. Infants seem to be very susceptible to the influence of lead, convulsions sometimes following the therapeutic administration of this metal (Eustace Smith). The so-called "uræmic" conditions frequently give rise to convulsions, though it is well to remember that we do not know what poison in the blood is the exciting cause, and that we do know that urea itself is innocuous. In 3 to 5 per cent. of cases of whooping-cough eclampsia is a complication. Fright, terror, anger, burns, scalds, morbus cæruleus, earache, laryngeal irritations, and organic diseases of the brain and spinal cord are to be borne in mind as more or less frequent causes of infantile convulsions.

Pathology.—Often after death from convulsions no morbid changes are to be found at all in the central nervous system. Usually there are signs of death by asphyxia, such as engorgement of the meningeal and cerebral veins with dark blood. Sometimes the passive hyperæmia is so intense that effusion of blood

takes place, or œdema may be present. Some authors have described anæmic conditions of the brain after death from convulsions. The pathology is of course not obscure when actual organic foci of disease are discovered.

Outside of the central nervous system the most various pathological conditions are found at times in the heart, lungs, and abdominal viscera, this depending naturally upon the varying nature of the exciting cause.

Symptoms.—The simplest form of spasm is the respiratory spasm, known by several names, such as laryngismus stridulus, spasmodic croup, spasm of the glottis, child-crowing, and inward spasm. It is a local spasm, affecting generally the glottis, but in severe cases all of the respiratory muscles may take part in the morbid movement. In mild cases there is a slight stridulous or crowing sound made by the infant during inspiration through the spasmodically contracted glottis; in severe forms this sound becomes more intense, and the child may become pale or blue before the obstruction gives way. The paroxysms may appear at any time without warning, sleeping or waking, when being fed, or when laughing or crying: but the usual onset is at night. The attacks last from a few seconds to a few minutes, and terminate in a coughing or crying spell. Sometimes rigidity of the limbs, opisthotonos, or even general convulsions may accompany the laryngeal spasm. These seizures may occur once or several times in one night, and be repeated on following nights, the child being apparently well in the intervals.

In general convulsions there are at times prodromal symptoms, but more often none. The prodromal signs are restlessness, starting and crying in sleep, grinding of the teeth, twitchings of the face or extremities, flexions of the thumbs, and the like. These are often, however, unimportant. There is considerable variation in the extent and severity of eclampsia in children, from slight jerky movements of the head and face and carpo-pedal contractions, to a condition not differing from epileptic fits. Then in some of the graver cases there may be a cry; consciousness is lost; there is at first a tonic contraction, often not so long as in epilepsy: then follow vigorous clonic movements of the face, eyes, tongue, jaw, arms, hands, thighs, and legs, which gradually diminish in extent as the nerve-storm abates, until the child becomes wholly quiet, and remains dazed or in a deep sleep or stupor for some minutes or a half hour afterward. There may be frothing at the mouth. The tongue is sometimes caught between the teeth and bitten. The pupils may be contracted or dilated, and the face cyanosed or pale. There may be a single such attack, or the seizures may be repeated daily or innumerable times during a day or two, resembling the status epilepticus. Sometimes the convulsions may be limited to one side or one extremity, or to some particular part, as in respiratory spasm. The repetition of convulsions continuously limited to one side or one extremity would lead one to suspect a localized organic lesion in or about the motor cortex. Consciousness is not always lost in the milder types of infantile spasm. The temperature is generally normal in laryngismus stridulus, but more or less fever may accompany general convulsions, especially when prolonged and frequently repeated, as in the condition resembling status epilepticus (Morris J. Lewis suggests the term *status eclampticus* for this condition). Death may occur during a paroxysm, either from asphyxia or from unknown influences on cerebral centres. It is important, too, to remember that hæmorrhage may take place from the turgid meningeal vessels, as I have pointed out in another article in connection with the causation of the cerebral palsies of early life.

Prognosis.—Convulsions in children are always a symptom of great gravity. Life may be terminated in a single seizure. Yet many children become robust and healthy after passing through successive series of attacks. Naturally, our

prognosis must be governed by a knowledge of the exciting causes, and these are often very obscure. In children afflicted with convulsions during the first few days of life the probability of meningeal hæmorrhage from instrumental delivery or tedious labor is strong, since eclampsia is rare from other causes in infants under the age of one month. Hyperpyrexia is a very grave concomitant symptom. General convulsions associated with respiratory spasm, whooping-cough, and toxæmia of any kind are of serious import. The same is true when they follow upon wasting diseases, such as cholera infantum and diarrhœa. In the exanthemata convulsions at the onset are not so ominous as in the later stages, though in scarlatina they are dangerous indications at all times. The possibility of the recurrence of spasms in the form of epilepsy in later life should be borne in mind, for in nearly 10 per cent. of epileptics a history of infantile convulsions is found. It is probable that the convulsions are a symptom, more often than is generally supposed, of organic lesions in the brain, and that associated conditions, such as hemiparesis, hemiplegia, and mental defects, often escape recognition until later development of the child brings them into prominence. It is therefore well to remember that eclampsia may be associated with such states, as well as occasionally produce them, as noted above. When convulsions are ascertained to depend upon dyspepsia or other mild disorders of the alimentary canal, or to be symptomatic of rachitis, the results may not be so serious as under other circumstances, but the prognosis should always be guarded.

Diagnosis.—Convulsions occurring in children shortly after birth are probably due to injuries received during labor or to congenital pathological conditions (like heart disease or atelectasis), though reflex digestive disturbances are to be considered if organic causes can be excluded. In infants above six months of age gastro-intestinal troubles or disorders of dentition are to be regarded as most commonly the exciting cause, particularly in such cases as are predisposed by rickets or general debility. The temperature and pulse should be taken, for these often furnish indications as to the possible onset of some of the exanthemata. Symptoms of meningitis, pneumonia, and bronchitis, and eruptions should be looked for. The urine should be examined for albumin. The manner of origin and of onset, the order of the attack, and the presence of paresis or paralysis should be carefully inquired into.

Treatment.—The treatment of the convulsions of infancy and childhood depends, of course, to a great extent, upon the cause. But this cannot always be ascertained. Where there is reason to suspect organic brain disease, such as hæmorrhage, the treatment is much the same as in the adult—perfect quiet, cold applications to the head, relief of the bowels by injection, and the relief of the convulsions by chloroform inhalation and later by small doses of bromide of potassium. Should there be fever, the tepid half-bath, with cold ablutions and rubbing, should be frequently employed. When the eclampsia is due to some reflex disturbance, the warm bath is useful (96°–97° F.), and if there be colic or abdominal disorder a warm bath containing mustard should be employed. An overloaded stomach or an alimentary canal containing indigestible food may be relieved by one or two grains of calomel. A good emetic is a teaspoonful of syrup of ipecacuanha mixed with alum. Tickling the fauces should not be forgotten. If the child be at the age of dentition, and there be actual evidence of painful and swollen gums, these should be incised.

If called to a case of infantile convulsions where the cause seems to be wholly obscure, it may be laid down as a safe rule to give a warm (not a hot) bath, if, indeed, this has not already been done by the family, and to give an enema of five grains of chloral in a little warm starch-water, using a few drops of chloroform for inhalation while the chloral injection is being prepared and

while awaiting its effects. In recurrent convulsions medicines may be given in the intervals, and among these the bromide of potassium in doses of 3 to 5 grains for an infant six months old, and chloral 2 to 3 grains, stand pre-eminent as antispasmodics. The bromide should be continued for a few days after the convulsions have ceased, in order to prevent their repetition.

In laryngismus stridulus chloroform inhalation will always stop the paroxysm, though simpler means should be resorted to at first—viz., ammonia to the nose, slapping with a cold wet towel, tickling the fauces, and the like. In the interim between attacks the treatment of special exciting conditions should be carried out, as in infants suffering from general convulsions.

In all cases the diet should be regulated, and morbid states, such as rickets, diarrhoea, worms, dyspepsia, earache, and the like, be given appropriate treatment.

EPILEPSY.

BY JAMES HENDRIE LLOYD, A. M., M. D.,

PHILADELPHIA.

EPILEPSY is not a disease ; it is a syndrome. By this is meant that it is a collection of symptoms or a comprehensive symptom-group. It was among the earliest recognized so-called diseases, because of its abrupt onset and dramatic features. Like many other symptom-groups of which the morbid anatomy was unknown, this one was made to include phenomena of a variety of distinct affections due to widely varying causes. With the growth of modern pathology these various disease-processes have been more and more carefully studied and differentiated. Hence one by one independent classes of epileptic, or *epileptoid*, affections have been separated from the main group. Thus the convulsions of hysteria major were first set aside. Later puerperal convulsions, or eclampsia, were defined. So, too, the convulsions of uræmia, of certain toxæmias, of infectious diseases, of degenerative processes such as general paresis, and those occurring in infancy, were demarcated. No one now would think of speaking of these fits as epileptic, and yet, except in hysteria, the convulsive crises, as well as some of the attendant sensory and psychic phenomena, are practically identical with those of epilepsy. Later still it was observed that in some cases the fits began always in one particular muscle or muscle-group, whence they radiated to a variable extent, sometimes persisting in only a few muscles or spreading to one limb or to one side, but in some cases extending to the whole body, involving consciousness only partially in the milder cases. These local fits were found to be due to a "discharge" from a limited area in the brain-cortex, determinable now by the principles of cerebral localization. This area of discharge is oftenest in the motor zone, but not always, because sometimes the first or "signal" symptom is sensory. This species of epilepsy is called "focal," or, after the writer who first described it, Jacksonian epilepsy. Not unfrequently such focal epilepsy is found to be due to a distinct local lesion, such as may be caused by trauma, by a neoplasm, or by some point of irritation or inflammation. Again, a large class of epileptics is associated with idiocy, arrest of development, or atrophy of the brain. The pathological processes underlying these are numerous, and some of them have not yet been clearly demonstrated.

Thus it is seen that the tendency of modern research is to demonstrate distinct pathological processes for the various diseases or conditions which have among their symptoms an occasional epileptic spasm. Hence there is left only a constantly narrowing group of epilepsies, of which the pathology is as yet unknown, and to which some writers illogically apply the terms "true" or "essential" epilepsy, or, still worse, *idiopathic* epilepsy. The author does not believe that epilepsy or any other disease is truly idiopathic, but he thinks, with Féré, that this group of essential epilepsies is one, not in which there is no pathology, but in which the pathology is unknown. But so long as this

group stands he recognizes that it will be desirable, even necessary, to give a clinical description of it in a text-book on practice, to state briefly the advances that have been made in its pathology, and especially to describe its proper treatment.

Etiology.—It follows from what has been said that the causes of the various forms of epilepsy differ. Focal epilepsy is usually dependent upon a local lesion, such as a trauma, a tumor, or a syphilitic or tubercular process. The causes of “essential” or vulgar epilepsy are often very problematical. It is the custom now to regard it as a manifestation of a degenerative process in the brain, dependent largely upon heredity or congenital imperfection. In this aspect it has its alliances with insanity on the one hand and with idiocy on the other. It is possible that some cases are the results of intra-uterine mishaps or diseases, or of injury, unobserved and unsuspected, at the time of birth. Others, again, may date from the insidious process of some infectious disease.¹ Alcoholism is an occasional, not a common, cause of confirmed epilepsy. It may act in the parents, however, to contribute to degenerative processes in the children, among the symptoms of which may be epilepsy.

Pathology.—Epilepsy, in its motor aspect, is an explosion of nerve-force from the brain-centres. But this is a crude and inadequate explanation of the disease-process. It does not explain all the phenomena, especially the loss of consciousness and the various psychological disorders. Bevan Lewis believes that the cells of the second layer of the brain-cortex undergo degeneration or “vacuolation”—that these cells are the sensory pole of a true sensori-motor arc, the motor pole being the large cells of the deeper layers. Hence the normal inhibition exerted by the sensory cells being destroyed, a periodical explosion of the motor cells occurs. It is needless to say that this is a mere theory.

Morbid Anatomy.—The gross lesions of focal epilepsy are usually easily recognized. Among the most common are tumors, especially in the motor region of the cortex. Next are wounds, causing either depressed fractures of the skull or localized inflammatory products, or both. Such wounds may be caused by blows on the head and by gun- and pistol-shots. Syphilitic lesions, as a localized pachymeningitis, may cause a focus of discharge. So may a tubercular deposit, often called massive tubercle. Focal discharges are sometimes, as the author has seen, among the earliest symptoms of tubercular meningitis. The gross deformities, such as porencephalon, and diffused processes, such as lobar sclerosis, which manifest themselves by idiocy and arrest of development, and are not unfrequently provocative of epileptic seizures, are not properly to be described here.

A number of diffused lesions have been reported as found in cases of chronic epilepsy. These are, as a rule, scleroses of different parts of the brain or bulb. Sclerosis of the Ammon's horn has attracted much attention and caused much debate. According to some, it is found in only 6 per cent. of brains examined, but, according to others, it is much more frequent. The facts of motor localization, as Féré says, do not lend countenance to the theory, and experiment shows that lesions of this part do not cause epilepsy; nevertheless, the observations are rather too frequent to be mere coincidents. With this author we may suppose that the induration of the cornu Ammonis is only a predominant localization of a more diffused lesion. Féré reports also plates of induration in various parts of the cortex and induration of the olivary bodies similar to that of the Ammon's horn. Chaslin claims to have found in brains of some of Féré's

¹ The infectious origin of epilepsy has lately been claimed by Marie (*Prog. Méd.*, 1887, No. 44), Lemoine (*Ibid.*, 1888, No. 16), and by Veysset (Thesis, 1889, *De l'influence des maladies infectieuses sur le développement de l'épilepsie*).

patients a diffused *neuroglial* sclerosis, a real gliosis—in other words, a proliferation of the neuroglial tissue of the brain, as distinct from a sclerosis of connective tissue.¹ The claim of Bevan Lewis that the distinctive lesion of epilepsy is a vacuolation of the cells of the second layer of the cortex has already been referred to. It still remains a vital point to be decided whether these various lesions are the causes or the effects of confirmed epilepsy.

Symptoms.—Adopting Féré's plan, we may divide the symptoms of epilepsy into four groups: (1) Sensory, (2) Motor, (3) Psychic, (4) Visceral. These blend in various ways in different cases; in fact, it may be said that no two cases of epilepsy are alike.

Sensory symptoms may precede or follow the fit, or both. The sensory *aura* is a very common signal or initial symptom. It may be a sense of numbness or tingling in one of the extremities, as in a finger or toe, or it may be a peculiar, indescribable sensation starting from the epigastrium and mounting to the head. This epigastric aura is perhaps the most common. When it reaches the head or neck, the patient usually loses consciousness and falls in the fit. Sometimes the aura is in one of the special senses, as flashes of light in the eyes or rumbling or other sounds in the ears. Aurals of taste and smell are more rare. Occasionally hallucinations of sight are described, as an image of some person or thing, either agreeable or terrifying, appearing and advancing to the patient. The aura, whatever it is, is usually unvarying; that is, the same patient always experiences the same aura in succeeding fits. The sensory symptoms following the attack are less striking and variable. The most frequent is headache, which may persist for some hours or even a day. Sometimes the sensory symptoms constitute the whole of the attack, and may consist in a crisis resembling migraine. In fact, some authors teach that all migraine is an epileptoid affection, but of this there is not satisfactory proof. Certainly, ordinary migraine does not show a tendency to pass into motor epilepsy.

The motor symptoms of epilepsy are by far the most conspicuous, and so dominate the scene that they are apt to be regarded as the most important; but this is an error. They present great variety, and, for the sake of brevity, can best be described in some of their typical forms. The first visible motor symptom may be in the form of an aura; that is, a signal symptom recognized by the patient. This may coexist with or immediately follow a sensory aura, such as has already been described. It is usually a tonic or clonic movement of the muscles of one of the fingers or toes, or of the external muscles of the eyes, or of the muscles of the face or neck. This motor aura is especially likely to occur in the focal epilepsy referred to above. This slight initial spasm soon radiates to other muscles, then to the proximal parts if in a limb, then to the whole limb, then to the limbs of one side, and then, in severe cases, to the whole body. The first movement of the convulsed muscles is nearly always tonic or spastic, rapidly giving way to vibratory and clonic movements. In some milder cases or attacks of this focal epilepsy the movement may consist of merely a slight spastic, followed by a jerky, clonic convulsion in a very limited muscle-group. In the most severe of all forms of epilepsy, known as vulgar epilepsy or *grand mal*, the motor phenomena are about as follows: Almost instantly, with a very brief aura, or even without any warning whatever, the patient utters a peculiar startling cry and falls convulsed. This cry is probably part of the motor symptom-group, being rather the result of the forcible expulsion of air from the chest by the vice-like spasm of the respiratory muscles than the expression of emotion or other psychic states. When he falls

¹ For an exhaustive discussion of this whole subject see Féré's treatise, *Les Épilepsies et les épileptiques*, Paris, 1890, chap. xxx, p. 437.

the patient is in a general tonic or spastic stage. The pupils are dilated. The face, at first pale, rapidly becomes congested and cyanosed. The teeth are firmly set, the tongue probably caught between them. The fists are clenched, the limbs extended, the head often drawn forcibly to one side. In a few moments vibratory movements begin in the muscles of the eyes, face, and extremities. These vibrations soon increase in range, and they pass into clonic spasms, which gradually diminish and usually terminate in wider shock-like movements. While they endure bloody or unstained froth escapes from the mouth; the urine, and rarely the feces, may be expelled. The patient often injures himself in his fall, besides biting his tongue. He is unconscious from the first moment, and sleeps heavily for many hours afterward. Exhaustion, even paralysis, of the convulsed muscles may follow the fit. Exhaustion and abolished kneejerks are seen after these severe attacks especially. Paralysis in the previously convulsed muscles is more apt to occur after focal epilepsy, especially when this depends upon a destructive focus, such as trauma or tumor, in the brain.

The psychic symptoms of epilepsy are of the very first importance. It is too often the custom, unfortunately, to regard epilepsy as a mere motor disorder characterized only by a fit. There is nothing wider from the truth than this. Epilepsy, or that for which it stands, is much more than a fit. Its essential factor is probably a widespread degenerative process which involves not only the motor and sensory cortex, but also the higher intellectual spheres of the brain. Hence, as was recognized long ago, epilepsy has important relations to the mental health. The transient psychic disorders usually attending the convulsion, or following it, have already been noted. They consist of very fleeting mental states, which accompany the aura, such as confusion, possibly in some cases terror, or even rage, and which soon pass into unconsciousness. This unconsciousness lasts for a variable time, usually persisting as a deep sleep for some hours after the fit. But there are other and more important psychic phenomena. Not only loss of consciousness, but also stuporous and confusional states, as well as various forms of mental derangement, attests how comprehensive may be this degeneration. Among the most common of these derangements are episodes of fury with forgetfulness, mania, substituting or following the paroxysm, delusional ideas, moral perversions, coma, and chronic deterioration of the brain-faculties. Many years ago Morel, a French writer, described masked epilepsy (*épilepsie larvée*), in which the motor crisis is not apparent, but is replaced by an explosion of maniacal fury. This is perhaps an extreme doctrine if applied to the cases of persons who have never been known to have any of the motor disorders of epilepsy. But this variety is very similar to the now well-recognized substitutional attacks. These are episodes of confusion, forgetfulness, automatism, and even violence, taking the place of a motor seizure in a confirmed epileptic. They are called also psychical equivalents. Another mental disorder is mania, a dangerous complication. It may appear as a substitute for, or as a sequel of, a paroxysm. Delusions sometimes persist in the epileptic, which appear to have had their birth in the disordered brain just before or after a convulsion. Homicidal and suicidal impulses are sometimes displayed. The terminal dementia of epilepsy is a state of degeneration of the mental faculties. As was said above, no two epileptics are alike. Hence it is futile to attempt to classify this great array of psychoses into "prodromal," "post-paroxysmal," etc., as some have done. Each case must be studied by itself. Commonly, mental symptoms appear just before or after or substituting a paroxysm; in other words, they are part of the epileptic discharge. Where they seem to come independently of a fit, it is well to recollect that the motor discharge may have been so slight as to have been overlooked.

The great viscera are variously affected in epilepsy. Death has resulted from asphyxia due to the spasm of the chest-muscles, or even from rupture of the heart occurring during the tonic stage. Crises resembling angina pectoris, also peculiar spasmodic affections of the larynx, are sometimes epileptic in character. Nocturnal incontinence of urine, especially if persisting after early childhood, may excite a reasonable suspicion. Disorders of digestion not unfrequently persist for some days after a convulsion; these are chiefly nausea, vomiting, anorexia, constipation, or diarrhœa. Jaundice even has been seen. Post-paroxysmal albuminuria has been observed, but not constantly, as some have claimed. Glycosuria is exceptional. Visceral symptoms are quite prominent in some cases of petit mal; thus with slight dizziness and confusion there may be nausea or palpitation of the heart. In a very few cases hæmorrhage into the brain has been found as a result of a fit.

The nutrition is variously affected by the epileptic seizure. Loss of weight and alterations in the blood, such as diminution in the quantity of oxyhæmoglobin, have been observed and studied by Féré, Henocque, and others.

Epilepsy leaves its marks or *stigmata* upon the body of the patient. These are most conspicuous in chronic cases that have begun early in life, and hence in cases that are most distinctly degenerative in origin and course. Some of these somatic signs, in fact, are identical with those that are now well recognized in constitutional or hereditary types of insanity, or even in arrest of development. Among them are cranial and facial asymmetry; also other cranial and skeletal deformities. Such epileptics, on the whole, are of poor or even stunted development, although many exceptions to this rule occur. Defective development of teeth, external ears, and genital organs is sometimes noted. The epileptic facies has been described, but it is too often the evidence of bromidism rather than of disease.

Varieties.—There are many varieties of epilepsy. *Focal* epilepsy has already been described. *Petit mal* is often only a minor form of this: it consists in a momentary dazed or confusional state, with or without localized muscular movements. *Grand mal* also has been described. *Nocturnal* epilepsy is not distinct, except for the fact that the attacks occur during sleep: *somnial* epilepsy would be a better term, because the attacks occur really during sleep, whether this be during the day or night. Cases have preserved this type for many years. *Procurive* epilepsy derives its name from the fact that the patient runs for some distance before falling in the fit. *Masked* epilepsy, already referred to, is the type in which the sensory and motor symptoms are replaced by a psychosis. A very grave complication is the epileptic *status*. In this the patient passes rapidly from one convulsion into another. He is comatose, with high temperature, a weak pulse, and a stertorous respiration. In this condition he may die.

Diagnosis.—Epilepsy is to be distinguished especially from hysteria, from the convulsions of uræmia, and from those due to gross organic brain disease. It can be distinguished successfully from hysteria by the absence of the hysterical stigmata, which cannot be described here; by the history of the case, and by a careful comparison with a typical grand attack as described elsewhere. It can be distinguished from uræmia by the history of the case and by the absence of evidence of organic kidney changes. In gross brain disease the symptomatic epilepsy is often focal, although not always, and other symptoms, such as various forms of paralysis of motion and sensation, changes in the optic disks, vomiting, vertigo, and acute mental symptoms, together with the history of the case, assist in the diagnosis. In children a grave question sometimes arises as to the exact nature of a convulsion, especially if it has been repeated after

a comparatively long interval without apparent cause. Reflex epilepsies in children from teething, worms, constipation, etc., are not nearly so frequent as has been supposed. The great majority of infantile convulsions are caused by some infection of the blood, such as the poisons of scarlatina, measles, whooping-cough, etc., or the products of indigestion. Where no such cause exists, and especially when the convulsions are repeated at comparatively long intervals, the case ought to be recognized as serious, as threatening the formation of the epileptic habit, and it ought to be treated accordingly.

Prognosis.—In early exceptional cases, not caused by gross brain disease, it is possible that a cure may be obtained. For chronic epilepsy there is no cure. The more inveterate and severe the fits, the greater is the chance of mental complications and ultimate deterioration. This rule is not universal, however, because mental symptoms are due to obscure causes and may appear in mild cases. Patients with severe, if infrequent, attacks often lead a long and even useful life. The epileptic status is always dangerous to life. Brain-surgery has relieved focal cases due to gross lesions, but even in these cases relapses have occurred.

Treatment.—The treatment of epilepsy must be both hygienic and specific. It has long been observed that over-eating, over-sleeping, and a slothful life are especially injurious to epileptics. In young patients, who do not yet show the marks of chronicity and deterioration, it is important to regulate the habits and the daily life. Attention ought to be paid to the gastro-intestinal tract; over-eating and constipation must be guarded against. Radeliffe of England also cautions against over-sleeping as provocative of more frequent seizures. An overloaded bowel will undoubtedly act injuriously upon the epileptic. This is a matter of common observation in the Philadelphia Hospital among the epileptics and the epileptic insane. An idle life is, unfortunately, often forced upon the epileptic; he both shuns and is shunned because of his affliction. It were far better if he could be kept busy at some light and agreeable task. In private patients this need can and ought to be met. Finally, the well-recognized rules of personal hygiene, which cannot be given here in detail, ought never to be relaxed.

The indications for treatment supplied by the advanced pathology of epilepsy, given above, are several. Drugs which have, or are supposed to have, a restraining effect upon connective tissue or neuroglial proliferation ought to have a thorough trial. Iodide of potassium is the first of these in importance. The mercurial drugs may have a somewhat similar effect, as may also nitrate of silver. Arsenic and zinc salts are of doubtful utility. It is but reasonable to suppose that the peculiar action of these medicines will be exerted best in recent cases and in young persons. Certainly, every such case ought to have a thorough trial of the iodide of potassium. If time shall prove that this latter drug exerts a true alterative action upon the sclerotic processes seen in epilepsy, it will deserve, rather than the bromides, the title of a specific.

The bromides are undoubtedly the surest remedy for epilepsy, especially for controlling the fits in confirmed cases. That they are ever curative, even when given early in young patients, is at least doubtful. The writer has never seen them effect a cure. Some authorities advise heroic doses given until the patient is "bromidized." It is well to try this plan in early cases in the hope of eradicating the disease. In chronic cases bromide in any doses cannot cure, but it can reduce the number of seizures. It does this, however, at the cost of much depression, and in advanced cases, if given in large doses for a long time, it probably promotes some deterioration of the brain. Children bear large doses of the bromides well. Of the various salts, the potassium is rather

the most reliable, the sodium is least likely to disturb the stomach, and the ammonium is stimulating to an insignificant degree. The iodide of potassium can be given with any bromide salt.

Antipyrin has been tried with apparently good effect in epilepsy. It belongs strictly to the same class as the bromides—*i. e.* it is palliative rather than curative. Chloral hydrate may assist the bromides, especially in urgent cases like epileptic status.

Of other drugs, none deserve special mention except belladonna and nitrite of amyl. The former has value, but its unpleasant physiological action is much against it. The nitrite of amyl is of use in some case of petit mal to abort the crisis.

Surgery offers relief in many cases of focal epilepsy due to gross lesion of the brain or skull, such as tumor and fracture. The seat of an old fracture, or even suspected fracture, ought to be trephined if epilepsy supervenes. The principles of cerebral localization may indicate the seat of a lesion in obscure cases. Even in cases where no organic lesion has been discovered, excision of that part of the cortex which contains the focus of discharge has done good.¹ Trephining in cases of epileptic idiocy caused by brain atrophy, porencephalon, and other gross defects, should be condemned. It is not based upon scientific principles, and the results in the cases in which it has been done are disappointing, and they have often been fatal.

CHOREA.

BY M. ALLEN STARR, M. D., PH. D.,

NEW YORK.

CHOREA MINOR, Chorea of Sydenham, or St. Vitus' Dance, is a functional nervous disease characterized by sudden rapid twitchings of any or all of the muscles of the body, by slight deficiency in the control of the muscles which twitch, and by mental irritability.

Description.—The *movements* produced by chorea are spasmodic, unexpected, and inimitable. They cannot be arrested by will for any length of time, but are much increased by attention, by excitement, or by any effort either to restrain them or to exercise the muscles involved. In the majority of the cases the movements are momentary and slight, and do not exhaust the patient. In a few most severe cases they are extended, violent, and continuous, endangering the patient's safety and even his life. These movements interfere greatly with voluntary acts, rendering them imperfect, awkward, excessive, or even impossible. When chorea is slight, such acts as dressing, writing, or playing the piano may reveal irregular motions not noticeable in a state of rest; and often it is this unusual awkwardness in the performance of these acts or nervousness which first attracts attention to the condition. When the disease is fully developed any movement involving fine co-ordination is impossible. While any muscle of the body may be involved in the choreic movements, it is more common to notice them in the extremities and face than in the muscles of the trunk. The facial muscles are frequently affected, and the child makes queer faces, especially while talking. The eyes are suddenly closed or opened; the mouth pouts; the tongue if protruded is seen to be affected, and may be suddenly withdrawn, or even be cut by an unexpected snapping together of the jaws; occasionally the laryngeal and respiratory muscles are affected, and noises are made in the throat. The neck is not as frequently affected as the shoulders, but the arms below the elbow are almost always involved, and irregular, awkward motions of the fingers are always seen or felt if the hands are held. While the trunk-muscles do not often appear to swell out in contraction, yet the entire body is uneasy, and frequent changes of posture are always to be seen. The legs below the knees are affected as often as the arms, but the thighs do not often twitch, and the patient is rarely seen to fall, though he may stagger in walking. These motions cease during sleep.

The *weakness* in the muscles affected may occasionally amount to paralysis, but this is rare. The awkwardness or ataxia is always noticeable. The disease might be supposed to be entirely muscular in its origin, were it not for the facts that it is very often unilateral and almost always associated with mental irritability. Hemichorea is about one-third as common as general chorea. In 474 cases of my own 169 were unilateral. It occurs on either side, and if the disease begins as a hemichorea it rarely becomes general. If it has once occurred as a hemichorea, it usually recurs as such.

The *mental irritability* is usually noticeable early in the disease. It may

be accompanied by inability to exert the mind continuously and by enfeebled ability and depression of spirits. The child frets and is easily irritated, is quarrelsome when previously of good temper, cannot be amused, and is said to be naughty when in reality it is unable to exercise self-control in a normal manner. It may act in a semi-imbecile manner, laughing too easily. It is always incapacitated for study. This mental excitement may interfere with sleep.

A child who is suffering from chorea is unusually pale, badly nourished, has little appetite, is constipated, passes but little urine, and that of high specific gravity, loaded with phosphates and urates. Very frequently, if examined, it will be found to have a loud systolic heart-murmur, which may be either functional and due to anæmia or organic and due to endocarditis. There is often obtained a history of muscular pains or of an attack of rheumatism preceding or coincident with the appearance of the chorea, and also of headache. There is usually diminution of the tendon reflexes and a hyperexcitability of the muscles to electrical stimulation. Temperature, pulse, and respiration are normal.

The disease appears suddenly sometimes after a fright, increases during the first two weeks, lasts for several weeks (ten is the average), and gradually subsides, but will probably recur after a year at the same season at which it first appeared.

This description applies to the majority of cases of chorea. There are exceptional cases which require mention.

In a few instances the motions are constant, excessive, and violent, so that the patient will be thrown off a chair or out of bed, and is liable to injure his limbs by their violent contact with objects. Unless these patients are kept asleep, they are soon worn out and may die of exhaustion.

In a few cases the mental irritation rises to the pitch of mania, and active delirium occasionally occurs in this form of the disease.

In some the weakness is so much more apparent than the twitching that the case impresses the observer as one of paralysis: this has been named the paralytic form. I have known a case of chorea to be mistaken for infantile spinal paralysis. Occasionally the twitching is less noticeable than the awkwardness, and were it not for the age of the patient and the absence of other symptoms the case might be thought to be one of locomotor ataxia.

In a few instances speech becomes affected early, and may be so indistinct that it cannot be understood: it is in these cases that grunting noises may be made. Sometimes nervous patients affected with twitching motions give vent to loud words unexpectedly, usually of a profane or obscene kind. This condition, known as coprolalia, is not choreic, but hysterical. So, too, is echolalia, in which the patient repeats the last word heard. Such patients often mimic motions and show other signs of hysteria.

Subcutaneous nodes, which are small, round, hard nodules appearing in many parts of the body, notably on the back and along the flexor surfaces of the extremities, are occasionally seen in choreic patients. They are to be regarded as evidence of rheumatism, and have no special relation to the chorea.

Duration of the Disease.—The duration of an attack of chorea is very variable in different cases. Sometimes the disease runs a rapid course, and terminates in recovery within a month; again it may continue for a year or more with varying degree of severity; occasionally it becomes chronic and lasts for years.

The large majority of cases of chorea last from six to ten weeks, and terminate in recovery; but there is always danger of a relapse, and the greater

number of the patients suffer from a second or third attack, which attack usually occurs at the same period of the year at which the first seizure occurred. I have treated a patient for seven successive years every spring, and have many cases on my books of fourth and fifth recurrences.

Death only occurs as an exception in children, though fatal cases in adults, especially when chorea complicates pregnancy, are not very rare. When a child dies of chorea it is because of exhaustion on account of the severity of the motions.

Etiology.—*Sex.*—Males are less liable to the development of chorea than females, the proportion being about 1 to 3. Of 466 cases of my own, 136 were males and 330 were females; of 436 cases collected by the Collective Investigation Committee of the British Medical Association in 1887,¹ 114 were males and 322 were females.

Age.—While chorea may occur at any age of life, instances having been reported both at birth and at the age of eighty-six, yet the large majority of cases appear between the fifth and fifteenth years of life. Table I. shows the age of onset in 467 cases under my own observation and in 436 cases tabulated in the report of the B. C. C. :

TABLE I.—Age of Incidence of Chorea.

Cases.	Under 3.	4.	5.	6.	7.	8.	9.	10.	11.	12.	13.	14.	15.	16 to 20.	21 to 25.	26 to 30.	31 to 35.	36 to 40.	Over 40.

	5	8	22	37	59	75	87	89	84	84	83	74	42	127	20	2	3	2	11

Classes.—While children in all classes of the community may be attacked by chorea, a large majority of the cases are found to develop among the lower classes, especially among children living in tenement-houses under bad hygienic surroundings and subsisting upon poor and badly cooked food.

Season.—Several interesting investigations have been made with regard to the relation between atmospheric and climatic conditions and the development of chorea. An attempt has been made by Lewis to trace some relation between the occurrence of storms, between barometric changes, between changes in humidity of the atmosphere, and the occurrence of the onset of chorea. While it appears from the tracings upon his table (see Table II.) that there is some connection between the conditions of the weather and the development of rheumatism, and while there is undoubtedly a distinct tendency for chorea to prevail in certain climates at certain seasons of the year, yet no precise statements in regard to the influence of climatic changes upon the production of chorea can be made.

Weir Mitchell and Sinkler have called attention to the fact that chorea appears with greater frequency at certain periods of the year, notably during the spring. Table III., which compares the months of onset of 170 cases of Weir Mitchell and 409 of the author's, clearly shows that the largest number of cases begins in the spring.

Relation of Rheumatism and Chorea.—For many years it has been admitted that there is an intimate relation between chorea and rheumatism. Many cases of chorea develop immediately after an attack of acute rheumatism, with or without accompanying endocardial complications. In many instances

¹ The results of this investigation are valuable, and will be referred to in the course of this article as the B. C. C., British Choreia Committee. (See *British Medical Journal*, Feb. 20, 1887.)

rheumatism and chorea appear alternately, one succeeding the other in some patients; in many cases they appear simultaneously. In Table IV. the relationship or coincidence of these diseases is displayed, and the large percentage of cases of chorea in which rheumatism has existed (26 per cent.) can not be ignored. The statement may be made that a certain poison in the blood, either of extraneous origin or internal development, under certain conditions, produces rheumatism or chorea or endocarditis. This poison may affect the joints or the nervous system or the heart, probably in accordance with the varying susceptibility of these organs in different individuals, and in many subjects it produces all three diseases at once.

Some authors regard the existence of "growing pains" of an indefinite muscular character as sufficient evidence of rheumatism, and in the statistics here collected it has not always been possible to determine whether the pains called rheumatic were of this character. In my own cases I only consider those rheumatic in which a history of acute articular rheumatism occurring within three months of the onset of the chorea has been obtained.

TABLE II.
PHILADELPHIA. 1870-1890. TABLE I.

1. 717 separate attacks of chorea; 2. Storm-centres passing within 400 miles of Philadelphia; 3. Mean barometer; 4. Mean relative humidity; 5. 674 separate attacks of acute inflammatory rheumatism.—(Lewis, *Trans. Assoc. Amer. Phys.*, 1892).

TABLE III.—Showing Month of Onset of Chorea. (409 cases of author, black line; 170 cases of Weir Mitchell, dotted line.)

Relation of Chorea to Endocarditis.—In a large percentage of patients suffering from chorea examination of the heart reveals the existence of a murmur.

This murmur is usually a mitral systolic murmur, heard at the apex, only occasionally being aortic or double. In many of the cases the murmur heard appears with the beginning of the attack of chorea, and ceases after the attack is over. Such murmurs are usually considered as blood-murmurs, owing to their association with anæmia, and are not thought to indicate any actual disease of the valves. A certain proportion, however, of patients who have chorea continue to have a cardiac murmur after the chorea has passed away, and just as rheumatism may leave a diseased heart, so chorea may leave a diseased heart; and this is true whether the chorea has been associated with rheumatism or not. It is true that the rheumatic cases of chorea are more liable to develop endocardial murmurs than the non-rheumatic cases, but it is not true that the development of a true endocardial murmur is evidence of the existence of rheumatism in a given case of chorea.

In my own records I have distinguished between cases in which a murmur has been present and has passed away after the chorea has ceased (65 cases), and cases in which the murmur has remained for a period exceeding six months after recovery from the chorea (83 cases). There were 300 cases in which the heart was carefully watched, and in which no murmurs, either functional or organic, appeared. Osler has shown that in a considerable proportion of cases of chorea the complicating endocarditis is independent of rheumatism, but lays the foundation of organic heart disease—an opinion which my experience confirms.

Other Etiological Facts.—It is well known that chorea occurs as a sequel of scarlet fever and measles, whooping-cough and varicella. It is possible that the original infectious agent producing these diseases acts as an irritant to the nervous system. The chorea which occurs during pregnancy need not be considered here as it is not a disease of childhood.

A large majority of the patients suffering from chorea present evidences of anæmia in greater or less degree. It cannot be stated, however, that anæmia is a cause of chorea. It is probable that the same conditions which give rise to anæmia conduce to the development of chorea. The anæmia is frequently so severe as to require treatment simultaneously with the chorea.

While it is possible that local twitchings of the muscles of the eyes or face or neck may be produced by eye-strain or by irritation in the naso-pharynx, true chorea is never, in my opinion, produced by these causes, and treatment directed to the relief of so-called muscular insufficiencies in the eye-muscles is useless.

The exciting causes of chorea are not fully determined, but a certain proportion of the cases develops after sudden mental excitement, such as fright or grief. Thus in 87 cases out of 490 of which I have records, a fright was assigned as the exciting cause, and in the B. C. C. report it is assigned as a cause in 96 cases out of 222. In order to be considered as an actual cause of chorea the mental shock must precede the development of chorea by not more than a week, for it is hardly to be supposed that the effects of any mental shock can appear after a longer interval.

Certain authors have called attention to hereditary influences acting as pre-disposing causes to chorea, and it is a fact that if the family history be carefully investigated, rheumatism, various nervous disorders, alcoholism, and tuberculosis are frequently discovered.

Pathology.—According to our definition, chorea is a functional disease. This implies that there are no organic changes constantly present as its pathological cause. That all functional diseases are undoubtedly due to disturbance in the nutrition or in the molecular structure of tissues is admitted, and that

in chorea such changes are present in the nerve-cells of motor function is highly probable; but inasmuch as the very large majority of patients suffering from chorea recover entirely, and inasmuch as in many cases of chorea there are no permanent objective symptoms which indicate a loss of any function, it must be admitted that a constant pathological condition visible by the microscope is not to be expected.

Nevertheless, numerous cases of chorea have been examined post-mortem, and many changes have been described in the nerve-cells, in the neuroglia, and in the blood-vessels as characteristic lesions of chorea. The statements made by some authors regarding hyperæmia of the nervous system as a cause of chorea may be dismissed without consideration, for, aside from the question whether hyperæmia or anæmia during life leaves any evidences in the nervous system after death—an open question—these appearances are described in other diseases besides chorea.

Some authorities have described minute hæmorrhages and capillary emboli as the lesions of chorea, but other equally good observers have failed to find these conditions.

Vacuolization of the nervous tissue and of the nerve-cells has been assigned as the lesion of chorea, as have also dilatations of the spaces around the blood-vessels; but this condition has also been described as the lesion of diabetes and of various functional nervous diseases, and cannot be accepted as characteristic of chorea alone.

Hyaline degeneration in the nervous cells of motor function in the cortex and in the basal ganglia has been described, but this is known to be present in epilepsy and in many organic lesions not attended by the twitchings of chorea.

Hyperplasia of the neuroglia has been seen, but this, too, cannot be considered as a necessary accompaniment of chorea, inasmuch as it is permanent, while the disease is temporary.

It is to be remembered that in the majority of cases which have come to autopsy other diseases than chorea have caused the death of the patient, or else the patient has succumbed to a condition of exhaustion which in itself might be sufficient to produce many of the changes described; therefore I do not believe that the pathological anatomy of chorea can be said to be known.

It is not positively determined whether the portion of the motor nervous system affected in chorea is the spinal cord, basal ganglia, or cortex. Probably various cases present various conditions. In the cases in which the mental symptoms are prominent the cortex is undoubtedly involved, and in the unilateral cases the lesion is undoubtedly cerebral. There is little ground for positive statement regarding the situation of the lesion in chorea, and writers too often indulge in theoretical argument.

Diagnosis.—There are many diseases in which the chief and most prominent symptom is a twitching of the muscles. These should not, however, be mistaken for chorea. Tic convulsif, which is a unilateral twitching of the muscles of the face, is usually a reflex spasm due to some irritation in the domain of the trigeminal nerve; which irritation, being conveyed inward to the pons, gives rise to a sudden impulse outward through the facial nerve, just as a bit of dust in the eye gives rise to a wink. The limitation of this spasm to the face, and the fact that in the majority of cases it can be arrested by pressure exerted upon some branch of the trigeminal nerve upon the face, will prevent its being mistaken for chorea.

There is a similar disease, called general convulsive tic or *maladie des tics convulsifs*, first described by Gilles de la Tourette, consisting of a sudden

twitching of any or all of the muscles of the body. This resembles chorea closely, but should not be mistaken for it. It is not attended by any weakness of the muscles or by any awkwardness of voluntary movement; the twitchings do not occur during voluntary movements, but only appear during rest. The disease is a chronic one, appearing as a rule about the fifteenth year and remaining during life. The twitchings are more sudden than those of chorea, and there is no mental irritability. The disease does not appear as early in life as chorea, and it does not yield to arsenic.

Habit-spasm has been mistaken for chorea, but should not be confounded with it. All children have a tendency toward mimicry, and a child who is afflicted by habit-spasm makes movements which have the character of voluntary movements, such as winking, pouting the lips, turning the head, shrugging the shoulders, or moving the extremities: such habit-spasms are not as quick and sudden as the spasms of chorea; after a time they are not easily controlled voluntarily, as they are in the early stage of the affection. Voluntary control can, however, be increased by forcing the child's attention to the necessity of it, and in this condition moral treatment and general hygienic measures, such as baths and proper exercise, are of more service than medicines.

Paramyoclonus multiplex is a spasmodic affection of the muscular system which resembles chorea. In this disease it is the muscles of the body and of the proximal portions of the limbs which are affected; the face and arms and hands and legs do not participate in the spasm. The spasms are bilateral and symmetrical; they occur at intervals, and are rapidly repeated, as many as ninety contractions of the muscles occurring in a minute. The movements during the attack of spasm are very violent, so as to throw the patient down if walking or to hurl him off a chair if seated. The spasm can be brought on by tapping the patellar tendon. During the interval between the spasms fibrillary tremor of the affected muscles may be seen. The disease may occur at any age; it usually develops after some mental or physical strain in patients of an hysterical temperament, and recovery generally takes place after a time. It will be seen from this description that the disease should not be mistaken for chorea.

The hemichorea which follows hemiplegia is characterized by slow, irregular ataxic movements on voluntary motion, and does not consist of twitchings in individual muscles. It should be regarded as hemiathetosis rather than as a species of chorea.

Multiple sclerosis may be the cause of irregular movements, but these never occur when the patient is at rest, and this is not a disease of childhood.

Prognosis.—In view of the facts stated it is evident that the prognosis given to the parents in any case of chorea should be a hopeful but also a guarded one. For while the chances are all in favor of a speedy recovery within three months, they are also in favor of a recurrence of the disease, and in no case is it possible to promise a cure, because of the fact that a few of the cases which cannot at the outset be distinguished from the ordinary cases become chronic and do not recover at all.

Another fact should be mentioned which should lead to a guarded prognosis—namely, that certain children are exceedingly susceptible to the effects of arsenic, which, as we shall see in the section upon Treatment, is the only remedy of value. These children either cannot take arsenic in sufficient doses, or if they take it develop arsenical poisoning or even arsenical multiple neuritis, both of which conditions hamper the treatment exceedingly.

The development of rheumatism during the disease does not necessarily make the prognosis very grave, for few children die of rheumatism. Nor does

the development of endocarditis with organic murmurs in the heart lead to any great anxiety as to the life of the patient: such murmurs may remain through life, and in later years the heart disease may give rise to much trouble; but it is very rare to find in children suffering from chorea and endocarditis any evidence of insufficiency of the heart's action, as demonstrated by œdema of the extremities or œdema of the lungs. Nor have I ever seen hemiplegia develop in the course of chorea as an evidence of cerebral embolism.

Treatment.—The first endeavor of the physician who is called upon to treat a case of chorea should be to direct such an arrangement of the patient's life and surroundings as will remove him from the bad hygienic influences which have conduced to the development of the disease. If the patient remains in a damp or ill-ventilated room, if he be not properly bathed and fed, and if he cannot be kept quiet and without excitement, the prospect of success in treatment is not good. The child should always be removed from school. Nutritious diet of varied character, the digestion of which should be aided, if necessary, by the use of digestants and of laxatives, is important. Long-continued baths are to be recommended, the child being allowed to play in the water for half an hour twice a day. The bath should be tepid, between 95° and 100° F., and no sudden shock of cold is to be used. The object of the bath is to have a soothing influence as well as to dilate the vessels of the surface, and the sharp contraction of the vessels produced by cold applications is to be avoided. Rest in bed or upon a bed or couch is very essential during the first two weeks of the disease. It is difficult to keep a child who is irritable in bed; therefore it is best for the child to be warmly clad in merino underclothing, but not fully dressed, and to be allowed to play about upon a large bed, but not allowed to run about upon the floor. Gentle massage to the entire body for an hour daily or for half an hour twice a day, the body being anointed with cocoa butter, is of decided benefit. It is better for a child with chorea to see but one or two members of the family, so as to be kept free from all mental excitement. After the child is kept at rest in this manner, being amused in every possible way, being fed frequently, bathed and massaged, a very marked improvement will be noticeable within two weeks.

The improvement can be hastened materially by the use of medicines. The treatment of a case of chorea will depend somewhat upon the mode of its onset. If the child has had an attack of acute articular rheumatism just preceding the chorea or associated with it, and if he has pains in the limbs and a rise of temperature in the evening, it is much more important to treat him with salicylate of sodium or salicin or salophen than with arsenic. These remedies may be used in connection with antipyrine, phenacetin, or exalgin, the latter drug being of considerable service in the early stage of an acute attack. In the use of these remedies the condition of the heart must always be taken into account, and heart stimulants added if necessary. I prefer camphor and caffeine to other heart stimulants in this condition. The dosage of these remedies must depend entirely upon the severity of the symptoms and upon the age of the child. It may be necessary to give to a child of eight years ten grains of the salicylate of sodium every two hours for several days; it may not be necessary to give more than ten grains three times a day. Exalgin is to be given in three-grain doses every four hours in a severe case, and three times a day in a mild case. With children I prefer to use these remedies in capsules, as the disagreeable taste is then avoided.

If there be no history of rheumatism, it is well to think of the possibility of malarial infection as a cause of chorea. If there be a daily periodical rise of temperature, with or without a chill, or if an examination of the blood

reveals the presence of the malarial plasmodium, a dose of calomel, followed by Warburg's extract in capsules, or quinine in capsules, kept up for a week, will be efficacious in cutting short an attack of chorea.

Arsenic is the chief remedy for chorea not complicated by rheumatism or by malaria. Fowler's solution is the best preparation to use, being tasteless. It is to be begun in three-drop doses three times a day, the number of drops being increased daily one drop until physiological effects are produced. These are a puffiness of the eyelids noticeable on waking in the morning, and slight nausea or griping pains with diarrhœa. It is possible in some children to reach a dose of fifteen drops of Fowler's solution three times a day without the production of these effects; many children take ten drops three times a day without discomfort. It is my rule to keep on increasing the dose until the physiological effects appear. When this occurs the medicine is to be stopped for twenty-four hours, and then resumed at the dose just below that which produced poisoning; and this dose is to be kept up regularly so long as treatment is needed. Arsenic should always be given after eating and well diluted with water. There are some children who cannot take it in efficient doses without producing poisonous effects. In these reliance must be placed upon the hygienic rules already laid down, and if the chorea is very severe chloral may be given, the condition of the heart being carefully regarded during its administration. In some cases which do not yield readily to arsenic it is well to employ chloral in combination with it, giving from five to ten grains three times a day. In some cases tincture of *cimicifuga* is of service.

A few cases of chorea present very severe symptoms, the spasms being so extensive and violent as to throw the patient about in bed and even to prevent sleep. In these the use of a combination of bromide of potassium and chloral (bromide 30 grains, chloral 15 grains), given two, three, or even four times a day by the rectum, is advisable, while at the same time arsenic is used by the mouth, being given in eight-drop dose in milk. A few patients are kept awake by the movements and rapidly become exhausted: in these cautious administration of chloroform by inhalation may be necessary in order to secure the needed sleep. The hypodermatic use of hydrobromate of hyoscine in dose of $\frac{1}{200}$ grain for a child of eight years, once in twelve hours, may be tried in very violent cases. Sulphonal and chloralamide are valuable hypnotics in such cases.

In addition to the foregoing treatment of the disease, it is usually necessary to remove the condition of anæmia which is present in the majority of cases, and therefore iron must be given in any form which may be preferred. The solution of the albuminate of iron is perhaps the best form to use for children, although the chocolate lozenges containing iron may also be given freely. Every form of nutritious food, especially milk and cream, and cod-liver oil, if the child can be made to take it, is also indicated.

When medicinal treatment appears to be of little service, a change of air, especially a change to the sea-shore, is often of very great benefit. The sea air is much more conducive to recovery than mountain air, though sea-bathing is not to be recommended. In any case a certain amount of open-air life should be enforced during the treatment.

TETANY.

By HENRY M. LYMAN, A. M., M. D.,

CHICAGO.

TETANY is a functional disease of the nervo-muscular apparatus, characterized by the occurrence of paroxysmal tonic spasms that involve certain groups of muscles, and that in severe cases may extend to nearly all of the voluntary muscles of the limbs and body. The nerves that are concerned in the production of these contractions exhibit a considerable increase of electrical and mechanical excitability.

The functional character of the disease has led many observers to doubt the propriety of dividing it from other functional spasmodic disorders. The infrequency with which it is encountered in certain localities and among certain races has also created a degree of scepticism regarding the disorder as a separate entity. But this lack of unanimity is principally due to the fact that tetany prevails chiefly among women and children who belong to neurotic families and are subject to unfavorable conditions of living. It will be observed more frequently by physicians in general practice than by those whose experience is limited to office and consultation practice.

Etiology.—Tetany occurs most frequently among children during the period of first dentition; it is especially connected with gastro-intestinal disorders which interfere with nutrition, and is associated with an exaggerated excitability of the nervous system at the period of life when those tissues are naturally more unstable than during later years. For somewhat similar reasons it is not infrequent among young people near the age of puberty. The influence of sex is not very decided; it is less conspicuous than are the influences that are derived from ancestral sources. The children of nervous, weakly parents are particularly liable to the disease. Constitutional causes and diathetic influences which favor the development of scrofula, arthritism, and rickets are powerful predisposing causes of tetany. The disease is, in fact, closely allied to those spasmodic tendencies that are so commonly witnessed among rachitic children. It is undoubtedly due to insufficient diet and to the other predisposing causes of rickets that the disease is so often encountered among children in orphan asylums, foundlings' homes, and similar congregations of ill-conditioned infants.

Among the exciting causes of tetany, exposure to cold exhibits great prominence. The disease is more often experienced during cold weather than in summer. Exposure to cold and wet has been noticed as an antecedent of the disease, and its manifestation is sometimes accompanied by articular swellings that are highly suggestive of rheumatism.

When a predisposition to tetany exists, almost any irritation of the cutaneous or mucous surfaces of the body may excite an attack of the disease. It is therefore frequently observed during the course of infantile diarrhœa

and other irritative disorders of the alimentary canal. Among female patients its occurrence is closely connected with menstrual disorders, pregnancy, and lactation. It has been observed as a sequel of various infective diseases, but it is probable that in such cases the infection merely lowers the resistance of the nervous system, so that morbid manifestations of various character are more easily excited. When a predisposition has been established, almost any active disturbance of a peripheral character, or even of a psychical origin, may suffice to arouse a paroxysm.

Symptoms.—The occurrence of an attack of tetany is usually preceded by certain premonitory symptoms of nervous disturbance. Occasionally the patient complains of dizziness, determination of blood to the head, humming sounds in the ears, and flashes of light before the eyes. Various perversions of sensation in the limbs may be also experienced. When, finally, the attack is matured, it is upon the fingers and toes that the force of the paroxysm is usually expended. The muscular spasms are generally bilateral, and in ordinary cases they are limited to the flexor muscles of the fingers, wrists, and toes; the extensor muscles escape more frequently than the flexors; sometimes the muscular groups of the forearm, upper arm, leg, and thigh are involved. In certain rare instances the muscles of the abdomen, thorax, neck, face, eyes, tongue, pharynx, diaphragm, and bladder may participate in the tonic spasm. The tips of the fingers and thumbs are frequently drawn together into the conical position assumed by the accoucheur when about to introduce the whole hand into the vagina. The great toe is flexed and bent laterally under the other toes, which are also drawn down into the position of plantar flexion. Occasionally the toes and fingers are spread apart, instead of being tightly drawn together. The upper arm is drawn against the side of the thorax, while the forearm is partially flexed and crossed over the front of the body. The legs are usually extended, but the thighs are adducted, and are sometimes flexed upon the body. When the muscles of the trunk and of the neck are invaded respiration becomes difficult, and suffocation sometimes appears imminent. When the paroxysms succeed one another intermittently, the phenomena of tetanus are closely counterfeited, though, fortunately, the comparative brevity of the attack and the rarity of a fatal termination mark a decided difference between the two diseases.

During the course of the paroxysm the peripheral nerves of sensation exhibit various disorders. Sensations of cold, heat, numbness, and formication are not uncommon. Neuralgic pains and a feeling of soreness in the contracted muscles are often experienced, together with headache, dizziness, and other cerebral symptoms of sensory disorder.

Three cardinal symptoms deserve notice: Trousseau many years ago remarked that pressure exerted upon the large arteries and nerves of the limbs of a patient would be often followed by the development of a paroxysm of tetany. In this way a latent predisposition may be aroused to active manifestation of the disease. This phenomenon is more easily produced in the upper extremity than in the lower. Occasionally the paroxysm may be excited by pressure upon the carotid artery and the sympathetic ganglia in the neck.

A second characteristic depends upon the increase of electrical excitability in the motor nerves of the body and limbs. When applied to the nerves, very weak faradic currents are sufficient to excite muscular contractions. The application of galvanic currents also indicates great increase of excitability, so that tetaniform contractions of the muscles can be aroused by currents which ordinarily would scarcely be noticed. This inordinate sensitiveness to

electrical excitation is frequently manifested in latent cases where the fully-developed paroxysm has never been experienced.

The increased excitability of the motor nerves is further indicated by their behavior under the influence of mechanical stimulation. A slight tap upon the trunk of a nerve is often sufficient to arouse a paroxysm, even though the muscles themselves cannot be thus thrown into contraction by direct percussion. When the facial nerves are involved the muscles of the face may be easily brought into a state of spasmodic contraction by tapping upon the trunk of the nerve at its point of emergence from the bony canal, or by drawing the point of the fingers across the face from the external angle of the orbit to the styloid foramen.

Besides the various disturbances of sensation that have been already noted, painful pressure-points are sometimes discovered over the spinous processes of the vertebræ.

The duration of a paroxysm may vary from a few minutes to many hours, or even two or three days. In cases of such long duration muscular spasm persists even during sleep, though its intensity is considerably diminished. The number of paroxysms during the course of an attack is also subject to great variation. A single paroxysm sometimes terminates the attack, while in other cases the spasms follow one another at brief intervals, almost like the paroxysms of genuine tetanus.

Pathological Anatomy.—Since tetany rarely proves fatal, the opportunity for investigation of its pathological anatomy is seldom offered. It is probably a functional disease of the whole nervous system, but many of the morbid processes that have been described are the results of predisposing diseases, or of the convulsive paroxysms to which the patient has been subjected, rather than causes of its phenomena. Among these, undoubtedly, are the slight hæmorrhages that have been noted in the membranes of the cord and in the cord itself. The various conditions of hyperæmia and actual inflammation that have been sometimes remarked are also of the same accidental or complicating character. The reflex nature of the symptoms and their production by irritation of the peripheral nerves render it probable that the disease has its principal seat in the spinal cord, though the reflex arcs in which the cranial nerves are included sometimes display evidence of disturbance in a way that indicates an extension of disorder throughout the entire length of the nervous axis. The occurrence of the disease after diarrhœa and other wasting discharges suggests the idea that this inordinate excitability of the nervous centres is in some way connected with malnutrition and with the exaggerated irritability that is thus induced. It is not impossible that these conditions are dependent upon an infection that has invaded the tissues of the spinal cord. The occurrence of the disease after extirpation of the thyroid gland has aroused a suspicion that tetany, like myxœdema, may be due to an auto-intoxication with mucin. But these speculations have not yet emerged from the realm of hypothesis.

Diagnosis.—Tetany may be easily recognized by the occurrence of paroxysmal tonic contraction in particular groups of muscles, usually the flexors of the extremities, and by the increased reaction that takes place after electrical or mechanical excitation of the peripheral nerves. By attention to these phenomena the disease may be readily distinguished from tetanus, a disorder which, moreover, usually commences with trismus—a symptom that is rarely observed in tetany. Similar facts of dissimilarity serve to distinguish tetany from the convulsive paroxysms of hysteria, and from the spasmodic movements that are sometimes witnessed in writer's cramp and the allied pro-

fessional neuroses. The spasmodic attacks that sometimes occur as a consequence of ergotism very closely resemble tetany, and should probably be considered as belonging to the same class of toxic disturbances of the nervous system.

Prognosis.—The disease is seldom fatal, but sometimes it persists for a considerable period of time. In such lingering cases a certain degree of muscular contracture and weakness is occasionally evident on careful examination, even after the cessation of spasmodic attacks. Mechanical or electrical excitation of the nerves may then suffice to arouse a more or less complete paroxysm.

Treatment.—In the management of tetany special reference must be made to the underlying causes of the disease in each individual case. Disorders of the alimentary canal require appropriate treatment; all exhausting discharges, such as hæmorrhage, diarrhœa, excessive menstruation or the opposite condition, prolonged lactation, inordinate perspiration, etc., demand attention. Rheumatic and tuberculous patients require the treatment that is appropriate to such diathetic conditions.

Electricity has been employed with but indifferent success. Counter-irritants of all kinds have been applied to the spine, and hydropathic treatment has also been prescribed with varying degrees of benefit. For the relief of the paroxysm the various narcotics are generally recommended. Bromide of sodium, cannabis Indica, hyoseyamus, belladonna, chloral, ether, chloroform, valerian, oxide of zinc, and the opiates have been exhibited with temporary advantage. In severe attacks it is advisable to administer ether by inhalation and to employ non-volatile remedies by hypodermatic injection. Calabar bean and curare are too powerful and uncertain for administration in this disease. The principal object of treatment should be the improvement of the general health of the patient and the removal of all unfavorable conditions that interfere with nutrition. For this reason hygienic measures and dietetic management are more important than specific medication for the palliation of symptoms.

PSEUDO-HYPERTROPHIC MUSCULAR PARALYSIS.

BY FRANCIS T. MILES, M. D.,
BALTIMORE.

THE essential feature of this disease is a progressive loss of power in certain definite muscles and groups of muscles, and its most characteristic and distinguishing symptom (from which it has received its name) is the increase of volume and apparent hypertrophy in some of the weakened muscles.

Symptoms.—It is a disease of early childhood, the great majority of cases occurring before the tenth year. It is but seldom that its invasion appears to begin about or after the time of puberty, and it is probable that the eye of one accustomed to the disease would have discovered indications of it long before that time. As a rule, the first symptom that arrests the attention of the parents or nurse is the seeming clumsiness manifested by the child in using his legs. A slight trip or jostle causes him to fall, and then he gets up slowly. He walks with a straddling, inelastic gait, ascends steps laboriously, clinging to the banisters and pulling himself up. Sooner or later (in some cases it is the first thing to attract attention) certain muscles begin to develop out of proportion to the rest, and are hard and elastic to the touch. Usually the first muscles to show this increase of volume are those of the calves of the legs, with which are generally associated the glutei, one or more of the divisions of the quadriceps extensor, and the erector spinæ in the lumbar region. But the hypertrophy affects other muscles than those of the lower limbs. Thus the infraspinatus is very commonly much enlarged, frequently the deltoid, and even the biceps and triceps are sometimes involved. The escape of the muscles of the hand and forearm, which have been but very rarely described as implicated in this affection, gives a distinctive peculiarity to this form of muscular paralysis. The neck and face do not show an absolute immunity, and cases of hypertrophy of the sterno-mastoids, temporals, masseters, and even of the tongue, have been recorded. In a case of Bergeron's all the muscles except the pectorals and sterno-mastoids were increased in volume, thus giving to the child an appearance of great athletic development.

In marked contrast to the Herculean proportions of the muscles is their strength, which is almost always so greatly diminished that they are incapable of performing their required functions. After a time these muscles cease to increase in size, and then begins a diminution of their volume, which may go on to complete atrophy, with corresponding absolute loss of power. But by the side of these enlarged and feeble muscles we observe others whose power is diminished more or less while they retain their normal size, or are from the first involved in a process of atrophy. In the lower extremity this loss of power is manifested in the flexors of the hip, which, though out of reach of direct observation, are thus evidently invaded by the disease. The extensors

of the hip and knee may be under-sized or atrophied, and always much weakened. The flexors of the knee are but rarely affected. Of the muscles of the upper extremity, those of the shoulder-girdle are generally more or less atrophic, especially (indeed, almost without exception) the costal portion of the great pectoral and the latissimus dorsi. Less frequently, but not uncommonly, the biceps and triceps are small and weak. If we attempt to lift the child by placing the hands under its arms, we find that the shoulders yield against the weight of the body, and are dragged almost to the back of the head.

This mixed and variable picture of hypervoluminous and atrophied muscles would seem to indicate that the pseudo-hypertrophy is, as it were, an accidental factor, and that the intrinsic nature of this disease is the progressive loss of power in certain muscular groups. Indeed, cases have occurred in which all the motor symptoms of pseudo-muscular hypertrophy were present, but in which the diseased muscles that caused these symptoms presented no alteration of volume. In the words of Charcot: "The hypertrophy is not, all things considered, an essential element in the constitution of the affection called pseudo-hypertrophic paralysis." We will return to this point farther on.

On account of the weakness of the muscles involved, the attitude in standing and the manner of walking in this disease are peculiar and characteristic. In a state of health, while standing erect the centre of gravity of the body falls slightly in front of the point of support, and the hip- and knee-joints are not in a position of complete extension; so that to maintain the equilibrium and to prevent the flexion of those joints a sustained action of the erector spinæ and the extensors of the hip and of the knee is demanded. In the disease under consideration an involuntary effort is made to relieve these enfeebled muscles by throwing the centre of gravity very far back. To do this the lumbar concavity is increased as much as possible, so as to throw the weight of the head and shoulders behind the hip-joint, thus producing a marked lordosis, with a corresponding protrusion of the chest and belly. The knee-joints are fully extended (locked), so that the weak quadriceps extensors are at rest, while the base of support is broadened by the wide separation of the feet. The lordosis disappears when the child is seated; but in an advanced stage of the disease, when the erectors of the spine are greatly weakened, a kyphosis may for the time take its place. When standing the patient may be able to raise himself on his toes, but cannot spring from the floor. In ordinary natural walking, while one foot is off the ground and is being propelled forward the centre of gravity of the body falls much nearer the median line than the supporting foot, and, indeed, it continues to move toward the opposite side until the advancing foot reaches the ground and receives the weight of the body. During this time the weight of the body is sustained upon the head of the fixed femur, principally by the glutei muscles. In pseudo-hypertrophic paralysis, these muscles being too weak to perform their task, the patient relieves them by throwing the body far over to the side of the sustain-

FIG. 1.

Pseudo-hypertrophic Muscular Paralysis.

ing foot, thus bringing the weight over the point of support, while the other leg swings forward. This manœuvre, being repeated alternately for the two limbs, gives a peculiar and characteristic swaying motion of the body from side to side in walking. This false position of the trunk and the weakness of the extensors of the knee hinder the foot being projected forward to the length of a full step, and, instead of the heel touching the ground first, as is usual in walking, the ball of the foot or the toes first descend, giving the appearance of an attempt to step softly. This stepping on the toes is sometimes caused by a contraction of the muscles of the calf, which may occur early in the disease.

Very characteristic and almost pathognomonic of this disease are the manœuvres executed by the child in getting into the erect from the recumbent position. They were first and with great clearness described and explained by Gowers. The weak extensors of the hip and knee are not equal to the work of extending these joints and giving the erect position to the body against the

FIG. 2.

Postures in rising to the Erect position (Gowers).

weight of the head and shoulders. The child, therefore, unable to assume the sitting position, takes that of "all fours," thus throwing the weight upon the hands and arms, while the legs are being straightened. He then works his hands backward along the floor until he gets to a position from which with an effort he can grasp the legs above the knee, and then, by alternately clasping them at a higher level, he thrusts the trunk into a more and more erect position, until by a final push he jerks the spine into the position of lordosis already described. To use the common and appropriate phrase, he "climbs up his legs."

We have already said that the hypertrophied muscles after a time lose their volume and become atrophied. This may not take place until after many (ten to fourteen) years, and does not affect all of the hypertrophied muscles at the same time. Those of the upper extremity are generally the first to undergo the change, the muscles of the calf being the last to lose their volume. Increasing weakness more and more circumscribes the movements of the patient, until at last he can no longer walk or stand, although the movements of the arms and hands may still, in a measure, be retained. Now contractions of the wasted muscles set in, and joints, as the knee and elbow, are fixed in the position in which they are usually maintained. The ankle-joint takes the position

of pronounced talipes equinus, partly from fixation in the position in which unsupported it hangs, and partly from contraction of the muscles of the calf. From loss of power in the spinal muscles there may result lateral curvature.

The tendon reflexes, as a rule, show no change, except that they grow more feeble as the muscles become weaker, until they are finally lost.¹ The sphincters are unaffected.

Fibrillary contractions have been observed so rarely as to make it presumable that they are caused by some intercurrent trouble, such as neuritis. While the electric reactions are gradually diminished and lost, they are qualitatively normal, and in the very few cases in which degenerative reaction has been described it is probably due to some secondary cause similar to that which causes the fibrillary contractions in certain reported cases. Sensation is normal, and mental impairment, although occurring in some instances, does not seem to be a consequence of the disease. A symptom which might be referred to an affection of the vaso-motor nerves is the bluish mottling or marbling of the skin of the lower limbs which is sometimes seen. There is no evidence of any disturbance of the sympathetic nerves.

The disease runs a chronic course, it may be of ten or twenty years' duration, and does not itself directly cause the death of the patient. This termination is usually the result of some intercurrent respiratory trouble, to which the enfeebled condition of the patient gives force.

Etiology.—Hereditary influence can be traced in a large majority of cases, and exclusively through the mother, who, without being herself a subject of the disease, may nevertheless transmit this developmental defect to her offspring. Males are much more frequently affected than females, and in the latter it tends to develop later in life and progress more slowly. The disease may be considered as a congenital affection, for even when it develops after the period of childhood, as it sometimes, though rarely, does, there is reason to assume that the defect of muscular development has merely lain dormant during the earlier years of life. No other etiological factors, as syphilis or alcoholism, have been recognized in the causation of the disease. For a long time after pseudo-muscular hypertrophy had been observed and fully described clinically, it was considered a disease of spinal origin, a myelopathy. But more recently the opinion that it is a primary disease of the muscles, an idiopathic myopathy, has received a very general sanction from pathologists. It is recognized as one (and the most frequent) form or type of a group of myopathic atrophies, or muscular dystrophies, of which Erb's juvenile type, the facio-scapulo-humeral or infantile type, and it may be Leyden's hereditary type, are the most distinctively marked forms: "The infantile type is characterized by the early facial paralysis, the juvenile type by the time of its development (early youth) and localization of the atrophy (in the muscles of the shoulder-girdle); the pseudo-hypertrophic type by its development in early childhood and the predominance of the lipomatous condition of the muscles; the hereditary type (Leyden's) by its heredity."

While these forms of muscular atrophy are fairly separable clinically when well marked, there are numerous transition forms which cannot be easily classified. Not infrequently the different types occur in members of the same family, and arise presumably from the same inherited defect.

As Erb has shown, there are no greater differences amongst these varie-

¹The writer has recently seen a case of pseudo-muscular hypertrophy in a boy nine years old, in which the knee-jerk was abolished, although he could still walk, and the partly hypertrophied quadriceps extensor could extend the knee almost completely when the patient was seated.

ties than there are amongst the individual cases of any one variety. Thus in the pseudo-hypertrophic form we have fairly constant atrophy of the muscles of the shoulder-girdle and arm—*i. e.* those characteristically affected in the juvenile type; and in some cases described by Erb there was atrophy of the muscles of the face, the mark of the infantile type. Indeed, Erb suggests that many cases having the clinical aspect of the pseudo-hypertrophic form, afterward, as the adipose matter is absorbed, take on the appearance of the juvenile type of muscular atrophy.

Pathological Anatomy.—The essential feature of the pathological anatomy in this disease is a degenerative change in the muscular tissue itself; and this change is probably the first which takes place. Pieces cut from the living muscles (which are much to be preferred to morsels extracted by the “harpoon”), and properly prepared, present the following microscopic appearances: The muscular fibres in cross-section are seen to have lost their polygonal outline, to have become rounded in contour, even to be complete circles. Amongst fibres of normal size there are those which are hypertrophied, and others which show atrophy in varying degree, even to the point of complete disappearance. The abnormal increase in volume of the muscular fibres would, from recent observations (Erb), appear to be an essential feature in the muscular atrophies, and it may be that it is a condition of the fibres which very generally precedes their atrophy. At any rate, such hypertrophied fibres are rarely, if ever, wanting in preparations of muscular tissue taken from these diseases. This increased volume of the fibres cannot be explained by their contraction after excision, since it is seen when precautions are taken to counteract this. In addition, the fibres show a splitting in the longitudinal direction and the formation of vacuoles in their interior. The muscle-nuclei are sometimes more, sometimes less, but always considerably, increased.

The alteration of the connective tissue must follow very closely, if it is not coincident with, that of the muscular fibres. A proliferation with increase of its nuclei goes on *pari passu* with the muscular atrophy, until finally it becomes excessively developed. In pseudo-hypertrophic muscles the connective tissue is not only increased, but is crowded with fat-cells. It is this condition, indeed, to which they owe their increased volume and hardness. In muscles primarily atrophied, and in the pseudo-hypertrophic muscles after they have undergone atrophy, there is little or no adipose matter, only a greater or less amount of connective tissue (connective-tissue cirrhosis of Erb). In muscle preparations from the dead body the microscopic appearances are practically the same as those seen in pieces from living muscles. It is of great importance to observe that the microscopic appearances in muscles taken from the different types of muscular dystrophy do not differ more from each other than do those in preparations obtained from different cases of the same type, nor, indeed, than those in different specimens from the same individual. Not only do the pathological changes in the muscles bear a very close resemblance in all the types of muscular dystrophy, but these changes as closely resemble those found in other forms of muscular atrophy, as, for instance, the spinal atrophies and those attending arthritic disease. “The proof for or against the pure myopathic nature of the progressive muscular atrophies cannot at present be furnished by histological research.”

Investigations of the nervous system, both central and peripheral, have in such a large majority of cases given a negative result that the reports of lesions of the spinal cord, though made by competent observers in recent cases, will scarcely change the generally accepted opinion that the muscular dystrophies do not depend on discoverable nerve lesions. The question, however, has

arisen, and still awaits its answer, as to whether the muscular dystrophies are absolutely myopathic, or whether functional disturbances ("dynamische Störung") in the trophic mechanism of the cord, too subtle to be ascertained by our present methods of investigation, may not set up at first hand nutritive changes in the muscles. Some considerations certainly point in the direction of classing these diseased conditions of the muscles with the tropho-neuroses.

Diagnosis.—When the disease has advanced to a point where the athletic proportions of the hypertrophied muscles stand in strong contrast to their weakness, and where, moreover, along with these over-developed muscles, we have others which are atrophied, there can be little difficulty in making the diagnosis. Gowers claims diagnostic importance for the "condition, which is seldom absent," "of enlargement of the infraspinatus, with a wasting of the latissimus and lower part of the pectoralis." In cases where the enlargement of the muscles is slight, or, as in some instances, where they retain their normal size, the difficulty may be greater. The peculiar position in standing, and, still more, the makeshift movements of the patient in rising from the recumbent position, are almost positive evidence of the disease, whose main characteristics depend on the invasion and weakening of the muscles employed in these acts.

From a progressive chronic neuritis, which might cripple these muscles, the diagnosis would most likely be made by the absence of fibrillary contractions and of degenerative reactions, both of which symptoms belong to neuritis. A history of other members of the family having suffered with atrophy of the muscles would be strong confirmation. Congenital spastic paraplegia, in which the muscles sometimes exhibit a considerable volume, is distinguished from pseudo-muscular hypertrophy by the muscular spasms and the increased myotonus, which shows itself in an exaggerated knee-jerk, and often in ankle-clonus. The different types of muscular dystrophies may be distinguished among themselves by marks already given.

Prognosis.—In this disease no hope can be entertained of recovery, and very little of delay in its progress, which in children is infallibly to utter helplessness, with all the intercurrent risks incidental to that state. The best cared-for will generally live longest, but the great majority never attain adult years. In girls the outlook is somewhat more favorable as to length of life. Cases where the disease has not developed till later years have been seen to progress more slowly, and even to come to a standstill before the power of standing and walking was lost.

Treatment.—It is in vain that we look for any drug which will exert direct influence on the diseased processes in the muscles. Tonics, arsenic, cod-liver oil, etc., can only benefit indirectly by improving the general nutrition. In children, as soon as the disease is suspected, or, indeed, in all the children of a family in which any one of the muscular dystrophies has shown itself, a scrupulous and untiring enforcement of all the rules of health with regard to diet, fresh air, and exercise should be observed. Gowers argues with convincing force on the probable benefit of judicious exercise of the affected muscles. The cold mottled limbs would indicate the employment of massage. Electricity, so far, seems to have exerted no beneficial influence. For the contractures so marked in the last stage of the disease, tenotomy is unhesitatingly to be employed. This is especially demanded in the contractures of the calf-muscles, which sometimes occur early in the disease and render walking or standing impossible.

FACIAL PARALYSIS AND PROGRESSIVE FACIAL HEMIATROPHY.

BY CHARLES W. BURR, M. D.,

PHILADELPHIA.

I. FACIAL PARALYSIS.

FACIAL PARALYSIS, Bell's palsy, or mimetic paralysis, is due to injury or disease of the motor portion of the seventh cranial nerve or its nucleus.

Etiology.—Cases occurring at birth are due frequently to pressure of the forceps upon the nerve at its point of exit from the skull; or even if forceps are not used and the labor is normal, though much prolonged, paralysis may ensue. In the latter case it is due to pressure exerted either by the promontory of the sacrum or by the ischiatic spines. A few cases have been reported which were caused by the pressure of intrapelvic tumors.

The causes acting after birth are the same as those which occur in adult life, but the affection is not nearly so common in infants as in older people. The most common cause is cold, which acts by setting up a neuritis—the so-called rheumatic palsy. Ear disease, especially if caries of the bone and suppuration be present, is a common causative factor. It is undoubtedly true, however, that the affection may develop when only the lining membrane of the tympanum is inflamed, without accompanying bone disease. Tumors, meningitis, or fracture of the base of the skull are occasional causes. Surgical operations in the region of the ramus of the jaw are quite frequently followed by palsy due to division of the nerve. A blow in the same region may have a like effect. Certain acute infectious diseases—as, for example, diphtheria—may be causative. Very rarely it occurs in acute infantile spinal palsy. Non-traumatic cases, in which the onset is sudden and the palsy complete, and in which there is no evidence of cerebral disease, must be due to hæmorrhage in the nerve-sheath or Fallopian canal. Gowers has seen two cases, and Wilks and Moxon have found the hæmorrhage after death.

Symptoms.—Often there is preceding pain in the ear or over the entire side of the head, and a slight swelling may be present in the region of the parotid gland. The onset is rapid—rarely, as stated above, sudden. The child may be put to bed well and wake up affected. Usually in from a few hours to a few days the palsy reaches its height. There is ordinarily little or no constitutional disturbance.

In very young children the signs of palsy may be very slight, on account of the greater quantity of adipose tissue, the greater elasticity of the skin, and the smaller muscular development. There may be when at rest only a slight drooping of the angle of the mouth. When, however, the infant cries or laughs, the deformity becomes marked. The affected side remains motionless, the eye cannot be closed, the cheek and ala of the nose fall in and out with inspiration and expiration, and the mouth is drawn strongly toward the sound

side. Most often the tongue and soft palate are unaffected, and the child experiences no difficulty in nursing. Taste may be lost in the anterior half of the tongue on the affected side. The reaction to electricity depends upon the severity of the attack and the time which has elapsed since the onset. In a typical case reaction of degeneration appears after a time. After some months in severe cases, but not in those in which the palsy remains complete, contractures develop on the affected side, making it on first view appear to be the sound side. Examination during movement, however, reveals that the diseased side moves much less. The contracture causes, furthermore, a wrinkle which has no analogue on the sound side. It must be remembered that in some cases only a part of the nerve may be palsied—only the mouth or only the orbicularis palpebrarum—and also that both nerves may be affected.

Diagnosis.—The palsy is unmistakable, and the only question is whether the lesion is central or peripheral. If the lesion be situated above the nucleus, there is never lasting, but sometimes transient, palsy of the eyelid. Emotional movement is less impaired by central disease than voluntary movement. Reaction of degeneration is never present in central disease, and is never absent in peripheral disease unless the palsy be very slight. In the former the reflexes are present, in the latter they are lost. If taste be lost, the lesion is within the Fallopian canal. In disease of the nucleus the orbicularis oris is not affected.

Prognosis is excellent in the cases due to pressure at birth and in those from diphtheria. Gowers justly lays great stress on the prognostic value of the electric excitability of the nerve. If, he says, it is not below normal at the end of ten days, recovery will probably follow in a few weeks. If at the end of a fortnight it is absolutely lost, the palsy will certainly last several months.

Treatment.—The first indication is, of course, to remove the cause if possible. In recent cases, due to cold, hot fomentations should be placed in front of and below the ear. Blisters should be applied over the mastoid process or occiput. Hot baths and free purgation are very useful.

Galvanism is useful when the condition has become chronic. The positive electrode should be placed below the zygoma, and the negative moved gently over the muscles. The least amount of current sufficient to produce muscular response should be used. But little can be done to influence contracture. Daily gentle massage of the face is at least harmless.

II. PROGRESSIVE FACIAL HEMIATROPHY.

PROGRESSIVE FACIAL HEMIATROPHY—also called Neurotic facial atrophy, Facial trophoneurosis, Prosopodysmorphia—is a chronic progressive disease characterized by wasting of the skin, fat, connective tissue, bone, and sometimes, but to a less degree, the muscles of one or very rarely both sides of the face.

Etiology.—The disease, while absolutely rare, is far more frequent in females than in males. Of 92 cases collected by Hermann Steinert, 60 occurred in the former, 30 in the latter, and in 2 the sex was not mentioned. It is most apt to occur in early life. In 29 cases the onset was before the tenth year, 24 began between the tenth and twentieth years, while only 22 occurred between the twentieth and fiftieth years; in 1 the onset was at sixty years. Traumatism seems to exert a positive causal influence, as in quite a number of cases injuries to the face, the jaw, or the head preceded but a little while the first symptoms. It sometimes follows an acute infectious disease.

Symptoms.—The major symptom, wasting, may begin either diffusely or

in one spot, spreading thence slowly, and involving skin, subcutaneous tissue, the muscles mayhap, and the bone. The atrophy is most marked in the bone if the disease begins during the period of active growth. Usually the process stops abruptly at the middle line, making the face look as if it were made up of halves from different people, but it may involve both sides, and even extend, it is alleged, to the shoulder and arm. The skin on the wasted side is thinner and paler. The hair may become simply gray, finer, and smoother, or it may fall out. The alveolar processes waste and the teeth are shed. The lower jaw becomes both thinner and shorter. The orbital fat disappears and enophthalmos develops, but the eyeball is not affected. There is sometimes an associated hemiatrophy of the tongue. Pain and numbness are not uncommon, but anæsthesia is rarely present. Anidrosis, weakness of the carotid pulse, and loss of the power to blush are occasional symptoms. There is never marked difference of the surface temperature of the two sides of the face. The special senses are never affected. There are no changes in the electrical reactions of nerves or muscles. The diseased side in well-advanced cases may produce an expression mimicking the drawn features of old age.

The disease follows a slowly progressive course, sometimes extending over many years, or it may, after reaching a certain stage, cease to progress.

Pathology.—The pathology of the condition remains as yet almost entirely theoretical. Mendel has made one autopsy in which he found an interstitial neuritis of the trifacial from its origin to the periphery. In an atypical case of Horner a tumor was found pressing on the Gasserian ganglion and the trifacial nerve. Taking all things into consideration, it is probable that the future will show that disease of this nerve stands in close causative relation to the affection.

Diagnosis in a well-developed case is easy. The only conditions with which it can be confounded are congenital facial asymmetry due to torticollis, facial paralysis, and facial hemihypertrophy. These need only be named to avoid error.

Treatment has so far been absolutely valueless. On theoretic grounds Dercum in 1891 recommended section of the various branches of the trifacial. He holds that the condition depends not upon failure of trophic nerve stimulus, but upon a radical perversion of that stimulus.

INFLAMMATORY DISEASES OF THE SPINAL MENINGES AND SPINAL CORD.

BY ARCHIBALD CHURCH, M. D.,
CHICAGO.

I. SPINAL MENINGITIS.

SPINAL MENINGITIS is an inflammation of the covering membranes of the spinal cord.

The varieties of meningitis ordinarily described have been somewhat arbitrarily based upon anatomical considerations. As the dura or the softer membranes are principally involved, the terms pachymeningitis and leptomeningitis are respectively employed, but a sharp division is impossible clinically, and is not found post-mortem.

For purposes of description we may consider—1st, Pachymeningitis, or external and internal inflammation of the dura; and 2d, Leptomeningitis, or inflammation of the pia. But inflammation of the inner surface of the dura must from contiguity involve the leptomeninges more or less, so that the conditions are usually associated, and meningitis originally external may finally invade the pia. Association with myelitis is hardly less frequent; mixed forms, therefore, or meningo-myelitis, are common, and are to be classed as the thecal or cord symptoms may predominate.

PACHYMENINGITIS EXTERNA.

Pachymeningitis externa, or external dural meningitis, is due to chronic irritation and inflammatory conditions invading the spinal canal, and is therefore secondary to other morbid states. Thus, vertebral tuberculosis, Pott's disease, abscesses and new growths near the spine, inflammation and purulent collections in the pleuræ, mediastinum, peritoneum, and pelvis, may be the source of the meningeal thickening, which gives rise to symptoms mainly by irritation of the sensory and motor nerve-roots which pass through the area of disease. When the thickening becomes extreme, as it rarely does, it may be sufficient to compress the cord itself and give rise to pressure symptoms and the spastic paraplegia of a cross-myelitis. There is local tenderness over the spine, shooting or constant pains in the distribution of the irritated nerves, twitching of their muscles, hyperæsthesia in their cutaneous areas, which may go on to anæsthesia and muscular palsy if the nerves be sufficiently compressed or inflamed to cause their complete degeneration.

Anatomically, the dura is found hyperplastically thickened, with much adventitious fibrous tissue, and is frequently covered by a caseous or purulent deposit or involved in a new growth. The various findings, of course, depend upon the nature of the primary disease. When the thickening is extreme, the soft membranes are adherent to the dural tumescence and may be indistinguishable. The cord then shows a constriction, and may, in severe cases of long

standing, be very considerably reduced in size at the place of disease, with inflammation and degeneration.

The diagnosis is usually not difficult if the primary disease is recognized. It may be confounded with a myelitis, with which late in the case it is often associated; but the clinical history shows a preponderance of pain, spasm, and irritation, a chronic course, and an early absence of paralysis; while in myelitis the rapid onset, the absence of pain aside from the girdling sensation, and the promptly developed paralytic state with early bladder and bowel symptoms, are distinctive.

Owing to the serious nature of the causal conditions, the prognosis is bad and treatment is practically surgical. The pachymeningitis externa associated with Pott's disease is perhaps the least grave, as the proper orthopædic and surgical management of such cases frequently, in very marked instances, is followed by practical recovery, even when the cord has been notably compressed.

PACHY-MENINGITIS INTERNA.

Pachymeningitis interna, or internal inflammation of the dura, is described as hypertrophic and hæmorrhagic. In reality, these forms are but stages of one and the same process, the thickening and hypertrophy following upon the organization of the hæmorrhagic exudate; and the term hæmatoma of the spinal dura mater has been sometimes used. The condition is a rare one, and usually the cerebral meninges are similarly affected. It is most commonly found in general paralysis of the insane, and consequently is practically unknown in childhood.

The portion of affected dura presents on its inner surface a very considerable thickening, which may be a layer of reddish-brown exudate or consist of a lamination of fibrous tissue, the apparent result of the organization of successive hæmorrhagic exudations, and may attain sufficient size to constrict the cord. The softer, more recent, and reddish or brownish layers consist of fibrin and blood. Its distribution is frequently extensive, but in some instances it is confined to a comparatively short vertical extent of the spinal envelope, and is then more frequently situated in the cervical region. This circumscribed cervical form was first described by Charcot and Joffroy.

Syphilis, trauma, alcoholism, and exposure are regarded as competent causes, and hence it occurs, as a rule, in adult males, though some cases in children are recorded.

The condition is essentially chronic and of slow onset. At first, irritation of nerve-roots gives rise to local pain and hyperæsthesia over the spine and in the peripheral distribution of the spinal nerves of corresponding origin. This is followed, months or years later, by gradual loss of power, atrophy, and anæsthesia in the corresponding parts, and, as compression upon the cord is produced, spastic symptoms appear below, with increased reflexes, rigidity, and paraplegia leading to exhaustion and death. Some cases present stationary periods, and a few recoveries are claimed.

The diagnosis is difficult when a general distribution and cerebral symptoms are wanting. Diseases of the spine, progressive muscular atrophy, cross-myelitis, tumor, and external pachymeningitis must be excluded. An operation may be required to do this, and as it presents, except in syphilitic cases, the best chances of favorably influencing the condition and preventing destruction of the cord, in the desperate situation that is presented and with the courage given by asepsis, it may the more reasonably be resorted to early. Where syphilis is strongly suspected specific treatment should be persistently tried.

ACUTE LEPTOMENINGITIS.

Acute leptomeningitis, or inflammation of the spinal pia mater, is due to infection, usually involves the inner surface of the dura, and extends to the substance of the cord.

Etiology.—The infection of cerebro-spinal meningitis in epidemics of the disease falls sometimes only on the cord, and the infective nature of the attack is obvious. In those cases, however, that are attributed to exposure, “insolation,” rheumatism, and other occult conditions, the infection is less readily comprehended, but in all probability is equally in operation, being favored by the physical conditions mentioned. The association of cases with septicæmia, pyæmia, and other infectious blood-states points to the same conclusion, and in the lymph and spinal fluid of these cases abundant pathogenic organisms have been observed. In some instances the spinal trouble is an extension from the cerebral meninges, the cervical portion of the cord being usually the only part involved. Injuries resulting in traumatism of the membranes by vertebral dislocations, strains, and severe concussions may incite a leptomeningitis over a limited area, from which it may extend or in which an infection may find a suitable field for development. Surgical operations upon the spine and penetrating wounds may afford access to and furnish the infection. Tuberculosis is a common cause, but the resulting meningitis is rather less acute, as is the case to a greater degree in syphilitic inflammation, which has a marked tendency also to remain localized.

Pathology.—The disease is usually of wide extent, the infection travelling rapidly through the arachnoid spaces, and finding in the spinal fluid an excellent medium for its propagation and extension. Congestion of the pia, of the adjoining inner surface of the dura, and of the cord, marked by increased vascularization and an increase of spinal fluid, passes into inflammation, with dulness of the membranes, opacity, thickening, and an exudation of large quantity, varying in color from an opalescent to a puriform, and of corresponding consistency. The microscope shows the diapedic elements of inflammation and often numerous bacteria, including at times those closely resembling the pneumococcus of Friedländer. Tubercles here correspond to their histological and bacterial characters on other serous surfaces. For a time the somewhat resistant pial covering of the cord and nerve-roots protects these structures, and especially in the purulent form of the disease; but usually the periphery of the cord and the roots show the inflammatory invasion, with corresponding changes in the nerve-fibrils, neuroglial framework, and vessels. In cases reaching a convalescent or chronic stage adhesions form between the cord and the dura, obliterating the arachnoid space over more or less extensive areas, distorting the nerve-roots, and sometimes changing the outlines of the cord itself, which, if softening in its substance has taken place as a result of the meningo-myelitis, presents degenerations of its conduction tracts and localized destruction of its gray matter. Large quantities of spinal fluid usually mark these late cases, causing, with the irregular adhesions, a sacculated condition of the dura.

Symptoms.—The abrupt onset of the disease may be preceded by a day or two of malaise and slight anorexia; but sometimes no invasive period is present, and a sharp chill is followed or attended by great pain in the back and darting pains around the body or down the limbs. In children, vomiting or convulsions may be present, and the former is a common symptom. Tenderness is at once developed over the spine, easily detectable, when not prominent, by the use of a sponge dipped in hot water or by sharp percussion with the finger. Spasm and rigidity of the muscles appear at once, causing stiffness of the neck

and back, sometimes notable retraction of the head; fixation of the limbs upon the body more or less marked, with a tendency to flexed attitudes; retraction of the belly from implication of the abdominal muscles; and sometimes difficulty of breathing, by involvement of the chest musculature aside from the dyspnoea, Cheyne-Stokes' respiration, and cardiac symptoms of medullary implication. The cramps in the muscles are painful, and yet tenderness and hyperæsthesia in the limbs prevent manipulations and passive movements. The rectum and bladder are the seat of similar spasms which may cause constipation and retention of urine, with frequent annoying and ineffectual expulsive contractions of these viscera.

Pulse and temperature are fickle, sometimes being subnormal, sometimes increased, and more often divergent; for instance, a subnormal temperature with an accelerated pulse. The lack of uniformity in their range is especially valuable in diagnosis, even when the cerebrum is apparently not involved. A temperature of 103° F. is not uncommon. Vaso-motor paralysis is usually shown by the vivid, persistent, but slowly-developed line which follows every stroke of the finger-nail or similar object upon the skin, and from the same cause the limbs may be congested and even slightly œdematous. At first, for a day or two, reflexes are inclined to be increased, and later may be wanting.

Cases which outlast the acute symptoms develop paralysis, anæsthesia, atrophy, and contractures in proportion as the cord and nerve-roots are affected. Paraplegia may result, presenting the features of a cross-myelitis with bladder paresis, bed-sores, increased reflexes, and spasticity. Symptoms vary with the location of the disease, but its tendency to involve the entire spinal apparatus is marked, and indications of its effect upon all spinal segments are to a greater or less degree present in a majority of instances. Some regions situated in the focus of the inflammatory action show early and emphatic involvement; those at a distance may be disturbed very little; and yet in some purulent cases, where the dural sheath is greatly distended through its entire length with the large accumulation, the pia protects the cord and nerve-roots from infection, so that pressure symptoms alone may be present.

Course.—Some cases terminate fatally within a day or two; others last a fortnight, and may then end fatally or recover. The nature and virulence of the infection are a determining factor, as is the location of the disease—extension upward or early involvement of the high levels of the cord tending to an early fatal issue. Complete recovery is rare, and the conditions resulting from myelitis are of long duration, and may even last a lifetime. The tubercular and syphilitic varieties, as already indicated, less rapidly run their course, and the latter is capable of material modification by treatment.

Diagnosis.—The diagnosis depends upon the rapid onset, the pain in the back, the radiating pains, the rigidity, the increase of pain on voluntary movement, the hyperæsthesia, and the fickle temperature and pulse. From myelitis it is distinguished by the paralysis and lack of pain which characterize the cord lesion, but the frequent association of the two is to be always kept in mind. Hæmorrhage into the subdural space, from the irritation of the nerve-roots, presents very similar symptoms, but is extremely rapid in the onset, usually following traumatism or a strain, and develops meningitis in a short time thereafter. Hæmorrhage into the spinal cord gives instantaneous symptoms and immediate paralysis, and is practically devoid of pain. The rigid form of tetany may present a very close counterfeit, but its long duration, remissions, and amenability to spinal sedatives, with absence of spinal tenderness and shooting pains, and with the possible history of previous attacks and the usual irritability from pressure upon nerve-trunks and arteries, should differentiate it. Tetanus

may be mistaken for spinal meningitis. The early trismus, the excessive hyperæsthesia, the fever of onset, the paroxysms of spasm, and the frequent history of traumatism point the way to diagnosis. Muscular rheumatism and strain present a very superficial resemblance.

Prognosis.—The outlook as to life is always serious and grave in proportion to the acuteness of the onset, to the virulence of the infection, to the implication of the upper portion of the cord, and to the height of temperature. The estimate is also to be guided by the previous condition of health and the age of the patient, children and the aged quickly yielding to the disease. Traumatic and surgical infection is less serious than auto-infection by leucococci. The possibility of the removal of sources of infection cuts some figure as to ultimate results, providing the patient survives the acute stage. The late results, due, for the most part, to permanent changes in the cord, are usually beyond the hope of marked improvement.

Treatment.—Complete and absolute quiet is to be insisted upon, and the patient maintained upon the side or face, if possible to do so without increasing the cramps. The partial knee-elbow position over a mound of firm pillows will often be found very comfortable, and at the same time will afford the best opportunity for local applications. These at first should be strongly counter-irritant, as the thermo-cautery, blisters, or detergents like leeches, vigorous dry-cupping, or wet-cups in robust or plethoric individuals. Should myelitis be associated, less active measures are indicated, and the skin must not be broken or highly irritated, owing to the tendency to bed-sores. A hot bath and pack at the onset with active catharsis have seemed to do good. Sedatives, especially spinal sedatives, are frequently required to control the spasms, and anodynes to relieve the pains. A thorough course of mercurial inunctions over the spine has strong advocates, the quantity used being sufficient to produce slight ptialism. Owing to the reflex irritability, these rubbings must often be impossible, and the therapeutic value of mercury in the acute stage of non-luetic cases is open to question. Iodide of potassium and ergot are also at this time of little or no value. The ice-bag to the spine is one of the most serviceable measures, but is rarely tolerated long by the patient, and its intermittent application is useless. It should always be tried. As the active stage subsides, light cauterizations with the Paquelin apparatus, mild sinapisms applied for six or eight hours, and the hot spray douche seem to assist the reparative efforts of nature. Cerebral symptoms usually mean the implication of the brain coverings, the spinal features become of secondary importance, and the treatment is that of cerebro-spinal meningitis. The paralysis, contractures, and other late results of the myelitis are to be managed in accordance with the rules of practice in that disease.

CHRONIC LEPTOMENINGITIS.

The chronic form of inflammation of the soft membranes is usually the sequential stage of an acute attack, but may follow alcoholism, syphilis, or tuberculous. Its origin as a primary affection is open to some doubt, but a very slowly-developed leptomeningitis may follow concussion, though it is impossible in such a case to exclude immediate slight histological injuries of which the later inflammation is a natural development. The formerly much-used term "chronic meningitis," which was given to every group of obscure subjective symptoms referable, however remotely, to the spine, only needs mention to be condemned.

The symptoms are practically those of the acute form much reduced in in-

tensity, and are dependent upon similar causes. Pain in the back predominates, and spasm is insignificant or absent. The radiating neuralgic pains are especially pronounced, and paræsthesiæ are prominent. Their distribution depends upon the nerve-roots involved and the location of the inflammation, which is much more circumscribed than in the acute form. The late manifestations are those due to neuritis originating in the roots, and myelitic symptoms are comparatively infrequent.

The anatomy of the disease is very little known, as opportunity for post-mortem examination rarely occurs, but a more or less extensive fibrous thickening may be found, and adhesions between pia and dura which constrict the nerve-roots and may girdle the cord. Degeneration of the spinal nerves traversing the lesion is not rare, and this accounts for the herpetic and other cutaneous symptoms of neuritis which are occasionally noted.

The prognosis will be guided mainly by the effect of treatment, but a complete recovery is very rare. Each case must be carefully estimated by itself.

The treatment in syphilitic cases consists in the heroic management of that disease, and iodides and mercury are also the most efficient drugs in non-luetic cases. General measures are of avail, and persistent counter-irritation over the spine is the most valuable local measure. Sometimes rest in bed and the ice-bag to the spine are of distinct value. Sedatives and analgesics are often required.

II. MYELITIS.

Myelitis, or inflammation of the spinal cord, is a generic term covering a condition presenting many varieties of a more or less arbitrary character, depending upon the mode of onset, the portion of the cord involved, the duration of the disease, and the exciting cause. Thus it is acute, subacute, or chronic; transverse, diffuse, focal, disseminated, central, or annular; parenchymatous or interstitial; and compressive, traumatic, secondary, syphilitic, infectious, etc., the adjectives sufficiently describing the modifications. The forms of myelitis constituting the so-called system lesions, poliomyelitis, locomotor ataxia, and other circumscribed scleroses, are described under separate headings. The clinical variations of the disease are multiform. So widely do the several tracts and segments of the cord vary in function that their implication gives rise to the most diversified symptomatology, for the comprehension of which a fair knowledge of the anatomy and physiology of the cord is requisite.

ACUTE MYELITIS.

Acute Myelitis, acute softening of the cord or transverse myelitis, is the most ordinary form, and not a rare disease.

Etiology.—While the disease may appear at any age, it is very rare in children; males from eighteen to forty years furnish the large majority of cases, syphilis, exposure, and muscular effort playing an important part in precipitating the malady. Next to trauma, syphilis is the most frequent cause. Benedict and Erb, indeed, are disposed to assign to the syphilitic cases a clinical entity; but the only variations are those attributable to the infection, the nature of the syphilitic process, and its partial response to treatment in some cases. Lead, mercury, and other chemical poisonings are at times provocative of myelitis. Acute infections, sapræmic and pyogenic conditions, may lead to it, the last sometimes producing an abscess of the cord. Pressure from hæmor-

rhage, pachymeningitis, tumors, fractures, dislocations, and from Pott's disease, very rarely from a thoracic aneurism, may incite it, and it has been attributed to sexual excesses. Wounds of the cord or in the neighborhood leading to infection, minute hæmorrhages in the cord from strains, violence, concussion, and arterial disease, thrombosis or embolism, may originate the softening. Whether concussion unattended by immediate histological injury to the cord is capable of producing myelitis or not is a mooted question, but the growing tendency is to look upon the material and anatomical factors as requisite to its development. The annular form, and sometimes other varieties, are due to extension from a meningeal inflammation.

Pathology.—The inflammatory process may be very slight or absolutely destructive in intensity. If the lesion be examined early, there will be found hyperæmia and swelling of the adjacent pia mater and of the affected portion of the cord. Later, the condition depends largely upon the amount of blood effused; in some instances the disintegration of the cord is such, and the extravasation of blood so considerable, that the gross characters of a clot only are found. In other cases softening is so pronounced that the cord is diffuent and of a creamy consistence and appearance. From the hæmorrhagic element "red softening," comparable to that in the brain, may be found, and this, by the resorption and change of the coloring matter, later becomes yellowish. In time the affected area, through the removal of the fat and the deposition of adventitious fibroid elements, looks grayish and translucent and is shrunken in outline. Thus, after some lapse of time, the cord may be reduced to a narrow filament. In these prolonged cases upward and downward, secondary, sclerotic degenerations in the white column ensue.

Peripherally, the muscles innervated by the involved cord-segments rapidly waste and degenerate, and dystrophic bed-sores are common even at an early stage. Implication of the nerves controlling the bladder frequently results in cystitis, leading to nephritis and uræmia.

Microscopically, the findings vary greatly with the intensity, form, and duration of the disease. When the cord has become entirely disintegrated and diffuent such examinations are of little value. In the mildest forms the vascular changes are the most noticeable, the blood-vessels being widened, crowded with the formed elements of the blood, and the perivascular spaces greatly distended with leucocytes. Minute extravasations are common. The gray substance of the cord is more granular than in health, its cells distorted, swollen, and devoid of processes when the condition is marked. Corpora amylacea and globules of myelin are common. In the white portions increase and alteration in the neuroglia are found. Spider-cells are frequent. The fibres show swelling of the axis-cylinder, and the myelin has a tendency to break up. At points of pressure the fibres are shrunken and may entirely disappear. In the parenchymatous forms the nerve-cells present the principal changes, the intercellular substance and interstitial material showing practically no change, and the vascular condition is less marked.

In cases of long duration both fibres and cells give place, in large part or completely, to an actual increase in the fibrous elements of the interstitial structure, and new fibroid tissue is deposited. The resulting ascending and descending degenerations show sclerotic features similar to those in the system lesions, and sometimes a more active inflammatory process extends a short distance up or down the cord, occasionally following the central canal, which may show dilatation, proliferation of the epithelial lining, and more or less distortion.

The distribution of the inflammation in the cross-section of the cord is

subject to no rule. In some cases it is scattered in random foci, in others confined to a few principal points; or the entire cross-section may be involved, and the gray matter does not, relative to its proportions, seem to be especially selected.

Symptoms.—The onset, except in traumatic cases, is gradual, but in the course of a few hours or days or weeks paraplegia may become complete. Very rarely, and usually only in syphilitic forms and those due to slowly-developed pressure, there are prodromata for weeks or months before the attack, consisting in temporary weakness, tingling and radiating pains; but ordinarily a feeling of numbness and weakness in the legs is experienced, the lower extremities feel heavy and unmanageable: in a few hours they refuse to bear the weight of the body, and in a few days may become completely paralyzed. During the first week the temperature may be elevated a degree or two, but very rarely attains a height of 104° F. Delirium and convulsions have been seen occasionally in children, and more rarely in adults. The reflexes, where directly related anatomically to the affected segments, are lost early and permanently, and below that level are increased after a few days, unless the cord has been entirely destroyed at the inflammatory focus, when they are abolished. Provided the posterior roots and meninges are involved, pain in the back and limbs is a prominent symptom, but rarely is of an excruciating character at the onset. At the upper level of the inflammation some pain is the rule, which gives rise to a band or girdle sensation and a zone of hyperæsthesia about the abdomen or chest. This sign, with the paralysis, definitely localizes the upper limit of the lesion, but if it be in the lower cervical region this sensation passes down the arms and is not so sharply defined. Lesions in the cervical region are also marked by implication of the cilio-spinal centre, with consequent dilatation of the pupil. Continuous priapism is then, too, a usual occurrence, and the intercostal muscles and heart may be affected. Below the lesion, and depending upon its intensity, there are variations in sensibility to all forms of stimulation, from slight blunting to the usually complete anæsthesia. Sensations of drowsiness and aching in the paralyzed and anæsthetic limbs are sometimes mentioned; and cramps and drawing up of the limbs frequently occur early, and later are the rule. Distinct muscular atrophy related to the portion of the cord

Fig. 1.

Showing Flexion, Cross-leg from Adduction, Contractions causing Drop-foot and Bed-sores.

affected takes place, but in the trunk is not readily discernible. The paralyzed limbs during the first few days are abnormally warm, but soon present a sub-normal temperature: sluggish circulation and emaciation ensue, with œdema of the feet and legs if the limbs are left any length of time in a pendent position. If the lesion is low down, the atrophy is a marked feature and the re-

action of degeneration is present. Under the influence of pressure bed-sores form on prominent portions of the body and limbs, and this very early. In some cases within the first week immense sphacelization may take place over the sacrum, which cannot be explained by pressure and the moisture from the urine, but implies a dystrophic condition of cord origin. Bed-sores of this nature are especially liable to form when the lumbar cord is the seat of the disease.

Course.—The onset, as already indicated, is moderately rapid, as a rule, and in the course of a few days the complete picture of paraplegia is presented. Although the case may stop short of this at any point, it may, on the other hand, rapidly progress to the formation of bed-sores, the development of cystitis, and rapidly progressive exhaustion, often terminating in a fatal issue. Non-fatal cases come to a standstill after two or three weeks, and if nutrition and strength are maintained improvement slowly takes place, sensation and motion gradually reappearing and increasing for a year or two. A complete, or apparently complete, recovery is rarely seen. For the most part, secondary degenerations, upward in the posterior columns of the cord and downward in the lateral tracts, cause inco-ordination on the one hand and spastic symptoms on the other—a combination suggestive of ataxic paraplegia, and no doubt sometimes confused with that disease. The implication of the pyramidal tracts leads to the spasms, tremors, and cramps which form such prominent features of these late cases, and gives rise to the spastic gait when walking is pos-

Fig. 3.

Chronic Myelitis, showing station and rigidity, with partial flexion and adduction of thighs.

sible, and to the flexed limbs, adducted thighs, and crossed legs of the bed-ridden cases, as shown in Figs. 1, 2, and 3. In these later stages the condition is often spoken of as chronic myelitis.

Diagnosis.—Regarding the location of the lesion, the best guide will be the upper level of anæsthesia and the hyperæsthetic girdle. After a few weeks increased superficial and deep reflexes occur below the disease, while those reflexes whose arcs are involved in the softening disappear. Thus, if the umbilical or mid-abdominal reflex is absent, those below being present and exaggerated, and a girdle sensation is present just above the navel with anæsthesia below, the lesion is at the tenth dorsal segment and opposite the body of the ninth dorsal vertebra, the guide to which is the eighth dorsal spine. With this the distribution of paralysis should also agree.

The intimate and usual association with myelitis of some more or less localized meningitis is to be constantly in mind, as the obtrusive symptoms arising therefrom may serve to very much embarrass the diagnosis, especially in the beginning, and mislead the judgment as to the future of the case. The nature of the lesion must be determined by a careful study of the clinical history and a careful clinical examination of the patient for spine disease, for neoplasms in other locations, for tuberculosis, for syphilis, and for injuries.

Prognosis.—While the prognosis is always grave as to ultimate recovery, and early in a given case must be carefully guarded as to the probability of a fatal termination, there are certain facts which modify the estimate. A dorsal myelitis is less serious than a lumbar, and very much less than a cervical involvement. The more sudden and complete the onset, the greater the probable damage to the cord. High temperature and early bed-sores are extremely ominous. Serious involvement of the bladder and bowel, implying lumbar cord lesions, are distinctly unfavorable. The reappearance of sensation in the anæsthetic area is hopeful, and usually followed by some return of voluntary motion. When improvement has distinctly commenced, it may be expected to continue for a year, and progresses even two years or more in some instances. Secondary degenerations mean an ataxic paraplegic condition. Myelitis depending upon Pott's disease or upon pressure may reasonably be expected to make a fair recovery if the causal condition can be removed. Indeed, it is marvellous to what an extent the cord may be slowly compressed, and eventually regain functional activity with disappearance of all the paraplegic symptoms. When the myelitis is due to active syphilis or to pressure by a syphilitic neoplasm, some considerable improvement under treatment is the rule, but an absolute recovery the extreme exception. This is especially true when the luetic lesion is confined to the cord itself.

Treatment.—The patient should be put at once to bed, and kept on the side, or, better, when possible, upon the face. This can usually be accomplished by building up a mound of pillows under the thorax and abdomen. In this position the bowels and bladder can be readily evacuated and the patient easily managed. A brisk cathartic should be administered and the bladder carefully watched, the catheter being avoided as long as possible, and used under the strictest rules of cleanliness when finally it is necessary. The tendency to retention of urine, with cystitis, and its unfavorable significance, cannot be too much insisted upon. To the spine counter-irritation with mild sinapisms is desirable. Here the dystrophic tendency must be borne in mind, and blistering or severe irritation below the line of inflammation absolutely avoided. A mustard plaster four inches wide and two feet long, made of one part mustard to ten of flour and thoroughly mixed, can be applied for hours and with benefit. The use of ergot and other drugs to control the circulation is of doubtful value, but may be tried if the stomach is tolerant. The mechanical causes of the disease must be met surgically. When present, except in syphilitic cases and Pott's disease, nothing but operation promises any reason-

able relief, and operation under strict aseptic methods adds practically nothing to the gravity of the situation. When bed-sores appear or the tendency to their formation is marked, a water- or air-bed kept at a proper temperature is useful, but, unfortunately, is rarely available. Great care to protect the skin from discharges and uncleanness of all sorts, with frequent applications of alcohol and unirritating dusting powders, and repeated changes of position, will do very much to obviate these dangerous complications. After ten days or two weeks systematic passive movements, massage, and the use of faradic electricity should be adopted to prevent the wasting and tendency to contracture. When, later, the contractures may be very prominent, splints should be employed. As sensation and slight voluntary motion return, a carefully guarded system of mild exercises should be instituted. The intelligent use of the faradic wire brush to the anæsthetic parts sometimes is of distinct benefit in hastening sensory improvement, which in turn is usually followed by more or less volitional activity.

Some syphilitic cases yield promptly to large doses of iodide of potassium and mercury, and nearly regain the condition of health. A certain residuum of impairment is always left, however, when the cord has been actually invaded. Other cases fail to respond to this line of treatment even when heroic doses are employed. One should not be satisfied in an adult to stop short of an ounce of iodide a day if smaller doses fail to make an impression, and by guarding the stomach with Vichy and the bowels with bismuth this can usually be accomplished without much difficulty. In children the dose must be proportioned to their age.

The bladder and bowel, except when the lumbar centres are destroyed, tend to regain some power and control, which can be assisted by rendering their contents unirritating and by encouraging regular habits regarding their evacuation, with the use of faradization to strengthen the sphincters. Everything conducing to the general healthy tone of the individual assists directly and indirectly the local disability.

CHRONIC MYELITIS.

Chronic myelitis is usually the terminal stage of an acute softening, and but very rarely, if ever, is a primary condition. Its separate consideration is only warranted by the fact that it is often mistaken for primary spastic paraplegia, for ataxic paraplegia, rarely for locomotor ataxia, and that its treatment requires description. Its diagnosis depends on its long duration and the history of an acute, or at least tolerably rapid, onset, on the involvement of bladder and bowels, on the paraplegic distribution of sensory and motor deficiency and wasting, on the absence of pupillary symptoms, lightning pains and inco-ordination, on the presence of rigidity, increased reflexes and contractures, and on the evidence of old bed-sores.

The treatment consists practically in the use of everything that will elevate the general tone; in guarding against bed-sores, cystitis, contractures, and wasting; in the use of massage, electricity, hot and cold spinal douches, and counter-irritation in the form of flying blisters and the thermo-cautery; in operation for pressure conditions from tumor or bone; in appropriate suspension and fixation in Pott's disease; in the persistent use of antisyphilitics in luetic cases, and in operation when these do not succeed or a gummy tumor is reasonably suspected. Exercises to develop the impaired muscular power, passive movements, and volitional efforts against resistance are valuable. The sphincteric paresis can also be improved by the passive and active movements

recommended by Brandt in prolapsus uteri, which serve to strengthen the pelvic floor, and consist for the most part in having the patient adduct and abduct the flexed thighs while lying on the back and raising the pelvis from the bed, the motions being resisted by the attendant. Continued and often-repeated voluntary attempts to contract the sphincters, as in restraining fæces, should be encouraged. Late in the disease, when it has become stationary, tenotomies and appropriate apparatus may enable an otherwise bed-ridden patient to get about. The tendency toward some improvement during the first two or three years should be kept in mind, and everything done at this time to assist the reparative efforts of nature.

ACUTE ANTERIOR POLIOMYELITIS.

BY ARCHIBALD CHURCH, M. D.,

CHICAGO.

ACUTE ANTERIOR POLIOMYELITIS, also known as myelitis of the anterior horns, atrophic spinal paralysis, infantile paralysis, or the essential paralysis of children, is a febrile disease the activity of which falls upon the anterior horns of the gray matter of the spinal cord; it is marked by rapidly developed and extensive paralysis, a portion of which remains permanently, and is usually followed by atrophy of muscle and often by non-development of bone, and by deformity.

Etiology.—It is a disease almost peculiar to childhood, and, though cases occurring in adult life have been recorded, it is probable that many of these late instances have been cases of peripheral neuritis, the diagnosis of which has only of late years been generally made. The great majority of cases occur before the tenth year of age, and three-fifths are encountered before the fourth year, being equally divided for the first three years of life. As it is comparatively rare during the first six months, the latter half of the first year of life is therefore the most susceptible period. The coincidence of the first dentition at this time has given an altogether undue importance to the rôle played by the eruption of teeth as a probable cause. At one time exposure to cold was considered an active etiological factor, but Sinkler of Philadelphia found that over four-fifths of all cases occurred during the hot months from May to September inclusive, with a heightened frequency during the hottest months, July and August. Heat may therefore be considered as a predisposing or favorable condition for the evolution of the malady. It is to be remembered, however, that slight colds among children are as frequent in warm weather, from draughts when lightly clad, as in winter. In nearly every case the history of a fall or blow of some sort is brought forward by the parents, too frequently resulting in casting unmerited blame upon the nurse or others in charge of the child. It must, of course, be admitted that a concussing force applied to the spine might lower resistance to the disease, but there is no good reason for attaching great weight to slight traumatism. In a numerous list of instances the disease is said to have followed acute diseases, such as the exanthemata, but in many such cases the initial fever of the poliomyelitis was probably mistaken for some other complaint, and a careful study of these reports reveals such a lack of detail that they must, as a rule, be accepted with caution. In others the original ailment is stated to have been obscure or atypical, and as a matter of fact the diagnosis of anterior poliomyelitis is very difficult during the initial fever, and, until paralysis is apparent, differs but little from the febricula of indigestion or other slight ailments.

Pathological Anatomy.—It is only since 1865 that the lesion in this disease has been known. In that year Provost thoroughly described it, and his findings have been invariably confirmed by workers in this field. Owing

to the fact that only rarely does death occur in the very early stages of the disease, or is then attributed to other causes, the initial appearances and conditions are practically unknown, but can from later observations be fairly well indicated. As a rule, the anatomical changes are limited to the anterior horns of gray matter, only involving the neighboring white tracts of the anterior and lateral columns by the extension of the inflammatory or hæmorrhagic processes which take place in the cornua, and which result in a softening and disintegration of their elements. The large motor and trophic cells either completely disappear or only a few shrunken representatives are left; in milder cases slight alterations in the cells alone are found. Later, from the shrinkage of the neuroglial tissue and from the deposition of other fibrous elements, a depression is found in the implicated part of the cord, and granular disintegration of the involved nerve-elements is present. When the pyramidal tract is involved, descending degeneration may take place, though this is uncommon, and when present is usually slight in transverse extent. The muscles depending for innervation upon the affected cornual cells rapidly waste, and the sarcode elements in extensive cases entirely disappear, nothing but the fibrous tissue being left. In less-pronounced cases individual fibres or groups of muscle-bundles are destroyed, or sometimes merely a diminution in size is found; and rarely isolated muscular fibres are encountered which show a true hypertrophy, probably of a compensatory character. Where the bones are affected, they are smaller, smoother, less well marked by muscle insertions, more compact, showing less cancellated structure, and are consequently more fragile.

The peripheral nerves arising from the affected anterior horns show degenerative changes of a corresponding degree. Sometimes in extensive cases nothing but fibrous cords are left, but usually all the fibrils are not destroyed, the cross-section of the nerve-trunk showing many normal elements. This, of course, is to be expected, as the sensory fibres which enter the cord by the posterior root are not implicated in the central lesion; but the same is true of sections of the anterior roots close to the cord, and the sympathetic fibres in the anterior roots also escape. Examinations of the brain are usually negative. In some extreme cases of extensive peripheral distribution of long standing the corresponding cortical motor area has been found smaller or undeveloped.

A number of cases are on record in which an acute polyneuritis has apparently coincided with the spinal attack, but these cases require more study, and the presumption is that the tenderness in the nerve-trunks in such cases is due to the degenerative process in the motor-fibres and the attending irritation of the adjoining sensory bundles which furnish the *nervi nervorum*.

Pathology.—The acute onset, the short duration of the fever, its comparatively uniform range, and the immediate paralysis point to a systemic infection, or, to adopt the expression of Gowers, “a blood-state,” which finds its local expression and its anatomical manifestation in the anterior spinal gray matter. The elective action of certain drugs upon the spinal centres leads naturally enough to the supposition that a ptomaine or leucomaïne might have a similar selective tendency, as, for instance, that of diphtheria is known to have for the peripheral nerves, or of hydrophobia for the central apparatus. This idea receives some support from instances in which more than one case occurred at the same time in a given family; and several practical endemics of the disease are on record. The whole question is yet undecided, but the infection theory would seem to be the best working hypothesis.

Symptoms.—Usually without apparent provocation the child is found to be feverish and ill. A temperature of 100° to 102° F. has been frequently noted, and this febrile invasion-stage lasts from a few hours to a few days, when

paralysis and flaccidity of one or more limbs are detected. It is not rare, however, for the child to go to bed apparently well and to awake paralyzed in the morning. The febrile movement may be attended by vomiting and diarrhoea, by convulsions of a generalized character, or by delirium and diffuse cerebral manifestations. As soon as the paralysis is noted the case is usually recognized. Most writers state that rarely there is a complaint of pain in the afflicted members, but the rule is that sensation in all its phases is entirely normal. It is probable, however, that early dysæsthesia, owing to the age of the patient and a lack of careful search for such difficulty, has been many times overlooked. In some considerable number of cases during the initial fever handling of the affected limbs provoked outcries, which were not elicited by similar manipulation of the other members; and it is likely that more attention in this direction will show localized hyperæsthesia or some kindred state to be usually present and of diagnostic importance. Indeed, complaints of pain and formication have been generally noted in cases of a comparatively advanced age,

FIG. 2.

Anterior Leg Type, with Drop-foot.

FIG. 1.

Leg Type, with Marked Calcaneus.

leading perhaps undue weight to the supposition that such cases are not of a true spinal type. The sphincters are almost never relaxed, so that control of the bladder and bowel remains unimpaired, but in the rare cases in which these sphincters are relaxed there is more or less apparent loss of sensation, the extent of the lesion is greater, and the prognosis is extremely unfavorable.

Even in fat children the implicated muscles can be seen, after a few weeks, to have wasted, and, if tested with the faradic current, either do not respond at all or show a remarkable diminution in their excitability. At this time the patient will have begun to show considerable improvement, the motor paralysis remaining complete only in the parts that are to permanently suffer, and a gradual improvement may be reasonably expected to extend over several months. In the muscles showing lessened faradic excitability galvanism produces exaggerated responses as compared with the sound limbs; and the complete reaction of degeneration or any modification of it may be encountered. In a well-marked case faradism fails by the tenth day, and the galvanic increased response appears, lasting for about six months, when it gradually fails. At this point faradic excitability returns, and the muscle regains something of its size and strength; or, if too seriously impaired, faradic response does not reappear, galvanic response disappears, and the muscle is irretrievably lost.

The reflexes are lessened or abolished in proportion as the muscles which are anatomically associated with them are involved; or perhaps it would be better to say that their alteration depends upon the implication of the cornual

cells making up a part of their arc. Bones which have not attained their full growth are retarded or fail entirely to develop if their trophic centres are implicated.

The seriously atrophied muscles become unyielding fibrous bands; and since they offer to the synergic and antergic muscles neither assistance nor opposition,

FIG. 3.

Shoulder and Arm Type (Kindness of Drs. Ridlon and Jones).

distortions soon develop with joint-changes and sometimes subluxations. Joints which depend upon muscular support, as the shoulder, may allow of so much deformity by the relaxation of the muscles which have lost their tonicity that the articular surfaces widely separate. The skin is inactive, often cold, and sometimes dry and scaly, but the atrophic conditions so usual in neuritis are practically absent, and bed-sores are almost unknown.

The distribution of the permanent paralysis and wasting is characterized by non-conformity to any type, and the resulting deformities are therefore of all grades and descriptions. The lower extremities are affected about three times as frequently as the upper, and the left leg twice as often as the right. A crossed form, in which the upper extremity on one side is involved with the opposite lower limb, is not rare; but involvement of both limbs on the same

side is extremely uncommon. In the lower extremity the extensors seem more susceptible than the flexors; hence drop-foot, with equine talipes, flexed knee, and flexed thigh are common. When the paralysis is below the knee the sural muscles usually escape. In the upper extremity the most frequently encountered wasting is in the small muscles of the hands, the deltoid, and the extensors of the wrist—the biceps and supinators generally escaping. For the most part, the central lesion is confined to the cervical and lumbar enlargements; consequently the body muscles usually are spared, and involvement of the cranial nerves is so rare as to always raise a doubt regarding the diagnosis.

Course.—The course of the disease may be clinically divided into (1) a stage of febrile invasion, lasting from a few hours to a few days, with local tenderness and rapidly developing and increasing paralysis; (2) a stationary stage, lasting for several weeks; (3) a period of improvement, lasting to the end of the year; and (4) a stage of permanent disability for the remainder of life. Relapses during the early weeks have been recorded in very rare instances, and second attacks are still rarer. Among the sequelæ the spastic contractions, dislocations, and deformities have been already mentioned. The fragility of the bones makes them liable to fracture, but union takes place with ordinary promptness under proper fixation.

Diagnosis.—In the early stages of fever, before paralysis has appeared, the diagnosis is usually missed except under rare epidemic conditions, and the termination of an apparently trivial ailment in extensive paralysis is frequently the cause of much chagrin on the part of the medical attendant, who may have expressed, naturally enough, a favorable prognosis. As already indicated, the initial fever may be readily mistaken for that of general disorders, and sometimes, though rarely, the pain in the limbs leads to the idea of rheumatism. If, however, the possibility of anterior poliomyelitis be in mind, and examination discloses some slight local tenderness or diminished muscular activity, or both, a guarded opinion will naturally follow. It is only when the paralysis is developed or is developing that the nature of the disease becomes certain, and even now, if there have been cerebral symptoms, such as delirium or convulsions, difficulties are not at an end. The cerebral palsy of children is almost invariably ushered in by convulsions, but these have a definite distribution involving one side or one limb, or only the face, while the convulsions of the disease under consideration are generalized. Localized pain from traumatism or inflammation may cause immobility of a limb, and when preceded by a fever gives rise to doubt; but the usual, indeed, almost invariable, absence of extreme sensory troubles in disease of the anterior horns is a distinguishing feature, while the local conditions can be otherwise made out. After a few days the electrical test gives absolute data. Faradic response is abolished in no other disease so early; even in severe neuritis it is longer maintained, and is then attended by a very marked sensory disturbance, which also usually precedes it for a long time. A few careful applications of the induced current at this period can do no harm. Diphtheritic palsy presents the history of the throat affection, and the involvement of the palate and muscles of visual accommodation is distinctive.

Prognosis.—As far as life is concerned, this disease terminates fatally very exceptionally, and if the patient survives but a short time the onset of the paralysis, life may be considered out of danger. Further, one can say with a reasonable degree of certainty that the paralysis at first developed will notably recede, but, unfortunately, it is equally certain that a portion of it will permanently remain. At the end of a fortnight a carefully conducted faradic examination of the muscles enables the physician to speak more specifically

regarding the amount of permanent disability. At that time any muscle which responds, however feebly, may be expected to regain a fair degree of its former tone and strength, while those that do not respond even to strong currents are not necessarily beyond hope of slight improvement. Even after several months faradic stimulation, at repeated intervals, of a, at first, perfectly inactive muscle may develop some contractility, and this is of favorable import for the given muscle. The extent of permanent paralysis governs the amount of resulting contracture and deformity; and likewise the retardation of development of the limb and of the bones is in similar relation. The anticipated amount of these deforming conditions will have a bearing on the probable general activity of the individual, his prospective physical health, and liability to fractures. Finally, the outlook is modified by any cachectic state, as tuberculosis, rickets, or syphilis.

Treatment.—Owing to the irregularities of the course of this disease in various cases, and its natural tendency to improve up to a certain point, it becomes a matter of great difficulty to estimate the value of any therapeutic agent or mode of treatment. In the early stage, as soon as the diagnosis is made—and that is usually as soon as the palsy is recognized—if fever still continues there is good reason to suppose that antipyretic antiseptics like the salicylates, or even bichloride of mercury, would do good. To the spine hot applications can be made if the circumstances of the patient will assure their intelligent and faithful employment; otherwise they are worse than useless, and very mild sinapisms can be more properly used. The child should be kept on the side or face, and the affected limbs should be thoroughly enveloped in cotton-wool to maintain the circulation and the nourishment of the muscles in the parts laboring under diminished trophic influence. The use of stimulants like strychnia or electricity while the lesion is active is to be strictly avoided; but when the active process has come to a standstill—that is, ordinarily at the end of a fortnight—the systematic use of electricity is one of the most important measures. Its object, however, should be thoroughly understood, and some occult influence on the central lesion or the peripheral nerves should not be expected of it. Its usefulness consists in maintaining the nourishment and normal contractility of the muscles which are temporarily deprived of their natural trophic and motor control, so that, as the inflammation subsides and the widespread inhibitory effect of the local lesion recedes, the central apparatus may find the muscular periphery in the most favorable state to respond to its enfeebled influence. For this purpose, as faradism is early abolished, the interrupted galvanic current must be used, the slightest intensity being employed that will cause a contraction, and care must be exercised not to unduly fatigue the muscles. A dozen contractions at most should be elicited at one séance, and often only one or two can be provoked by a strength of current that is bearable. Care not to alarm the child is imperative, as a daily struggle will probably do more harm than the electricity will do good. It is well to commence with dry or wet sponges alone until the young patient is accustomed to the manipulation. As the muscles often react better and with less pain to the positive pole than to the negative, it is well to have for the negative electrode a broad sponge which can be placed on the sacrum or breast, and with a smaller positive sponge the muscles can be exercised. Applications of galvanism through the cord are quite useless, and even if such currents reached the lesion, which is doubtful, their effect for good is questionable.

Later on, as faradic response returns in the muscles only slightly affected or temporarily inhibited, this form of electricity is efficacious for the purpose of local stimulation, and the presence of this reaction in any muscle is always, as

already indicated, a gratifying circumstance. To entrust electrical treatment to the parents, however intelligent they may be, is a mistake.

In the same way, local frictions and salt baths, warm wrappings, and massage are valuable measures which can be more rationally entrusted to parents or nurses who take an intelligent interest in the work. The moment a group of muscles weaken, the limb tends to assume an abnormal position, and it is very highly important to meet this tendency from the very first moment, even in cases where there is every probability that the paresis will recede. It can be easily accomplished by means of the warm wrappings, or even by the application of light apparatus. There can be no question that recovering muscles will find their task much easier if their proper relations have been maintained, and unbalanced muscles will be much less liable to contractures if an artificial balance has been provided and joint surfaces have not been altered by vicious positions long maintained.

As soon as the permanent paralysis can be fairly well foretold, massage should be especially directed to obviate the contractures and deformities that ordinarily result, as indicated by the anatomical knowledge of the physician. Stretching of the unopposed muscles by passive movements of the joints will accomplish much, and the moment a tendency to contracture is perceived the case becomes one for permanent mechanical appliances. The tendency to equine talipes, for instance, can be met by a slight elastic cord from the toe of a shoe to a band at the knee; and more elaborate orthopædic apparatus should be employed at the knee and hip if required. These cases are, therefore, practically orthopædic troubles from the very first.

Nearly all the improvement that is to take place in the muscles will have developed by the end of the first year, and what is slowly gained subsequently in this direction is quite independent of any treatment whatsoever.

The treatment of a late or neglected case is practically surgical. Shortened tendons may be cut and joints straightened. A resection at the knee is sometimes of advantage to secure a straight limb instead of a useless contortion or a dangle leg; by using a high shoe or other appliance crutches may often be laid aside. In some of these cases electricity also does good. Though the first few applications to the paralyzed muscles may show no response, slight contractions not infrequently appear later, and voluntary control soon follows—weak, to be sure, but in proportion to the amount of muscular tissue undestroyed, and better by far than no motion whatever.

The local hypodermatic use of strychnia has had many advocates, not only in these late cases, but also in the early treatment. As any results to follow its use depend upon its stimulating action on the spinal centres and upon its general tonic value, the hypodermatic method is, in the case of timid children, the cause of useless pain and often of harmful mental excitement.

The arrangement of exercises to increase the strength of the involved muscles which retain some fraction of their muscular elements is of distinct advantage, and must be devised to meet the requirements of each case, but no elaborate apparatus is necessary. By passive and active movements and effort against resistance everything of this sort can be accomplished. Underlying systemic conditions like rickets, rheumatism, syphilis, tuberculosis, and bad hygienic surroundings of course require early and suitable attention. A fatty dietary, and particularly cod-liver oil, is often distinctly valuable.

SUBACUTE AND CHRONIC ANTERIOR POLIOMYELITIS.

Analogy to other febrile and inflammatory conditions would lead one to the expectation of encountering subacute and chronic forms of poliomyelitis, but

there are many who apparently doubt their entity or classify such instances under other headings. Though Gowers devotes several pages to these forms in the latest edition of his *Diseases of the Nervous System*, the impression conveyed is one of uncertainty as to their existence and discredit as to the cases reported under this caption. Other recent systematic treatises make no mention of the subject, except the description of the classic form of progressive muscular atrophy of the spinal variety. Cases, however, are encountered presenting every gradation between the sudden acute form and the pre-eminently chronic variety which produces our dime-museum "living skeletons."

In some instances there is a gradually developed weakness in one or more limbs, without or with an initial fever,

FIG. 4.

Chronic Anterior Poliomyelitis.

and the palsy increases slowly for several weeks. After a stationary period of considerable duration it recedes, and only a trace is permanently left. In others the paralysis, insidious in its onset, goes progressively forward, involving limb after limb and producing conditions indistinguishable, as regards gross appearances, from those of progressive muscular atrophy.

Of the milder forms the following case is an example: A child of three, of healthy parentage and living in fairly good surroundings, active, bright, and lively in disposition, was noticed to have difficulty in getting up and down the stairs. Two weeks later she was unable to rise from the floor except by drawing herself up with the aid of her hands; she could not walk, and the lower extremities would quickly give way under her. The hands and arms then became slightly affected. A

month later the symptoms commenced to recede, and, a year after, nothing was left but a little wasting of the anterior tibial muscles with slight quantitative electrical changes. There has been no absolute loss of faradic excitability at any time, no pain and no tenderness.

Of the chronic forms, the case figured in Fig. 4, from a photograph, is an instance: A boy of fourteen years, with no family or personal history of significance, at the age of six had an attack of "malarial fever" (?) lasting several weeks, and then could not use his legs or even stand. He gradually improved and after a year was quite active, when his muscular power again became impaired in the legs. Atrophy and weakness have steadily progressed to the trunk, neck, and upper extremities, with numerous contractures. He is able, however, to use a bicycle and get about on crutches. Many muscles fail to respond to all currents, some show only quantitative changes, and some comparatively recently affected show the reaction of degeneration.

Perhaps some cases of pseudo-hypertrophic paralysis should be classed in this place.

Diagnosis.—From neuritis the distinction is confessedly difficult, especially from that variety of neuritis which involves mainly the motor filaments, and

is not marked by the dysæsthesia and sensory difficulties, usually of importance and prominence in the history and differentiation of the peripheral disease. It is not unlikely that many reported cases of subacute poliomyelitis have been mistaken in this way.

Treatment is practically futile in the progressive form, but those measures which commend themselves in chronic myelitis should be faithfully tried, and local measures, such as vigorous massage and electricity, have produced temporary improvement. In the subacute variety these measures seem to be distinctly productive of good, and what has been said of the prevention of contractures and deformity in the acute form of cornual disease may be reiterated.

LANDRY'S PARALYSIS.

BY ARCHIBALD CHURCH, M. D.,

CHICAGO.

THE obscure paralysis known, since Landry's description of it in 1859, by his name, and designated "acute ascending paralysis" by English writers, while presenting a striking clinical entity in typical cases, shades off materially from early descriptions in many instances more lately observed. It may be roughly described as an acute disease marked by paralysis commencing in the lower extremities, usually in the feet, which progresses steadily upward, involving the trunk, upper extremities, the neck, until finally deglutition, respiration, and the heart are implicated. There is slight or no modification of sensation; the muscles do not rapidly waste nor usually lose their electrical excitability and myotatic response; the sphincters are exempt; bed-sores do not occur; and the temperature is frequently normal throughout the attack. In cases that recover the parts last and least affected soonest regain power, and improvement, therefore, extends from above downward. Fatal cases terminate by respiratory or cardiac failure in from one to two weeks.

Etiology.—The causation of Landry's paralysis is practically unknown. It occurs in men more frequently than in women, and most frequently between the ages of twenty and forty. In children it has been recognized very rarely. It is known to follow infectious diseases which are provocative of neuritis. Exposure to cold, and very rarely trauma, alcoholism, and syphilis, have preceded it.

Pathology.—In some well-marked cases the most thorough examination of the cerebro-spinal apparatus by competent pathologists has failed to discover the slightest abnormality. Several cases have presented a diffuse myelitis; one or two, a cross-myelitis; a few, well-marked neuritis, and some have shown changes both in the spinal cord and in the peripheral nerves. No constant lesion is present. In some instances there has been pronounced swelling of the spleen, pancreas, and mesenteric glands.

The frequent lack of anatomical findings, the onset and course of the disease, its relations to antecedent infectious maladies, such as typhoid, small-pox, influenza, etc., and its close resemblance to multiple peripheral neuritis, with which, indeed, a large number of observers consider it identical, lead to the almost positive conviction that it is the result of some infection or toxine. Bacteriological investigation has thus far been inconclusive, though highly suggestive.

Symptoms.—Generally without malaise, fever, or premonitory symptoms, usually without tingling, numbness, or other sensory disturbance, a feeling of weakness begins in the feet and legs, and slowly creeps upward, becoming more and more pronounced in the lower levels as the disease mounts. At the end of two or three days or a week the lower extremities are completely paralyzed and the weakness has involved the trunk and upper limbs. The breathing becomes

superficial from involvement of the diaphragm, and difficulty of swallowing soon appears. In severe cases every voluntary muscle below the face is completely paralyzed and relaxed. Cerebral and mental symptoms are absent until the dyspnoea or cardiac failure is pronounced and induces them. The sphincters are, as a rule, not relaxed; there is no tendency to bed-sores or dystrophy; the tendon and superficial reflexes are usually present; the electrical responses are normal; and sensation, together with the special senses, is not perverted. If a fatal issue do not occur, the symptoms of paralysis slowly recede in the reverse order of their appearance, and when they have distinctly subsided from the upper levels recovery may be anticipated.

In some cases the onset is reversed, the upper extremities first showing weakness; and, indeed, the ordinary type may be infinitely modified, as can be readily understood from the varying anatomical distribution of the organic lesions in well-authenticated observations. In one case falling under the writer's attention, where the clinical history was typical, complete wasting of isolated muscle-groups in all four extremities occurred, and was persisting four years later, without any appearance of ultimate improvement. Paræsthesia and dysæsthesia are not rare. Loss of reflexes has been noted. The progress of the paralysis may stop at any point, and then recede. A temperature of 101° to 103° F. has been rarely observed, but as a rule it does not rise above the normal.

Course.—The course from inception to fatal termination may be very brief, less than two days, and fatal cases usually end within ten days. Prolonged cases may only reach their acme in a month. After a stationary period of varying length in the hopeful cases, improvement takes place usually in a retreating order, but convalescence is slow and may require months. On the other hand, it may be rapid, or, as in the case mentioned above, permanent injury may result.

Diagnosis.—The diagnosis in some cases must necessarily be extremely difficult, but in the typical form is readily made, providing the existence of this rare disease is kept in mind. It rests upon the method of invasion, the pure motor paralysis, the negative conditions as to reflexes, sensation, and electrical reactions, and the history of some possible toxæmic state. Some cases are complicated by hysteria, which is capable of greatly obscuring the diagnosis. When slight electrical changes and paræsthesia are present, it is impossible to exclude neuritis, and the integral character of the peripheral disease in some instances has already been pointed out. In general myelitis we have all spinal cord-functions involved. In meningitis the pain and rigidity are distinctive.

Prognosis should always be grave, since even in the irregular and prolonged cases one cannot foretell at what moment bulbar symptoms may appear, and the main danger to life depends on their presence. Rapidly-ascending symptoms imply a speedy termination, but there is no invariable rule. Only when the tide has turned and symptoms are receding can one entertain a reasonably hopeful prognosis. The presence of neuritic conditions or of electrical changes implies a prolonged convalescence and some doubt as to ultimate recovery. Where cerebral symptoms appear, they are of bad import, signifying either profound toxic conditions or the near approach of death from cardiac and respiratory failure.

Treatment will be directed against any general toxic condition present or reasonably suspected. The salicylates, tincture of the chloride of iron in full doses, bichloride of mercury to the point of toleration, thorough cleansing and disinfection of the alimentary tract, supportive diet, conservation of nervous energy and strength, are valuable. To the spine a narrow sinapism the whole

length of the back, frequently repeated, is of service ; even the thermo-cautery is advised by some. Full and frequent doses of ergot or ergotine have strong advocates. The paralyzed limbs should be gently massaged to improve circulation and give comfort. When swallowing becomes difficult or impossible, feeding by the stomach, nasal, or rectal tube must be adopted, and the preference is for the nasal tube, providing care be exercised to avoid passing it into the larynx. During convalescence massage, electricity, local douches, tonics, generous diet, and general measures are the main reliance.

TUMORS OF THE SPINAL CORD.

By JAMES HENDRIE LLOYD, A. M., M. D.,

PHILADELPHIA.

UNDER the head of Tumors of the Spinal Cord will be considered tumors not only of the cord itself, but also of its enveloping membranes. The latter are the most common. Tumors originating in the bones of the spine, if they make pressure upon the cord, are very similar clinically to tumors of the membranes, but they are exceedingly rare.¹

Tumors of the spinal cord and its membranes are comparatively rare at all ages, but they are not unknown among children. Thus in a table of 50 cases of cord-tumors analyzed by Dr. Mills and the author, 14 per cent. were in patients under twenty years of age. Four were in the first decade of life, and three in the second.

Etiology.—The causation of tumors of the spinal cord is usually very obscure, just as it is for tumors of other parts of the body. The nature of these growths, as will be seen, varies, and the causes that produce them vary as well. Syphilitic and tuberculous tumors are of course caused by their respective infections in the blood and tissues. Carcinomata and sarcomata have here, as elsewhere, a totally unknown essential cause. Gliomata and myxomata are equally obscure in origin. The gliomata originate always in the neuroglia, and are probably the product of a proliferation of germinal tissue which has remained in an embryonal state. They are most apt to occur in the central gray matter and in the posterior gray commissure in the neighborhood of the central canal. In this region they break down and form cavities to which the term "syringomyelia" is applied. As this process is now recognized as a distinct disease, it has been described apart. Other cysts, simulating tumors, may be caused by small hæmorrhages, and possibly by emboli. Parasitic growths, such as echinococcus, have been found in the spinal cord.

As a direct exciting cause trauma has been regarded by many as not infrequent. Where there is predisposition to a cancerous growth or a syphilitic deposit it is possible that trauma may so act. Exposure to cold, sexual excess, and overwork have probably nothing to do with the origin of tumors of the cord.

These growths are apparently about equally divided between the sexes. In the table already referred to it is seen that 22 cases occurred in males, 21 in females, and in the remaining 7 the sex is not recorded.

Symptoms.—The symptoms of tumors of the spinal cord may be conveniently classified according as they are sensory, motor, trophic, visceral, and intracranial. They may then be grouped according to the level of the cord at

¹ Mr. Wright of Manchester removed a fibro-sarcoma of the neck which had invaded the spinal canal by way of one of the intervertebral foramina, causing pressure symptoms. (Reported by Thorburn, *Surgery of Spinal Cord*, p. 168.)

which the tumor occurs. This twofold plan will be adopted here for the sake of both clearness and brevity. Finally, a comparative study of symptoms will be made under a separate head for the purposes of diagnosis.

It is doubtful if a distinction can always be made in diagnosis between the meningeal and medullary growths. In some cases, however, this may be possible. The tumors springing from the membranes are more likely to cause pain as an initial and persistent symptom than are tumors within the substance of the cord. They cause pressure symptoms later. It is probable, too, that the early symptoms caused by them are more distinctly local, because they press upon and irritate or destroy a comparatively small area of the cord at first.

The sensory symptoms of all tumors of the cord and its membranes are sooner or later conspicuous. Pain, as has just been said, is common. This pain may be limited in the early stages to one or few nerve-trunks, in one of the limbs or in the abdomen, for instance, simulating neuralgia, or it may radiate from the spine in association with stiffness of the muscles of the neck or back. It is often an urgent and distressing symptom. Hyperæsthesia, which is closely allied to pain, may appear in the course of the disease. In cases in which the lesion is unilateral this hyperæsthesia may exist in the paralyzed side: in other cases its distribution is variable and its duration uncertain. Hyperæsthesia, and especially pain, may exist along the spinal vertebræ, and localized pain may sometimes be elicited by tapping vigorously on the spine at and near the seat of the tumor. Paræsthesia, or perverted sensibility—as, for instance, burning and pricking sensations and formication—is closely allied to hyperæsthesia, and may appear like it, especially in the early and middle stages.

Anæsthesia is a very common symptom of these tumors, yet the time of its appearance, as well as its distribution, varies greatly according to the site and progress of the neoplasm. As with pain, its early distribution may be quite limited; for instance, it may be confined to the area of distribution of one or few nerve-trunks or to one limb. This limitation of the early symptoms, whether motor or sensory, is a characteristic of these growths. The anæsthesia may be associated with pain in the affected area—the *anæsthesia dolorosa*. In the later stages of the disease the anæsthesia is more widely extended, and may be profound. Thus it is often complete in the trunk and limbs below the seat of the tumor. Thermo-anæsthesia may be observed in some forms of cord-tumors: perhaps it would have been oftener reported if it had been oftener looked for. In the central gliomata, especially when they form cavities, as in syringomyelia, anæsthesia to heat and cold is a common symptom; it is then associated with analgesia, while tactile sensation is preserved, thus forming a "dissociation" symptom which is quite characteristic. This thermo-anæsthesia is probably not a common symptom of meningeal growths; in fact, it is doubtful if it ever appears as a result of them, especially in this dissociation. Analgesia, or loss of pain-sense, may be seen in some cases of tumor of the cord. It may be associated, as above noted, with loss of temperature-sense, or it may exist alone. It is always an accompaniment of profound anæsthesia.

A not uncommon symptom is the girdle-sense. This consists of a feeling of constriction, as of a cord tied around the part. Its location varies with the seat of the tumor. Thus it may be felt around the neck, chest, waist, or abdomen, and a rare case is reported in which it was felt even in the legs.

The motor, like the sensory, symptoms of tumors of the spinal cord vary in kind and extent according to the seat and stage of growth of the lesion.

Like them, too, they are apt to be very limited when they first appear, and to gradually extend. This mode of appearance and extension is very characteristic of a neoplasm at some point in the spinal canal. The earliest motor symptom may be a paresis or a cramp of the muscle, or these may alternate or exist at the same time. Paresis may be limited at first to a muscle-group, whence it may gradually extend to involve a limb or the limbs of one side or both lower limbs. Before, however, it has spread thus far, it will most probably have deepened into a paralysis. When this paresis has well advanced, contractures in the affected muscles appear. These contractures distort the limbs, and often become so firmly set that they can be overcome only with great difficulty, and perhaps only with great pain to the patient. The tone of the muscle and the state of its reflex activity to a tap on its tendon vary according to whether its centre in the cord is involved in, or is below the seat of, the tumor. In the former case the muscle is flaccid and its reflex lost, while in the latter case, the centre in the cord being cut off from the inhibitory centre in the brain-cortex, the myotonus and the tendon reflex are much exaggerated.

Muscular atrophy may be caused by tumors of the spinal cord, according to the well-known pathological law that a muscle wastes when its trophic centre in the cord is destroyed. Hence in cases of these tumors the atrophy usually occurs in limited muscle-groups, or in one limb, or possibly in both arms if the cervical enlargement is affected, or in both legs if the tumor is in the lumbar enlargement or cauda equina. Hence a not uncommon type of motor disorder is seen in cases of tumor of the cervical region; in which cases, the trophic centres in the anterior horns being destroyed, a muscular atrophy in the arms results, while, the descending motor paths in the lateral columns being injured, a spastic paresis, without atrophy, but with increased knee-jerks and with ankle-clonus, is seen in the legs. When the process in the cord is rapidly destructive, the atrophied muscles present very soon, as a rule, changes in their electrical reactions. During the very early stage, or stage of irritation, the electrotonus may be increased to both currents, but sooner or later this is diminished, while modal changes occur; and in very rapid or advanced cases, in which the anterior horn has been quickly destroyed, the true reactions of degeneration may occur. In slowly progressive cases, in which the horn is destroyed very gradually, the qualitative changes may not appear in a typical manner.

Spasms, twitching, and contractures of the affected muscles are frequently seen. Cramps in the back and limbs are sometimes complained of. Contractures, as already said, are usually secondary to advancing paresis. Fibrillary contractions, so common in progressive muscular atrophy, are rarely seen: in the table of fifty cases referred to they are mentioned only once. Epileptic convulsions do not occur. In the only case to which the author has a reference the fit must have had some origin not recognized. Tetanoid cramps and spasms, opisthotonos, torticollis, and scoliosis are all symptoms which may arise in the course of tumors of the spinal cord.

Ataxia is not a common symptom of these tumors. This may be because tumors occupying the exact region of the lesion of locomotor ataxia—*i. e.* the posterior columns, horns, and root-zones—must be exceedingly rare.

Various trophic lesions may occur. These lesions are identical with those caused by other affections of the spinal cord producing transverse or extensive destruction. The most important are bed-sores. These bed-sores may be attended in time with septic infection of the blood, and thus cut short the patient's life. Other trophic lesions are œdema, glossy skin, maculæ, and

bronzing of the skin, and perhaps in some cases more destructive lesions. Vaso-motor involvement has been noted by some observers. Flushing of the skin and excessive sweating are among these phenomena. Alterations in temperature in the paralyzed parts occur. The most common permanent alteration, especially when paraplegia is complete, is a slightly subnormal temperature. Early in the case the more paralyzed parts may present an increase in temperature.

The visceral symptoms of tumors of the spinal cord depend to some extent upon the location of the growth. The most common is paralysis of the bladder. It is the most common because the centre for the bladder is low in the cord, and consequently is cut off from volitional control by tumors at almost all levels. When the tumor is in the lumbar enlargement the centre for the bladder may be destroyed, causing complete paralysis, both direct and reflex, of the viscus. When the tumor is above this level, however, the reflex irritability of the bladder may be retained for a while. In the former case retention is much the more common; in the latter, incontinence. Later, in all cases, retention, with overflow, is apt to be the rule. Paralysis of the sphincter ani is caused in exactly the same way as that of the bladder.

In lesions in the cervical region embarrassed breathing and rapidity of the heart's action may occur. Choking sensations are sometimes experienced. Vomiting is not a common symptom.

Intracranial symptoms are, from the very nature and seat of the growth, not common in tumors of the spinal cord, but they are not unobserved. Vertigo has been recorded in one case in which the tumor was high in the cervical cord. Changes in the optic disk have also been seen in similar cases. Headache is noted in only three instances in the table of fifty cases already referred to. Alteration in the pupil might be caused by paralysis or irritation of the sympathetic centre in the cervical cord. Mental symptoms are not caused by tumors in the spinal canal except as secondary phenomena due to pain, weakness, and abandonment of hope.

Among other secondary symptoms are cystitis and pyelo-nephritis. Priapism has been reported in a few cases.

Tumors of the spinal cord present several clinical types according to the area and the level occupied by the new growth. In some cases in the early stages one lateral half of the cord is first and most involved. Such a case presents the type first described by Brown-Séguard.¹ There are paralysis and loss of muscular sense, with hyperæsthesia, on the side of the lesion, and anæsthesia, and possibly analgesia, on the opposite side. This distribution depends on the fact that some of the sensory fibres decussate at or about the level of their entrance into the cord. A notable absence of sensory symptoms occurred in a patient of the author's. A carious spot in one of the cervical vertebræ caused hemiplegia without any sensory involvement whatever. The case exactly resembled hemiplegia of cerebral origin. An operation was performed by Dr. Deaver.

Other types depend upon the level of the cord at which the tumor occurs. The favorite sites for these tumors are the cervical and lower dorsal regions. Of the 50 cases in Mills and Lloyd's table, 22, or almost one-half, were included entirely or in part in the cervical cord; 4 were in the upper dorsal region; 12

¹ The author gives a place in the text to a description of this type, although he knows that recent experiment throws much doubt upon the accuracy of the claim to any such clinical findings. Thus Gotch ("Recent Research on the Spinal Cord," *Liverpool Med.-Chir. Journ.*, Jan., 1893) says: "Recent physiological research shows that, in opposition to the views formerly advocated by many neurologists, the path for sensory conduction is almost entirely on the same side as that of the entering sensory nerves."

in the lower dorsal; and of the remainder, 4 were in the lumbo-sacral region, 3 in the filum terminale and cauda equina, and the rest were of doubtful location or nature.

The type presented by a cervical tumor is often quite characteristic. Pain is located in the neck, arms, and upper part of the back. Torticollis or retraction of the head may occur. Anæsthesia is variously distributed according to the region most involved. The anterior cornua, entire or in part, on one or both sides, may be destroyed, and consequent atrophy of muscles in the arm or arms, with altered electrotonus, may be observed. Paraplegia, beginning perhaps as crural monoplegia, is sure sooner or later to appear; and this is of the spastic type, with increased knee-jerks and ankle-clonus, but without muscular atrophy in the leg muscles. Complete anæsthesia in the trunk and legs supervenes; paralysis of the bladder and bed-sores complete the picture.

Tumors in the dorsal region present the type of a simple transverse lesion slowly advancing to paraplegia and anæsthesia, with bed-sores, incontinence, and cystitis, but without involvement of the neck and arms. The signs of irritation, such as neuralgic pains, girdle-sense, and zone of hyperæsthesia at the level of the growth, are sometimes very characteristic. Dyspnœa, due to partial paralysis of respiration, may be caused by tumors in the cervical and upper dorsal region.

Tumors in the lumbar region and in the cauda equina give a still different type, depending upon the fact that the trophic cells in the anterior horns, the anterior nerve-roots, and the nerve-trunks are implicated. Hence, in addition to paraplegic symptoms and neuralgic pains about the lower part of the trunk and in the legs, there may be muscular atrophy, reactions of degeneration, and abolished tendon-reflexes in the legs, and possibly an irregular distribution of anæsthesia in areas supplied by nerve-trunks in the cauda equina most involved. Moreover, the reflex centre for the bladder in the lumbar cord being destroyed, obstinate retention, with overflow, may occur. In tumors limited entirely to the cauda equina the symptoms are simply those of neuritis—*i. e.* neuralgic pain, often intense, anæsthesia, muscular atrophy with reactions of degeneration, abolished reflexes, and paralysis. The distribution of these symptoms will depend entirely upon the distribution of the nerves implicated. This distribution may be very irregular, and by this irregularity constitute a distinct type. Paralysis of the bladder may occur in these cases.

Morbid Anatomy.—According to the table already referred to, the most common forms of tumor of the spinal cord are the sarcomata and the structures allied to them. Thus, of 50 cases, 12 are described as sarcomata and gliomata: 9 are distributed in the list among myxomata, psammomata, and fibromata, of which number it is fair to assume that some at least were structurally similar to the sarcomatous type; while of the 2 described vaguely as “cancer,” and of the 6 unclassified, a proportion would probably have been found to be sarcoma or glioma on more exact observation. Carcinoma occurred but once, parasitic growths three times. Syphilitic growths were found in 5 cases, massive tubercle in 4.

Dr. Herter, in a contribution to the pathology of solitary tubercle of the spinal cord, has analyzed 26 cases. His study shows that the affection is a disease of adolescent and early adult life. 20 of these cases occurring before the age of thirty-five. In all but one the massive tubercle was solitary. In most of the cases tubercular disease existed in other parts of the body and antedated the cord lesion. Hayem, however, quoted by Herter, reported a case which he regarded as primary.

Secondary lesions are usually found in cases of tumors of the spinal cord. Meningitis and œdema of the membranes, also inflammatory exudate, are occasionally noted. The cord is usually compressed, its substance softened both above and below the tumor. Secondary degeneration occurs in the system-fibres of the cord. Hæmorrhages have been observed. Cysts may be formed, or the central canal may be dilated (hydromyelia). Gummata and carcinomata have caused erosion of the vertebræ.

Diagnosis.—Tumors of the spinal cord may be confused with hæmorrhage, pachymeningitis, transverse myelitis, spinal caries, fractures of the vertebræ, neuritis, and hysteria.

Hæmorrhage into the spinal canal or spinal cord, unless the result of violence, is extremely rare. When it happens from diseased blood-vessels it is very sudden, and the symptoms attain almost at once their maximum of intensity. Compression and destruction of tissue may be sufficient to cause paraplegia in a few hours. It is possible that some of the early symptoms, due to compression, might abate in time, and that the permanent results would be focal with secondary degenerations. The usual result, however, is death.

Pachymeningitis, especially in the cervical region, is very difficult to distinguish from a tumor. It causes, perhaps, on an average, more acute pain and stiffness in the neck than does tumor, and it is more widely distributed in vertical extent.

Transverse myelitis also closely simulates tumor. In some of these cases the lesion is very limited in vertical extent. The onset of myelitis, however, is not usually so gradual as that of tumor, and this is probably the best distinguishing point. Another distinction is the degree of pain. In myelitis pain is sometimes not very severe. Cases are seen in which the girdle-sense and a zone of hyperæsthesia are the nearest approach to it. The writer has seen also white softening of the cord, very limited and entirely transverse, cause symptoms very similar to transverse myelitis, the absence of pain being very conspicuous.

Spinal caries in its early stages may resemble a tumor, but the cases must be very rare in which a deformity of bone cannot be detected comparatively soon. As a rule, pressure-symptoms do not appear until long after the deformity is apparent.

Fractures of the spinal vertebræ are indicated by the history, even though deformity is not very apparent, as is sometimes the case. It is not probable that confusion could often arise between this, or any other form of trauma in which the history were known, and tumor.

Neuritis might simulate a neoplasm in some cases; in fact, neuritis is one of the symptoms of tumor of the spinal cord. When it is caused, however, by a tumor within the spinal canal, it is not likely to be the only symptom; thus evidence of compression is soon made manifest. Multiple neuritis is not apt to be confined to the arms: in a case in which it were, compression symptoms in the legs would be wanting. If confined to the legs, it would not cause paraplegia with involvement of the bladder, etc. But such a distribution of multiple neuritis is rare. It is usually apparent in both arms and legs, in which case confusion with tumor is hardly possible.

It is customary to say that hysteria simulates all diseases, but this statement is based upon superficial observation. Blocq is nearer the truth when he says that hysteria does not simulate any disease perfectly—that there is always something wanting. To detect this missing element is often the rather easy forte of the expert. No rule can be given in brief space. It may be said, however, that the symptoms most dependent upon organic change are most apt

to be wanting in cases simulating tumor or other organic disease of the cord; excessive knee-jerks, very free ankle-clonus, muscular atrophy, and the reactions of degeneration are not usually seen. In fact, the latter two symptoms are never seen. But more important even than to detect the negative evidence is to observe the positive symptoms of hysteria itself. These are the so-called stigmata, which in probably all cases simulating grave organic disease can be detected. Among these stigmata are hemianæsthesia, including the special senses, concentric narrowing of the visual fields with alteration of the color fields, segmental anæsthesia in paralyzed limbs, tremor, and convulsive phenomena. Transfer and suspension of symptoms by suggestion (hypnotism) may be obtained. The mental stigmata, emotional, lethargic, etc., are often characteristic.

Prognosis.—The prognosis of tumors of the spinal cord is not quite so bad as formerly, because, in some cases at least, surgery may come to their relief. The success of surgery will depend primarily, of course, upon the successful localization of the growth and upon its situation at an accessible part of the spinal canal. Even then some permanent damage may have been done by the neoplasm before its removal. The prognosis, if dependent upon treatment by drugs, is uniformly bad. No exception to this rule can be made in favor of a syphilitic tumor, because syphilitic lesions large enough to be called tumors are not, in the author's experience, removable by such means.

The duration of these cases varies. Some cases are rapidly fatal, lasting only a few months; others are reported as lasting for more than three years.

Treatment.—As has just been said, treatment by drugs offers no hope in any case of tumor of the spinal cord. While we believe that the syphilomata are no exception to this rule, we should, nevertheless, give the patient very active antisymphilitic treatment if he had a clear history of syphilis. We should do this in the hope that the lesion were not truly a tumor, but rather a more diffused process, such as pachymeningitis, and that it had not yet irreparably damaged essential portions of the cord. When the syphilitic neoplasm has become sufficiently massive to be worthy of the name of tumor, it has usually produced, and will continue to produce, such destruction of the nerve-elements that repair on the one hand, and arrest on the other, cannot be obtained by drugs. The writer says this from personal experience, not exactly with syphilitic tumors of the cord, but with their congeners, meningeal gummata within the skull. In several cases, in which progressive erosion of the bone occurred, no perceptible influence was exerted by the so-called specifics.

Surgery offers the only rational treatment of these cases, but this remedy must be used with rare caution after the most painstaking diagnosis, and with the clear understanding that success may not be obtained. The following points, according to Thorburn, must be considered in all spinal lesions: First, the curability without operation; second, the dangers of the operation; third, disastrous results, such as weakening of the vertebral column; fourth, the selection of appropriate cases. In the case of a spinal tumor it may be said, in reference to these four points, that, first, the case is not curable without operation; second, that the dangers of the operation are not so great as the risk of going without it; third, that the spine would not be weakened seriously, except in the very rare event of extensive erosion; and, finally, that the selection of appropriate cases depends entirely upon the successful diagnosis and localization of the tumor at as early a stage of its growth as possible. Hence, the operation is not only advisable, but, it would seem, in properly selected cases, imperative. Tumors of the spinal cord have been successfully localized and

removed. Such an operation was performed by Mr. Horsley on a man with myxofibroma in the upper dorsal cord. The symptoms were complete paraplegia, motor and sensory, of slow development, accompanied with attacks of agonizing pain. Although degeneration of the lateral pyramidal tracts had existed, as shown by intense spastic paraplegia, every indication of this is reported by Dr. Gowers to have since passed away.

In cases in which, for any reason, surgery is declined or ignored, and exclusive reliance is placed upon other treatment, the most important, and, in fact, only useful, means to give comfort to the patient are the water-bed and opium. Antiseptic treatment of bed-sores is important.

SYRINGOMYELIA.

BY JAMES HENDRIE LLOYD, A. M., M. D.,

PHILADELPHIA.

SYRINGOMYELIA is a disease of the spinal cord, characterized by the growth of a gliomatous tissue, which breaks down and forms a cavity, usually in the mid-region of the gray matter.

Syringomyelia has been recognized within only a comparatively recent period. The word was coined by Ollivier in 1837, and applied by him to all canals or cavities in the cord. Every such canal or cavity was considered pathological until Stilling demonstrated the normal central canal. Virchow and Leyden used the word "hydromyelia" to designate cavities in the cord, which they claimed were always dilatations of the normal central canal. Simon, in 1875, pointed out the pathological process which interests us here. He demonstrated that cavities, quite apart from the central canal, may occur in the cord in the midst of a newly-formed gliomatous tissue by the breaking down of which they are caused. He proposed to reserve the term "syringomyelia" for this special form of cavity; and this specialization is now accepted by most writers. Syringomyelia therefore has come to be regarded as the product of a gliomatosis. The word "hydromyelia," on the other hand, may be restricted to the dilatation of the central canal, which happens occasionally as a secondary phenomenon in various cord lesions, and which is different, both anatomically and clinically, from true syringomyelia.

Of late years a quite voluminous literature of syringomyelia has grown up. Among monographs we may note especially that of Bruhl, which brings the subject quite up to 1890. Since that time some reports of cases, proving the accuracy of the symptomatology of the disease, as verified by the post-mortem findings, have appeared.¹ Doubt lingered in the minds of many for a long time whether syringomyelia could justly be regarded as a disease-entity, but these accumulating observations in very recent years must effectually silence all criticism.

Etiology.—Syringomyelia is much more common in males than in females. Bruhl found the proportion as 28 to 8. Roth is reported as saying that the disease is three times more common in males than in females.

The disease appears usually at a comparatively early age. Charcot, quoted by Bruhl, says that the first manifestations appear between the fifteenth and twenty-fifth years. In some cases the time of the début of the disease is uncertain. The author's case was in a male, and appeared first about the twenty-seventh year.

From the above facts it is seen that syringomyelia, while not exactly a disease of childhood, is usually a disease of adolescence or early adult life. It

¹ See report of a case by the author, with photographs of sections of the spinal cord, *Univ. Med. Mag.*, Philada., March, 1893.

probably has close affiliations with at least one well-recognized disease of childhood—viz. hereditary ataxia or Friedreich's disease.

Traumatism and exposure to cold seem to have been exciting causes in some cases. The infectious diseases also have appeared to be the starting-point.

Syphilis and alcohol do not seem to be causes of this disease.

According to Bruhl, syringomyelia is a disease probably of evolution, a congenital affection having its origin in an anomaly of development of the ependyma. We shall refer to this subject again.

Pathology.—Cavities in the cord, as already said, are the results probably of several pathological processes. Thus they may be formed by the dilatation of the central canal, this dilatation being an accompaniment of some other morbid state, such as inflammation, hæmorrhage, or neoplasm. They result sometimes perhaps from small hæmorrhages into the substance of the cord. Some recent authors, notably Hoffmann, still classify all these varieties, and make, as it were, one general group of them. We believe this is wrong. Most of such cavities are merely accidents or terminal products left by various pathological processes. The true syringomyelia is, in our opinion, a process *sui generis*, and is in no way identical with the other members of the rare and heterogeneous groups alluded to. We accept the theory, adopted now by Schultze, Bernhardt, Simon, Westphal, Charcot, Dejerine, and others, that syringomyelia is the product of a true gliomatosis, which occurs usually in that region of the cord that is developmentally the weakest—*i. e.* the region of the posterior gray commissure and posterior median septum. This proliferation of neuroglial tissue leads to the formation of a cavity by the gradual softening and absorption of the new growth. Its usual site in the gray commissure and posterior septum suggests that it may result from an anomaly in the development of that region of the cord last formed by the folding over of the medullary folds in the embryo. According to this theory, the central canal is not necessarily the starting-point of the process, although it may be involved ultimately in it. In the author's case this profuse overgrowth of neuroglial tissue was a conspicuous feature, while the central canal, as marked by a mass of epithelial cells, was entirely distinct from the cavity. In another case, however, published recently by Dr. James Taylor, the cavity was lined in some places with epithelial cells, proving conclusively that the central canal had become included in the syringomyelia.

Morbid Anatomy.—The cavity is usually largest in the cervical region, whence it extends downward to various levels in different cases. In some cases it trends to one side. It may extend as far as, or even into, the lumbar enlargement, but this is not the rule. In many cases the lumbar enlargement, with exceptions yet to be noted, is normal. At its seat of greatest extent the cord may be literally a hollow tube. In the fresh state the cord is flat or ribbon-like, and gives to the finger a sense of fluctuation.¹ There is usually not much, if any, evidence of inflammation. The integral parts of the cord are much distorted and even injured by the syringomyelia. The cavity (see Fig. 1) occupies the central gray matter or commissure, the anterior, or white commissure, usually escaping. The normal central canal may exist apart, in which case it is apt to be disfigured, and perhaps only recognizable by its epithelial cells, or it may be included in the cavity, in which case the latter is lined at places with columnar epithelial cells. The cavity is often widely extended laterally, and may run down the posterior horns or even the posterior median septum. It pushes before it the gray matter, which is seen in the author's case to be stretched around the ends of it. The anterior horns are distorted, and

¹ In two cases observed post-mortem by the writer, this macroscopic appearance was very striking.

the multipolar cells in them are in many instances atrophied. The posterior horns, the posterior root-zones, and the posterior columns are especially liable to injury. The horns and root-zones may be distinguished only with difficulty, and the posterior columns present various stages of degeneration. The lateral

FIG. 1.

pyramidal tracts are often very much degenerated, as are, also, the direct pyramidal tracts. The cavity itself is usually surrounded by a newly-formed tissue. This is seen, under the microscope, to be a densely felted tissue, with fibrils making innumerable meshes. It is rich in neuroglial nuclei. Some writers point out a lining membrane to the cavity, composed apparently of a comparatively more densely felted layer of gliomatous material. Blood-vessels are scattered but sparsely through this tissue. Above and below the region of

FIG. 2.

Upper Dorsal Region of the Spinal Cord from the author's case of Syringomyelia. (*Univ. Med. Mag.*)

greatest extent of cavity the morbid anatomy varies. System-lesions may extend in either direction according to their nature. The medulla oblongata is variously affected. It may be the seat of nuclear degenerations identical with those of bulbar palsy. In the author's case one pyramidal tract was degenerated through the decussation, and the ascending cerebellar tract on one side, as well as the funiculi gracilis and cuniati on each side, was deeply sclerosed. Below the cavity the lateral pyramidal tracts are often degenerated to their extreme limits in the lumbar enlargement. The lumbar enlargement, even when it apparently escapes invasion, may exhibit, on close microscopical search, the presence of gliomatosis in a small area in the gray commissure. The anterior horns in the lumbar cord, unless the cavity extends thus far, are not affected.

Symptoms.—The symptoms of syringomyelia may be divided into two classes, according as they are dependent upon lesions, first, of the gray matter of the cord, and second, of the white matter. The first class includes the essential symptoms; the second, those that are secondary to them. These essential symptoms may be subdivided into three groups, according to the region of the gray matter affected.

The first probably of these essential symptoms to appear is a characteristic disorder of sensation. This presents a type. It is an analgesia, or loss of pain-sense, combined with thermo-anæsthesia, or loss of power of distinguishing heat and cold, without true tactile anæsthesia and loss of muscular sense. This peculiar type has been called by Charcot the *dissociation* symptom of syringomyelia. It is more typical of the disease than any other one symptom-group, and is truly typical of no other affection, although occasionally seen in hysteria.

These sensory changes usually show a segmental distribution. They are sometimes hemiplegic in type, sometimes monoplegic, but usually distributed only to segments of the limbs or trunk. Exceptions and variations occur. Thus in the author's case zones of anæsthesia were found on the shoulders and about the waist. Occasionally areas of hyperæsthesia exist; thus, in this same case, while one side presented quite typically the "dissociation" symptom, the other was the seat of hyperæsthesia. The zone of anæsthesia to heat and that to cold do not always exactly correspond. The analgesia of syringomyelia is often very profound, so that the patients may be quite insensible to most destructive trophic or traumatic lesions, to which reference will be made later. The exact affected region of the cord that gives rise to the sensory symptoms is probably the posterior gray commissure and parts of the posterior horns.

The essential motor-symptoms of syringomyelia depend upon a progressive atrophy of the cells of the anterior horns of the gray matter. As the cervical enlargement is invaded much more commonly than the lumbar, it follows that the arms rather than the legs are the parts involved in the consequent muscular atrophy. This progressive muscular atrophy is usually of the atonic variety—*i. e.* the muscles are not spastic and do not show exaggerated myotonic and tendon reflexes. This is the type called Aran-Duchenne. There are exceptions to this rule, however, as in the author's case, in which the tonic or spastic type, with exaggerated reflexes, was present. The affected muscles exhibit fibrillary movements. Reactions of degeneration are not seen in these muscles, although in advanced cases quantitative changes occur, and in extreme cases very little if any response can be elicited by either current. This wasting often begins in the hand—for instance, in the thenar and hypothenar eminences. It may be the first symptom to attract the patient's attention. Loss of power is proportionate to the atrophy. One hand may be affected before the other. The wasting in the muscles of the shoulders and arms may become extreme. The biceps, deltoid, infra- and supra-spinati and lower part of the trapezius may be almost entirely lost. The forearm and deeper neck-muscles also may be much affected. The weakness of the neck-muscles may become so extreme that the head falls forward on the chest, and even requires an assistant to support it when the patient sits upright. Tremor has been observed not unfrequently, especially in the hands and fingers.

The third group of essential symptoms is a somewhat arbitrary one. It is composed of those symptoms that are claimed by some writers to depend upon the invasion of the mid-region of the central gray matter. Bruhl includes in this group trophic lesions, scoliosis, vaso-motor disturbances, weakness of the sphincters, oculo-motor disorders, and involvement of the bulb. Without

criticising this grouping we may accept it for convenience in clinical description. Whatever their exact origin, it is certain that some at least of these symptoms are common in this disease.

The trophic lesions occur in the skin and in the bones and joints. The skin may show hypertrophies, callosities, ulcerations, various eruptions and macule, or may be glossy in places. The nails of the fingers and toes are sometimes involved. They become thickened, have transverse ridges, and may even fall off. Panaris, or whitlow, is an obstinate and destructive lesion in that form of the disease first described by Morvan and named for him. These whitlows are painless and chronic, and they often destroy the ends of the affected fingers. Abscesses may occur in various places. Arthropathies are not unusual in syringomyelia. They are very similar to those occurring in locomotor ataxia. They cause great deformity of the joints affected, with exudation within the capsule, increase in the articular surfaces, denudation of bone, stalactites, etc. Any one of the large joints, either the knees, shoulders, elbows, hips, or ankles, may be involved: occasionally more than one joint suffers. Fragility of the long bones, leading to easily-produced fractures, occurs.

Deviation of the spine is a very common affection in syringomyelia. Bruhl says it is present in 50 per cent. of cases. The most common form of deviation is scoliosis. In the author's case this scoliosis was so marked in the neck that it presented the appearance of torticollis. It is most marked usually in the dorsal region. Kyphosis is the next form in frequency, and lordosis the last. Scoliosis may be an early symptom of the disease. Many theories have been advanced to account for this symptom, but that of Roth, who attributes it to an atrophy of some of the transverse muscles of the spine, appears to us the most reasonable.

Vaso-motor disturbance may be shown by œdema or coldness of the extremities, or by burning sensations in them, by excessive sweating and by persistence of lines, marks, or maculæ left after contact of objects with the skin. Pilocarpine by injection, according to Dejerine, is delayed in its action, and causes much more abundant sweating in the analgesic regions than in other parts.

Affections of the sphincters are certainly rare in syringomyelia. They might occur in extreme cases in which the cavity in the cervical region was so expanded as to act as a total transverse lesion. Yet in the author's case, in which the expansion was extreme, there was no interference with the innervation of either the bladder or bowel.

Pupillary and oculo-motor symptoms have been reported. The sympathetic centre in the cervical cord may be either paralyzed or irritated, causing contraction or dilatation of the pupil as the case may be. When the bulb is involved, the symptoms of bulbar palsy may appear. In Taylor's recent case the aqueduct of Sylvius was dilated, probably causing, by involvement of the underlying nuclei of the third nerve, the nystagmus which his patient had.

The second class of symptoms observed by us includes those caused by involvement of the white matter of the cord. These are, briefly, the symptoms, first, of lateral sclerosis; and, second, those of posterior sclerosis. It can easily be understood that a widely-extended destructive process, like syringomyelia, in the cervical region, must involve inevitably some of the fibres in the white matter. The extent of this involvement of course varies. The most common is lateral sclerosis. This produces, as is well known, spastic paresis in the legs. The knee-jerks are exaggerated, ankle-clonus is present, the gait is feeble, the muscles are spastic, but not wasted, and the innervation

of the bladder and rectum is not affected. The symptoms of posterior sclerosis, or locomotor ataxia, are not so common. Ataxia, however, and swaying with closed eyes, may be present, possibly dependent upon involvement of Clark's column and the ascending cerebellar tract. Fulgurant pains are rare.

The brain is not involved in typical cases of syringomyelia. The author once saw, however, a diffuse gliomatous lesion in the mid-brain and cerebellum which strongly suggested an identity, in all but position, with the gliomatosis of the cord.

Diagnosis.—The diagnosis of syringomyelia rests upon the recognition of certain groupings of the various symptoms already described. The most common grouping is that of muscular atrophy, especially in the shoulders and arms, spastic paresis of the legs, the "dissociation" sensory symptom, and a variety of trophic disorders. The most characteristic of these symptoms is the peculiar disorder of sensation. Hysteria may simulate this sensory change, but it does not present true muscular atrophy. Anterior poliomyelitis does not cause sensory changes. Amyotrophic lateral sclerosis is undoubtedly identical in some reported cases with syringomyelia. Tumors of the cord and localized myelitis may closely simulate the disease, and can best be distinguished by the history of the case and a careful study of the sensory and trophic disorders. Trophic changes may be conspicuous, and direct the attention from other symptoms. Thus, destructive whitlow, described as Morvan's disease, is a type of syringomyelia. Friedreich's ataxia has some analogies with syringomyelia: Griffith's statistics prove that 25 per cent. of autopsies in the former present cavities in the cord. Cases of precocious locomotor ataxia ought to be most carefully studied for the symptoms of central gliomatosis. Finally, hemiplegia and monoplegia have been caused by syringomyelia; they could probably be distinguished by sensory and trophic symptoms.

Prognosis.—The course of syringomyelia is slow, but its termination is never favorable. Many patients die from some intercurrent affection.

Treatment.—There is no specific, or even palliative, treatment for such an inveterate degenerative process as that which produces syringomyelia. It is possible only to treat some of the isolated symptoms, to preserve the strength, to guard against accidents, and to avert the tendency to death by intercurrent disease.

HEREDITARY ATAXIA.

BY ARCHIBALD CHURCH, M. D.,

CHICAGO.

HEREDITARY ATAXIA, or hereditary ataxic paraplegia, also known as Friedreich's disease, is a form of spinal sclerosis appearing usually before twenty years of age, with marked hereditary features. It is usually characterized by generalized ataxia beginning in the legs, by nystagmus, and by impairment of speech, and pursues a chronic progressive course.

As compared with Friedreich's description of this interesting disease published in 1863, this scant definition is too brief; but succeeding groups of cases observed in various parts of the world, practically of a similar nature, have shown that features of the malady at first insisted upon as essential are not invariably present or even usual. Cramped by the rigid lines of the early description, many observers have either slavishly followed, seeing only what had been before pointed out, or, if finding marked variations, regarding them as unusual and anomalous. Even Ladame so late as 1890 erected a clinical criterion which does not include a very fair proportion of these cases, although at that time some two hundred had been published, and probably very many more overlooked because of the false standard of measurement that was, and still is, followed. Gray, for instance, in his recent work, states as a "cardinal symptom" that "the knee-jerk is always absent," and Gowers looks upon the report of a case beginning at sixty-six years of age as a coincidence to be relegated to a foot-note. As a matter of fact, aside from the ataxia and perhaps the family history, no single item can be insisted upon in every case, yet the symptom-group is a very striking one, and the numerous variations are merely the expressions of an unsystematized and widely-distributed lesion.

Etiology.—The most striking fact in this disease is its transmission from generation to generation, either in the same form or by related sclero-neurotic disease, and the increasing susceptibility that is encountered in the later generations, where it numbers many members of the same immediate family and shows a distinct tendency to appear at a constantly earlier period of life. In this way may be explained the fact that many of the progenitorial cases have been misunderstood, overlooked, or misclassified. In this connection I wish to refer to the instructive family tree published by Sanger Brown,¹ and here reproduced by his permission. (Fig. 1). Nonne describes a somewhat similar group, and the one post-mortem obtained showed only an abnormal smallness of all the parts of the spinal cord, a deficient development which had not taken on sclerotic degeneration. Occasionally a generation escapes this disease, but atavism is likely to occur. The developmental defect is therefore strongly pronounced, and constitutes the background of the picture. It is as if portions of the nervous system, especially of the spinal cord, were incapable of maintaining their functions in accordance with the demands of growth and active life,

¹*Chicago Medical Recorder*, Feb., 1892.

and underwent regression, producing the sclerotic changes to be described later.

The developmental periods of life are those at which it is most likely to

appear—the seventh and eighth years of age, the age of puberty, and at about twenty, the age of full physical and sexual strength. But it sometimes is congenital, and may appear at any period of life. This is clearly shown in the

remarkable series of Brown and of Nonne, in the cases reported by Wells, and in the instances of Everet Smith. The sexes are about evenly affected, though in some family groups males or females greatly predominate, and it is somewhat more liable to be transmitted through the females than by the male branches, probably because the males affected early do not marry, and in later cases are impotent.

Pathological Anatomy.—With the exception of a few cases, notably one reported by Menzel, post-mortem changes in the nervous matter have been confined to the spinal apparatus, including the posterior nerve-roots and an occasional peripheral nerve, and to the cranial nerves, especially the hypoglossal, optic, and motor-oculi, and their centres in the medulla. In Menzel's case gross changes were traced into the cerebrum and cerebellum, and the latter was markedly atrophied. Very few autopsies are on record, however.

The change in the spinal cord is histologically practically identical with that in ataxic paraplegia and locomotor ataxia, for a full description of which the reader is referred to articles on those diseases. Dejerine and Letulle, however, basing their observations on a single case, claim that the sclerosis in this disease is peculiar in being confined to neuroglial hyperplasia without vascular changes. The distribution of lesions is the matter of most interest, for upon it depends the preponderance of symptoms in any given case. In every instance subjected to a post-mortem examination, except Nonne's, the postero-internal and postero-external columns have been found involved throughout the entire length of the cord. In the large majority of cases the pyramidal motor-tracts in the lateral columns have been sclerosed, and this process has, at different levels in different cases, invaded the anterior horns, the anterior columns, the direct cerebellar tract, and the posterior roots. The tract of Lissauer and Clark's columns usually escape. It is this multilocal distribution of the sclerosis which gives rise to such a variety of clinical manifestations and accounts for the confusion in literature. It is apparent that as the posterior columns or the pyramidal tracts are principally involved, the locomotor and spastic symptoms will vary, just as occurs in ataxic paraplegia. It is not incredible that even knee-jerks lost early in a case may later reappear, or myotatic irritability of a highly exaggerated type subsequently diminish or entirely fail.¹ The lesion has been traced through the medulla and pons involving the post-pyramidal nucleus. In the posterior columns it is that of an extremely intense tabes, and the involvement of the posterior roots is also analogous, but less marked. In the lateral columns it is that of spastic paraplegia plus the involvement of the cerebellar tract, the anterior direct motor-tract, and the frequent implication of the anterior horn.

Symptoms.—Unsteadiness upon the feet, a tendency to tumble, and clumsiness are the first noted indications. Ordinarily the symptoms advance slowly. As a rule, and in the type of Friedreich, the knee-jerk is lost very early, but the writer now has two cases under observation in which it is greatly exaggerated, and in both of them there is ankle-clonus. A number of Brown's cases also show increase of myotatic excitability, and the same thing has been not infrequently recorded. The superficial reflexes may be present or absent. Sexual power is frequently undeveloped or disappears, though in one of the cases under the writer's care, where the deep reflexes are prominently increased, sexual inclination is pronounced. As the case advances the ataxia increases, though standing with the eyes closed is often possible when the gait is sprawling and extremely bad. The trunk may be involved, so that, in sitting on a chair without arm or back support, marked swaying is

¹ In one of the writer's cases an ankle-clonus is rapidly diminishing.

present. The gait is simply staggering. The stamping of tabes is rarely seen, and even in the cases marked by clonus and exaggerated knee-jerks the stiff-legged gait of spastic cases is absent or only slightly present. Eventually, the upper extremities and the neck are involved, so that the patient becomes practically helpless, and the head, under very little control, rolls around on the shoulders. From the implication of the musculature of vocalization speech is characteristically modified. It is drawling, with the accent and modulation misplaced, hesitating, sometimes slightly explosive; in a word, ataxic. Usually early, and almost invariably late, in these cases nystagmus is present. It is readily overlooked if the patient be not examined carefully. It is not constant, subsiding when the line of vision is directly forward, and only occurring when the eyes are moved. Early in the disease it is necessary to have the eyes turned sharply outward, upward, or outward and upward to demonstrate it. The nystagmic movements are of comparatively short range, unequal in length, and tend to subside as the eyes settle down to the new position, seeming to the writer to be part and parcel of the general lack of balance in the entire voluntary muscular apparatus. A few instances of temporary strabismus and diplopia are on record. Pupillary symptoms and optic atrophy are absent in the Friedreich type, but frequent in Brown's cases.

There is not much pain, even in the markedly ataxic types; the lightning pain of locomotor ataxia, the girdle sensations, and the visceral crises are absent, but dull rheumatoid aching, pain on starting micturition, and painful cramps at night are not infrequent. Until late in the course of the disease errors of sensation are slight or absent. Slight anæsthesia, retardation in the transmission of sensations, variations in sensitiveness relative to temperatures, pressure, and electricity, have all been occasionally noted.

Muscular power is ordinarily greatly reduced, but paralysis only appears very late, and is comparatively of moderate extent. Sometimes there is distinct atrophy, owing either to the involvement of the anterior horns or to an occasional peripheral neuritis, and it is only in these cases that any notable changes in electrical responses are found. After the patient is bedridden general emaciation ensues. A coarse tremor is sometimes present, and choreoid movements of head and limbs of an ataxic character, ceasing when the part is supported, are common.

The facial appearance of these cases, when the disease is moderately well developed, has not received sufficient attention. The lines of expression are lost, the jaw drops, the mouth is partly open, the eyelids droop and look heavy, the whole expression or lack of expression is of apathy, and even of imbecility. In some families the change in the face has been the first intimation to their relatives, familiar with the type, of the invasion of the malady, though an intelligent examination would probably have sooner discovered it. This facies is imperfectly shown in the series of photographs published herewith. When pleased or disappointed, emotions are tardily and clumsily or grotesquely shown in their faces, which shortly return to an appearance of blankness. The mind is not necessarily impaired, but mental enfeeblement has resulted in some cases, and the enforced inactivity leads, perhaps naturally, to some hebetude. The drooping head, the scoliotic spine, and clubbed foot, which are common, are other evidences of muscular weakness and lost synergism. Sexual attributes are greatly delayed in the younger cases or fail entirely to develop, giving the patient a childish appearance and bodily formation.

Course.—The disease is essentially chronic, and very rarely the immediate cause of death, which results from intercurrent maladies, to which the inactivity of the patient in some instances no doubt conduces. Some cases have

lasted over forty years, and some have terminated in two or three. As in other respects, there is in this regard a striking similarity among the members of any family group, but it is not unusual to see the younger members of such a family attacked at an earlier age and in a more active manner. Some cases present long-stationary periods or even temporary slight improvement under treatment and bettered conditions of life. The progressive tendency, however, toward physical helplessness is apparently invariable; and even after the patient is bedridden life may last many years with ordinary care, as there seems to be no especial liability to bed-sores or other dystrophic condition. Occasionally acute myelitis has terminated the case.

Diagnosis.—The diagnosis hangs upon the youth of the patient, the slow onset, the history or presence in the family of other similar cases or of instances of spinal or cerebral sclerosis (among which parietic dementia should be included), upon the ataxia, the nystagmus, the halting peculiar speech, and possibly upon the facial appearance. Absence of locomotor pains, of pupillary symptoms, of acquired syphilitic infection, and of pronounced sensory disturbances are negative conditions of corroboratory value.

Treatment.—The prognosis is always grave, as has already been implied, and treatment seems to be of exceedingly little value. A course of arsenic, of massage, of stretching the spinal column, especially by Benedickt's method, have all apparently caused slight amelioration in progressing cases. Those measures recommended in tabes should be tried, and cauterization with the thermo-cautery over the spine repeated at intervals of two weeks may be employed for a prolonged period. A light touch of the smallest point opposite each vertebra is quite sufficient and not particularly painful. General measures to maintain the physical state are of course always in order. With young patients it is well to allow a reasonable amount of instruction, as they are often dependent upon themselves for entertainment during long years of helplessness.

RAYNAUD'S DISEASE.

BY THOMPSON S. WESTCOTT, M. D.

PHILADELPHIA.

IN a thesis published at Paris in 1862, Maurice Raynaud first called attention to a complex of symptoms to which, for want of a more satisfactory title, he gave the descriptive name "Local Asphyxia and Symmetrical Gangrene of the Extremities." This essay was founded upon the clinical histories of 25 cases collected from various sources, only five of which came under his personal observation. Some of the cases drawn from other sources dated back many years and were very inadequately reported, but Raynaud succeeded in presenting a clinical picture that was at once recognized by his contemporaries, and which soon took a place in medical literature as a new disease worthy to be named for the author who first described it. In this and later studies Raynaud defined the disease as "a neurosis characterized by enormous exaggeration of the the excito-motor energy of the gray parts of the spinal cord which control the vaso-motor innervation." The stage of cyanosis he considered as due to a spasmodic closure of the arterioles of the parts affected, with a regurgitation of venous blood into the capillaries; and if this condition was continued sufficiently long, gangrene of more or less gravity supervened. This gangrene, which is often strikingly symmetrical in its distribution, he distinguished from all other varieties of local death as not being due to embolism, thrombosis, or changes of an inflammatory character in the intima of the blood-vessels. There can be no doubt that many of the cases subsequently described under this name, and indeed some of those collected in Raynaud's original thesis, do not properly come within the definition laid down by this author. So recent a writer as Sturmendorf, of New York (*Medical Record*, Aug. 1, 1891), goes so far as to question the existence of such a disease, which, he states, cannot be diagnosed during life; for, "admitting the possibility of excluding all other conditions capable of producing gangrene, we must exclude" that form of "endarteritis [Meigs] whose presence could be demonstrated only on the post-mortem table, and whose absence is a *sine quâ non* to the acceptance of Raynaud's disease in the sense of its author's conception." It is quite probable that modern pathology may succeed in disproving the existence of Raynaud's disease as a morbid entity, but it is certain that there are a sufficient number of cases on record—and, curiously enough, many of them are in children—which bear out in all essential respects the original clinical picture.

The leading characteristic of the disease consists of paroxysms of more or less continuous and complete spasm of the arterioles of the extremities, usually occurring, with a fair degree of symmetry, upon like parts of the two hands or two feet, or upon both hands and feet, or—and this less frequently—upon other symmetrical regions, such as the ears, sides of the nose, or buttocks. This spasm, if sufficiently long continued, gives rise to more or less extensive trophic changes, or even death of the parts involved.

Symptoms.—As originally described by Raynaud, this affection may be conveniently divided into three principal stages: 1, Local Syncope; 2, Local Asphyxia; 3, Gangrene. The first stage, local syncope, may be transitory, or even wanting altogether, but when the disease assumes its severest form the second and third stages always occur in the order named.

LOCAL SYNCOPE.—This term was employed by Raynaud to designate a condition, usually of one or more fingers or toes, which in its slightest manifestation is not incompatible with health. The patient, usually a female of neurotic temperament, after exposure to slight cold, or even under the influence of moral emotion, observes one or more of the fingers become pale and cold. The skin assumes a dead-white or parchment-yellow color, cutaneous sensibility is quickly abolished, and the digit feels icy-cold and dead. While tactile sensibility may be for the time abolished, the heat-sense may still, in a measure, be maintained. At times a cold perspiration may cover the affected part, while at others it is dry and shrivelled as if frozen. This spasm of the arterioles, with the consequent temporary abolition of local circulation, which is popularly known as "the dead finger," is insignificant from its transitory duration, being succeeded by a variable period of usually very painful reaction, in which the blood gradually returns to the part. It is simply an exaggerated form of what so commonly occurs after the hands have been exposed to a low temperature when confined in tight kid gloves. This, the slightest and in some cases the only stage of the disease, has been but rarely observed in children.

LOCAL ASPHYXIA, or cyanosis, may be preceded for a time by more or less frequent occurrences of local syncope, or may be the first manifestation of the disease. In the latter case the onset is generally sudden, but sometimes is preceded by paræsthesiæ or pain, usually limited to the fingers or toes about to be affected. After exposure to a more or less marked depression of temperature, or even without appreciable cause, one or more fingers or toes become cold and usually somewhat swollen. The particular phalanx or phalanges will be found to have assumed a dusky or cyanotic tint and to feel icy-cold to the touch, while the whole limb is colder than the rest of the body. Tingling or shooting pains of varying severity are felt, and hyperæsthesia or anæsthesia of the parts may be observed. The cyanosis affects most intensely the distal portion of the phalanx, but it may extend in decreasing degree as far upward as the wrist-joint or ankle, or may even pass beyond, while venous marblings may be traced far up the limb. This condition may affect one phalanx or several in varying degree, either upon a single limb or upon both hands or feet, or even upon all four extremities. When both hands or both feet are affected, the degree of cyanosis is generally more marked upon one side; and in some paroxysms in the same patient the asphyxia may be confined to one member alone, while in others both feet or both hands or a hand and foot are affected. In any particular case, however, in the successive paroxysms local asphyxia generally involves the same phalanx or manifests the same order and intensity of involvement of several phalanges. After a variable duration the cyanosis gradually passes away and the parts regain their color; this reaction may even be excessive, and redness and burning pain be noted. Such paroxysms vary greatly in severity and duration. In some instances the attack passes off in a few seconds, to be frequently repeated at the slightest exposure to a change of temperature; while in other cases it is prolonged for several hours or even several days. Pain is also a very variable symptom, some patients experiencing little discomfort during the asphyxial attack, while others complain bitterly of intense burning sensations in the part. As with the preceding stage, local asphyxia may be the most serious manifestation of the

disease, and in this case we find it occurring at irregular intervals, but often as frequently as several times daily, usually during the winter months, being provoked by the slightest exposure to cold.

A symptom frequently noted during this stage is hæmoglobinuria, to which attention has been lately directed principally by the observations of Barlow and Southey in England. Shortly after the beginning of a paroxysm of local asphyxia the child may pass very dark urine, which is found to contain albumin, and responds to the guaiacum test for hæmoglobin. Both Southey and Barlow report cases of this kind in which, during some of the paroxysms, the urine was found to contain no blood-corpuscles, but showed fine granular brown débris and a profusion of oxalate-of-lime crystals. This phenomenon does not occur after every attack; but it has been observed that a copious deposit of urates may at times replace the loss of hæmoglobin. It is most likely to occur when the attack is preceded by yawning, drowsiness, nausea, or pain in the belly referred to the ensiform cartilage, which are the symptoms preceding hæmoglobinuria due to other causes.

When an attack of local asphyxia has lasted several days, the nail ceases to grow, and the occurrence is marked upon the nail by a transverse striation of variable distinctness. When paroxysms have frequently occurred, the affected digits may become rather soft and flabby from an increase in the subcutaneous fat.

General symptoms are very slight, and fever, if present, does not usually exceed 100° F: if higher, it is attributable to other causes. A stage of local erythema has been said sometimes to replace the asphyxial stage, being ascribed to an irritation of the vaso-dilator nerves; but it has rarely been followed by gangrene, and would seem more properly to be classed as the erythromelalgia of Weir Mitchell. In rare cases the tip of the nose or the ears, and occasionally other symmetrical regions of the body, may be affected with local asphyxia, but the symptoms are the same as in the more common variety.

GANGRENE.—When local asphyxia persists sufficiently long, the vitality of the part suffers. Small blebs form upon the tips of the affected digits, partly at the expense of the outer layer of corium; these rupture, discharging a serous or sero-purulent, often blood-stained, fluid, and leave an excoriation which heals with some little loss of substance. When this process has attended repeated attacks, the fingers or toes exhibit numerous little white cicatrices, and become somewhat conical in shape, with distorted nails and shrunken parchment-like skin. In the severer cases the destructive process may involve a more extensive portion of one or more digits. In this event there are no phlyctenulæ, but the part at once assumes a dark violet or blackish color, and passes through a condition similar to senile gangrene, with subsequent elimination of the sphacelus—a process requiring usually two or three weeks. And thus the patient may pass through an attack with the loss of one or more distal phalanges, or even more extensive portions of the member. Loss of a portion of the margin of the external ear may thus occur, but similar loss of substance of the tip of the nose has rarely, perhaps never, been observed.

Many cases of symmetrical gangrene of greater severity than here described have been reported as Raynaud's disease without seemingly good grounds. Some of these have shown concomitant constitutional symptoms which throw grave doubt upon their accepted pathology; and in others, again, ergotism or vascular disease has not been satisfactorily excluded. As seen in children, where the ground is considerably clearer, the most carefully studied cases have rarely shown lesions more serious than those above described.

Etiology.—As far as its occurrence in children is concerned, sex or age

seems to have little influence. It occurs most commonly during the winter months, often being excited by exposure to the slightest depressions of temperature. Heredity seems to play some part. Raynaud observed a female infant who exhibited a marked disposition to local asphyxia during the first five months of life, at a time when her mother was passing through attacks of dry gangrene of all the extremities. A neurotic family history must be accepted as a powerful predisposing cause, since many victims of this disease show a distinct nervous inheritance. Makins saw symmetrical gangrene in a brother and two sisters whose mother had died of progressive muscular atrophy; and Colman and Taylor report local syncope in a girl of ten years, whose mother was extremely neurotic, and whose maternal grandfather and grand-uncle had suffered from similar local syncopal attacks. As regards previous conditions of health, in some cases the disease has followed upon acute and depressing illnesses; but in others no such exciting cause could be assigned.

Pathology.—Raynaud ascribed this affection to an exaggerated vaso-constrictor irritation dependent upon an increased excitability of the vaso-motor centres of the cord, since, according to his observation, galvanization of the cord modified the arterial spasm, and in one case, carefully studied by himself and Galezowski, there was a remarkable coincidence between the peripheral circulatory disturbances and like phenomena observed in the retinal vessels. Weiss, however, inclined to the theory of peripheral irritation arising in the skin, viscera, or the brain, and thus ascribed many of the cases observed in neurotic women to uterine or ovarian irritation. As the disease is rarely in itself fatal, no satisfactory pathological study has as yet been possible. The most important addition to our recent knowledge of the disease is the occurrence of intermittent hæmoglobinuria. Of ten children suffering from local asphyxia and symmetrical gangrene, as reported principally by English observers, at least eight at some time during the course of the disease exhibited undoubted evidence of blood coloring-matter in the urine. Dickinson, the chief English authority on renal diseases, states that the two conditions, Raynaud's disease and intermittent hæmoglobinuria, seem so to approach each other and mingle as to render it impossible to make a distinct demarcation between them. Abercrombie holds that we are warranted in believing that both paroxysmal hæmoglobinuria and Raynaud's disease are symptoms of a more general affection, and he suggests that the jaundice sometimes found after attacks of hæmoglobinuria (and also after attacks of local asphyxia) is the result of arterial spasm of the hepatic vessels. But it seems more probable, as Barlow believes, that this jaundice is due rather to breaking up of blood coloring-matter elsewhere in the circulation. Several observers have noted that during a paroxysm of intermittent hæmoglobinuria blood drawn from a cold extremity showed changes in the red corpuscles, which exhibited a decided tendency not to form rouleaux and appeared markedly crenated, with granular masses in the surrounding serum. In a very interesting case of a boy of twelve years, who manifested both intermittent hæmoglobinuria and local asphyxia of the extremities, with gangrene of the tips of the ears, Myers found that blood taken from ears and hands during an attack of hæmoglobinuria showed changes similar to those just described. It is thus seen that in this case blood-changes, local asphyxia and gangrene, and hæmoglobinuria occurred in the same patient.

This association with paroxysmal hæmoglobinuria at once suggests a relation to malarial infection—a relation which, in not a few cases at least, is borne out by the existence of previous malarial attacks in such patients. Hereditary syphilis also has obscured the earlier history of several children suffering from well-marked Raynaud's disease; and it is doubtful how much of the symptoms

in these cases could be attributed to specific endarteritis capable of causing vascular obstruction. It is noteworthy, perhaps, that both Boas and Murri, as well as Flensburg more recently, mention syphilis together with ague as probable etiological factors in the production of hæmoglobinuria.

Course, Duration, and Results.—As observed in children, symmetrical gangrene pursues a more benign course than in adults. Local asphyxia may be the only stage, and the disease may be a regular accompaniment of cold weather, disappearing as summer approaches, to recur the next winter. Paroxysms may occur frequently during the day on the slightest exposure to cold, or they may be seen at irregular and longer intervals. Other cases may terminate speedily in gangrene, and leave the child with deformed fingers or toes and only a tendency to blueness of these extremities after exposure to severe cold; while, again, the repeated occurrences of superficial sloughs may result in painful conical fingers with blunted tactile sensibility.

Diagnosis is comparatively easy, provided satisfactory exclusion can be made of cardiac or vascular disease, diabetes, frost-bite and ergotism. From chilblains it may be distinguished by the history, by the absence of itching, and by the presence of pain during spasm which passes off after relaxation. Its localized character at once serves to exclude congenital cyanosis.

Prognosis.—As regards life prognosis is almost always good. Only in one or two reported cases in very debilitated children has a fatal result been traceable to exhaustion from the disease. The prospect of its duration as a chronic or subacute condition or as a periodical visitation is not to be disposed of so easily, and there seems to be no means of judging upon this point at any time during the earlier paroxysms of the disease. The occurrence of hæmoglobinuria, so far as yet observed, has not proven more than a curious episode without much serious import. It is possible, however, that aggravated forms may occur in which a more profuse loss of blood may seriously affect the outcome of the case.

Treatment.—When the milder stages of this disease are first manifested much may be done to prevent the more serious results of repeated paroxysms. If the general health and constitution of the child be satisfactory, and the symptoms seem to depend entirely upon exposure to cold, great care must be exercised to guard against all chances of chilling of the surface or the extremities. He should not be sent out into the open air until he has partaken of food; woollen underclothing and stockings must be constantly worn. If the child is ill-nourished or cachectic, a plentiful supply of nourishing food and appropriate constitutional treatment must be secured. Imperfect circulation of blood and coldness of the extremities certainly predispose to attacks of local asphyxia, and therefore douches may be ordered, the effect of which must, however, be carefully watched. A rapid sponging in a bath of water at a temperature of about 100° F. may be followed by a douche of colder water of about 70°, emptied upon the back and shoulders as the child sits in the warm water. This bath, which is best given in the morning, together with a few minutes' exercise with a skipping-rope or football after breakfast, will do much to keep the extremities warm during the day. By this means attacks of local asphyxia may be prevented; but if they should occur care must be taken not to employ the bath while any blueness of the extremities is noticeable, nor for some hours after the subsidence of a paroxysm.

Raynaud was the first to call attention to the beneficial influence of galvanism applied in the form of descending currents either to the spine or down the affected extremity. In the former case the positive pole is applied over the fifth cervical vertebra, the negative near the commencement of the cauda

equina: while in the latter the negative pole is applied to the closed fingers or the toes. Barlow has obtained most satisfactory results by placing one electrode on the upper part of the limb and the other in a basin of warm salt water in which the affected extremity is immersed. As many elements as the patient can bear should be used, and the current should be made and broken at frequent intervals. The séance should be given daily for about ten minutes. Shampooing is often valuable in conjunction with galvanism, especially in the chronic forms in which the extremity of the limb undergoes atrophy.

Beyond an appropriate tonic treatment little is to be expected from internal medication. Quinine is the only drug whose use in some cases has apparently produced beneficial results, as might be expected from the frequent association with symptoms which suggest the probable etiological importance of malarial infection. This drug should certainly be given a fair trial in every case. Nitrite of amyl has been tried during the asphyxic stage upon theoretical grounds, but without any observed effect.

If pain is severe, much relief will be experienced from the local use of chloroform liniments. In some cases, curiously enough, cold applications, like the ice-bag, give greater relief than warmth.

When gangrene has begun the limb should be maintained in an elevated position, well wrapped in cotton, and kept clean with an antiseptic wash. Stimulants may be required in this stage, and occasionally hypnotics and sedatives to secure sleep, allay restlessness, and alleviate pain. When the line of demarcation has formed, dry hot applications should be kept to the part to favor the process of elimination and repair. In rare cases the destruction of tissue may be so great as to demand a more or less formal amputation.

PART VIII.

DISEASES OF THE RESPIRATORY SYSTEM.

DISEASES OF THE NOSE.

By W. E. CASSELBERRY, M. D.,

CHICAGO.

I. ACUTE RHINITIS.

ACUTE RHINITIS, colloquially termed "cold in the head," is an acute inflammation of the mucous membrane lining the nasal cavities from the anterior nares to the naso-pharynx. It is prone to extend to adjoining mucous surfaces, and usually embraces the naso-pharynx, at least to some degree, and thence invades, not infrequently, the middle ear.

Etiology.—Reasoning from analogy and from its pathology and clinical history, we must regard acute suppurative rhinitis as an infection by pathogenic micro-organisms, although germs specific to this particular form of suppuration have not, as yet, been identified. This statement, however, will bear indefinite qualification, which we must limit to two phases: 1. Some special predisposing condition of the part is essential to infection. 2. It follows certain exposures with such regularity and precision that we must infer a causal relationship between chilling of the body and rhinitis. A draught between the shoulders, permitting the feet or other parts of the body to become cold and damp, or too rapid checking of the perspiration, causes, through the intervention of the vaso-motor nervous system, a sudden turgescence of the nasal vessels, especially of of the turbinated bodies. In the majority of instances this congestion is but transitory, passing off in a few minutes or a few hours, and followed merely by increased mucous secretion; but in other instances it does not subside, but augments in violence, and is followed in from twelve to twenty-four hours by a muco-purulent, and then almost a purulent, discharge. The congestion of the nasal vessels occasioned by thus "taking cold" evidently favors a microbial invasion of the mucous membrane by impairing, in some manner, its powers of resistance.

Instances are not wanting of direct infection of one person by the discharges of another—an accident which is apt to happen among children by the use of handkerchiefs in common. Suppurative rhinitis in infants is also attributable to direct infection from the vaginal discharges during birth.

Symptoms.—A sense of stuffiness in the nostrils, with burning and dryness, together with slight febrile reaction, is succeeded in a few hours by an acrid watery discharge, which later leads to a free muco-purulent secretion. A simultaneous congestion of the frontal sinuses, which occasions headache, is frequent, but this does not argue pressure by accumulated muco-purulent secre-

tion within these cavities, for actual empyema of the frontal sinuses is very rare. Mere swelling of the orifice of the Eustachian tube will occasion tinnitus aurium and impairment of hearing, and a direct extension of the inflammatory process to the middle ear is, seemingly, the cause of nearly all cases of abscess of the cavity of the tympanum. Certain individuals, and even certain families, manifest a decided predisposition to this complication. Associated conjunctivitis is common, and, at times, the external nasal appendage appears swollen, florid, and excoriated by the irritating discharges.

Treatment.—It is much too customary to permit this acute inflammatory disease of a delicate part of the body to progress without efforts to mitigate and abbreviate it. Such a course is fraught with immense possibilities of ultimate damage, chronic catarrh of the nose and accessory organs being thereby established. Many remedies are of real service, but a multiplicity of recommendations is confusing and tends to lessen confidence in any one line of treatment. We will therefore describe simply our own methods of dealing with these cases.

If it is sought to abort the attack of rhinitis, a single average-sized dose of Dover's powder, proportionate to the age of the child, is given at bed-time, also a laxative if needed. The patient is especially well covered in bed, outside night air is excluded, and the temperature of the apartment maintained during the night at 60° to 69° F., but no effort is made to produce profuse perspiration.

The following day, or even the first day if called upon to prescribe before evening, this formula will meet the indications:

- R. Tr. aconiti ℥ xij.
- Tr. belladonnæ ℥ xxiv.
- Morphinæ sulphatis gr. ¼.
- Potassii bromidi ʒj.
- Spts. menthæ piperitæ ℥ xx.
- Aquæ q. s. ad f ʒijj.—M.

Sig. Adult dose, one teaspoonful every hour, to be lessened for children according to age.

The same ingredients could readily be prepared in the form of a capsule, pill, or compressed tablet.

Local treatment is of the utmost importance, and the following mixtures render satisfactory service by atomization:

Spray No. 1.

- R. Cocainæ hydrochloratis, gr. ij.
 - Sodii boratis gr. xx.
 - Sodii bicarbonatis gr. xx.
 - Ol. eucalypti ℥j.
 - Ol. gaultheriæ ℥j.
 - Thymol gr. j.
 - Menthol gr. ss.
 - Glycerini f ʒss.
 - Aquæ q. s. ad f ʒj.—M.
- Sig. Dilute, adding one or two teaspoonfuls to one ounce of warm water for use as a spray.

Spray No. 2.

- R. Cocainæ hydrochloratis . gr. ij.
 - Ol. pini Canadensis ℥v.
 - Ol. gaultheriæ ℥ij.
 - Ol. eucalypti ℥ij.
 - Thymol gr. ss.
 - Menthol gr. j.
 - "Vaselin oil" f ʒj.—M.
- Sig. Use with double bulb (Davidson) atomizer, either alone or following the use of Spray No. 1.

For young children, who are often terrified by spraying, may be substituted a small syringe or an ordinary medicine-dropper used as a syringe, with which

to project, gently, either of these solutions through the nostrils. Spraying or gentle syringing in this manner may be performed twice or three times daily, or even every three hours in severe cases. The cocaine can be omitted from either spray formula, if there be any objection to its use, without seriously impairing the effectiveness of the remedy. All solutions for nasal use should be somewhat warm.

Of the many inhalations, we will mention only camphorated steam as a domestic remedy of power. It is conveniently used by placing a pint of steaming hot water in a glass fruit-jar and adding two fluidrachms of spirit of camphor. A funnel, preferably of glass, is then inverted to cover the mouth of the jar, and the rising steam is inhaled through the nostrils as it escapes from the small end of the funnel. So used, especially during the evening, for a half hour, it conduces to a comfortable night's rest and facilitates recovery.

II. SIMPLE CHRONIC RHINITIS AND PURULENT RHINITIS.

Recurrent attacks of acute rhinitis establish, in children and young people especially, a chronic inflammation of the mucous membrane, which is characterized by variable degrees of proliferation of the epithelium, and by mucopurulent secretion, which is often profuse. The disease is not accompanied by material enlargement of the turbinated bodies or distention of the erectile tissues, and stenosis is not a prominent symptom; which differentiates it from hypertrophic rhinitis.

Etiology.—Bosworth plausibly contends that children are particularly prone to inflammation of the epithelial lining of mucous membranes, and that the epithelial proliferation of muco-lymphoid glands becoming organized without desquamation accounts for enlargement of the tonsils, etc., while an allied inflammation in the nose, with rapid desquamation of the epithelium, constitutes the most important element in purulent rhinitis. The disease bears no constant relationship to scrofula, tuberculosis, or syphilis, since it affects children who are otherwise robust quite as frequently as it does the subjects of these dyscrasiæ. Inattention to hygienic matters, leading to frequent attacks of acute rhinitis, and failure to treat the same effectively, are potential factors in the establishment of this form of catarrh.

Symptoms.—A profuse muco-purulent discharge from both nostrils, swelling and redness of the external nasal appendage, and excoriation, with incrustation of the anterior nares, are the chief manifestations, a too profuse discharge being the sole complaint in the milder cases.

In the course of years, if the purulent type of rhinitis be not arrested, the mucous glands atrophy, the secretion grows less but thicker, and tends to accumulate in crusts. In other words, the disease passes gradually into the atrophic form of rhinitis, which is the successor to purulent rhinitis perhaps more frequently than to hypertrophic rhinitis, although commonly credited to the latter disease.

On the other hand, if simple chronic rhinitis does not assume the purulent type, it is prone to pass gradually into hypertrophic rhinitis.

Diagnosis.—Hypertrophic rhinitis is accompanied by more nasal obstruction and less secretion, although it is sometimes difficult to draw the line between these two affections, however distinct one type may be from the other; indeed, in rare instances the two pathological processes are seemingly associated. Hereditary syphilitic rhinitis can be excluded by rhinoscopic examination, and the purulent discharge occasioned by a foreign body in the nose is commonly unilateral, and the object can be discovered by the probe.

Treatment.—The first indication and most important point in the treatment of purulent rhinitis is to maintain absolute cleanliness of the nostrils. Mucopus must not be permitted to accumulate and decompose in the sinuosities around the turbinated bodies, thus perpetuating the disease. In not too inveterate cases thorough cleansing by means of an antiseptic alkaline and mildly astringent spray, used three or four times daily with a hand-ball atomizer, is all that is necessary to effect a cure. The following modification of Dobell's solution answers this purpose admirably:

R̄. Sodii boratis	gr. xv.
Sodii bicarbonatis	gr. xv.
Ol. eucalypti	℥j.
Ol. gaultheriæ	℥j.
Thymol	gr. j.
Menthol	gr. ss.
Glycerini	f̄ss.
Aquæ	q. s. ad f̄j.

Sig. Dilute, adding two teaspoonfuls to one ounce of warm water for use as a spray.

The patient should be directed to use the spray several times at intervals of five minutes, especially during the morning and evening toilet, and to cleanse the nose by "blowing" in each interval.

If a more active astringent is necessary to check the hypersecretion, sulpho-carbolate of zinc, two to five grains to the ounce, may be used as a spray following the cleansing solution. In young children, who are terrified by spraying, these solutions, well warmed, can be used by means of a small syringe.

Where the purulent type of the disease is complicated by the presence of hypertrophies of the turbinated bodies, deformity of the septum, adenoid vegetations, etc., any of which obstructions will impair the drainage and cause a mucopurulent discharge, surgical treatment appropriate to this special cause or complication is usually indicated. However, the case should not then be regarded, strictly speaking, as one of simple rhinitis.

III. HYPERTROPHIC RHINITIS.

This is a chronic inflammation of the mucous and submucous tissues of the nose, characterized by enlargement, especially of the turbinated bodies, which encroach upon the normal lumen of the nostrils and cause impairment of nasal respiration and drainage. The disease is stated to be rare with children, especially under ten or twelve years of age, but we are convinced that a mild form, or early stage, of the affection is very common at all ages.

Pathology.—Advanced hypertrophic rhinitis is characterized by enlargement and proliferation of all the elements which compose the turbinated bodies: the epithelial surface is thickened; the adenoid layer, which lies between the epithelial and submucous layers, is wider, and the lymph-corpuseles and fibrous connective-tissue bundles are more numerous; the acinous mucous glands are increased in number and size. The submucosa, which is composed largely of blood-vessels of a venous character—sometimes called a venous plexus—is particularly affected, the vessels being enlarged, more numerous, their walls thickened, and the intervascular connective tissue proliferated. The blood-vessels are more or less continually congested, causing "erection" of its structures, and they are no longer capable of complete "retraction" under favorable

influences or under the action of cocaine, but shrink only moderately or but little.

As Bosworth truly remarks: "These are changes which can only ensue during the lapse of years;" and to this extent we would not, therefore, expect to encounter them in children. However, in children and adolescents persistent enlargements of the turbinated bodies can and do present themselves in consequence of mere dilatation and engorgement of the vessels of the submucosa, without any considerable degree of cell-proliferation. Complete retraction in this form is possible, either spontaneously on one or both sides at intervals, or by means of cocaine, the mucous membrane shrinking close to the bony base.

This condition is occasionally referred to as a vaso-motor paresis, permitting over-distention of the vessels of the turbinated bodies and other parts affected; or, again, it is designated by Ingals as a distinct affection under the name of "intumescent rhinitis." But I am disposed to view it simply as an early stage, or, at most, a variety of hypertrophic rhinitis, for cases which present each degree of gradation between this and the advanced stage of the disease above described are continually encountered.

In addition to the intumescent type, even somewhat advanced grades of hypertrophic rhinitis are certainly met with in children.

Etiology.—The most prolific source of hypertrophic rhinitis in young children is adenoid vegetations, which by partial occlusion of the posterior choanæ interfere with the proper drainage and evaporation of nasal secretions, the irritation of retained and decomposing secretions serving to excite proliferative changes in the nose. It would seem, also, that the same dyscrasia—lymphatism, which predisposes certain children to hypertrophy of the tonsils and to naso-pharyngeal adenoid hypertrophy—favors the development of hypertrophic rhinitis. Clinically, these conditions are frequently conjoined, and it is certain that they sustain some dependence upon each other, for removal of the "adenoids" is often followed by subsidence of the nasal hypertrophies.

Recurrent acute rhinitis is another potent factor in the development of hypertrophic rhinitis, and, therefore, whatever serves to excite acute rhinitis must be accorded etiologic consideration in reference to hypertrophic rhinitis.

Symptoms.—Nasal stenosis, or obstruction on one or both sides, is the most prominent symptom, together with many indirect effects due to the stenosis. As a rule, one side of the nose is stopped at a time, the two sides alternating in this respect, sometimes changing with great rapidity and without apparent cause. Again, absolute stoppage of one or both nostrils may manifest itself only under certain conditions, as during railroad travel or otherwise from inhalation of dust, from superheated apartments, and from exposure to a cold, damp atmosphere—conditions which necessarily arise so commonly as to cause much annoyance to the patient.

The secondary results of nasal stenosis are a nervous restlessness, which is excited in many by the sense of obstruction and pressure in the nose, inability to sleep soundly at night or intellectually to apply themselves persistently by day, together with headache and reflex pressure symptoms, such as hemicrania, or nervous sick headache, asthma, spasm of the glottis, and even epileptoid seizures. The most frequent of the reflex nasal symptoms in childhood are asthma in association with bronchitis, and spasm of the glottis in association with laryngitis; in fact, so common, in childhood, is dependence, at least in part, of chronic bronchitis with asthmatic symptoms upon nasal stenosis and adenoid vegetations that the closest scrutiny and attention should be given to the upper respiratory tract in all such cases.

Plethora of the blood-vessels of the nasal mucous membrane tends to develop

a like plethora in the bronchial mucous membrane, and anæmia induced in the turbinated tissues tends to effect an anæmic state of the bronchial tubes. The physiological relationship between the two regions—the nasal erectile tissues being designed to warm and moisten the inspired air—demands, through the vaso-motor system, an intimate correspondence between their blood-supplies. As might therefore be expected, a pathological correspondence also obtains, and, without entering into a discussion of the hypothetical details of nervous mechanisms, we simply state the oft-observed fact, that turgescence and vaso-motor paresis of the nasal erectile tissues may occasion vaso-dilation, congestion, and inflammation of the bronchial mucous membrane.

The term "reflex" is doubtless often misappropriated, yet it has a definite significance, and the pathological reflexes which originate in nasal or naso-pharyngeal irritation, and terminate in cough, laryngeal spasm, or asthma, follow much the same pathway as the physiological reflex known as sneezing. The nasal branches of the ophthalmic division of the fifth nerve and the nasal branches of the anterior palatine, descending from Meckel's ganglion, which is in connection with the superior maxillary division of the fifth nerve, conduct the sensory impression to the medulla. It is there reflected to the respiratory, pneumogastric, and other centres, whence the deep inspiration, forced expiration, and the coincident spasm of the pharyngeal and laryngeal muscles, termed a sneeze. This mechanism, of course, varies somewhat with the different pathological reflex acts.

But nasal irritation does not in every case result in reflex phenomena. Evidently, still other conditions are essential, which must be sought in functional derangement tending toward special susceptibility of certain nerve-centres, including those wrought upon by peripheral nasal irritation; and in chronic inflammation or a predisposition to acute congestive states of particular organs, which unquestionably favors the development in that organ of the ultimate link in the reflex chain. Thus, one affected with bronchitis would suffer the more readily from asthma, excited reflexly by nasal irritation; laryngitis predisposes under like conditions to spasm of the glottis, and digestive derangements to migraine. So, in the completed cycle, three factors obtain—nasal-irritation, superexcitable nerve-centres, and a susceptible peripheral organ. But the nasal irritation is the initial link without which the peculiar reflex is not excited, and to which the other factors are subservient.

Another symptom of hypertrophic rhinitis, secondary to this stenosis, is compulsory mouth-breathing with its many deplorable consequences—*e. g.* drying out of the mouth and pharynx, facial deformity, and mental obtundity—a symptomatic sequence which has been sufficiently elaborated in the article on "Naso-pharyngeal Adenoid Hypertrophy."

Also, concerning secondary impairment of hearing, what is said in that article pertains equally to this disease.

A very annoying symptom, and one which may first attract attention, is dysphonia; in fact, such children are constantly declared to be tongue-tied and the lingual frænum cut without benefit, when the real defect in speech lies in occlusion of the nares or naso-pharynx.

Diagnosis.—This is established by direct rhinoscopic examination anteriorly and posteriorly; the latter, however, is not always possible with young children. The turbinated bodies appear red, turgid, and swollen, but they occupy their natural positions and maintain their normal relations to each other and to surrounding parts; by which fact this disease can readily be distinguished from nasal polypus. A polypus occupies one of the spaces beneath,

between, or beside the turbinated bodies; it is, moreover, movable, and is of paler color than the inflamed mucous membrane.

Treatment.—When dependent upon adenoïd vegetations, the surgical removal of these growths in children usually results in subsidence of the hypertrophic rhinitis. Resolution will be favored in these cases, however, as well as in the milder forms of the disease not secondary to naso-pharyngeal adenoïd hypertrophy, by the use twice daily of an antiseptic, alkaline, and mildly astringent spray or lotion, formulated as prescribed in the section on “Simple Chronic Rhinitis.” This is especially important as a cleansing measure in cases in which some degree of hypertrophy is conjoined with the suppurative type of rhinitis. Refined petroleum products, variously known as “albolene,” lavolene, benzoinol, etc., are just now extensively employed in many combinations in all forms of rhinitis, but antiseptic, alkaline, aqueous solutions are certainly more effective when the parts are to be cleansed of muco-purulent accumulations. Petroleum sprays are, however, often soothing and protective to the parts, especially at times of acute and subacute exacerbations, and may be used in such cases following the aqueous spray twice daily, or used alone with patients who have no retained muco-purulent secretions. “Vaselin oil,” being more viscid than the whiter products, and yet sufficiently fluid to be converted into spray by a good double-bulb hand-atomizer, is best adapted to this use, and may be prescribed in the following combination:

R̄.	Ol. pini Canadensis	℥v.
	Ol. gaultheriæ	℥ij.
	Ol. eucalypti	℥ij.
	Thymol	gr. ss.
	Menthol	gr. j.
	“Vaselin oil”	q. s. ad f̄ ʒj.—M.

Sig. Use with a double-bulb atomizer.

A more astringent spray is occasionally beneficial, although strong astringents are not well borne by the nasal mucous membrane:

R̄.	Zinci sulphocarbolicis	gr. v.
	Iodi	gr. j.
	Potassii iodidi	gr. ij.
	Menthol	gr. j.
	Ol. gaultheriæ	℥ij.
	Glycerini	f̄ ʒj.
	Aquæ	q. s. ad f̄ ʒj.—M.

Sig. Use with atomizer.¹

Persistent use of these remedies, together with the surgical removal of adenoïd vegetations and enlarged faucial tonsils, and hygienic guards to prevent frequent “colds,” will effect a recovery in the majority of cases of hypertrophic rhinitis of children. A minority, however—which includes, especially, the older children—will not yield to this treatment, and will require reduction of the hypertrophy by means of the electro-cautery in order to overcome the nasal stenosis. One should not hesitate to adopt this method in suitable subjects, for the results are very satisfactory and the disadvantages trivial; but considerable technical skill is necessary to ensure entire safety; consequently it should not be attempted by one who is unfamiliar with intranasal operating.

¹ “Vaselin oil” or albolene can be substituted for the glycerin and water in this formula.

Five per cent. cocaine solution on cotton is first placed in contact with the whole length of the inferior turbinated body for ten minutes. The knife electrode is commonly used, but we prefer, as better adapted to the purpose, the ordinary point electrode, which we curve slightly upon the flat, using the surface of the platinum end, and not the very point, with which to burn. This makes a broader eschar than the knife electrode, it is less apt to occasion hæmorrhage, it requires less space in transit through the nostrils, and it adapts itself better to the curved contour of the turbinated body, permitting application farther toward the posterior end of that body.

The cocaine retracts the erectile structures and temporarily provides space through which the unheated electrode is passed: the length of the platinum tip is pressed against the turbinated body, commencing as far posteriorly as one can see, and then, when at white heat from the battery, it is drawn slowly forward, marking its passage by the production of a white linear eschar. Through this same linear eschar, in order to deepen it, one now draws the instrument a second and a third time. Many will direct that the electrode be employed at a cherry-red heat, but during use the point is sunk in a moist tissue, and what is a white heat in the atmosphere is no more than a cherry heat when in contact with the moisture of the turbinated body.

The two nostrils should never be treated at the same sitting, and more than one linear cauterization should not be made at one time, although it may be well to draw the electrode two or three times along the same track in order to obtain sufficient depth, as the subsequent cicatrix, in addition to breaking up the free continuity of blood-vessels and substituting a certain overplus of tissue, should serve also to bind down the neighboring portions by attachment to the bony base. Bad cases require six to eight applications of the cautery at intervals of one to two weeks, two or three on each lower turbinated body, and others of less extent on the middle bodies. Antiseptic cleansing sprays should be used during the intervals. Moderate sepsis has followed this operative treatment in a few instances; consequently it is best to see the patient on the second and fourth day after operating for the purpose of effecting absolute cleanliness.

The best substitute for the galvano-cautery when this is not available is chromic acid, which may be used by fusing a bead on the end of a probe and applying it much as one would the electrode. It is apt to produce excessive breadth and insufficient depth of eschar.

IV. ATROPHIC RHINITIS.

This disease, termed also dry catarrh, ozæna, and fetid rhinitis, is characterized by atrophy of the mucous membrane, of the underlying cavernous structures, and of the bony projections within the nose, which leads to increased spaciousness of the nostrils: also by atrophy with impairment of function of the mucous glands, by reason of which the muco-purulent secretion becomes inspissated and accumulates in the form of crusts, which, in turn, undergo decomposition and occasion fetor.

Etiology.—Fränkel first promulgated the theory that atrophic rhinitis was a sequel to hypertrophic rhinitis, a late stage of that disease: and his views have seemingly been adopted by most other writers, a few guarding this dictum by stating that this disease can also arise independently.

In a discussion before the American Laryngological Association in 1891, I made this statement: "With regard to the transition of hypertrophic rhinitis into atrophic rhinitis, . . . I have never seen a case in which distinct hypertrophy had passed, definitely, into the atrophic condition."

The life-histories of the two affections are dissimilar. Atrophic rhinitis is common in childhood and early adult life, becomes rare after thirty-five years of age, and is very infrequently observed in patients exceeding forty years of age.

Hypertrophic rhinitis of the early intumescent variety is not uncommon in childhood and early adult life, but the disease does not become firmly established, with permanently organized infiltration of the turbinated bodies, at least until maturity; and in the vast majority of cases the quantity and density of infiltrated tissue continues to increase until advanced age.

Since it is conceded that about ten years' duration of the hypertrophic type is usual before transition into the atrophic type, it is apparent that this theory leaves us without an adequate explanation of the many cases of atrophic rhinitis which occur in early life.

The few cases which are explicitly reported by competent observers as having undergone this transition were doubtless illustrations of coincidence, in which, notwithstanding the previous existence of hypertrophy, some other unnoticed or obscure intercurrent cause had served to effect the atrophic change. Bosworth has advanced the most rational explanation of the etiology of atrophic rhinitis in designating "suppurative rhinitis of children" as the real cause—a view which harmonizes with the life-history of the disease, and which is consistent with the undoubted occurrence of the coincidence above mentioned; for it is possible for one already the subject of hypertrophic rhinitis to acquire, in addition, the suppurative type of rhinitis, which latter may terminate in the atrophic state in spite of the previously existing hypertrophy.

Bosworth's theory, moreover, is of special value from a prophylactic standpoint, since it teaches us the importance of promptly suppressing chronic suppurative rhinitis, viewed as a cause the ultimate effect of which, atrophic rhinitis, is, itself, difficult of suppression.

Bosworth says, in brief, that the predominating morbid condition of purulent rhinitis is desquamation of epithelium: that as long as this desquamation is confined to the superficial epithelial cells the disease is attended with a thin and fluid muco-purulent discharge, but that, sooner or later, the desquamative process extends to the epithelial lining of the muciparous and follicular glands; the glandular function is then impaired, and the muco-purulent discharge becomes thick and firmly adherent, in the form of crusts and scales, to the sinuosities of the nose. Further, that this film of desiccated muco-pus, in drying, contracts, and embraces the underlying turbinated tissues in a grasp which necessarily must interfere with the circulation of blood—a condition which limits glandular action still more and conduces to general atrophy.

Hereditary predisposition to atrophic rhinitis is often pronounced. For instance, a patient, aged twenty-two, has developed the disease during the last two years: her mother, for some years deceased, suffered from the disease in a typical form: the patient's child, aged three years, is likewise affected.

Pathology.—The prominent features of the atrophic process are thus summarized by Bosworth: "*First.*—Decrease of covering epithelium, with profuse desquamation. *Second.*—Decrease of the adenoid layer, with lack of blood-vessels, together with destruction of the acinous glands. *Third.*—A total disappearance of the venous sinuses of the submucous layer of the membrane."

Symptoms.—Crust-formation and fetor are the most prominent symptoms of the disease, although other secondary manifestations are numerous.

The crusts may accumulate only in thin scales or in large masses of horny consistency, which may even occlude the nostrils at times, being firmly

adherent and impacted in the sinuosities of the nares, until by decomposition and softening of the layer adjoining the mucosa they are finally cast loose and expelled in large pieces by blowing, often leaving abraded surfaces behind.

The fetor varies in intensity in different cases, but is rarely entirely absent, and in its severe forms is so horribly nauseating and penetrating as to contaminate the atmosphere of an entire room in a few minutes, and to necessitate comparative isolation of the patient. The fetid odor is apparently due solely to decomposition of the incrusting secretion *in situ*, but there is reason to believe that this decomposition may extend to the secretion which is still in process of elaboration in the substance of the glands themselves, although this is difficult of absolute demonstration: for, however thoroughly one may cleanse the parts, fetor, persisting, might still be caused by small invisible particles of crust in the accessory cavities, ethmoid cells, or sphenoid sinuses.

In advanced cases, commonly, the sense of hearing is impaired, the patient's own sense of smell obtunded, the external nose broadened, its alæ thickened, and the physiognomy lacking in acuteness of expression.

The disease extends after a time to adjoining surfaces, constituting atrophic naso-pharyngitis and atrophic pharyngitis. The naso-pharynx becomes so incrustated that the fetid masses must be literally pried out with probes and forceps. The pharynx presents a capacious, glazed, and dry aspect characteristic of the disease. Much more rarely even the larynx and trachea become involved, crusts accumulating in these passages to the point of occasioning dyspnoea.

Diagnosis.—On rhinoscopic examination, both anteriorly and posteriorly, one is impressed by the spaciousness of the nasal cavities and the presence of scales or crusts. After thorough cleansing the mucous membrane appears smooth and thin, although oftentimes congested and abraded in spots from the irritation of long-retained incrustation. In advanced cases the turbinated bodies appear merely as rudiments.

The disease is likely to be confounded, especially in childhood, with hereditary syphilitic rhinitis, which is also accompanied by fetor and incrustation. Unfortunately, by reason of the fetor the term "ozæna" has been applied to both diseases: consequently it is a bad name for either affection, especially since it refers only to the symptom fetor.

In atrophic rhinitis there is uniform atrophy and incrustation without deep destructive ulceration. In syphilitic rhinitis the atrophic process, if present at all, is not uniformly distributed, the nostrils being contorted by deep ulceration and destruction, with subsequent cicatrization, of various parts. Reference may be made to the section on hereditary syphilis of the nose for additional details.

Prognosis.—Atrophic rhinitis requires persistent thorough treatment over a period of from four months to two years, in order to effect recovery even in young subjects and in recent cases. Both patient and physician are prone to become discouraged and to abandon treatment, much to the disadvantage of the former. Old, inveterate cases must continue cleansing measures for years, as part of the toilet, with the same regularity that is given to the teeth. In the worst cases the difference between persistent treatment and total inattention is the difference between the lot of an acceptable member of society and that of a social outcast.

The fact that the disease is rarely observed at an age of over thirty-five to forty years argues a natural predisposition to recovery as life progresses, and should operate as a further incentive to persistent treatment.

Treatment.—The first essential to successful treatment is absolute and continuous cleanliness of the parts. The crusts must not be allowed to form, much less to undergo decomposition. One of the most efficient means to this end, especially for young children, is the nasal douche. I believe it to be justifiable, for the sake of efficient treatment of this particular disease, to assume the slight risk of inflammation of the ear possible by this instrument. This risk, with proper use of the instrument, is remote in comparison with the danger to the same organ from atrophic rhinitis inefficiently cleansed. The original instrument of Thudicum was of glass, but the ordinary soft-rubber

FIG. 1.

Anterior Nasal Douche and Method of Using it.

bag gravity douche, fitted with a nasal nozzle (Fig. 1), answers the purpose still better. It should be suspended from a nail over a convenient basin at such a moderate height that the bottom of the bag is only about three inches above the level of the nose as the head is held over the basin. The patient must maintain breathing by the mouth, well opened: when on applying the nozzle to one nostril the liquid will gravitate gently and slowly into one nasal passage and out through the other, the oral respiration sufficing to close the naso-pharynx from the oro-pharynx by the velum palati. Not force, but thorough maceration, is requisite to detach the crusts; therefore one to two pints of fluid should be gently and slowly used twice daily as a part of the morning and evening toilet. The liquid employed should be *alkaline*, to facilitate solution of the crusts; *antiseptic*, to counteract the fetor; and *stimulating*, to encourage regeneration of the atrophied glands. These qualities are provided in the following formula:

R. Sodii bicarbonatis ʒij.
 Sodii boratis ʒij.
 Extracti pini Canadensis fluidi . . . fʒj.
 Glycerini fʒiv.
 Aquæ q. s. ad fʒviiij.—M.

Sig. To be diluted according to tolerance, adding one ounce to the pint or quart of warm water for use with the nasal douche.

With older children, who can be taught the necessary manipulation, Warner's post-nasal douche (Fig. 2) should be substituted for the anterior douche of Thudicum, on account of greater safety relative to the ear. The same solution in the same proportion can be used with it. One must first draw up a part of the liquid through the instrument into the rubber ball; then insert the curved nozzle through the mouth, behind the velum palati, into the naso-pharynx, and squeeze the ball, thus expelling its contents forward through the nasal passages. This procedure should be repeated until half a pint of liquid is thus used morning and evening. Children who will not tolerate either of these means can conveniently have the nostrils syringed by an ordinary soft-rubber-tipped ear-syringe.

Peroxide of hydrogen has the property, by rapid oxidation, of disin-

tegrating muco-purulent matter, and, when sprayed into the nostrils, it will thus assist materially in loosening the desiccated secretion. It should be used a few minutes before the employment of either form of douche, of a strength just insufficient to cause smarting, sprayed by a powerful double-bulb hand-atomizer. On account of variability and instability of the drug, an exact strength cannot be named, but a 20 to 40 per cent. solution of a 10- to 15-volume peroxide of hydrogen is suitable.

The patient should receive treatment, preferably, from one to three times weekly in the office, at which time any resisting crusts should be detached by a cotton probang, and more actively stimulating and antiseptic medicaments applied. Of these, the powder insufflation of dithymol iodide (aristol) is one of the most satisfactory.

For the excoriation and incrustation around the anterior nares and over the cartilaginous septum, which is often one of the most annoying features with children, the following ointment, thoroughly used each night, being inserted into the nostrils as far as the finger will reach, gives the most satisfactory results:

R. Hydrargyri oxidi flavi gr. j.
 "Vaselin" ʒj.—M.

Sig. For local application.

Sprays of "liquid vaselin," with which antiseptic and stimulating medicaments, such as thymol and menthol, may be incorporated, are also serviceable at times, tending to retard crust-formation.

Of extraordinary measures, electricity is advocated by Delavan of New York, and "vibratory massage" by Braun of Trieste.

Cod-liver oil and syrup of iodide of iron are seemingly the most useful internal remedies, although neither can be relied upon to the exclusion of local treatment.

V. NASAL MYXOMATA.

Nasal myxomata, or mucous polypi, are connective-tissue neoplasms which originate from the mucous and submucous tissues of the nose. The disease does not exist as a primary affection—a dictum which is more emphatically, albeit less elegantly, expressed by stating that polyps will not grow in healthy noses. They are always associated with, and caused by, some other nasal malady. Indeed, the removal of such associated maladies together with the polypi is the "keynote" to the proper and effective handling of the patient.

Polyps are stated to be rare with children, but are probably only relatively so, since the diseases which influence their development are somewhat less usual in young children than in adults. We have observed them in children from the age of eight years upward.

Recognition of the exact points of origin of the neoplasms is essential to a clear understanding of their etiology and treatment.

In the outer wall of the middle meatus of the nose is the ethmoidal fissure, or *hiatus semilunaris*, the antero-inferior boundary of which is a sharp-edged ridge of hook-like curve, and hence termed the unciform process of the ethmoid

FIG. 2.

Post-nasal Douche.

bone (Fig. 3). The fissure itself communicates through its upper end with the frontal sinus, and through its lower extremity, the ostium maxillare, with the antrum of Highmore. All of these parts lie high up beneath the middle

FIG. 3.

Representing the Outer Wall of the Left Nasal Fossa, with the middle turbinated body turned upward to show beneath the hiatus semilunaris (printed in deep black), to the edges of which polyps are frequently attached.

turbinated bone, which, in the natural state, hangs down over them like a curtain.

To summarize Zucherhandl's post-mortem observations of forty-two distinct growths, he found that *two-thirds* originated from the middle meatus, and that, approximately, *two-thirds* of this number were attached to the edges of the hiatus semilunaris. With this knowledge, and judging from the superficial position of the neoplasm and the direction of its pedicle toward its attachment, we can be reasonably certain of the deep point of origin even when such is not visible, and can often destroy the very root of the growth by insinuating a properly-curved cauterizing point-electrode to the spot.

Etiology.—The most common complication, acting also in a causal relation to nasal polypus, is hypertrophic rhinitis. Of course, additional factors are necessary to influence the perversion of a simple hyperplasia of the mucosa into one of myxomatous type.

Stenosis, whether induced by hypertrophy of the inferior turbinated bodies,

septal deflections, or excrescences, results in defective drainage. Muco-purulent secretion, imprisoned and decomposing in the middle meatus and around the middle turbinated body, excites irritation and furnishes the most favorable soil for polyp growth.

Very narrow nostrils, because more readily stenosed, are predisposed, in this manner, to myxomata, and peculiar curvatures or deformities of the septum and middle turbinated bodies, by obstructing drainage, have a like effect.

A tendency to vaso-motor paresis of a diathetic or hereditary nature, which, in certain subjects constitutes the basic lesion of bronchial asthma, will in the same individual underlie the development of nasal myxomata.

The influence of hypertrophic rhinitis on the etiology and treatment is well illustrated in the following history :

Miss T——, æt. ten years. Total obstruction of the left nostril of one year's duration. Enormous hypertrophy of the inferior turbinated bodies. Numerous polypi were closely impacted between the turbinated bodies and the septum; they proceeded from the middle meatus, and were continuously imbedded in a mass of thick, viscid muco-purulent secretion (Figs. 4 and 5). The

FIG. 4.

Polypi in the Middle Meatus, caused by hypertrophy of the inferior turbinated body (child aged ten years).

FIG. 5.

Lateral View of the Same (Fig. 4).

polypi seemed secondary to the hypertrophic rhinitis and defective drainage. On the right side hypertrophy was present, but was insufficient to obstruct the drainage, and no polypi were visible.

Operations first by the cold wire snare resulted in the removal of numerous growths during repeated sittings, but without improvement. The polypi developed as rapidly as removed, springing up like mushrooms in the soggy soil maintained by the imprisoned secretions. The inferior turbinated body was next cauterized along its entire extent, being reduced in front almost to a rudiment, where it previously interfered with vision, instrumental passage, and drainage. One was enabled then to trace the tumors to their exact seat of attachment in the immediate vicinity of the hiatus semilunaris, and to thoroughly eradicate them by reaching that position with a cautery point. No recurrence. Cure complete.

Again, Miss R——, æt. twelve years. Has had catarrhal symptoms for some years, with adenoid vegetations and obstruction to the left nostril. Examination Feb., 1893. A single polypus proceeds from the left middle meatus, and is traceable in the direction of the hiatus semilunaris, to which it is evi-

dently attached (Fig. 6). The inferior and middle turbinated bodies are hypertrophied, and obstruct drainage from the middle meatus.

In Fig. 7, taken from an older subject, is depicted the manner in which a septal excrecence, by serving as an obstruction to respiration and drainage,

FIG. 6.

Single Polypus in the Middle Meatus, caused by hypertrophic rhinitis (child aet. 12).

FIG. 7.

Polypus in the Middle Meatus, associated with hypertrophy of the inferior turbinated body and excrecence of the septum.

especially when conjoined with hypertrophy of the opposite turbinated body, as illustrated, may dam up the secretions in the middle meatus and encourage the growth of polyps.

Septal excrecence often originates during the developing period of child-

FIG. 8.

hood, and is a deformity of the septum narium characterized by an exuberant and projecting growth of bone and cartilage along the sutural lines of the component bones and cartilages of the septum narium. The most frequent location

is the sutural line of the vomer and the superior maxilla and cartilaginous septum just within the anterior nares and close to the floor of the nose (Fig. 8).

Necrosing ethmoiditis of Woakes also figures as a persistent cause and complication of nasal polypus. It involves the nasal tributaries of the ethmoid bone, especially its process, the middle turbinated body, which usually appears cleft asunder, leaving a fissure down its centre, from which will protrude the polypi. This is illustrated in Fig. 9, which was taken from a patient, aged twenty years, who had suffered since childhood.

Empyema of the antrum of Highmore, although rare with children, is also a prolific source of nasal polypus in adults, apparently caused by the constant presence of fetid pus in the middle meatus as it escapes from the antrum through the hiatus semilunaris.

The form, aspect, and consistence of a myxoma has been compared to a grape-pulp. The natural shape is pyriform, but this is often varied by pressure. When small, it is sessile, but it becomes pedunculated by gravity as development proceeds, and the point where the pedicle is confounded with the tissues of attachment is known as the "root." The color varies according to vascularization from gray to yellow and from yellow to pink and red.

Pathological Histology.—A typical myxoma, or "myxoma hyalinum," resembles in structure the vitreous body of the eye and the gelatin of Wharton of the umbilical cord. Microscopically, there are observed either a few roundish cells, as in the vitreous body, or scattered fusiform and stellate cells which send off anastomosing trabeculae, as in Wharton's gelatin, or both together, and these are imbedded in a large quantity of a homogeneous gelatinous mucin containing intercellular substance.

But myxomata rarely appear in this purely typical form, the "myxoma hyalinum" being prone to transformation into allied histological structures or to be represented from the beginning by one of its modified forms. Of these, the most common is the myxo-fibroma, which contains a greater but variable quantity of fibrous tissue. Those which are ordinarily called myxomata usually contain enough of the fibrous element to include them, strictly speaking, within the class of myxo-fibromata.

Symptoms.—The chief symptom is nasal stenosis, which increases with the development in size and number of the polypi until complete obstruction of one or both nostrils results. Mucous or muco-purulent discharge, cephalalgia, aural complications, and other symptoms of a catarrhal nature, together with those incident to mouth-breathing, are observed. To quote the words of a sufferer: "It affects the sight, the hearing, the taste, and the smell, of course." Spasmodic asthma, paroxysmal cough, and sneezing attacks are among the reflex phenomena which are occasionally excited.

Diagnosis.—For diagnostic purposes it is usually only necessary to look with a good light and to feel with a probe in order to establish correspondence with the physical characters just described, but more rarely an accurate knowledge of all pathological states is essential to a precise diagnosis.

Treatment.—The treatment consists first in the establishment of free nasal passage for respiration, drainage, vision, and instrumental manipulation, and, to this end, in the reduction of hypertrophied turbinated bodies, and removal when

FIG. 9.

necessary of septal excrescences by means of the nasal saw. Adenoid vegetations, if present, should be removed.

While this work is progressing such polypi as can be reached should be removed, and others as rapidly as access is gained. This is done preferably by the cold wire snare.

But the real success of the treatment, after having gained access to the polypi, consists in tracing them to their points of attachment, and in thoroughly cauterizing these so-called roots; if not at the same sitting, then at the next, remembering meanwhile the exact spot. Knowing the hiatus semilunaris to be a favorite point of origin, those polypi which proceed from beneath the middle turbinated body should be followed up by insinuating to this point a fine electrode slightly curved on the flat.

The permanent success of the treatment will depend upon the possibility, in individual cases, of thus reaching the deep points of origin, and upon the establishment of good drainage in the nose.

VI. HEREDITARY SYPHILIS OF THE NOSE AND THROAT.

Hereditary syphilis manifests itself in children at any time from birth to four months of age. It has, of course, originated during intra-uterine life, and simply progresses to the point of becoming particularly apparent in the upper respiratory tract during the period stated. In rarer cases it seemingly thus manifests itself first at the age of puberty, or, indeed, at any time previous to this age, but in these cases it is doubtful whether the slighter symptoms at the earliest period of life have not simply been overlooked.

From birth onward the disease passes through stages which in their symptomatology and pathology are identical with the secondary and tertiary stages of acquired syphilis. Thus, soon after birth syphilitic rhinitis is manifested by coryza, which, as the disease progresses, gradually develops into a mucopurulent discharge, the acrid secretion causing excoriation and incrustation at the margins of the nostrils. It is probable that infiltration of the superficial layers of the mucosa by embryonic cells, and subsequent degeneration of the same into "mucous patches," also occur; but a satisfactory examination of the interior of the nose is impossible at this early age, and a definite diagnosis of this stage may be dependent upon the concomitant symptoms of syphilis. The disease, however, usually runs a rapid course, and the later manifestations, which correspond to the tertiary symptoms of the acquired form, are sufficiently characteristic. A gummatous infiltration, either diffused or circumscribed, occurs in the depths of the tissues, the entire thickness of the mucosa, the cartilages, and bones being alike subject to an infiltrating deposit of small round cells of embryonic type. These deposits readily undergo degeneration, and result in deep destructive ulceration of the tissues and cartilages and in necrosis of bones.

The disintegration may commence either in the centre or depths of the tissue or upon its surface, and is seemingly occasioned by the cutting off of the blood-supply to this lowly-vitalized material by pressure exerted in all directions by the cells themselves. The cartilaginous septum narium soon disappears, the vomer is attacked, the nasal bones affected, and the external nasal appendage sinks backward and downward, acquiring the "saddle-back" deformity or "flat nose." One or both alæ are not uncommonly destroyed, and subsequent cicatrization may obliterate the nasal orifices. In fact, there is no limit to the horrors of this disease when left unchecked, necrosis continuing until death is caused by hæmorrhage or meningitis.

In the throat favorite points of attack are the velum palati and the junction of the velum with the hard palate, as well as the palatal processes of the palate bone and of the superior maxillary bone. Thus, the cavities of the nose and mouth are caused to communicate by perforations of greater or less extent. The pillars of the fauces and the posterior pharyngeal wall are by no means exempt. The ulceration being deep, the following cicatrices must be extensive, and are found to be thick, dense, and prone to extreme degrees of contraction, so that they appear, oftentimes, stellated or twisted and contorted into various shapes. They are comparable to, but worse than, the cicatrices which follow deep burns. In this way the pharynx and velum become adherent, the throat being contorted and twisted apparently into one cicatricial mass, which may leave but a minute opening between the pharynx and naso-pharynx. Crusts accumulate in the nasal cavities, and the fetor is intense, occasioned both by the decomposing incrustations and necrosis of bone.

Treatment.—The patient should be placed as rapidly as possible under the influence of mercury, which is best done by inunction with mercurial ointment. In many cases mercury alone seems superior to the potassium iodide or the mixed treatment. Attention to the bowels and care of the general health are not to be omitted, nutritious diet, fresh air, and tonics being indicated.

The local treatment is of the utmost importance. The ulcers must be kept absolutely clean and free from decomposing discharges. The means to this end are the same as those detailed in connection with atrophic rhinitis. As a topical application to the ulcers we value most highly the following solution:

R_x. Iodi,
 Acidi tannici,
 Potassii iodidi āā ʒj.
 Glycerini fʒss.
 Aquæ q. s. ad fʒj.—M.

Sig. Apply by a cotton swab.

Under this treatment it is a veritable pleasure to watch the absorption of infiltrated masses and the cicatrization of the ulcers.

CATARRHAL LARYNGITIS (SPASMODIC CROUP).

BY H. ILLOWAY, M. D.,

CINCINNATI.

CATARRHAL LARYNGITIS, termed also spasmodic laryngitis, pseudo-croup (false croup), and acute laryngitis, is an acute inflammation of the mucous membrane lining the larynx, and not infrequently involves that of the trachea. The disease may present itself with varying intensity; clinically, three distinct forms have been recognized—the *mild*, the *severe*, and the *very grave*.

In addition to the usual symptoms we may have—and this is more especially true of the severe form—paroxysms of dyspnoea manifesting themselves, which by some are regarded as true laryngeal spasms. The catarrhal laryngitis with the paroxysms of dyspnoea superadded, which is frequently treated as a distinct disease, has been designated laryngitis stridulosa, angina stridulosa, and spasmodic laryngitis; it is also called pseudo-croup or false croup, to distinguish it from true croup or pseudo-membranous laryngitis.

Catarrhal laryngitis is a disease that occurs at all periods of child-life from birth up to the fifteenth year. Pseudo-croup is seen with greatest frequency between the second and fourth years. It is rarely seen before the second year, and still more rarely after the fifth year. It attacks children both strong and weak, and does not make much distinction between the children of the rich and those of the poor. It is said that boys are more prone to the disease than girls; there are, however, no sufficiently reliable statistics upon this point, as this disease has been confounded by many writers with laryngismus stridulus (spasm of the glottis), for which this statement holds good.

Catarrhal laryngitis presents itself either as an idiopathic affection or as a secondary and symptomatic one, and then usually in the course of some general disease. It occurs with greatest frequency in the colder months, about the beginning and end of winter. In certain latitudes, where the winters are rather mild and the snow melts very quickly and the streets are thus wet and slushy, it prevails throughout the whole winter. The sudden setting in of cold, wet days in summer may cause an outbreak of catarrhal laryngitis.

Etiology.—The principal etiological factor is taking cold. A very young child may contract a cold by sitting on a cold floor, by throwing off the coverlet at night after the temperature of the room has cooled considerably, by a sudden transference from a very warm to a cold room, more particularly a cold draughty hall, or by being taken out on a cold, windy, blustery day; older children take cold by going out insufficiently clothed, by taking off top-coats in the street after having become heated at play, by wading in water or in snow. Cold air inspired directly, and especially whilst the vocal organs are violently exercised, as in screaming or yelling, is not an infrequent cause of laryngeal catarrh. In some instances I have attributed attacks of pseudo-croup to the cold, moist atmosphere created in the bed-room by a floor scrubbed late in the evening and not thoroughly dried before the child was put to bed.

In some children a predisposition to catarrhs of the upper air-passages undoubtedly exists as the result of a faulty physical training, faulty domiciliary hygiene, and perhaps improper diet in combination with some of the other factors. Scrofulous, weak, anæmic children, with proneness to coryza and to inflammatory affections of the tonsils, are more especially liable to attacks of pseudo-croup. A characteristic of this latter form of catarrhal laryngitis is the tendency to recurrence: children who have once had an attack of spasmodic laryngitis are liable to have a like attack after every, even very slight, exposure. After the fifth year, especially if placed under more favorable hygienic conditions, they soon outgrow this tendency: I have, however, observed instances where children have remained croupy as late as their ninth year. It is this affection which people really mean when they speak of their children having had three, four, or more attacks of croup.

Whilst catarrhal laryngitis may be of the mild or severe type from the onset, the grave form is always an acute progression, chiefly due to neglect, of one or the other milder form. The child is allowed to play around at its will despite hoarseness and cough, to expose itself to draughts, to get wetted by rain, till all at once the symptoms of the grave type manifest themselves. The majority of the cases of this character observed by me were due to premature exposure after an attack of measles, before the catarrhal laryngitis that usually accompanies that disease had fully subsided.

Laryngo-trachitis is frequently but part of a general inflammatory condition extending downward from the nose to the bronchi; more rarely it is due to the upward extension of a tracheo-bronchitis.

Occasionally it is due to the exciting influence of local irritants. The inhalation of hot steam, a very dusty atmosphere, and irritating vapors are not infrequent causes of catarrhal laryngitis. Baginsky reports a case where the prolonged inhalation of coal-gas produced a violent laryngo-trachitis.

As a symptomatic expression of a general affection catarrhal laryngitis occurs in measles, scarlet fever, variola, and erysipelas. It may appear as a complication in typhoid fever, in broncho-pneumonia, and in pulmonary phthisis.

Pathology.—The most reliable data concerning the coarser anatomical changes occurring in this disease have been obtained by laryngoscopic examination. The principal features of a catarrhal laryngitis are hyperæmia, swelling of the mucous membrane, and rather abundant muco-purulent secretion, somewhat viscid in character and found adhering to various sections of the laryngo-tracheal mucous membrane. Diffusion and intensity of the hyperæmia may vary greatly. The inflammation may be confined to the entrance of the larynx or to the epiglottis (*angina epiglottidea*); it may be more marked in the middle portion of the laryngeal cavity; it may attack only the vocal cords and the posterior commissure, or it may be diffused over the whole of the larynx. The color of the mucous membrane may range from that of a slight vascular injection to a deep dusky red. The vocal cords may present an almost normal appearance, their lustre perhaps somewhat dimmed; they may be more or less hyperæmic, or they may appear as two large rolls of deep red color by reason of marked swelling of their under surface. The tumefaction also varies in extent—sometimes so slight as just to prevent free movement of the vocal cords, at other times so great as to cause marked stenosis. The epithelium is exfoliated in patches, and shallow erosions there appear; in other parts it will be seen swollen up and forming grayish circumscribed elevations. Small ulcers are sometimes seen, the result of destruction of the epithelial covering and of bursting of distended muciparous follicles. The secretion is at first scant, and if the catarrh be of the mild form and remain limited to the vocal cords, may

continue so throughout the whole course of the disease. Usually it is at first viscid and transparent like glass; later on, by the addition of cell-detritus, it becomes turbid and yellowish gray.

In the severe forms of catarrhal inflammation of the larynx the epiglottis presents a characteristic change of form; the incurvation of its lateral borders, which to a certain extent is normal in childhood, becomes greater, and frequently gives it the appearance of a deep-red swollen stump, which can be seen even without a mirror by simply depressing the tongue.

In the trachea the vascular injection is rarely a diffused one; only in the more intense forms do we find the whole mucous membrane deep red and velvety. Ordinarily the redness is here found in patches; the tracheal rings can be readily recognized, and the mucous membrane covering them is less injected, paler than that of the interspaces.

In the grave form the inflammation frequently involves the submucous tissue.

For greater lucidity and better comprehension the various types will now be considered separately.

I. THE MILD FORM (LARYNGITIS CATARRHALIS SIMPLEX; SUPRAGLOTTIC LARYNGITIS).

Symptoms.—The main features of the disease are the change in the voice or cry and the cough. In young infants it is only the cry that is altered, whilst in older children the speaking voice is also changed; they are hoarse. This hoarseness may be very slight, only noticeable to those familiar with the child, or marked and apparent at once to every one. There is almost never aphonia; however, in infants who cry and scream a great deal aphonia may result from this. Older and more intelligent children may complain of a tickling or burning in the larynx or about the sternal region. Pressure over the cricoid cartilage or over the trachea usually produces manifestations of pain. There is not much cough; it is chiefly due to voluntary efforts at expulsion of mucus. The cough is dry at the outset, but very soon becomes looser and softer, an indication of the resolution of the catarrhal process. It never has the barking tone of the *severe* type. Respiration remains unchanged. There are no paroxysms of dyspnoea. Generally there is greater hoarseness and more cough in the morning just upon awakening and in the evening. Fever is most frequently wanting; when it does present itself, it is usually of slight degree. There is but little disturbance of the economy as a rule; the child eats, plays and sleeps about as usual. Acute rhinitis is almost always present; at times some redness and swelling of the pharyngeal mucous membrane may be noted. In some instances the child may complain of earache, which, however, very soon disappears, or he may complain of a "cracking" in the ear, heard in the act of swallowing. Occasionally some bronchial catarrh may be present, as indicated by râles heard over the thorax.

Laryngoscopic examination discloses a moderate hyperæmia of the larynx or a more intense hyperæmia of the larynx and trachea. In the majority of cases it is limited to the supraglottic portion of the larynx. The posterior portion of the vocal cords, the posterior commissure, and the mucous membrane of the ventricular bands are the principal seat of the catarrh. There is but very little or no swelling of the mucous membrane.

Course and Duration.—Under fair conditions the disease runs a very rapid and favorable course, ending in recovery. Its duration, dependent somewhat upon the degree of intensity, is from three to eight days. Either from

neglect of the primary affection or from some inherent idiosyncrasy the disease may become chronic; this, however, is rather a rare occurrence in young children. An acute progression into the severer forms is not very frequent.

Complications.—Bronchitis or catarrhal pneumonia may develop in the course of a catarrhal laryngitis as a result of the downward extension of the inflammatory process.

Diagnosis.—The diagnosis is not difficult. The hoarseness of the cry or of the voice, the cough, and the tenderness over the larynx will clearly indicate the seat of the affection. The mildness of the special symptoms, the absence of fever or its low degree, the undisturbed condition of the general economy, and the coincident rhinitis will indicate the type.

Prognosis.—The prognosis is always favorable; recovery is the rule.

Treatment.—The treatment is simple. The child must be kept in the house and if possible in one well-ventilated room, the atmosphere of which is maintained at an equable temperature. If the room be heated by a stove, a pot of water should be kept constantly thereon to moisten the air. Attention must be paid to the child's clothing that it shall be sufficiently warm, lest he should be chilled every time the door is opened or if he should happen to run out into an adjoining room or hall. If the bowels are costive, a laxative—*e. g.* a dose of castor oil—must be administered. When children object to taking oil or do not retain it upon the stomach, I have found the following formula answers the purpose very well:

R. Mass. hydrargyri grs. ij.
Syr. mannae f ʒv.
Syr. rhei aromat. f ʒij.—M.

Sig. One teaspoonful every two hours till bowels are moved (for a child from two to four years old).

Or this.

R. Aquæ laxativæ Viennensis (Ph. G.)¹ f ʒj.
Syr. rhei aromat. f ʒij.—M.

Sig. One teaspoonful every two hours till bowels are moved.

For the local process in the larynx mild demulcent drinks are given, as warm milk sweetened, or milk and seltzer water, or oatmeal- or barley-water sweetened. Of medicines, some preparation of ammonia (I prefer the carbonate on account of its more agreeable taste), of ipecacuanha, or of both combined, or a combination of syrup of ipecacuanha and syrup of senega, will be of great benefit. For example:

R. Ammonii carbonatis grs. ij-v.
Syr. ipecacuanhæ f ʒij-ʒiij.
Syr. senegæ f ʒij-ʒiij.
Syr. toltan. q. s. ad f ʒj.—M.

Sig. One teaspoonful every two hours (for children from two to five years old).

¹Very much like the infusum sennæ compositum of the U. S. P.; instead of Epsom, Rochelle salts are used.

For children under two years I use the following formula :

R _y . Ammonii carbonatis	grs. ij.
Mucilag. acaciæ	f ℥ij.
Vin. ipecacuanhæ	gtt. xxxv.
Syr. senegæ.	f ℥j.
Syr. toluatan.	q. s. ad f ℥i.—M.

Sig. One teaspoonful every two hours.

Externally a stimulating embrocation, as camphorated oil, with or without the addition of a little turpentine or of tincture of ginger, or amber oil, may be applied.

If the child be of sufficient age and of sufficient intelligence, an inhalation from a steam atomizer of a mild solution of sodium bicarbonate in glycerin and water (a few drops of carbolic acid can be added to the solution for its antiseptic properties) may be given twice a day. In very young children inhalations cannot be satisfactorily administered, and are therefore useless.

The rhinitis that is usually present should receive prompt attention. The nose should be sprayed every four hours; for this purpose either a 1 or 2 per cent. solution of menthol in albolene or some astringent solution, like the following, should be used :

R _y . Cocaine hydrochlorat	grs. ij-ijj.
Acid. tannic.	grs. v.
Aq. destillat.	f ℥iv.
Hydrogen peroxide	f ℥j.
Glycerini	f ℥iii.—M.

Sig. Use as a spray.

If fever be present, a few small doses of quinine will allay it. The chocolate quinines (for very young children I have them powdered and administered in milk) are, by reason of their tastelessness, excellent for this purpose; two to four tablets may be given every four hours. If the cough is very troublesome at night, one-half to two grains of Dover's powder or five to fifteen drops of the syrup of Dover's powder, according to the age of the child, or a few doses of the bromide of ammonium, will procure a good night's rest.

Throughout, the diet should be a bland but nutritious one.

II. THE SEVERE FORM; SPASMODIC LARYNGITIS (LARYNGITIS STRIDULOSA; PSEUDO-CROUP; CATARRHAL CROUP).

Symptoms.—The characteristic feature of the disease usually sets in suddenly. The child has been asleep for three or four hours, sleeping quietly, when, either with preceding manifestations of restlessness or suddenly, it wakes up with a suffocative attack. It coughs; the cough is short, barking, deep-toned; between the coughs the deep inspirations have a stridulous, crowing sound. Great anxiety is manifested by these little patients; very young children will want to be taken up and held upon the arm; older children will sit up in bed and clutch at the throat, as if to remove the obstacle they imagine there. The face is somewhat congested; the skin is bathed in perspiration, and the pulse is accelerated. Generally the accessory respiratory muscles are not called upon; at most there may be noticed a slight distention or increased movement of the *alæ nasi*. In very severe paroxysms, which are of exceptional occurrence, the accessory respiratory muscles are called into activity, the epigas-

trium and false ribs are drawn in on inspiration, and the face is somewhat cyanotic. The dyspnoea lasts for about a minute, a little longer in the very severe cases, when it begins to diminish in intensity, and in half an hour has entirely or almost entirely disappeared. In about an hour the child has quieted down, and soon goes to sleep again. It may cough several times during the night: that short, barking cough, without, however, being disturbed thereby. The next morning the child is apparently well; older children will want to get out of bed or even out of the room, and nothing but an occasional raw, barking cough remains to tell of what has occurred the preceding night. Occasionally towards the afternoon the cough may become dryer and tighter, and the child have another suffocative paroxysm the succeeding night. This usually ends the matter, and nothing but a loose cough remains.

There may be some variation in this picture. The dyspnoea may last for a longer period than above described, although the child may fall asleep after a while; but even during sleep the inspiration will be attended by a stridulous or sawing noise. Or there may be no dyspnoea at all, nothing but the croupy, barking cough (and that is the phenomenon that fills the family with terror). This is more frequently the case when this form of catarrhal laryngitis occurs in older children, those beyond the fifth year.

It is stated that there may be a recurrence of the paroxysms for from three to five nights. In a large experience I have never seen such recurrence; in fact, never noted a recurrence on the second night. Steiner and Monti observed the recurrence of the suffocative attacks for ten or twelve nights; this was, however, more particularly noted in rachitic children. The special tendency of such children to laryngismus stridulus is perhaps no unimportant factor in the protraction of an attack of pseudo-croup.

The occurrence of an attack of spasmodic laryngitis during the morning or day sleep is exceedingly rare. Barthez and Rilliet state that they have occasionally observed the second paroxysm to set in during the early morning hours.

Frequently the paroxysms are preceded a day or a few hours by a mild catarrh of the upper respiratory tract—a coryza; there may have been some hoarseness of voice and some cough, but of so mild a character that no attention was paid to them by the parents, and no measures for their cure instituted. Or there may have been marked hoarseness and sonorous cough. Occasionally, and not infrequently, no such preliminary manifestations have occurred, the suffocative attack setting in suddenly after some prolonged exposure on the part of the child some hours previously.

As to the mechanism of the paroxysm of dyspnoea opinions differ. It is possible that true spasm of the laryngeal muscles may, in a certain category of cases, as in rachitic children or children who have at one time been afflicted with laryngismus stridulus, be a prominent factor in its production; in the majority of instances, however, it is undoubtedly primarily due to the increase of the tumefaction during sleep, when the child is lying down—to the dryness of the laryngeal and pharyngeal mucous membrane at this time, and the incrustation of mucus upon the vocal cords, still further narrowing the already somewhat contracted glottis, and producing an impediment to respiration sufficient to wake the child. That these are the main and necessary conditions for its production is proven by the rapidity with which the symptoms abate after the child has been taken up and some warm drink given it. It is also more than probable that the hoarse, barking cough with which the child usually awakes is the result of reflex irritation proceeding from the inspissated mucus—in other words, the attempt of nature to dislodge it.

There is not much elevation of temperature. I have never found the thermometer to indicate more than 101.5° – 102° F. shortly after the abatement of the paroxysm.

Laryngoscopic examination will disclose considerable hyperæmia and tumefaction of the mucous membrane, especially of the ventricular bands, so that these may lie over the true vocal cords and the latter appear narrower. The vocal cords themselves may have a tumefied and rosy appearance, the tumefaction pertaining more particularly to their under surface. The mucous membrane of the thyroid cartilages, of the ary-epiglottic folds, and of the trachea, is considerably swollen, and either uniformly injected a deep red or hyperæmic only in spots; the surface sometimes presents a grayish appearance, as if it had been touched with caustic; this is undoubtedly due to a swelling of the epithelium. Incrusted mucus is also seen upon the interarytenoid mucous membrane and along the posterior portions of the vocal cords.

Course and Duration.—The disease with proper attention usually runs a mild course; the cough soon becomes loose and soft; there are no further returns of the paroxysms, and in from five to fourteen days the child has entirely recovered. It is well enough, however, to remember the fact, already mentioned, that there is a tendency to a recurrence of the disease with every fresh exposure.

Complications.—Bronchitis and broncho-pneumonia.

Diagnosis.—The diagnosis of pseudo-croup does not usually present any difficulties. The brief invasion, the characteristic paroxysm with its sonorous, barking cough, and the rapidity with which it passes, the time of onset, the rather mild febrile movement, are features sufficiently distinctive to make error almost impossible. The only two diseases with which it could be confounded are laryngismus stridulus and true croup. From the former it is readily distinguished by the cough, the hoarseness in the voice, and the fever—phenomena altogether wanting in laryngismus stridulus. From the latter, for which only a very severe attack of spasmodic laryngitis could be mistaken, the differential diagnosis can be made by remembering the following points: In true croup the symptoms are at the outset very mild and *gradually* grow in intensity. This increase in gravity continues both day and night. The difficulty in breathing grows by degrees, and continues so to grow till the climax, marked dyspnoea, is reached. The cough is harsher and more smothered. The voice is hoarse and rather muffled. There is a high degree of fever and great disturbance of the general economy. Furthermore, in 50 per cent. of the cases of true croup false membrane can be seen upon the tonsils, uvula, fauces, or pharynx. In pseudo-croup the suffocative attack comes on suddenly in the night, at once with maximum intensity, and abates entirely in a very short time. The cough is sonorous. The voice, soon after the paroxysm is over, regains tone, though it may be somewhat hoarse. There is much less fever and much less disturbance of the general economy.

Prognosis.—The prognosis is as a rule favorable; no death from pseudo-croup has ever been reported. Nevertheless, it should be a guarded one, for the reason that this form of catarrhal laryngitis may, either from total neglect or even insufficient attention to the child, progress into the grave form, or that a pseudo-membranous laryngitis may supervene upon the catarrhal, the inflamed mucous membrane forming an excellent nidus for the lodgement and propagation of disease germs.

Treatment.—Ordinarily the paroxysm *per se* does not require the attention of the physician; it is usually over by the time he reaches the house. Only in exceptional cases, where the paroxysm is very much prolonged, where

spasm of the laryngeal muscles has probably been excited by the laryngitis, must special measures for its abatement be instituted. For this purpose the child should be placed in a warm bath, temperature 100°–101.5° F., and allowed to remain therein from ten to fifteen minutes, so as to obtain its full relaxing effect; or a hot mustard foot-bath may be given in its stead. A sponge wrung out of hot water may be applied over the pomum Adami, as described farther on. Or 20–25 drops of ether may be given to a child two years of age, and if necessary it may be allowed to inhale a little. The ether acts by its relaxing effect on the laryngeal muscles and its expectorant effect on the mucous membrane. (For other remedial measures employed for this purpose see the article on Laryngismus Stridulus.)

The treatment of pseudo-croup, with the exception above noted, is rather simple. The remedy mainly indicated is one that has both expectorant and relaxing properties, and the one that best fulfils these indications here is some form of ipecacuanha. The formula I have employed with unvarying success is this:

R̄. Vin. ipecac.	fʒj.
Tinct. aconiti	℥ ij.
Syr. toltan.	fʒij.
Liquor. ammonii acetat.	fʒi.—M.

Sig. Teaspoonful every hour till cough is loosened; then every two hours.

In children under two years I use the following formula:

R̄. Liquor. ammonii acetat.	fʒvj.
Tinct. aconiti	℥ j.
Syr. ipecac.	fʒiiss.
Syr. toltan.	fʒiiss.—M.

Sig. Teaspoonful every two hours.

In these formulæ we have the expectorant properties of the ipecacuanha aided by those of the mild ammonium preparation and by the relaxing effect of the aconite. The liquor ammonii acetatis has, furthermore, diaphoretic properties very advantageous in the treatment of inflammations of the respiratory tract. The aconite acts as a febrifuge and is reinforced by the ipecacuanha.

If after twelve to eighteen hours I find that the respiration is still accompanied by a sawing noise, is still somewhat stridulous or whistling, although there is no dyspnoea present, I prescribe pilocarpine:

R̄. Pilocarpin. hydrochlorat.	gr. ʒ.
Acid. hydrochloric. dilut.	℥ v.
Aq. destillat.	fʒij.
Ext. ipecac. fl.	℥ ij.
(aut. vin. ipecac.	fʒj.)
Syr. scillæ	fʒij.
Syr. toltan.	fʒss.—M.

Sig. Teaspoonful every two hours for a child two and a half years old.

I have never derived any benefit from the other preparations of ammonium usually employed, the muriate and the carbonate, in any form of acute subglottic laryngitis; on the contrary, I have always found them, more especially the latter, absolutely detrimental. I have had such uniform success with the

described remedies and formulæ that I have never had occasion to resort to opiates; and in this respect I agree with Bosworth that, as a rule, they should be avoided. Emetics are never required.

Externally, an application of camphorated oil, as already described, may be made, or a layer of fat bacon or a piece of fat salt pork, upon which some pepper is sprinkled, may be tied around the throat. Sometimes benefit is derived from the application of warm flaxseed poultices.

If rhinitis be present, it will be treated as already described in the previous section.

The child must be kept in a warm, well-ventilated room, and under no consideration allowed to be taken out or to go out. After five or six days, if the disease have progressed favorably and the weather be good, it can be taken out for a couple of hours during the warmest part of the day. The diet must be bland, but nutritious. The bowels must be kept soluble.

III. THE GRAVE FORM. (LARYNGITIS HYPOGLOTTICA ACUTA GRAVIS; ACUTE SUBGLOTTIC LARYNGITIS, OF GRAVE FORM; SPASMODIC LARYNGITIS, SEVERE FORM; CATARRHAL CROUP.)

Symptoms.—This form of catarrhal laryngitis is almost always an acute progression of one or the other of the milder forms. This progression may be slow, requiring from five to ten days till the climax is reached, or it may be very rapid, thirty-six hours to two days. It is marked by an exaggeration of all the phenomena above described. The suffocative paroxysms are of greater intensity and of longer duration; in fact, once established, the dyspnoea is continuous, with but temporarily diminished intensity during longer or shorter intervals. Usually the onset is marked by increased frequency of cough, which is short, hoarse, and markedly croupal; it is a dry cough; it is painful, the child crying between the coughs and complaining that it hurts him. The voice is very hoarse or altogether extinguished. The effort at speaking is frequently painful, and the little patient will indicate his wants by pantomimic motions. Then the respiration becomes somewhat difficult and rather loud, and the child becomes restless and irritable, and wants to be held upon the mother's arm or lap. After a longer or shorter period, preferably in the night, the suffocative paroxysm manifests itself in all its severity. The cough is continuous, hoarse, barking, short; it is not sonorous, rather more muffled; the respiration whistling and long drawn; the long-drawn, stridulous, crowing, or hissing inspiration, interrupted by short, hoarse, rather muffled coughs, and followed by the prolonged expiratory sound, can be heard at a distance. With every respiration the larynx makes marked excursions. All the accessory respiratory muscles are brought into full play; the sterno-cleido-mastoid, the pectoral, the serrati, and other muscles are observed acting energetically. With every inspiration the thorax is markedly elevated, whilst at the same time the jugulum, the intercostal spaces, and the epigastrium sink in deeply; on the following expiration the thorax does not at once return to its normal position, and the active efforts of the abdominal muscles are required to effect this. The veins of the neck are distended and filled with dark blood. The extremities are slightly cyanotic. The skin is somewhat turgid; perspiration may be abundant over the whole surface, or only a cold, clammy sweat cover both head and face. These symptoms persist, with perhaps somewhat lessened intensity, throughout the night; generally toward morning there is more marked abatement; the child will fall asleep, gain a few hours' rest, and wake up again with another suffocative attack. The cough is now almost toneless,

occurs at but long intervals, and is very short. If the voice was only hoarse at the outset, it is now altogether abolished. The respiration is much more difficult; all the accessory respiratory muscles are in activity; the whole attention and energy of the patient are directed to his breathing; the stridulous, sawing noise accompanying inspiration is still more marked. The child cannot lie down, but sits propped up in bed or upon the mother's lap. Gradually there is an apparent relaxation in the patient's efforts at breathing; he lies back a little more; the pulse becomes small and thready and extremely rapid; the face assumes a pale, cadaveric appearance; the child becomes comatose or delirious, and death supervenes either from asphyxia or in an attack of general convulsions.

Exceptionally the laryngitis may be of the grave type from the outset, its first manifestations being the severe suffocative paroxysm just described.

The course, however, is not always so stormy: in rare instances the progress of the disease is very insidious; the symptoms are of a comparatively mild character, until suddenly, without any warning, death seems imminent. The child has a laryngitis of mild type, to which no attention is paid, and he is allowed to run around at pleasure. After a few days, perhaps a week, he becomes aphonic; there is but little cough, and that very much muffled and dry. Suddenly the parents observe that the child, which has lain down, is evidently unconscious; the eyeballs are rolled up under the upper lids, the face is cyanotic or of cadaveric paleness; the body is cool; the pulse very feeble, nearly imperceptible; the respiration almost completely arrested. With an effort the child may be recalled to consciousness for a few moments, but he will quickly relapse into the state of stupor, from which he may never awake.

The fever, except in the class of cases last described, is always very high; the thermometer ranges from 102° to 103° F. at the onset, and from 104° to 105° and higher at the period of greatest intensity. There is generally great thirst, the patient constantly craving cold drinks, of which he will take but a sip, on account of the interference with respiration. The appetite is completely gone, and it is with greatest difficulty that the child can be persuaded or made to take a little milk or beef-tea.

When the disease tends toward recovery the severity of the symptoms gradually abates, and when convalescence is fully established they have all disappeared, with the exception of the aphonia, which frequently continues for a considerable time; or, even if the voice be regained soon, it will have a husky tone for quite a long time.

Laryngoscopic examination discloses an exaggeration of the picture described in the previous section. The mucous membrane of the whole larynx and trachea is markedly hyperæmic and swollen; the ventricular bands are greatly injected; the vocal cords are either pinkish or normal in color; beneath these, projecting into the line of vision, can be seen the deep-red or almost purplish rounded masses of tumefied subglottic tissue, bellying out far beyond the line of the true vocal cords and narrowing the glottis down to a slit. On the free border of these folds of infiltrated subglottic tissue the muco-purulent secretion collects, becomes inspissated, and forms ragged and jagged incrustations, which tend to still further aggravate the stenosis. As the disease abates these incrustations disappear, and the folds diminish in size and become pale in color.

Course and Duration.—The course and duration of the disease depend to a great extent upon the degree of intensity developed, upon the period at which medical treatment is resorted to, whether early or late, and upon the mode of treatment. Usually with a sufficiently energetic treatment the acute

symptoms subside in from two to three days. They never last over five days. The duration of the disease from its onset to its definite cure may occupy a period of from two to three weeks.

Complications.—Bronchitis, broncho-pneumonia, convulsions.

Prognosis.—The prognosis will depend in a great measure upon the period at which the physician first sees the case. If at an early period, before the pathological process has involved the submucous tissues, before the disease has reached its climax, a favorable prognosis can usually be made at once. If, however, he is called at a late period, when the laryngeal stenosis is already very marked, it should be very guarded, and more especially so if the condition be due to too early exposure after measles. In my experience these have been the hardest to deal with, and I have seen such cases die despite tracheotomy, despite intubation. Then it must be remembered that one or the other of the complications mentioned may develop and carry off the patient.

Treatment.—In the early stage, when the grave form is just developing, when, although the voice is very hoarse or altogether lost, the short cough is still somewhat sonorous or but slightly muffled, the respiration is still comparatively easy, without very much stridor, excellent results will be obtained with very small doses of tartar emetic:

R. Antimonii et potassii tartrat. gr. $\frac{1}{3}$ — $\frac{1}{2}$.
 Syr. toltan. f̄ $\bar{3}$ ss.
 Aq. destillat. f̄ $\bar{3}$ iss.—M.

Sig. One teaspoonful every two hours, for children from two to four years old. If this dose produces emesis or nausea, but one-half to one-third of a teaspoonful are subsequently given.

When the disease is fully developed and the dyspnoea great, energetic treatment is required.

It is in this form of catarrhal croup that the emetic finds its justification, and should be promptly administered.

The preferable one here again is tartar emetic:

R. Vin. antimonii
 Oxymel. scillæ āā f̄ $\bar{3}$ ss.—M.

Sig. One-half to one teaspoonful every ten or fifteen minutes till emesis results.

Or it may be combined with ipecacuanha:

R. Vin. antimonii f̄ $\bar{5}$ ij.
 Syr. ipecac. f̄ $\bar{5}$ v.—M.

Sig. One-half to one teaspoonful every ten or fifteen minutes till the desired effect is obtained.

Or the compound syrup of squills may be employed, though the stimulating character of the squills and senega contained therein makes it less desirable than the preceding formulæ. If the effect be delayed, it can be hastened by tickling the fauces with the finger or with a feather. After this the antimony is continued in fractional doses, as above described.

If, despite free emesis, the dyspnoea continues marked and threatening, the application just above the manubrium sterni, or the jugulum, of from two to six leeches, according to the age of the child, is recommended by some authors. Though bleeding is not favored by many pædiatrists, nevertheless in children

of full habit, and if care be taken to arrest the hæmorrhage promptly as the leeches fall off, the measure will undoubtedly be of great benefit. If the stridor in the respiration continues marked, though the dyspnœa has greatly abated, the application of a blister to the neck at the side of the larynx, followed by a dressing of unguentum hydrargyri, is likewise recommended by some writers.

If the bowels are confined, they should be freely moved, and for this purpose a dose of calomel, alone or in combination with sodium bicarbonate, may be prescribed; and if its action be tardy, it can be hastened by an enema of water or of glycerin.

J. Forsyth Meigs recommended the following formula as one that had given him good results:

R. Hydrarg. chloridi mitis gr. vj.
 Antimonii sulphuret. præcipitat. gr. j.
 Potass. nitrat. gr. xij-xxij.—M.

Ft. pulv. et divide in part. æqual. No. xij.

Sig. Powder every two hours.

He also stated that in some cases where, despite emetics, bleeding, and antimony, the dyspnœa had gone on for four or five days, it yielded rapidly under the sedative and cathartic effect of four grains of calomel administered in one-grain doses every hour.

Rauchfuss reports some cases that he treated with calomel in small doses internally, and inunctions of mercurial ointment, with excellent results.

In addition to the measures already described, inhalations from a steam atomizer or sprays of a solution of sodium bicarbonate, with the addition of a little carbolic acid,¹ will prove of great advantage.

During the paroxysm counter-irritation by means of mustard plasters can be resorted to, or the measure so highly recommended by Trousseau may be employed: A sponge is dipped in water as hot as can be borne, placed under the chin, and gradually pressed out, so as to have the hot water flow over the larynx; in ten or fifteen minutes the process is repeated. Rauchfuss also recommends cleansing the pharynx and the vestibulum laryngis by means of the finger, brush, or the cotton-holder wrapped with cotton, and believes that by the coughing and choking thereby excited better results are obtained than with an emetic. Or the administration and inhalation of ether, as already described, may be resorted to.

Warm drinks, especially warm milk, should be freely given. Even when the child has fallen asleep after the subsidence of the most threatening symptoms, it should be awakened every few hours and a warm drink given it, and, if it be old enough, an inhalation, to keep the parts moist and thus prevent a return of the paroxysm.

When, despite these measures, the dyspnœa grows greater and asphyxia is imminent, as indicated by stupor, and by rolling up of the eyeballs underneath the upper lids; or if these symptoms have already supervened at the time the physician is called, intubation or tracheotomy should be at once resorted to.

¹ R. Sodii bicarb. ℥j.
 Sodii benzoat. ℥iiss.
 Acid. carbol. cryst. m. xij.
 Glycerin. f ℥j.
 Aq. destill. f ℥ij.—M.

Sig. Two teaspoonfuls with an equal quantity of water in cup of steam atomizer.

After the imminent danger has been averted one or the other method of treatment can be employed. If antimony be selected, it should be the wine that is directed, and in such small doses that it cannot produce retching or emesis, so as not to dislodge the tube. Intubation is, in my opinion, to be preferred to tracheotomy for the middle and poorer classes, as it is almost impossible for them to give the necessary attention to the patient that is required after the operation. The tube can be removed in from twelve to twenty-four hours.

During the attack the child must be kept in bed in a well-ventilated room, the atmosphere of which should have a certain amount of moisture; after subsidence of the attack, although he may be allowed to be up in the room, great care must be taken that he shall not run out or expose himself in any way.

Convalescence being fully established, the warm drinks may, to a great extent, be withheld and the moisture of the room markedly lessened. The inhalations can be continued for some time, a weak astringent solution (alum 1 per cent.) taking the place, later, of the soda solution.

An accompanying bronchitis or coryza must not be neglected.

Prophylactic Treatment.—With children who have a tendency to catarrhal affections of the upper respiratory tract a prophylactic treatment should be instituted early. They should be accustomed in the summer months to cold bathing, cold sponging, and cold frictions. If possible, they should be taken to the sea-shore or to the mountains for the summer. In winter, after being washed with warm water, the face, neck, and hands should be sponged off with cold water (just as it flows from the hydrant); after their warm bath (which should always be given in a warm room) the body should be well rubbed with cold water or cold alcohol and water, and thoroughly dried. They should not be allowed to keep on topcoats or hats or shawls whilst in the house, or to run out of the house insufficiently clad. They should be dressed properly and not made sacrifices to the vanity of their parents, especial attention being paid to their foot-gear that it be water-proof; during wet or snowy weather the shoes should be changed two or three times in the day. Their diet should be plain and wholesome, and not too stimulating. They must not be overburdened with studies. They should be allowed sufficient exercise in the fresh air, even on very cold days, but with the direction that as soon as tired they must come into the house to rest: they must not rest out of doors.

If the children are anæmic or have a scrofulous taint, the proper remedies must be administered.

LARYNGISMUS STRIDULUS.

BY H. ILLOWAY, M. D.,

CINCINNATI.

THIS condition—termed also *Spasmus glottidis* (spasm of the glottis); *Asthma Millarii*; *Asthma thymicum Koppii* (thymic asthma); *Asthma rachiticum*—consists of paroxysms of spasmodic closure or narrowing of the glottis, causing complete or almost complete arrest of respiration, and occurring at longer or shorter intervals.

Laryngismus stridulus is a neurosis of the larynx, that organ being generally in a healthy state. It is an affection entirely distinct from spasmodic laryngitis (pseudo-croup), with which it has been identified, especially by many English writers. It is not to be confounded with true infantile asthma, which is an entirely different disease. Neither must it be confounded with internal convulsions (inward spasms), though it is true that spasm of the glottis may occur in inward spasms, and, *vice versâ*, inward spasms may occur in the course of a protracted case of laryngismus; in either instance, however, it is more in the nature of a complication which adds to the dangers of the primary affection and makes its prognosis more unfavorable.

The paroxysm sets in always during inspiration, and is produced by spastic contraction of the muscles which normally possess the function of narrowing or closing the glottis—the adductors, the two thyro-arytenoids, the two lateral crico-arytenoids, and the arytenoideus muscle. This abnormal muscular action is the result of irritation, either direct or reflex, of the laryngeal recurrent nerve, or of the vagus above the point where the laryngeal recurrent is given off.

Escherich, in his address before the Tenth International Congress, clearly indicates his belief that laryngismus stridulus is not a morbid entity, but merely a symptom of another affection—namely, latent tetany. He claims to have found the characteristic symptoms of the latter disease (Trousseau phenomenon, etc.) in all the cases presenting themselves for treatment for laryngospasm. Loos by his investigations confirms the views of Escherich. He also affirms that in all cases coming under his observation for laryngospasm he found, like Escherich, the characteristic symptoms of tetany. In his summary he says that it remains to be proven whether we ever have laryngospasm independent of the other symptoms of tetany.

The disease is somewhat frequent in France; more prevalent in England and Germany. From the latter country we have the greatest number of cases reported. According to good authority, it appears to be much more frequent in certain localities there than in others. In this country it is exceedingly rare, and but few American physicians have the opportunity of studying it by personal observation. This rarity is, I believe, readily explained by the fact that pap-feeding to infants is almost entirely unknown here.

Laryngismus stridulus is essentially a disease of infantile life, from birth to the close of the first dentition—two and a half years. The period of most frequent occurrence is, according to Friedreich, from the fourth to the fourteenth month. Barthez and Rilliet have observed the spasm almost exclusively between the third week and the eighteenth month; Fleisch, between the fifth week and twenty-first month. Of 226 cases of laryngospasm observed by Steiner, 174 were in their first year, 52 in their second or third year. Salathé saw four cases of laryngospasm in new-born infants; Bowen, a fatal case in an infant six days old. The majority of cases occur undoubtedly between the fourth and eighteenth months. This, however, does not preclude the occurrence of the disease at a much later period of child-life: Steffen reports a case of spasm of the glottis in a boy eight years old; Salathé, one of a child of twelve years.

As regards sex, it is the consensus of observers that male children are more liable to the disease than female children. This is very clearly demonstrated by Steffen: of 554 cases compiled by him, 386 were boys and 168 were girls.

The greater number of children attacked are rather stout and present a bloated appearance, as if they had undergone the stuffing process; much less frequently are really atrophic children affected. Most of them are markedly nervous; they do not sleep very well, cry a great deal and without cause, have a tendency to holding-breath spells, have very bad tempers, and want to be carried around the greater part of the time.

The disease is most prevalent in the cold months of the year, winter and early spring, especially in March. Some would have this frequency due to the greater prevalence of catarrhal conditions at these periods. According to Fleisch, it is due to the fact that children are kept much more confined to the house during these months. The experience of Mr. Robertson seems to fully corroborate this: he recommends "the free exposure of the infant out of doors for many hours daily to a dry cold atmosphere, and, if the air be dry, the colder the better." It is more frequent in northern than in southern latitudes.

Etiology.—The etiological factors of this disease can be properly divided into two groups: the *constitutional* and the *local*.

CONSTITUTIONAL CAUSES.—*Rickets.*—Two-thirds of the children affected with laryngospasm present the stigmata of rickets, and some of these can be detected as early as the third month. The causal relation between the constitutional state and the laryngospasm is therefore apparently established; as to its nature, opinions differ. Elsässer believed that it lay in the craniotabes. This view has, however, been sufficiently controverted by the observations of many that the paroxysms occur not only when the child is lying down, but also when it is held up upon the arm or sitting up in its chair, and no pressure upon the head made. Furthermore, in many cases craniotabes has been found altogether wanting, although other symptoms of rickets were present.

In children afflicted with rickets the general nervous irritability is morbidly exaggerated. This Steffen holds responsible for the laryngismus. Moreover, by reason of the characteristic change in the shape of the thorax the respirations are more superficial and necessarily more frequent. Now, if, by any cause, as an attack of coughing, screaming, great fright, swallowing the food too hastily, sudden awakening or being awakened, sudden change of temperature from warm to cold (when the child is carried from a warm to a rather cold room), the uniform rhythm of respiration is interrupted, a hyperæmia of the brain and medulla is produced, and the conditions favorable to the production of a spasm of the larynx developed.

Fleisch admits the very frequent coincidence of laryngismus and rickets as set forth, but does not believe in the causal relation of the latter to the former.

For him, not the rachitis, but the factors that gave rise to the cachexia, are the causes of the laryngeal spasm. "Faulty nutrition and injurious food, this and nothing else, are the *fons et origo* of spasm of the glottis."

Hereditiy.—Instances have been reported where the greater number or nearly all of the children of one family were affected with this neurosis. An hereditary predisposition has therefore been presumed. The cases, however, really prove nothing more than a continuance of the same vicious mode of nurture that called forth the disease in the first child; for in other instances, where already two or more children had been affected, better attention to hygienic requirements and correct feeding kept all the subsequent children free therefrom. The supposed special hereditary influence as an etiological factor has been discarded by most authors.

LOCAL CAUSES.—*Dyspepsia*; over-filling of the stomach; intestinal catarrh; over-distention of the intestines by fæcal masses; great flatulence. Kopp's theory that the disease is always due to enlarged thymus gland has been proven untenable by Friedleben and others. In rare instances it may be the etiological factor. Bronchial or tracheal glands enlarged or undergoing caseous degeneration, diseases of the heart, and enlarged liver are occasional causes of the spasm. Material diseases of the brain do not, according to Steffen's observations, produce spasm of the glottis. Kyll quotes a case from Corrigan of Dublin which, despite all treatment, had lasted over three months. Accidentally it was discovered that pressure over the third and fourth cervical vertebræ was very painful and produced loud cries from the child. Two applications of four leeches, at an interval of two days, over the painful point removed all the symptoms and the child made a perfect recovery.

Dentition is banished by many from the category of causes. Nevertheless, it is not at all improbable that in such vitiated states of the system, with perversion of many of the physiological functions, as the majority of the children present, the process of teething has a certain causative influence in the production of morbid phenomena.

Catarrhs of the larynx, trachea, or bronchial tubes cannot of themselves produce spasm of the glottis by reflex irritation, but when they supervene in cases where it already exists they will aggravate it, and even recall it if it be disappearing.

Mantel reports the case of a rachitic infant eight weeks old, in whom a very much thickened, congested, and elongated uvula appeared to be the cause of the spasm; its removal, after other measures had failed, was followed by perfect recovery.

J. H. Bryan reports the case of a child suffering since its second week with tonic spasms of the larynx. The epiglottis was found irregular in outline and bent backward over the laryngeal cavity. The child also had a phimosis, and was fed upon undiluted cow's milk. The spasm was attributed to a binding of the epiglottis, causing the aryteno-epiglottic folds to come almost into apposition, so that a slight stridor was produced on inspiration. With reference to this last point, it is well known that a certain amount of recurvation of the epiglottis is normal in young children, and cannot be regarded as a cause of the spasm. This seems confirmed by the results of the treatment in the case just referred to. On diluting the milk and relieving the phimosis by gradual dilatation the respirations lost their spasmodic character and became normal. Whether the phimosis had any direct effect in the production of the cramp remains to be determined by further observations: that it may give rise to morbid nervous phenomena is well known.

In easily excitable children violent and prolonged crying, undue exertion

in running so as to materially interfere with the respiration, are capable of provoking a mild attack of spasm of the glottis.

In a small number of cases, and more particularly of those occurring after the third year, no special cause for the cramp can be discovered. According to my observation, a hot, vitiated atmosphere in the sleeping apartment, whole families sleeping in one room, two, three, or more children in one bed, with doors and windows tightly closed, will account for some of these. In support of this view I would recall here the influence of this factor in the production of trismus.

Pathology.—The structural changes found upon necropsy vary considerably. In so far as the spasm itself is concerned, the results are entirely negative, nothing abnormal having as yet been discovered either in the nerves or the muscles of the larynx.

In the majority of cases the rachitic changes in the bones and soft tissues present themselves. Craniotabes is frequently found wanting. Various morbid changes are found in the brain, mainly those due to the cachexia. In rare instances softening of the medulla oblongata has been seen. In the larynx traces of catarrh have been found; occasionally a croupous exudation upon the larynx and trachea; very rarely ulceration. Bronchial or tracheal glands enlarged or undergoing caseous degeneration are sometimes found. The thymus gland is occasionally voluminous and juicy. A variable degree of pulmonary emphysema, as the result of the spasm, is always present. Various cardiac lesions have been noted.

The stomach is not much affected. In the jejunum and ileum the solitary glands and Peyer's patches are enormously swollen, broad, and pale; concomitantly we have hyperplasia and sometimes caseation of the mesenteric and retroperitoneal glands. The liver presents evidences of fatty degeneration.

Symptoms.—A typical paroxysm presents the following picture: Suddenly, without any prodroma on the part of the larynx or the other respiratory organs, the child, who has just been sleeping nicely or has been lively and playful upon its mother's arm, in its chair, or has perhaps been a little fretful and crying, is seen to gasp for breath. It becomes rigid; the head is thrown back and the neck arched forward. The face, more particularly about the nose and mouth, becomes pale, cyanotic, or dusky red. The *alæ nasi* are distended, and the forehead is covered with a cold perspiration. After a few seconds to a quarter of a minute a few whistling or crowing inspirations are heard; arrest of respiration again follows, lasting from a few seconds to a minute, when the whistling sounds are again heard. After two or three more repetitions of this alternate crowing inspiration and arrest of respiration the crowing inspirations are followed by expirations, the child can soon cry out lustily, normal respiration is established, and the paroxysm is over. These whistling or crowing sounds are made by the entrance of air through the narrowed glottis, and are not followed by expiration until the spasm is over. In the milder forms these crowing sounds are heard several times in each paroxysm; in the very gravest form they are heard only at the beginning and end of the paroxysm, respiration being entirely arrested during the middle period. When the closure of the glottis is complete, the thorax, diaphragm, and abdominal muscles become immobile; when it is incomplete, laborious respiratory attempts on the part of the various muscles concerned may be noted. The heart's action is at first stronger but irregular, then feebler and more frequent, and the pulse becomes small, sometimes barely perceptible. The severer the seizure the earlier there is loss of consciousness. Frequently there is involuntary discharge of the urine and feces.

The paroxysms vary in severity. In the mildest form, which may pass unnoticed by the parents, especially if it occur during the night, there is but a momentary suspension of respiration, followed by a few whistling or crowing inspirations, and the attack is over.

The number of seizures in the twenty-four hours varies from a few to as many as thirty or forty. Frequently a few seizures will follow each other in rapid succession; then a longer period of rest and well-being for the child ensues, to be interrupted again by a recurrence of the spasm. It has been observed that the shorter the intervals between them the milder are the paroxysms. A number of very mild attacks may be followed by a very severe one. The spasm cannot last longer than two minutes at most without bringing about a fatal issue. The paroxysms occur as frequently in the daytime as during the night; there is no special predilection for the night, as has been supposed by some. With the progress of the disease convulsive phenomena—namely, tonic spasms in other parts of the body—generally make themselves manifest. The earliest and most frequent are the so-called *carpopedal* spasms. The thumbs are drawn into the palms and the fingers extended in various directions. The great toe is adducted and drawn upward, and the other toes spasmodically flexed. Sometimes the hands are bent upon the forearm and the forearm upon the arm. The dorsum of the foot may be drawn up firmly against the shin. The ocular nerves also become involved very soon, as shown by the rolling up of the eyes. Clonic spasms occur only when a general eclamptic seizure supervenes, which, according to Henoch, is not so infrequent.

The disease is *apyretic*. When fever does set in it generally depends upon some intercurrent affection. Symptoms of dyspepsia are almost always present: eructations, flatulence, constipation, clay-colored stools; very rarely diarrhœa or vomiting.

In older children—*i. e.* after the third year—the tendency to laryngeal spasm is markedly lessened. This may be accounted for upon the ground that they have arrived at a period of greater digestive power, when the problem of nutrition is very much simplified, and also one of greater stability of the nervous system. The paroxysms, when they occur at this later period, are much less severe, probably for the reasons above mentioned, and the further reason that the larynx at this age has grown wider and the cartilages have become firmer. When these children feel the respiration becoming impeded they grow fretful and want to lie down. The face becomes pale, never cyanotic or dusky red. The whistling or crowing sounds are not very marked or do not occur at all, and the only complaint is of a tightness about the throat and an inability to swallow. The voice is feeble and speech labored. The cramp lasts at longest but a few seconds, and when it is over the child is as cheerful and apparently as well as before.

Course and Duration.—The course of the disease is rather irregular. It may set in with great intensity, the paroxysms being very severe and recurring at short intervals; again, it may begin in a very mild fashion, a few rather mild paroxysms recurring at longer intervals, with periods of entire freedom of from ten to twelve days. Usually, however, it runs a circuit of aggravation, climax, and diminution. Until the climax is reached seven to eight weeks may elapse. There is also considerable tendency to relapse: even after an interval of months of entire freedom, under the influence of exposure, of an inflammatory attack of some part of the respiratory tract, or of a fit of indigestion, the spasm may reappear, and with greater intensity than characterized it previously. The duration of the disease is rather uncertain: the first attack may prove fatal;

it may prove fatal in a few hours or it may last for months. Flesh avers that since he has recognized the true nature of the disease he has been able to effect marked improvement in all his cases in a very short time, and cites a case which was discharged well at the end of a month.

Complications.—The complications that may occur in the course of a case of laryngismus are many. When the disease is of great severity, transudations between the membranes of the brain, into the ventricles, may occur, or already existing effusions (of rachitic origin) may be dangerously increased. We may have effusion of blood between the membranes or upon the brain itself.

Whooping cough is a dangerous complication. Catarrhs of the larynx, trachea, and bronchial tubes have been already mentioned. Inflammatory affections of the lungs may supervene; during their continuance the spasm is generally much weaker or ceases altogether.

The most frequent complications are entero-colitis and eclampsia.

Diagnosis.—In uncomplicated cases the diagnosis is readily made. The suddenness of the seizure, the brief duration of the apnœa, the intervals of perfectly undisturbed normal respiration, the absence of fever, of cough, of change of voice, are features so distinctive that it is not possible to mistake the disease for croup, œdema of the glottis, or other organic disease of the larynx. The only disease with which it could possibly be confounded is spasmodic laryngitis (pseudo-croup), but spasmodic laryngitis has so different a clinical history that the differential diagnosis is not difficult. From bilateral paralysis of the glottis-dilators it is readily distinguished by the absence of the constant and marked dyspnœa which attends that condition. If there should be any doubt it can be readily solved by a laryngoscopic examination.

In complicated cases, especially where eclampsia follows in the wake of laryngismus, the diagnosis may be more difficult, likewise in those cases where a catarrhal affection of the larynx and trachea has supervened; however, a history of the case from its onset will very soon enable us to arrive at a correct conclusion.

Prognosis.—The prognosis should always be a guarded one, even in the very mild cases. Older statistics show a great fatality. Of 289 cases observed by Reid, 115 ended fatally. Rilliet and Barthez had 9 cases with 8 deaths; Herard, 7 cases with 6 deaths. Henoch, however, has had a more favorable experience: he says that the majority of the cases recover. Flesh reports that in the last twelve years he has lost but two cases.

Of course much will depend in any case upon the character of the surroundings of the child, the severity of the paroxysm, the degree of impairment of the general health, and the intelligence of the parents. In children past thirty months a favorable prognosis can generally be made.

Treatment.—This can best be considered under two heads: I. The temporary relief of the spasm. II. The cure of the underlying pathological condition.

I. From the brief duration of the spasm the physician is but rarely present when it occurs; and only accidentally, or if the paroxysms recur at short intervals, may he happen to witness it. The treatment, therefore, for the temporary relief of the spasm lies mainly in the hands of the mother or nurse, and she should be properly instructed. In light cases it is not necessary to intervene at all; only when the paroxysm is of longer duration or when it is made up of a series of attacks should measures for its arrest be instituted. The tongue should be looked after to see that it is not curled back over the laryngeal orifice, as occasionally happens. A large evacuating enema should be given at

once. The child should be placed in a semirecumbent position, all clothing loosened, and an abundance of fresh air provided. Cold water may be splashed into the face and upon the chest, or sinapisms applied to the back of the neck and to various parts of the chest to excite respiration. A piece of ice wrapped in a cloth and applied over the epigastrium and lower part of the sternum has occasionally proved effective. Ammonia or ether may be held to the nose. Chloroform inhalations, recommended by Simpson, West, and others, are not regarded with much favor, probably for the reason that it is a dangerous remedy to leave in the hands of laymen, and for the further reason that when the respiration is completely arrested it can do no good. Morphia is highly spoken of by Henoch. It is given until drowsiness is produced, then stopped. A rectal injection of chloral hydrate, gr. v, in milk of asafœtida, fʒij, will very frequently prove effective. Pressure on the pneumogastric nerve, on the carotid arteries, is recommended. The fauces may be tickled with the finger or with a feather until emesis results. Morrell Mackenzie recommends putting a pinch of snuff into the child's nose to produce sneezing.

If the paroxysm be of great severity, cyanosis marked, and apnœa persistent, the child may be placed in a warm bath (temperature 95° F.), whilst cold water is dashed from a height upon the head and face; or the child's feet can be placed in a hot mustard foot-bath and a cold compress applied to the head. If the apparatus be at hand, the application of a strong induction current to the phrenic nerve, or of a galvanic current to vertebræ and thorax or over vertebræ and larynx, may prove beneficial. If the danger be imminent, intubation should immediately be resorted to; if that alone prove ineffective, air can be blown into the lungs through the tube and expiration promoted by pressure on the sides of the thorax. Tracheotomy is not in favor.

Flesh, who has had a large experience, deprecates, as a rule, all interference with the child, with the exception of the evacuating enema. He asserts that all the other various measures resorted to are not only not beneficial, but positively injurious.

As soon as the child can swallow the best remedy to be administered is musk, as tincture, in doses of 10–15 drops, or after the following formula (Mackenzie):

Rʒ. Moschi gr. iss.
 Sacchari albi
 Pulv. acaciæ āā gr. ij.
 Syr. aurantii florum ℥xx.
 Aquæ ad fʒj.—M.

Sig. For one dose, to be given every two hours.

Tincture of castor and tincture of valerian are also recommended.

In the interval, to prevent recurrence, or at least to modify the severity and frequency of the paroxysms, numerous remedies have been recommended: musk, castor, valerian, bromide of potassium, bromide of sodium, and chloral hydrate are the most effective. The selection of the remedy will depend in a great measure upon the condition of the child; in feeble children chloral hydrate should rather be avoided; in dyspeptic cases the bromide of sodium will be preferred. Scarification or lancing of the gums is of no benefit, and therefore unnecessary.

Care must be had that the child be not vexed or irritated, especially for the first forty-eight hours after instituting treatment; its wishes should be complied with and its whims humored. Some friendly face should be with the

child when it goes to sleep, and more particularly when it is about to wake up, so as to avoid all fright. Proper attention must be paid to the ventilation of the room and to all other hygienic requirements. The child must be taken out into the fresh air whenever the weather permits; the experience of Robertson in this respect has been already referred to.

II. The principal point to be kept in view is undoubtedly the cure of the underlying pathological condition. All authors agree that the diet must be strictly regulated and all farinaceous food prohibited. All aliment must be given in fluid form, as thin as water. The only articles permitted are milk and beef tea. If the child be at the breast and the supply be ample, no other food must be given. If bottle-fed, the bottle must be put aside and the child fed with a spoon or feeding-cup. The milk must, at first, be diluted one half with water. It is of the greatest importance that the number of meals and the intervals at which they are given be properly regulated.

In children under four months six meals per day at intervals of three hours are allowed; over that age, only five meals per day are given. If possible, nothing should be given in the night; if the child wake up and cry for its accustomed food, a little water can be given it, and after a while it will fall asleep again, and thus in two or three nights the habit of taking food at night may be broken up. As to quantity, at the outset not more than one half of the normal quantity, according to the child's age, should be given at one feeding. As the digestion improves, as shown by the improved character of the stools, the milk is diluted but one-third, and the quantity gradually increased, until the child gets about the full quantity for its age. When the stools have become normal and have continued so for some time, Fleisch recommends, for children over six months old, the addition to the beef tea of a small quantity of boiled lean beef finely chopped, and claims for it great restorative powers. After there has been no recurrence of the stridor for weeks, and not till then, a little zwieback or dry roll may be allowed; at first but very little, and if well borne gradually increased. No solid food must be given till after the child has passed its second year.

The remedies employed in conjunction with this treatment are, in rachitic cases, cod-liver oil and phosphorus. Of the latter agent Baginski says that in some cases it has proved remarkably effective, inhibiting the paroxysms even before any effect upon the rachitis was noted. Where marked anæmia exists some preparation of iron is indicated. For enlarged glands the syrup of the iodide of iron or iodide of iron and manganese must be prescribed.

Local causes must be properly attended to; complications must be treated according to their nature.

FOREIGN BODIES IN THE LARYNX, TRACHEA, AND BRONCHI.

BY JOHN B. DEEVER, M. D.,

PHILADELPHIA.

THE entrance of a foreign body into the larynx or any of the more remote portions of the air-passages is, fortunately, a condition of somewhat rare occurrence. When such entrance does happen, it is, in the majority of instances, by way of the mouth, but it may also occur through penetration of the walls of the larynx or trachea. The infrequency of such accidental lodgements as may occur through the normal opening of the larynx is directly due to the rapidity with which the orifice is closed by the epiglottis.

A foreign body having, however, entered the cavity of the larynx, it is very likely to have its downward progress arrested by the apposition of the contiguous borders of the aryteno-epiglottidean folds and the true vocal cords, and to be expelled from this position by the cough which its presence excites. On the contrary, it may, owing to relaxation of the vocal cords, pass through the glottis, and into the trachea or one or other of the bronchi. It is rather exceptional for a foreign substance to enter the larynx during deglutition, except where there is paralysis of the gustatory muscles, such as may follow diphtheria, or where, as the result of ulceration, there is a partial or complete destruction of the epiglottis. Strong inspiratory efforts while feeding or while the mouth contains any substance are most frequently responsible for the entrance of particles of food or other material into the larynx. A sudden attempt to breathe, laugh, or speak, a sneeze, or a sudden blow, all favor the occurrence of such an accident through relaxation of the muscles.

The amount of obstruction occasioned by the entrance of a foreign body into the air-passages depends upon the character as well as the size of the object. If of organic nature, such as a bean, pea, or grain of corn, the obstruction will be progressive, owing to swelling through absorption of moisture. Of inorganic materials, the most frequently met with are pins, needles, buttons, coins, and teeth.

The situation and mobility of the foreign body are dependent upon its general characteristics, such as its shape, size, and weight, and the amount of force with which it enters. Statistics show that the most common location is in the trachea, next in the larynx, and lastly, in the right bronchus. The right bronchus is more commonly the seat of obstruction than the left, for the reason that it is the larger and arises higher, and that the septum at the point of bifurcation inclines to the left.

Symptoms.—The symptoms excited by the entrance of a foreign body into the air-passages are—violent convulsive cough, a sense of suffocation, fear of impending death, and pronounced dyspnœa. If the body is retained but does not entirely occlude the passage-way, these symptoms recur with less-

ened severity in the form of a short, harsh cough attended with pain referred to the lower part of the neck, and increased expectoration, which may or may not be bloody. If the position of the foreign body is changed by respiration, the symptoms recur at shorter intervals. The body not being expelled with the subsidence of the symptoms is an evidence of impaction. A foreign body which has been lodged in the air-passage for a considerable period may suddenly give rise to symptoms of obstruction due to displacement from the seat of impaction. The symptoms excited by the presence of an irregular, angular, or sharply-pointed mass are always more severe; the cough is increased, the interval between the spasmodic attacks is shortened, and the pain is more commonly referred to the larynx. In addition to these symptoms there are evidences of inflammatory disturbance, such as elevation of temperature, increased pulse-rate, increased secretion and expectoration, and dyspnoea with pain and tenderness over the seat of lodgement. Symptoms suggestive of incipient pulmonary tuberculosis consequent upon the presence of an unsuspected and impacted body have suddenly abated upon the expulsion or removal of the same. In case of impaction, constant pain, generally located in the upper part of the chest, or a dragging sensation referred to either side of the chest, coupled with the above symptoms, may aid in locating the body. There may be also huskiness of the voice, stridulous breathing, and a cough resulting from deep inspiration, which may be accompanied by mucous or muco-purulent expectoration. If a bronchus be entirely occluded, the lung of the corresponding side may collapse, in which case the normal respiratory phenomena will be absent. As a result of the extension of the inflammation by contiguity, the lungs may become involved, and the character of the expectorated material will be changed, becoming darker and more offensive. Paroxysms of cough, night-sweats, loss of sleep, and great depression will follow and death from exhaustion probably result. When the foreign body is smooth, rounded, and movable, but little inconvenience may be experienced from its presence, and if in the person of a child old enough to describe his sensations, he may complain simply of a feeling of something moving in the windpipe.

Diagnosis.—The character of the symptoms and a careful inquiry into the history of the case will materially assist in forming a diagnosis. In the absence of any history of the entrance of a foreign body, the abrupt onset of symptoms of suffocation in a child previously well is sufficiently significant to suggest the character of the obstruction. Acute laryngitis and croup are conditions which may simulate to some extent obstruction by a foreign body, and may call for careful examination in making a diagnosis. In the case of a foreign body the voice is not necessarily changed unless the offending substance be located in the larynx, in which case there is aphonia; in croup the voice is harsh and high-pitched. In croup or acute laryngitis there is stridulous breathing, which becomes more marked as the case advances; this is not true of a foreign body. In the latter case, the respiratory embarrassment is more pronounced on expiration, while in croup the difficulty occurs on inspiration.

To distinguish obstruction by a foreign body in the air-passage from one in the pharynx or œsophagus, it will suffice to make a digital examination of the pharynx or an exploration of the œsophagus with the œsophageal bougie. In a case of impaction of a partial plate of artificial teeth in the commencement of the œsophagus, where I was obliged to perform œsophagotomy for its removal, the symptoms were believed to be due to its presence in the larynx. The introduction of an œsophageal bougie immediately cleared up the doubt as to location and position in this particular case. As symptoms of respiratory embarrassment and the expectoration of muco-purulent material were present,

it was found at the autopsy that an opening into the larynx had occurred as the result of ulcerative perforation.

While œdema of the glottis may result from the presence of a foreign body, yet it may arise as an independent condition, following injury to the larynx, or the swallowing of chemical irritants of any kind, or it may accompany tubercular, syphilitic, or some other form of ulceration. The diagnosis between foreign body and œdema of the glottis rests largely on the history of the case and upon digital examination, by which is detected swelling of either the epiglottis, the glottis, or of both as the case may be. Further, as mentioned before, the respiratory embarrassment in foreign body is more marked on expiration, while in œdema of the glottis, if seen early, the embarrassment occurs on inspiration only, and in the later stages during both inspiration and expiration.

Laryngeal obstruction associated with lymphatic enlargement of the deep chain of cervical glands gives rise to a series of symptoms, the onset of which are gradual, and consist in the presence of a tumor of slow growth, with some constitutional evidence of a tubercular diathesis. The symptoms of apparent obstruction in this class of cases are not due so much to pressure upon the air-passage as upon the laryngeal nerves.

The advantages to be derived from a laryngoscopic examination in children are practically *nil*, unless anæsthesia be employed, and even under these conditions may prove unsatisfactory. The urgency of the symptoms in the case of a foreign body would contraindicate an examination of this kind in the majority of cases, because the manipulation necessary to accomplish it would be attended by more risk than the operation for removal. In those cases where the immediate symptoms of obstruction subside consequent upon the impaction or the lodgement of the body, an examination may be attempted. Auscultation may be of value in locating the position of the mass, which, if in the larynx, may create rough sounds synchronous with respiration. In connection with the other symptoms of obstruction, if in the trachea, the body may be detected moving with respiration, and even heard to strike against the wall of the windpipe, while, if in a bronchus or one of the bronchial tubes, the normal vesicular murmur upon the corresponding side is absent or modified.

Prognosis.—The presence of a foreign body in the air-passages subjects the patient to great danger. For the first seventy-two hours at least the greatest danger is from suffocation, as the body is liable to be forced into the larynx and cause total obstruction. Thereafter the risk is from hæmorrhage, inflammation, ulceration or abscess, septicæmia, and death from exhaustion. When the substance becomes impacted in a bronchial tube the irritation excited by its presence may involve the parenchyma of the lung, causing a local pneumonia which is sometimes followed by pulmonary abscess. Other organs may become involved through the extension of inflammation by contiguity of tissue—namely, the pericardium, the pleura, and the liver.

Treatment.—All cases of foreign body in the air-passages giving rise to urgent symptoms call for prompt and, in most instances, radical treatment. Nature alone should not be depended upon to expel the offending mass; neither should delay be encouraged in the event of the subsidence of the symptoms, granting that there be no doubt as to its presence. To induce vomiting by the administration of emetics or by mechanical means, is fraught with, to say the least, some risk, and may cause obstruction by impaction in the glottis. If emetics be employed, everything necessary for immediate operation should be in readiness. The practice of inverting the patient and employing succussion with the hope of dislodging the body should be practised only under

exceptional circumstances, and resorted to only when no other means are at hand. This form of treatment, like that by emetics, is open to the objection of danger from immediate suffocation. The class of cases in which either of these means is most likely to prove successful is where the obstruction is due to lodgement of the mass in the pharynx or œsophagus. Here, however, if the body cannot be extracted through the mouth or forced into the stomach by the introduction of an œsophageal bougie, it is not likely that emesis or inversion and succussion will succeed in dislodging it.

The diagnosis of the presence of a foreign body having been established, the advisability of immediately opening the windpipe, in the event of extraction through the mouth not being feasible, I believe cannot be too strongly urged, as the imminent risk of suffocation is thus removed and the safety of the patient increased. For if the body is not expelled after the windpipe has been opened, impending suffocation is relieved. During the time necessarily consumed in opening the windpipe the respirations, which are already embarrassed, may cease. Should this occur, the operation is to be hastily completed and artificial respiration resorted to. If possible, an anæsthetic, preferably chloroform, should be administered to prevent pain and allay spasm. With the child anæsthetized the surgeon works to a better advantage, both to himself and to his patient. If time is not a factor, the interval between the paroxysms of dyspnœa is the most favorable for operation, as in this period the child is comparatively comfortable, and the operator can work without undue haste. The mere opening of the windpipe does not entail much risk if performed during the period of calm; in fact, less than when done for other conditions. With the extraction of the foreign body the chief source of danger is removed, and if done early the necessity for the introduction of a tracheal tube may not be called for, thus simplifying the case, and lessening, particularly, the chances of post-operative pneumonia.

On the location of the foreign body depends the choice of operation. If diagnosed as occupying the larynx, laryngotomy is advisable on account of its simplicity, the rapidity with which it can be performed, and its affording a more thorough command of the interior of the larynx. If the body is too large to be extracted through this opening, which may be the case in very young children, the space may be enlarged by cutting the cricoid cartilage, and, if necessary, prolonging it into the trachea, making a laryngo-tracheotomy. The entrance of air through this opening may cause the body to be expelled upon expiration through either the incision or the mouth. If the mass is supposed to be located in the upper part of the trachea the high operation is preferable, while if situated lower down in the trachea or in a bronchus the lower operation will be necessary. Occasionally the foreign body, if sharply pointed and impacted, may be detected from without, and then an incision may be carried directly down upon it.

In performing any operation on the air-passages the child should be brought under the effect of the anæsthetic before being placed in the customary position. A free incision should be made in the median line of the neck, and the trachea or the crico-thyroid membrane exposed, as the case may be, by carefully dissecting down upon it. The mistake which I think is often made is that of too small an incision through the skin and fasciæ. A free incision not only affords more room, but gives the operator a better opportunity of recognizing the anatomical landmarks, and of completing the operation with rapidity and safety. In the high operation of tracheotomy the middle lobe (isthmus) of the thyroid gland is to be displaced downward or divided between two ligatures. In the low operation the anomalous position sometimes

held by the vessels must be borne in mind; also the difficulty which may be experienced in dealing with the thyroid plexus of veins. Upon the exposure and division of the tracheal fascia (the last layer of the structures overlying the trachea) air enters between it and the trachea, giving rise to an emphysematous condition by which is occasioned a sound not unlike the entrance of air into the trachea when opened, and this may mislead the operator. A free incision should also be made into the trachea, thus allowing the entrance of a large volume of air, which favors the expulsion of the body. Immediately upon opening the trachea there escapes a frothy mucus or a muco-purulent secretion, depending upon the length of time the foreign body has been present. The tracheal wound should be retracted, when, if the body is not seen or expelled, an attempt to favor its expulsion should be made by exciting cough by irritating the lining membrane with a feather or a camel's-hair brush. If the body be not expelled by either of these means, an attempt to locate and to extract it should be made. Should this fail, inversion and succussion may be resorted to, this practice not being objectionable after the windpipe has been opened. The finger, with well-smoothed nail, undoubtedly offers the best means of locating the foreign body when the size of the windpipe is sufficient. The sensation communicated to it is far more accurate than that obtained through the medium of an instrument. When this manner of procedure is not feasible, the location of the foreign body may be attempted by the introduction of an English catheter without the stylet, a tracheal probe, or the curved laryngeal forceps. The body having been located, its extrac-

FIG. 1.

Durham's Flexible Forceps

tion with a pair of laryngeal forceps should follow; when it holds a transverse position in the air-passage, a blunt hook may facilitate its removal.

If the foreign body be retained, despite all efforts for its removal, a tracheal tube should not be introduced, but the wound in the trachea is to

FIG. 2.

Blunt Hook.

be kept widely open by retractors retained in position; or the edges of the tracheal wound, including the skin and fascia, may be transfixed by sutures, the ends of which are left long and tied at the back of the neck. During

this time the patient must be constantly watched, so that if the body appears at the bottom of the wound, it can be removed. A foreign body in the larynx too large to be extracted through the wound made in the crico-thyroid membrane or the windpipe may call for partial or complete division of the thyroid cartilage (thyroidotomy). The propriety of introducing a tracheal tube after operation will depend upon the amount of injury the larynx or trachea has sustained. When the operation is completed without the introduction of a tube, I should advise against suturing the trachea.

If the foreign body occupies a bronchus, its extraction can only be safely accomplished by means of low tracheotomy, and the subsequent use of Durham's flexible laryngeal forceps or a stout flexible wire bent in the shape of a blunt hook. The hope of opening a bronchus through the chest-wall, as a preliminary to extraction, has been clearly demonstrated by experiments upon animals to be both a useless and a fatal procedure, especially in the light of the cases where a foreign body has been expelled from a bronchus several days after the operation of tracheotomy.

FIG. 3.

Author's Retractor.

I would call attention to the retractors I have devised, shown in Fig. 3. They occupy but little space in the wound, are readily introduced, are easily held in position, are out of the way of the operator, and thus afford the best possible means of inspecting the interior of the windpipe.

POST-NATAL ATELECTASIS.

BY SAMUEL S. ADAMS, M. D.,

WASHINGTON, D. C.

POST-NATAL ATELECTASIS is a condition of the lung in which the once-inflated alveoli become emptied and collapsed from partial or total absence of air in them. It occurs in weakly infants and young children, and varies in extent from a few lobules to an entire lobe or even a whole lung. It is claimed by some that it is a common condition in foundlings and in wasted infants who die during the first year of life.

Etiology.—The predisposing causes of post-natal atelectasis are such as weaken the constitution, whether they operate before birth, as inherited vices, such as syphilis, scrofulosis, malformations, etc.; at birth, as premature delivery or injuries received during parturition; or after birth, as rachitis, improper feeding, neglect, exposure, as in foundlings, unsanitary habitations, and debilitating diseases.

The exciting causes are such as prevent air from entering the alveoli, and permit them to collapse after the residual air has been rarefied, absorbed, or expelled. They may be classified as intrathoracic and extrathoracic. The most frequent intrathoracic cause is bronchial catarrh, more especially of the smaller subdivisions, in which the lumen of the tube is obstructed by the resulting exudation and the ingress of air prevented. Gairdner of Glasgow has explained the mechanical action of a plug of mucus in a bronchiole in gradually diminishing the entrance of air to the area supplied by it, and the resulting collapse of the alveoli. This ball-valve shuts out the air at every inspiration, but allows the expulsion of that within the alveoli. If this obstruction be not displaced, the pressure exerted by the atmosphere upon the thoracic walls and the contractile force of the pulmonary tissues cause the alveoli to collapse. It may also be caused by whooping-cough, the paroxysms expelling the residual air and decreasing the power of the inspiratory forces. Measles is cited by some as an etiological factor, but the more immediate cause is probably the attendant bronchial catarrh. Effusion into the pleura or pericardium may cause collapse of the pulmonary alveoli in varying degrees proportionate to the pressure exerted by the fluid and the resistance of the lung. The lodgement of foreign bodies, as beans, peas, seeds, or metallic or porcelain substances, in a bronchus may prevent ingress of air and lead to alveolar collapse.

Among the extrathoracic causes are spinal curvature, deformity of the chest-wall, constricting clothing, and solid or fluid tumors in the abdominal cavity. Any one of these might be sufficient to compress the lung to the degree of collapse by diminishing the capacity of the thoracic cavity. It may also be of cerebral or spinal origin. Disease of the brain, cord, or nerves which paralyzes or over-stimulates the respiratory centres or prevents the transmission of nerve-force may produce atelectasis by impeding the inspiratory or increasing the

force of the expiratory muscles of respiration in a weakly or rachitic infant. Finally, it may originate independently of affections of the air-passages, as from the exhaustion of long-continued illness, constant dorsal decubitus, diarrhœa, or ileo-colitis.

Pathology and Pathological Anatomy.—Post-natal atelectasis, unlike the congenital form, is a pathological condition in which the expanded lung-alveoli return to the ante-natal state, from arrest of function owing to some mechanical impediment to the ingress of air. The extent of the collapsed area is either circumscribed or diffused, depending upon the calibre of the obstructed bronchus. It is usually situated at the postero-inferior margin of the lung parallel to the spinal column; or it may involve a whole lobe or a whole lung. When it complicates bronchial catarrh, it occurs in small, scattered areas, corresponding to the ramifications of the obstructed bronchus. In pericardial and pleuritic effusions of moderate extent the lower lobes are involved, but if the exudation is abundant the entire lung may be collapsed from compression.

The atelectatic lung-tissue, being devoid of air, is shrunken, depressed below the level of the surface of the lung, is of irregular outline, and dark-brown, violet, or reddish-blue in color. On section the collapsed tissue appears dark-red and smooth, and a serous or bloody fluid exudes from it. From its resemblance to flesh it is called "carnification." It is firm, dense, tough, without crepitation, airless, and sinks in water. If the collapse be recent, the alveoli can be re-inflated by removing the obstruction and blowing into the bronchial tube. If bronchial catarrh be present, the mucous membrane is swollen, soft, and hyperæmic, and the tube is filled with thick, tenacious mucus forming a complete plug. Around the affected areas are air-vesicles in a state of compensatory dilatation. This physiological emphysema is only found when the child has had sufficient strength to increase the inspiratory efforts, and is but rarely seen in the feeble.

Symptoms.—The atelectatic areas may be so small, so scattered, or so obscured by the adjacent compensatory emphysema as to be wholly overlooked, although frequent and careful physical examinations may be made. This is especially true of cases in which there is no recession of the chest-wall, and where the neighboring alveoli are so distended as to increase the vesicular murmur and intensify the percussion resonance.

As post-natal atelectasis usually happens to emaciated and puny infants, the general symptoms vary according to the extent of the lesion. In mild cases the infant is indifferent to its surroundings, gives vent to a whining expiration, is slightly cyanosed, and refuses its nourishment; but these symptoms quickly disappear upon the dislodgement of the occluding mucus plug. In severe cases restlessness and sleeplessness are well marked; there is evidence of distress and exhaustion depicted upon the face; the features are pinched; the eyeballs are sunken and without shimmer, and the livid eyelids droop; the mouth is drawn and the lips are livid; and the head and face are bathed in a profuse, cold, clammy perspiration. The tongue is dry, swollen, and purple; the appetite is lost, the infant refusing to nurse, suck the bottle, or take food from a spoon; the bowels are normal, unless there be some gastro-intestinal derangement. Collapse is often rapid and pronounced, but is not always fatal. There may be convulsions, in one of which the infant may die, though they are not necessarily fatal. The pulse is accelerated and small, and its tension decreases as the atelectatic area increases. Cough, though not always present, is due to bronchial catarrh. The integument is dusky, and becomes livid and clammy as the disease progresses. The temperature is normal or subnormal even when atelectasis occurs during the course of a febrile disease.

Physical Signs.—It is not surprising that this disease is so frequently confounded with pneumonia, when we remember that its physical signs are indicative of more or less consolidation of lung-tissue, with a catarrhal inflammation of the bronchial mucous membrane. So the physical signs vary with the extent of tissue involved.

Inspection.—The nares dilate with the respiratory movements, which are superficial and rapid, varying from 60 to 90 per minute, and their normal ratio to the pulse is lost. Inspiration is slower and more labored than expiration, and is followed by a pause. Retraction of the chest-wall varies with its elasticity and the extent of the collapsed lung beneath. If a considerable area of lung is involved, the chest-wall yields to atmospheric pressure, resulting in depression of the supraclavicular and intercostal spaces, with a deep furrow over the affected area. The deformities of the chest-wall are exaggerated if spinal curvature or rachitis exists.

Auscultation.—The vesicular murmur is feeble or absent unless there is compensatory emphysema around the atelectatic areas. Bronchial respiration and bronchophony are present when a large collapsed area surrounds a bronchus. When fine crepitant râles are present, they indicate an extension of the catarrhal process to the neighboring bronchioles and alveoli.

Percussion.—Dulness is usually found at the base of the lung posteriorly, but is often slight or entirely absent, and if the neighboring alveoli are emphysematous the percussion resonance may be greatly exaggerated. The dulness may extend upward parallel with the spinal column: it may remain stationary, or it may be transient or change with the position of the infant. If it is due to compression from a collection of fluid in the pericardial, pleural, or abdominal cavity, the signs of this causative factor may be defined.

If it is coincident with bronchial catarrh, whooping-cough, diarrhœa, typhoid fever, or any exhausting ailment, the symptoms of the primary affection will be present.

Duration.—The duration of life is uncertain, and in some infants it is surprisingly long. Some die very early from asphyxia or in a convulsive attack, while others linger for weeks or months to die of slow asphyxia or exhaustion.

Diagnosis.—If the atelectasis is in scattered areas, it is seldom recognized, and even if large areas are involved, it may be overlooked unless frequent and careful examinations are made. It is most common in the feeble and emaciated infant, and is directly caused by some disease which impedes the respiratory movements. It frequently accompanies broncho-pneumonia, pertussis, measles, or some long-continued and exhausting disease. The respirations are rapid and shallow, dyspnoea is progressive, cyanosis marked, and exhaustion increasing. Auscultation reveals an absence of vesicular breathing and the presence of bronchial respiration and bronchophony, and there is dulness on percussion over the affected area. A differential diagnosis is generally difficult, owing to the similarity of post-natal atelectasis to other diseases. Some of the physical signs of croupous or broncho-pneumonia are often observed in atelectasis, but the characteristic general symptoms of these two diseases are either indistinct or absent. In pneumonia the temperature is high, and is frequently accompanied by delirium or convulsions; the pain is acute; the face is flushed; the skin is hot and dry; there are fine crepitant râles and percussion dulness over a large area; and retraction of the chest-wall during inspiration is absent. In atelectasis there is a normal or subnormal temperature; pain is absent; the face is livid; the skin is cold and wet; râles are

only present when bronchial catarrh exists; dulness is in small scattered areas; and the chest-wall retracts during inspiration.

While it is possible to confound atelectasis with acute miliary tuberculosis, still there are so many well-defined symptoms, as the previous history, cough, great fluctuation of the daily temperature, emaciation, and exhaustion, which precede the stage of solidification in tuberculosis, that the differentiation should be made with a degree of certainty.

Atelectasis should not be mistaken for pleuritic effusion, as the absence of bronchial breathing, bronchophony, and vocal fremitus, taken in conjunction with the alteration of the line of dulness with the changing position of the patient, will settle the diagnosis. In doubtful cases aspiration would be the determining factor.

Prognosis.—The prognosis is always grave, and recovery is extremely rare, owing to the low vitality of the infant. If it complicate bronchial catarrh or broncho-pneumonia in a puny, rachitic infant, atelectasis is fatal. Convulsions greatly jeopardize life. If somnolence, increasing cyanosis, superficial and hurried respirations, and refusal to take nourishment supervene, the prognosis is unfavorable; but if intelligence return, cyanosis disappear, the respirations become stronger and deeper, and the child take nourishment liberally, the chances are favorable to recovery.

When complicated by whooping-cough, general pulmonary emphysema, broncho-pneumonia, tuberculosis, or pleurisy, it is fatal. When caused by compression, as in hydro-, pyo-, or pneumo-thorax or tumors, the prognosis depends upon the removal of the cause. When dependent upon the presence of a foreign body in a bronchus, recovery is conditioned upon its dislodgement. It must be remembered, however, that in some cases the infant may recover from the immediate effects of atelectasis to die later of cheesy pneumonia or phthisis.

Treatment.—This being a disease which is superinduced by the lack of resistance of the enfeebled infant, the prime factor in the treatment is to improve the general health so as to enable it to repel all causes that depress the vitality. To this end personal and domiciliary hygiene should be carefully regulated. In seasonable weather the infant should be taken in his perambulator into the open air; removal into the country, or, when practicable, to the mountains or seashore, is advisable. An occasional tepid, alcoholic, or moderately cool sponge-bath will prove beneficial. Sleep should be encouraged at stated times, care being taken not to permit too much. The clothing must be of the proper quality and quantity, and should permit of the freest movements of the chest. Very feeble infants may be wrapped in cotton-wool. The domicile must be scrupulously healthful in having pure air by free ventilation and the best sanitary equipment. The temperature of the room must be from 70° to 75° F.

Care should be taken in supervising the quality and quantity of the infant's food. If the nursing infant has progressively emaciated and weakened, the mother's milk needs attention. If bottle-fed, the management is even more perplexing, but the proportion of albuminoids, fat, and sugar can be changed until a combination is found that will be digestible and nutritious. Broths and beef-juice may prove valuable adjuvants to the milk diet. If the infant be too weak to nurse, or even to swallow, gavage or stomach-feeding is indicated. When the stomach will not retain food, the strength must be sustained by concentrated nutritious enemata.

There are no specifics for the cure of atelectasis, but its different phenomena must be met promptly and energetically. When secondary, the treatment must be directed to the primary affection. If a foreign body be lodged in a bronchus,

its removal by operation is recommended. If the obstruction is a plug of ropy muco-pus, it may be removed by active emesis induced by teaspoonful doses of syrup of ipecacuanha, one or two grains of the sulphate of copper dissolved in water, or the hypodermatic injection of apomorphia.

Cardiac and respiratory depressants, especially preparations of opium, must be positively interdicted, while cardiac and respiratory stimulants must be judiciously administered. The cardiac stimulants of most importance are strophanthus, sparteine, nitro-glycerin, camphor, musk, and ammonium carbonate. Brandy, in frequently repeated doses, is one of the most efficient stimulants. The force of the respiratory movements can be increased by $\frac{1}{300}$ to $\frac{1}{200}$ grain of atropine sulphate, which stimulates the respiratory centre. Compressed air or oxygen may be inhaled, but neither has proved to be particularly beneficial. Convulsions must be treated by hot mustard baths and antispasmodics. Finally, to ensure any hope of success, the infant requires the most careful handling, the most rigid regimen, and the most judicious dosage.

BRONCHO-PNEUMONIA.

BY WILLIAM PEPPER, M. D.,

PHILADELPHIA.

BRONCHO-PNEUMONIA—also known as catarrhal pneumonia, lobular pneumonia, and capillary bronchitis—is an inflammatory disease of the terminal bronchioles and air-vesicles of the lung, affecting scattered groups of lobules. Though in the main a catarrhal inflammation of the bronchioles and air-sacs, the interventricular and peribronchial tissues are also involved, and the term “catarrhal pneumonia” is therefore not altogether accurate, nor are the other terms by which it has been designated wholly appropriate in all cases. The disease varies widely in its course and duration, often proving fatal in a few days, at other times becoming a lingering chronic affection, leading to secondary changes or creating a tendency to subsequent tuberculous infection.

Etiology—Broncho-pneumonia is in the great majority of cases a secondary disease, and, as a rule, bronchitis is the primary cause. This may be either a simple bronchitis or that which occurs as a part of infectious diseases, prominent among which are measles, whooping-cough, diphtheria, influenza, and typhoid fever. The manner in which a bronchitis affecting the smaller tubes might lead to a broncho-pneumonia is readily appreciated, but will be considered more minutely in the description of the morbid anatomy. A most important cause is tuberculosis affecting the bronchi and lungs. In all cases of chronic phthisis there occur from time to time attacks of localized broncho-pneumonia, from which the patient recovers, or there may be more widespread and fatal attacks. The primary focus of tuberculosis is sometimes so small as to have escaped detection, and in such cases the broncho-pneumonia is apt to be looked upon as of the ordinary type. Broncho-pneumonia may also arise without bronchitis as a primary disease of obscure origin, or as a result of inspiration of irritants from the mouth, nose, or upper respiratory passages, and in the new-born it may be the result of respiration of the liquid secretions of the genital tract during birth.

The specific cause of the inflammation is probably, in most cases, the pneumococcus of Fränkel, but the staphylococcus and streptococcus pyogenes, the bacillus of Friedländer, or, as we have seen, the tubercle bacillus, may be the excitant in certain cases.

Of the predisposing causes of catarrhal pneumonia, by far the most important is the age of the patient. A study of mortality statistics of young children shows pneumonia to be second only to infantile diarrhoea as a cause of death, and in children under five years it is the lobular form of pneumonia which is found in the great majority of cases. It is especially during primary dentition that broncho-pneumonia occurs, and most of the fatal cases in particular occur before the age of two years. The preponderance of this form of pneumonia during the early years of life is to be explained partly by the anatomical condition of the lungs, and partly by the marked tendency to catarrhal processes generally in infants.

In addition to age, malthygienic surroundings exercise a powerful influence on the prevalence of the disease, and particularly is this the case in times of epidemics of measles, diphtheria, and whooping-cough, when children of the poorer class are especially exposed and are apt to suffer from improper care. The disease is most common during the winter and spring, and particularly at times when the weather is changeable. Previous conditions of health, aside from the infectious diseases, exercise some influence, and children suffering with rickets or scrofula are prone to be attacked by the disease in its most fatal form.

Morbid Anatomy.—As stated before, the more important part of the pathological changes is the catarrhal inflammation of the lining of the smaller bronchioles and air-vesicles, the epithelial cells rapidly desquamating and accumulating within. As a rule, the cells are cast off singly, and lie intermingled with a smaller number of leucocytes or red corpuscles. In more rapid and virulent cases the epithelial lining may be detached in large flakes, and sometimes there is considerable diapedesis of red blood-corpuscles, giving the section a decidedly hæmorrhagic appearance. The latter, however, is rare. As the disease continues the cellular desquamation and exudation increase, and at the same time a more or less copious outpouring of mucous secretion occurs, until the bronchioles and air-vesicles become completely filled. Beginning in the terminal bronchi, the inflammatory process advances, and invades the adjacent air-vesicles in several ways. In the first place, there is always a direct extension of the inflammation to the surrounding peribronchial tissues, which are seen to be invaded by round cells and to be the seat of active cellular proliferation. The secondary peribronchial inflammation gradually spreads to the walls of the adjacent air-vesicles. Thus it is seen that the peribronchial and perivesicular involvements are important elements in the morbid anatomy, and in cases where the disease becomes chronic these secondary changes lead to the induration processes characteristic of chronic broncho-pneumonia. The extension from the bronchioles to the alveoli is, however, also effected in other ways. There may be a continuous inflammation extending along the epithelial lining, or the irritating matters within the tubes may be directly conveyed by the strong inspiratory efforts following a paroxysm of coughing. These inspired substances may directly excite vesicular inflammation, or by obstructing the terminal bronchial tubes may first produce areas of collapse of the lung-tissue. The occurrence of pulmonary atelectasis in the course of bronchial catarrh and broncho-pneumonia is entirely a mechanical result of the obstruction of the tubes. In some cases the obstructing material acts as a ball valve, permitting the air to pass out, but not re-enter the affected area. More frequently the expiratory efforts expel the air through partially obstructed tubes, but the weaker inspiratory force proves inadequate to refill the vesicle; and finally, in cases where there has been complete obstruction of the tubes, the air enclosed within is gradually absorbed. In any case, the vesicular structure collapses, the blood-vessels become surcharged with blood, and the most favorable conditions for inflammatory action are thus supplied.

When the disease begins to undergo resolution the cellular material within the vesicles suffers fatty degeneration, and with the mucous secretion is expectorated or absorbed coincidentally with resolution of the peribronchial inflammation. In cases, however, in which chronic pneumonia results, the peribronchial connective-tissue hyperplasia undergoes fuller organization, and induration follows in consequence. The bronchial walls are thickened, and

not rarely show fusiform dilatations, the result of traction of the newly-formed connective tissue.

The macroscopic appearance is highly characteristic in most cases. The involvement of scattered lobules of both lungs in itself is a most distinctive condition, though sometimes by confluence a whole lobe may be affected. In such cases the distinction from croupous pneumonia becomes one of great difficulty if, as sometimes happens, the vesicles contain fibrinous exudate and the incised surface presents a granular appearance. Even in these cases, however, it will be noted that the process is not entirely a uniform one, and that there is a certain tendency to lobular limitation. Examination of the pleural surface of the lung shows a moderate deposit of lymph over areas which have reached the periphery. The inflamed lobules project slightly from the surface, and have a dark-red or in later stages a grayish appearance, which at once distinguishes them from the depressed, blue-black, and indurated spots of atelectasis. The latter may be small and lobular or more extensive, and they are most frequently seen posteriorly along the spinal column or anteriorly in the middle lobe of the right lung or the lingula of the left. In the early stages they may usually be distended by inflating the lungs through a tube, but later, as inflammatory changes occur within them, this becomes difficult or impossible. The incised surface of the lung presents a similar picture. The distinct lobular invasion is again quite evident, and the atelectatic areas are recognized by the same characters as on the pleural surface. The lung is smooth and airless in the affected portions, or in rare cases may be slightly granular when the exudate contains fibrin. The smaller bronchi are distended with clear viscid mucus or turbid yellowish muco-pus. The lobules adjacent to the affected ones are emphysematous, as are also the anterior margins and the upper lobes of the lungs, and occasionally subpleural emphysema may be seen. In one instance I found pneumothorax resulting from rupture of the pleura in such a case.

When resolution takes place, the inflamed lobules become lighter in color, the exudate softens, and is finally removed. More rarely abscess or gangrene may result, or chronic broncho-pneumonia may occur in lingering cases. The termination in cheesy pneumonia, of which much was formerly written, is perhaps always the expression of tubercular infection, either primary or consequent upon the broncho-pneumonia.

Symptoms.—The onset of broncho-pneumonia is rarely marked by decided symptoms. If the primary measles or whooping-cough has not been entirely recovered from, a slight increase of the existing fever, with acceleration of the pulse, dyspnoea, and a change of the cough to a short and hacking character, may be the only symptoms to indicate beginning trouble. In cases in which broncho-pneumonia arises primarily the same symptoms follow an initiatory stage of bronchitis. The fever rises gradually, reaching the maximum in three or four days, and is throughout the disease markedly irregular, the diurnal excursions ranging from three to four degrees. In ordinary cases the evening maxima are from 103° to 104.5° F., but it is not unusual to find higher temperatures, and in one case which recovered I have seen it reach 107°. The decline of the temperature, like the ascent, is gradual, and for a long time during convalescence feverishness may be noted toward evening. With increase of the fever the pulse-rate accelerates to 130 or 140 beats per minute, and in exceptional cases a rate of 200 may occur. Dyspnoea, however, is a more decided symptom, the ratio between the respiration and pulse not infrequently becoming 1 to 2, or even less than 2. The alæ of the nose dilate with each inspiratory effort, the base of the chest sinks in, and the child mani-

feels by its expression that pain is felt in the side. When areas of the lung collapse, there are paroxysms of more decided dyspnoea, the expiration becomes more grunting, and duskiness or decided cyanosis of the skin makes its appearance. The cough at first is sharp and short, and is attended by grimaces and a cry of pain; later it is heard to be looser, and in children over seven years of age there may be muco-purulent expectoration. In younger children the

FIG. 1.

Chart of Temperature, Pulse and Respiration of Broncho-pneumonia in a patient two years and two months old; recovery.

sputa are swallowed. With the fever and dyspnoea there is nearly always a complete loss of appetite, but excessive thirst. Nursing infants are unable to retain hold of the nipple for more than a moment or two on account of dyspnoea, and older children refuse food entirely. The child becomes fretful and irritable, but sometimes the urgency of dyspnoea may be such that it suffers itself to be taken up or examined without complaint. The general strength rapidly declines, and, as the interference with respiration continues, a soporose or somnolent condition or complete stupor presages an early death unless relief be afforded. Not infrequently vomiting is present at the onset or during the course of the disease, and with diarrhoea may still further add to the general depression and the unfavorable outlook.

In cases in which resolution occurs the symptoms gradually ameliorate, the fever subsides, and in the course of a few days or a week convalescence is established. In less favorable cases, after subsidence of the urgent symptoms, the disease may linger and become chronic, or from the start it may assume a

chronic type. In such cases there is persistent, irregular pyrexia, with cough, dyspnoea, and acceleration of the pulse, and the general health of the patient becomes more and more depressed.

Physical Signs.—At the inception of the disease the physical signs of bronchitis affecting the smaller tubes will nearly always be present. At first there are heard on auscultation numerous dry râles throughout both lungs; later, coarse moist râles make their appearance, but the pulmonary resonance remains unaffected. The physical signs of the developed disease are by no means distinctive. Defective expansion and an up-and-down type of breathing are manifest, and with each inspiratory effort the base of the chest may be seen to recede. At the same time, careful percussion of the lateral and posterior portions of the lungs may detect localized patches of dullness, but this is by no means constantly the case. In not a few the percussion note is hyper-resonant, perhaps from associated emphysema of the unaffected lobules, or, on the other hand, the extent of dullness is rendered considerable by coexistence of large areas of atelectasis. Vocal fremitus is slightly increased over the consolidated areas when the bronchial tubes are not unduly filled with mucus, but over the collapsed portions it is usually wholly absent. Auscultation shows the continuation of the preceding bronchitis, but in addition to these coarser dry and moist râles there is also heard fine moist crackling over the consolidated areas. These fine subcrepitant râles are heard on inspiration and expiration, and are perhaps the most suggestive sign of the disease. The breath-sounds themselves vary widely with the condition of the terminal bronchi and the degree of distention. Sometimes the sounds are weak and faintly blowing, at other times harsh and clear, but only rarely do we find the distinct bronchial breathing of croupous pneumonia. It will be noted, then, that the signs of broncho-pneumonia are in no sense characteristic; but when to the râles of bronchitis there are superadded fine subcrepitant râles, with harsh or somewhat blowing breathing, and areas of even indistinct impairment of resonance at the postero-inferior portions of the lungs, the evidence is fairly clear as far as physical examination is concerned.

Complications and Sequels.—As has been said in the description of the pathological anatomy, pulmonary collapse is a more or less constant factor in the disease, and is therefore hardly to be looked upon as a complication. Yet in some cases the extent of the atelectatic areas is so great, and the attending dyspnoea and appearance of suffocation so severe, as to merit the place of complicating symptoms. It is in such cases that the old title “suffocative catarrh” finds a not inapt application. Pleurisy, so commonly present in slight degree, rarely becomes a troublesome complication, though some observers, among them myself, have met with purulent effusion. Abscess and gangrene rarely follow broncho-pneumonia, but are most apt to do so in aspiration and deglutition pneumonias, in which the inflammation from the beginning may take on a serious character. Subpleural emphysema and pneumothorax are rare complications. The most dreaded sequel of broncho-pneumonia is tuberculosis. In some of the cases the broncho-pneumonia is undoubtedly tubercular from the beginning, but in any case the vulnerability of the system is so heightened by the attack that subsequent infection becomes an easy matter, and frequently occurs. The marked nervous symptoms during the course of broncho-pneumonia or toward its termination may suggest meningitis, but it is more probable that in the majority of such cases the symptoms are due to hyperæmia of the meninges or the toxæmic state of the patient rather than to actual meningitis.

The termination of protracted cases in chronic pneumonia has been alluded to before.

Diagnosis.—In the first place, it is essential to recognize the development of pneumonia during acute bronchitis at the very earliest moment. It may be suspected when there has been a sudden increase of fever and acceleration of the pulse and respiration, but such might occur independently of broncho-pneumonia. If, however, in addition to these symptoms, fine subcrepitant râles and blowing breathing be heard, and percussion detects small areas of impairment of resonance, pneumonia may be diagnosed with considerable certainty.

The disease when fully developed may readily be confounded with croupous pneumonia in cases in which the confluence of lobular involvement has led to a considerable area of consolidation. This, however, is rarely the case, and even when it does occur the consolidation is not so definitely localized in one lobe, and scattered patches will probably be found in the other lung. In ordinary cases the dulness, the vocal fremitus, and bronchial breathing are not developed to nearly the degree which they commonly attain in croupous pneumonia, and in typical cases there could scarcely be the possibility of confounding the one disease with the other. The difficulty, however, of making accurate physical examinations in young children is often considerable, and in such cases the history of the disease is of greatest assistance. The gradual onset and the marked irregularity of the fever, the existence of a preceding bronchitis, and the character of the sputa when present, are in all cases highly suggestive of broncho-pneumonia, as the abruptness of the attack and the greater regularity of the temperature curve give strong evidence of croupous pneumonia.

The diagnosis from pleurisy with effusion presents little difficulty, altogether aside from the fact that the latter disease is rare in children under six years. The coexistence of moderate pleuritic effusion may, however, be difficult to recognize. In such cases the decided dulness and the variation of its outlines with changes in the position of the patient, and the more distant and muffled character of the breath-sounds, may serve to indicate the actual pathological conditions; but the complication so rarely occurs that its recognition hardly merits further study. More commonly, plastic pleurisy accompanies broncho-pneumonia, and may confuse the physical signs, but careful study of the degree of dulness, compared with the auscultatory phenomena, will in these cases usually point to the proper diagnosis, and the evidence of great pain in the side would still further strengthen this opinion.

In cases in which nervous symptoms or gastro-intestinal disorders become prominent, it may happen that the underlying pneumonia is wholly overlooked. Such an error can only be avoided by a critical study of the symptoms in every case, particularly by close observation of the rate of the pulse and respirations and by careful and repeated examination.

Prognosis.—Broncho-pneumonia is always a most serious disease, the mortality ranging from 30 to 50 per cent., according to the nature of the cases and the surrounding conditions. It is most fatal in children under two years, and the form which occurs in the new-born from aspiration of irritating or infectious particles during the transit through the maternal passages is almost invariably fatal. In children over two years of age the mortality grows progressively less with the age of the patient. The cases which complicate whooping-cough are most apt to be fatal or lingering. Rickets or other debilitating diseases and the occurrence of gastric disturbances, diarrhœa, marked nervous symptoms, and pyrexia, all make the prognosis highly unfavorable.

Duration.—The duration of ordinary cases is generally from fifteen to twenty-five days; milder cases may terminate in a week or ten days. Chronic

broncho-pneumonia is uncertain in duration, ranging from a few to many months.

Treatment.—It is difficult to lay down fixed rules for treatment in a disease in which so much depends upon the actual extent and nature of the pathological changes and upon the reaction of the patient.

In many cases of bronchitis or of infectious diseases attended with bronchitis, it will be possible to prevent the development of broncho-pneumonia by careful attention to hygiene and by strict insistence upon every detail of treatment. It will be necessary in such cases to maintain an even temperature of 70° or 72° in the sick-room, to avoid all drafts, and to adapt the clothing of the patient according to his powers of resistance. In very young children the mouth should be carefully cleansed with some simple mouth-wash like glycerin and boric-acid solution, and older children should in addition be directed to expectorate the sputa.

When pneumonia has actually become established, the hygienic details of the sick-room must be still more strictly maintained. The temperature of the room must be kept as nearly as may be at an even point, and it is always well to have the air moistened by allowing water to steam at the hearth or over a flame. In severe cases a tent of sheets may be erected over the bed and steam from a boiler be directed into it. A light woollen shirt should be worn, and the chest will require special protection. Formerly flaxseed poultices were in common use in the treatment of pneumonia, but they are so apt to become cold and disordered, and their constant application is attended by so much risk and disturbance of the patient, that their use is now generally abandoned. The best protection is afforded by a jacket of cotton or wool batting, lightly quilted and covered on the outside with oiled silk. This may be so constructed as to be easily applied and removed without the slightest disturbance of the patient, and it is so light as to cause little discomfort by its weight. Practically the same thing is accomplished by stitching cotton batting on the inside of a light merino shirt, and oiled silk outside, but the jacket is more convenient. It is unnecessary in ordinary cases to change the jacket oftener than every seven or eight days. The use of counter-irritants, such as turpentine stupes, mustard plasters, and blisters, while occasionally advisable, has, as a routine treatment, fallen into disrepute; but the repeated application of tincture of iodine diluted with alcohol, so as not to prove too irritating, is often attended by good results.

The diet of the patient should be at once light and nutritious, so that the digestive functions may be kept in the best possible condition, and at the same time the patient's strength preserved. Milk, gruels, light broths, arrowroot, and egg albumin dissolved in water or milk answer the requirements, and are the most suitable foods obtainable. In addition to proper regulation of the diet, it is sometimes desirable to administer a mild laxative at the onset or during the course of the disease if constipation be present; but it must be remembered that gastro-intestinal irritation is apt to complicate the case, and nothing must be done which might invite its occurrence. Minute doses of mercury with bicarbonate of sodium or Dover's powder, or the mildest salines, may be of value, and in certain cases may exercise a happy regulating influence on the gastro-intestinal system, provided that free purgation is not induced.

For the condition of the lungs themselves expectorants are highly important. During the early stage, when bronchitis is marked and the sputa tenacious, small doses of ipecacuanha or apomorphine, in combination with alkalies like citrate of potassium, are useful. Such a combination as the following is readily taken by children, and rarely fails to render the mucous secretion less tenacious:

R. Potassii citratis ℥iiss.
 Syr. ipecac. f℥ss.
 Syr. limonis
 Aquæ āā q. s. ad f℥iv.—M.

Sig. Two teaspoonfuls every three or four hours, for a child of five years.

A small dose of apomorphine—a sixteenth or a twenty-fourth of a grain—may be added with advantage in case the mucus is unusually tenacious. Generally, however, recourse must soon be had to the more stimulating expectorants. The ammonium salts, the chloride and carbonate, in combination with squills or senega, are the most desirable. In cases in which depression is marked the carbonate is preferable to the chloride, and when painful cough is urgent minute doses of morphine or paregoric may be added to the mixtures. Opium, however, should never be given with such freedom as to benumb the sensibility, and in the later stages of the disease should be avoided if possible. In some cases, where the stomach is particularly irritable, the aromatic spirits of ammonia may be better retained than other preparations, and is acceptably administered in combination with brandy or other stimulant.

The following combination is especially valuable for children, being pleasant to take and more stimulating than such as contain the chloride of ammonium:

R. Ammonii carbonatis gr. xlvij.
 Pulv. acaciæ et sacchari āā q. s.
 Spt. lavandulæ comp. ℥ij.
 Aquæ q. s. ad f℥iv.—M.

Sig. A teaspoonful in water every two or three hours, for a child five years old.

The general strength of the patient, and particularly the respiratory function, require special attention. To this end quinine in small doses and alcoholic stimulants are highly beneficial, but for respiratory and muscular stimulation no drug compares with strychnine in efficiency. E. g.—

R. Quininæ sulph. gr. xxiv.
 Strychninæ sulph. gr. ¼.
 Acid. muriat. dil. gtt. xvj vel gtt. xxxij.
 Glycerini ℥ij.
 Liq. pepsini q. s. ad f℥iv.—M.

Sig. A teaspoonful in water every three or four hours, alternating with the expectorant remedies, for a child of five years.

In cases where the stomach is non-retentive quinine may be given in suppositories of two or three grains each. The use of such expectorant and tonic treatment usually suffices to keep the bronchi free and to prevent the occurrence of atelectasis; but when these unwelcome accidents make their appearance and suffocating paroxysms occur, active treatment must be instituted. The administration of emetic doses of ipecacuanha, five grains of the powder in a little syrup, is an old method of treatment which serves admirably to clear the respiratory passages. In some cases it may be well to combine alum or sulphate of zinc with the ipecacuanha, but the preparations of antimony formerly so commonly used are depressing agents which had better be avoided. When vigorous emesis fails of the desired purpose, a warm bath or alternate hot and cold douches may be resorted to, and stimulants given by the mouth and

hypodermatically. In all cases in which the strength of the child is greatly affected it is necessary to change the position from time to time, so that hypostatic congestion may be avoided.

Fever in catarrhal pneumonia does not usually call for active treatment, from the fact that the pyrexia is not constantly maintained at a high point, but such is not always the case. In the very early stages a few doses of the tincture of aconite, a half or one drop repeated every hour or two, are of distinct value; and in the later stages small doses of antipyrin or phenacetin exert a powerful influence on pyrexia. The use of either aconite or more active antipyretics must always be most cautious, and the first indication of general depression would call for the immediate withdrawal of the medicines. Unquestionably the use of hydrotherapeutic measures is most valuable in controlling fever, in stimulating the general and respiratory tone, and in quieting the nervous system. The patient may be carefully sponged with lukewarm or cold water or wrapped in sheets wrung out in water, or he may be placed in a bath of temperature varying according to the age. With very young children the temperature of the water should be near that of the body, and gradually cooled after the patient has been placed in it; in older children the initial temperature may be 85° or 80°. After removal from the bath the skin should be lightly dried with a towel or woollen cloth and the patient wrapped in a blanket.

Excessive nervous symptoms are to a large extent controlled by sponging or bathing, but in cases where this is inadequate small doses of chloral may be given in enemata, or asafœtida in 5 grain doses, may be added to the quinine suppositories.

In more chronic cases the general health and the respiratory action should be maintained by the closest attention to daily life and by administration of suitable tonics.

During convalescence of acute cases renewed exposure must be avoided, and the child should receive cod-liver oil, arsenic, iodide of iron, or other tonics; and, if possible, a change of climate is of material advantage.

CROUPOUS PNEUMONIA.

BY WILLIAM PEPPER, M. D.,

PHILADELPHIA.

CROUPOUS PNEUMONIA—designated also lobar pneumonia and fibrinous pneumonia—is a specific inflammatory disease of the lungs, characterized by fibrinous exudation into the vesicular structure and consolidation of the lung, presenting a characteristic clinical course and terminating by self-limitation in seven to ten days. The croupous pneumonia of children differs from that of adults only in some of the less important manifestations, in the situation of the lesion, and in the smaller mortality.

Etiology.—One of the most important causes of croupous pneumonia is exposure to cold. The history of a large majority of the cases will disclose the fact that the child has suffered chill from exposure, and the study of mortality statistics shows that two-thirds of all cases occur during the winter and spring. Cold cannot, however, in the light of recent knowledge, be looked upon as the exciting cause of the disease, though there are still some who maintain that a small number of idiopathic cases from exposure do exist.

Age is an important factor in determining the form of pneumonia. The croupous variety, though it does sometimes occur in infants at the breast, is rare before the age of three, and in children is most common between five and ten. On the other hand, broncho-pneumonia is a prevalent disease in children under three or two, its frequency being explained by the great tendency to catarrhal processes manifested in young children.

The previous health of the child is another point in which the croupous form differs from broncho-pneumonia. Unlike the latter, it affects children who are robust and in good health. Rilliet and Barthez said that in only one-quarter of the cases was the child in good health before, but this may have arisen from confusion with broncho-pneumonia, and in the statistics of private practice of Dr. J. F. Meigs and myself there were but 7 of 52 cases secondary to previous diseases. Of the diseases upon which croupous pneumonia may be consequent, pulmonary tuberculosis, measles, whooping-cough, influenza, and typhoid fever may be named; but in all of these in children under three years of age broncho-pneumonia is more apt to occur as the complication.

Mallygienic influences may induce pneumonia, either by causing exposure or by reducing the power of resistance in some other manner.

The exciting cause in a great majority of all cases is the pneumococcus of Fränkel. This lance-shaped coccus usually occurs in pairs as a diplococcus, and is surrounded by a transparent capsule. It has been found in a very large percentage of cases of croupous pneumonia, but also in the catarrhal form, and it seems to bear close etiological relations also to cerebro-spinal fever, to middle-ear disease, and to endocarditis. The pneumococcus is a normal constituent of the saliva; and it is held that after exposure to cold or similar

predisposition the micro-organism gains greater virulence or the lungs become less resisting. There are, however, other micro-organisms which occasionally seem the causative agents. Among these the bacillus of Friedländer, the bacillus of influenza, the streptococcus pyogenes, and staphylococci are prominent.

The evidence in favor of contagiousness of pneumonia of both forms is fairly convincing, though the contagiousness is slight. I have seen a local epidemic in a children's hospital in which the disease crept from bed to bed around the ward, and similar instances are common in the recent literature of the disease.

Morbid Anatomy.—The stages in the morbid anatomy are exactly the same as in the adult, but more frequently there is a coexistence of the several stages in the child, so that when one part of the lung is newly congested another may show the most advanced consolidation or beginning resolution. The stages are those of congestion, consolidation, red and gray, and resolution. During the first stage the lung is swollen and red, and the surface of a section is smooth and moist. The fluid which flows from the cut surface contains air and is bloody. In the stage of consolidation the lung becomes solid or hepaticized; it is friable, so that the finger easily tears through it, and the surface is granular and dry. The granular appearance is due to the fibrinous exudate which fills up the air-vesicles and smaller bronchioles. Microscopically, the vesicles are seen to contain a fibrin network enclosing leucocytes, red corpuscles, and a few desquamated cells of the lining membrane of the vesicle; and the blood-vessels of the intervesicular septa are over-full. In the first stage of consolidation, that of red hepaticization, the number of red corpuscles is very great, but in the stage of gray hepaticization they have largely been removed. During resolution the exudate rapidly undergoes softening and is expectorated or absorbed.

More rarely, termination in abscess-formation or gangrene results, or chronic pneumonia may follow as a sequel.

As in adults, croupous pneumonia of children is a lobar process, but it is far more frequently a bilateral disease in children. The lobe most frequently affected is the lower lobe of the right lung, as in adults. Apex pneumonia, however, is as common a disease in children as it is uncommon in adults, and some writers claim the right apex as the more frequent seat.

In every case in which the pneumonic consolidation reaches the pleural surface of the lung there is a certain amount of plastic pleurisy. More rarely effusion of liquid occurs, and I have seen extensive empyema result. In some cases there is also a concomitant bronchitis. This condition is occasionally found in croupous pneumonia of adults, but with not nearly so great frequency as in children.

Symptoms.—The onset of croupous pneumonia in children, as in adults, is usually abrupt, but there may be a short prodromal period during which the child is drowsy or restless and chilly, or coughs slightly and complains of pain in the side. As a rule, however, the onset is decided, a paroxysm of vomiting or convulsions, with rapid rise of temperature, at once calling attention to the seriousness of the malady. Rigor may be present, but distinct chill, such as is so constantly noted in adults, is rarely met with. Instead of this, convulsions and vomiting, especially when indiscretions in diet have preceded the onset, are very common in young children. The temperature rises rapidly, and in a few hours may reach 104° F. It continues during the course of the disease with moderate daily remissions, and declines at its termination by rapid crisis. More rarely decided remissions and gradual decline may mark

the case. With the rise of temperature great rapidity of pulse is noted, but even greater relative rapidity of the respirations, and in bad cases dyspnoea is a most urgent symptom. The child lies on the affected side, and from time to time is seized with paroxysms of sharp, short cough. In young children the grimaces and cry give evidence of the pain experienced during coughing, and older children complain of pain in the side or abdomen. Expectoration is rarely seen excepting in children over seven years, when it may occur, and presents the characteristic hæmorrhagic or rusty character so commonly seen

FIG. 1.

Chart of Temperature (rectal), Pulse, and Respiration in Croupous Pneumonia of the apex of the left lung in a patient three years old; recovery.

in the pneumonia of adults. The child may be restless and irritable, and insist upon being constantly changed from the nurse's arms to the bed; but when the disease is most severe and dyspnoea is marked, complete apathy is apt to be developed. The face is flushed, and particularly a bright red spot may be seen on the cheek or region of the zygoma of one or both sides; the alæ of the nose dilate with each inspiratory effort; herpes is often seen upon the lips. The tongue is coated, the appetite is lost, and in certain cases vomiting and diarrhoea may persist throughout the disease. Ordinarily in mild cases, when convulsions or delirium have been present at the onset, they rapidly dis-

appear with full development of the disease, but in severe cases nervous symptoms may take a prominent place throughout the case, and in some malignant forms death may occur in convulsion before the appearance of the ordinary symptoms of the disease.

In bad cases as the disease nears a fatal termination the respiratory efforts become more and more rapid and irregular; the pulse becomes more rapid and weak; duskiness or cyanosis may develop, with increasing drowsiness and stupor, and the child may die convulsed or comatose. In favorable cases the temperature rapidly declines about the seventh to the tenth day, and during the early days of convalescence remains subnormal. Coincidentally with the decline of temperature the dyspnoea becomes less urgent, the pulse gains in force, the nervous symptoms, if marked, soon disappear, and convalescence proceeds. Sometimes, however, convalescence is rendered tedious by diarrhoea or stomatitis or by tendency to slight recrudescences of the fever.

Varieties.—Though, as a rule, the symptoms in croupous pneumonia have a typical and regular course, there are occasional cases in which the manifestations are so irregular as to warrant the description of certain clinical varieties: (1) Cerebral pneumonia is a type in which from the onset excessive pyrexia and nervous symptoms, such as delirium, convulsions, or coma, so dominate the case that the underlying disease might readily be overlooked, and the existence of meningitis be suspected, especially as cough and other pulmonary indications may be wholly absent. Such cases are most frequently observed in children debilitated by previous disease, and very often the pneumonic changes affect the apex of the lung. The relation of apical involvement to severity of nervous symptoms has, however, been greatly exaggerated. (2) Abdominal pneumonia is a less common variety, in which vomiting and diarrhoea, with marked abdominal pain, are prominent symptoms. In some cases these may be so decided as to indicate the existence of gastro-enteritis, or, when pain and abdominal distension are excessive, of acute peritonitis. In a small number of cases, especially of basal pneumonia of the right side, jaundice is noted, and to such the term “bilious pneumonia” has been applied. (3) Wandering pneumonia, or *pneumonia migrans*, bears so close a similarity to broncho-pneumonia that the distinction requires the greatest care. The disease affects one portion of the lung after another, and gives to the case an irregular and lingering nature quite unusual in the croupous form of pneumonia. By the completion of the disease consolidation may have been present in every part of the lung, but the consolidation is usually not well marked.

Physical Signs.—The physical signs are often less distinctive than in adults, and it is especially to be remembered that the apex is almost as frequently the seat of the disease as the base, and that bilateral pneumonia is a much commoner condition in young children than in adults. In a typical case, however, the signs are quite decided. The respiratory expansion is often seen to be lessened on the affected side; percussion and auscultation give evidence of the consolidation of the lung. Dulness on percussion is never so decided as in older persons, and sometimes the emphysematous condition of the lung surrounding a centrally located pneumonia may cause the percussion note to be hyper-resonant or tympanitic. In these cases deep percussion may reveal the true condition of things, or the consolidation may subsequently extend to the surface of the lung. On auscultation the typical crepitant r le of pneumonia may be heard in a minority of the cases, either with ordinary breathing or during the deep inspiratory efforts after coughing. In 31 cases of the late Dr. Meigs and myself, the crepitant r le was heard in but 10.

Subsequently, when consolidation is complete, the breath-sounds become decidedly bronchial, as we found in 46 of 57 cases; and the vocal resonance and fremitus may be found increased over the affected areas. The latter, however, are untrustworthy signs and difficult to determine. In children under five or six it is not unusual to find evidences of bronchitis in addition to the signs of consolidation, and coarse moist râles may persist throughout the case. In any case moist râles become prominent during resolution and give evidence of the softening of the exudate.

The physical signs are subject to wide variations in certain atypical cases. Thus the existence of a large pleuritic exudate of plastic nature would render the dulness decided, without altering the breath-sounds otherwise than by muffling them to a greater or less extent. In the rare cases in which liquid effusion occurs this condition becomes still more marked, and the auscultatory signs may be completely obscured. Wandering pneumonia is apt to be peculiar, not only in its migratory character, but also in the incompleteness of the consolidation, so that but a small area of dulness may be detected.

Complications and Sequels.—Pleurisy is a constant accompaniment of pneumonia which reaches the surface of the lung, but is usually of no great severity. Effusion may, however, supervene, and in the pneumonias of measles, scarlet fever, and typhoid fever, purulent effusion is occasionally met with. Pericarditis may also occur, either alone or following the pleuritic complication. The excessive nervous symptoms of cerebral pneumonia frequently create the suspicion of meningitis, but this does not actually occur so frequently as the symptoms would indicate. In such cases also hyperpyrexia becomes so decided as to amount to a complication. The occurrence of jaundice has been alluded to in the reference to abdominal pneumonia. Nephritis is a complication met with in a certain proportion of cases, and one which materially increases the gravity of the disease. It is much commoner in the pneumonia of children than in that of adults. Abscess and gangrene of the lung are rare sequels, as is also chronic indurative pneumonia.

Diagnosis.—The sudden onset of pneumonia with vomiting and convulsion and high fever simulates very closely the onset of scarlatina. The distinction is, however, rarely difficult if the excessive rapidity of the pulse, the soreness of the throat, and the early appearance of a rash in scarlet fever be kept in mind, and the physical examination for the signs of pneumonia be carefully applied.

When the disease is fully developed it may be extremely difficult to distinguish it from broncho-pneumonia, especially from cases of the latter which become lobar by confluence. On the other hand, a wandering type of croupous pneumonia with imperfectly developed consolidation may simulate an ordinary form of broncho-pneumonia, but the diagnosis is sufficiently detailed in the description of that disease. Acute meningitis is often suspected when profound nervous symptoms make their appearance, and indeed the latter may obscure the underlying pneumonia. In such cases only a careful physical examination will reveal the existence of pneumonia; and, as for a complicating meningitis, it must be remembered that such is far less common than we might suppose from the symptoms. The abdominal type of pneumonia is sometimes mistaken for gastro-enteritis, peritonitis, or even acute ileus, and is only recognized by careful study of the breathing of the patient and by the physical signs.

Pleurisy with effusion is distinguished by the decidedly dull or flat percussion note and the movable character of this dulness; by the absence of breath-sounds, râles, and vocal fremitus; and by the milder character of the symp-

toms. At its onset pain is more severe than in pneumonia, but fever and the general depression of the child are decidedly less marked.

Prognosis.—Primary croupous pneumonia of young children is a disease of little gravity compared with the same disease in adults or with bronchopneumonia of children. Of 60 cases, nearly one-half of them under two years, Baginski lost but 4. In secondary cases, however, the prognosis is much more grave, and in those dependent upon primary septic diseases the mortality is very high. As a rule, marked dyspnoea, high fever, and pronounced nervous symptoms are indications of evil omen; but common experience has shown that in this disease, of all others, a favorable termination may follow the most desperate case. Complications, such as pleurisy or pericarditis and extensive involvement of one or both lungs, naturally make prognosis more unfavorable.

It is to be remembered also that croupous pneumonia tends to relapse, and that second attacks at remote periods are not unusual.

Treatment.—The seriousness of the disease requires that the patient be at once placed at rest in bed. The room should be kept at an even temperature of about 68° to 70°, and drafts must be carefully avoided. It is always well to protect the chest by a jacket made of cotton batting lightly quilted. The food must be light, but nutritious; broths, junket, and milk, as a rule, prove most acceptable. Sufficient water should be permitted to relieve thirst. The medicinal treatment need not generally be a vigorous one, care being taken, however, that the strength of the patient be properly maintained. In the early stages small doses of tincture of aconite in combination with the solution of ammonium acetate or with sweet spirits of nitre serve to control the temperature and to quiet excessive action of the heart. If, however, fever becomes more decided, aconite will prove inadequate, and recourse to stronger antipyretics may be necessary; but hydrotherapeutic measures are more efficient. Sponging with cool water and the cold pack or bath are the safest and surest means of controlling temperature, and when carefully used give rise to no unpleasant consequences. The prejudices on the part of parents may, however, prevent their use, in which case small doses of antipyrin or phenacetin become necessary. When cough and pain in the side are troublesome symptoms, opium may be given in quantity sufficient to allay the irritation, guarding carefully, however, against excessive opiate effect. In severe cases, where general depression and cardiac weakness are marked, recourse must be had to stimulating remedies. Brandy or whiskey may be used in liberal quantity, and carbonate of ammonium is useful in cases in which the cough is tight and irritating. For the support of the heart digitalis is unquestionably the most reliable remedy, though care must be taken lest it prove disturbing to the stomach. In cases of extensive or double pneumonia, in which the strength of the child is profoundly affected and the heart and respiration losing force, stimulation must be pushed to the utmost. In such cases the hypodermatic administration of strychnine and of such diffusible stimulants as ether and aromatic spirits of ammonium may help to carry the child over the crisis, and the inhalation of compressed air or oxygen may prove of signal service. Throughout the disease the general systemic tone is well maintained by the use of quinine in suppositories, to which asafetida may be added in case nervous symptoms become pronounced. If asafetida does not suffice, chloral by enema may be tried, and usually exercises the happiest control.

Of late the use of serum from the blood of convalescent patients has been advocated, and has seemed to effect a crisis in some cases, but the time is not yet ripe for a definite expression on the value of such treatment.

GANGRENE AND ABSCESS OF THE LUNG.

By HENRY JACKSON, M. D.,

BOSTON.

I. GANGRENE OF THE LUNG.

GANGRENE OF THE LUNG is a necrosis of the pulmonary tissue, with decomposition of the affected portion, due to the invasion of the tissue by the bacteria of putrefaction.

It is important to remember that gangrene may be closely simulated by a post-mortem putrefactive softening of the lung, due to the action of the contents of the stomach. These spots may be multiple, are dark-greenish or black in color, and have a sour smell. This process is identical with the post-mortem softening so often found in the stomach and œsophagus. There is rarely found a necrosis of the lung-tissue without putrefaction; this form usually occurs in small patches. The tissue is reddish-brown in color and easily torn, but there is no odor, as in true gangrene of the lung. It is usually found in patients suffering from diabetes, and, so far as I know, it has not been met with in children.

Etiology.—Gangrene of the lung is not met with as a primary disease, but is always secondary to some other pathological condition. It is found in two classes of cases essentially different: First, gangrene may result from a lobar pneumonia; this occurs only in individuals whose general health has been seriously affected, and is especially common in drunkards. On account of the impairment of the circulation, either from local disease of the arteries or from extreme weakness of the heart, the inflammatory exudation is not absorbed; it becomes foul from the entrance of the bacteria of putrefaction, and gangrene ensues. This form of gangrene is rare in children. On the other hand, gangrene may be the result of wounds of the lung or may follow severe contusion of the chest; in the latter instance, as Orth says, the process probably results from the decomposition of unabsorbed blood. Another class of cases is found where the gangrene is the direct result of inoculation from putrefactive processes situated at a distance from the lung, which is infected by septic emboli through the blood-current, or from the aspiration of foul secretions from bronchiectatic cavities or gangrenous ulceration in the mouth and naso-pharynx.

Gangrene of the lung in children is usually met with in those of a weak constitution, with poor circulation, where some local cause can be found as the origin of the septic process. It is rarely met with except as an intercurrent disease. In 16 cases treated by Barthez and Rilliet the gangrene was associated as a complication with the following diseases: Measles, 3 cases; small-pox, scarlet fever, intestinal catarrh, tuberculosis, each 1 case; pulmonary and general tuberculosis, 3 cases; intestinal catarrh, with collapse, 2 cases; meningitis, typhoid fever, bronchitis, and pleuro-pneumonia, each 1 case.

A very considerable number of the cases of gangrene in children are associated with acute septic processes in the middle ear or foul ulcerations in the mouth or naso-pharynx. Several cases have been reported where gangrene of the lung has followed the inspiration of some foreign body. It is especially noteworthy that recovery appears to be the rule in such cases even after extensive destruction of the lung-tissue has occurred, as evidenced by the expectoration of large masses of foul pus and the demonstration of cavities by physical examination. Small patches of gangrene are not infrequently found in lungs which contain tuberculous cavities, the gangrene being dependent upon the aspiration of bits of putrid material from these cavities. Again, it is not an unusual accompaniment of chronic bronchitis with cavity-formation. The only case of gangrene in a young individual which has come under my observation was of this character. A young girl of eighteen presented herself at my clinic with the history of cough for several years; she was never strong. For many months the cough had been paroxysmal in character, and accompanied by the expectoration of large masses of fetid sputum. After moderate cough she raised at once several ounces of greenish fetid pus; the sputum contained many bacteria, but no bacilli of tuberculosis. Physical examination showed a pale, thin girl; chest long and narrow, shoulders rounded. No dulness on percussion; throughout both lungs numerous coarse, moist râles. The breath was fetid. This case was apparently one of chronic bronchitis with large bronchiectatic cavities, as shown by the sudden expectoration of large masses of sputum.

In the autopsy records of the Boston City Hospital I do not find a case of gangrene of the lung in a child, though the hospital receives quite a large number of children among its patients. I find thirteen cases of gangrene of the lung, and the list fairly covers the varying conditions in which gangrene may occur: Four cases of acute fibrinous pneumonia with gangrene: 1st. A drunkard aged fifty-four, with delirium tremens and pneumonia of both upper lobes; 2d. A woman aged thirty-five, acute abscess in peritoneal cavity and acute suppurative perihepatitis; 3d. A woman aged twenty-eight, much reduced by chronic empyema of eight months' duration; 4th. A man of thirty-six, habits not given, etiology obscure. Three cases of tuberculosis with gangrene: 1st. A man of thirty-eight, chronic nephritis, chronic endarteritis; 2d. A woman aged seventy, acute broncho-pneumonia, bed-sores, and fracture of the thigh; 3d. A man aged fifty, putrid bronchitis, cough for many years, emaciated, recent abscess in the throat. Two cases associated with surgical operations: 1st. A man aged forty-five, drunkard, syphilis, stricture of long standing, with urethral tears; 2d. Old man, operated upon for cancer of the tongue, inhalation pneumonia, and gangrene of the lung, with gangrenous pyo-pneumothorax. Two cases of injury to the head, with inhalation pneumonia, both old. One case of typhoid fever in a drunkard, with broncho-pneumonia. One case, a man aged twenty-seven, who had a gangrenous abscess of the lung and gangrenous pleurisy. These cases are collected from a large number of autopsies which include many cases of tuberculosis of the lungs and pneumonia. The only case in which there was not some previous local or constitutional disease explanatory of the gangrene is the last one mentioned.

Gangrene of the lung is, at any age, a rare disease, and, except in a few cases where it follows acute pneumonia, is usually met with in individuals of weak constitution in whom some septic process offers a point of origin for septic emboli which may be carried to the lung. It is interesting to study the autopsies made on cases of diphtheria at the Boston City Hospital as bearing upon the etiology of gangrene. In 26 cases in a continuous series, 19, or 73 per

cent., had some affection of the lungs: of these cases, 14, or 50 per cent., had acute catarrhal pneumonia; 5 had atelectasis. One of the cases of atelectasis had also a small abscess. None of these 19 cases presented evidence of gangrene of the lungs. As all these cases of pneumonia occurred in individuals with a serious local septic condition, it is evident that gangrene of the lung is rare, even in septic cases, unless the resistant power of the pulmonary tissue is impaired by a previously-existent general feebleness of the individual. In other words, the pulmonary circulation is so favorable that an acute inflammatory process does not tend to become gangrenous simply because the immediately exciting cause of the inflammation is a septic material.

A few cases of gangrene of the lung have been observed in which careful examination failed to elicit any reasonable explanation of the etiology. Such a case is reported by Holt. A child three years of age, who had not been sick except for an attack of bronchitis two years before, was suddenly taken ill; the disease ran its course with signs of acute pneumonia and bronchitis; death in two weeks. Autopsy showed right-sided pleurisy with gangrene of two-thirds of the right lower lobe.

Pathology.—Gangrene of the lung may be met with as a diffused or a circumscribed process. The circumscribed form occurs more frequently in children; small patches are found scattered through the lungs; they are greenish or black in color, the tissue is softened, easily broken down, and has a most intensely fetid odor. Surrounding the patches of gangrene there is usually an area of acute inflammation, comparable to the line of demarcation which surrounds a slough. It is usual to find, in one or more of these areas of gangrene, cavities which contain a foul, dirty material composed of broken-down lung-tissue, while the walls of the cavities themselves are shreddy. When the primary lesion is in the upper part of the lung, numerous areas of gangrene are found in the lower lobes, due to the inspiration of small bits of necrotic tissue. Microscopical examination of the contents of such gangrenous areas shows the presence of bits of elastic tissue of the lung, numerous cells exhibiting fatty degeneration, and immense numbers of bacteria of many kinds; fat-crystals and globules of free fat are also met with in abundance. No specific bacteria have been found in cases of gangrene of the lung; the bacteria belong to the various species which are the etiological factors in ordinary putrefactive processes. Streng describes two cases of gangrene of the lung in which he found infusoria. The infusoria were cells about the size of a white blood-globule: they had cilia and were capable of active motion.

When the gangrenous area, in its extension, reaches the pleural surface, there results a gangrenous pleurisy, which may become encapsulated by the formation of adhesions. This formation of an encapsulated pleurisy gives at times an important hint for treatment, making it possible in suitable cases to open the lung by free incision and drain a gangrenous cavity without causing a general pleurisy. It is not unusual that during the progress of the disease small blood-vessels are eroded, thus giving rise to hæmorrhage of greater or less severity.

Symptoms.—In many cases the symptoms of the gangrene are masked by the more prominent symptoms of the primary disease, and the gangrene is only discovered at autopsy: this is especially true of children, in whom expectoration is rare. Loss of flesh and strength is rapid; the complexion is pale, gray; sweating is a prominent sign. The temperature is irregular, much more intermittent than in pneumonia; the course of the temperature may be an important guide in the differential diagnosis between an acute pneumonia and a

diffused gangrenous affection of a large part of the lung, where the physical signs point to consolidation of a large area of lung-tissue. The pulse is rapid and feeble. Physical examination yields varying results according to the area of the diseased tissue: we may find only the evidence of a bronchitis, but if

FIG. 1.

Temperature Chart of Gangrene of the Lung following operation for cancer of tongue—adult patient.

the area of gangrene is large we find dulness due to consolidation. Where large areas have been destroyed by the gangrenous process we may find, after cough with expectoration, amphoric respiration and a high-pitched tympanic note, indicating the presence of a cavity. The breath is exceedingly foul and has a peculiar fetid, sickening odor: it is important to bear in mind that a local gangrenous process in the mouth may give rise to an odor almost as disagreeable as that of gangrene of the lung. Caries of the nasal bones with retained secretion, ozæna, gives an odor even more similar to that of gangrene of the lung. If there be expectoration, the sputum is dark greenish-yellow and very fetid: it may be large in amount, even in quite young children, as the gangrene causes the formation of large cavities, which are usually emptied at irregular intervals. An important diagnostic sign is hæmoptysis, which is of especial value in children, since with them, in other diseases, this symptom is rare. Kohts records the case of a child of three years who, after an excision of the hip-joint, spat up four or five tablespoonfuls of blood, and soon became very weak, had exceedingly foul breath, and died in a few weeks after the onset of the unfavorable symptoms.

Prognosis.—The prognosis in gangrene due to septic emboli or inhalation pneumonia is almost necessarily fatal. It is about equally bad in gangrene following pneumonia, as it is only met with in children previously much reduced. Several cases have been reported of recovery from gangrene which

had followed the swallowing of a foreign body. Kohts describes such a case which occurred in his own practice. A girl of six years swallowed a bit of bone: eight weeks later she had excessive cough with foul expectoration and fever. Ten months later she coughed up the foreign body, and finally, after a year, was completely restored to health.

Treatment.—The first indication is to sustain the strength by giving the greatest possible amount of food; stimulants may be pushed to an extreme degree. Small doses of strychnia are at times useful in asthenic forms of pneumonia as seen in diphtheria, and may be tried in gangrene. This drug acts as a stimulant to both the circulation and respiration. Direct cardiac stimulants, like tincture of strophanthus or of digitalis, are indicated if the pulse be weak and rapid. Where there is fair reason to suppose that the gangrene is circumscribed and not of very large extent, incision of the lung is admissible: this surgical procedure is, however, limited to cases that are free from general septicæmia; that is, practically, to cases of gangrene dependent upon the swallowing of a foreign body. If there be a pyo-pneumothorax, free incision of the pleural cavity is always indicated. If the child is old enough to inhale, sprays of creasote or turpentine should be used, as these modify the odor of the breath, and may aid in hastening a curative process.

II. ABSCESS OF THE LUNG.

Abscess of the lung, like gangrene, may be an occasional sequel of acute lobar pneumonia in children. In such cases physical examination shows an absence of the usual signs of resolution after the subsidence of the fever. There ensues an irregular rise and fall of the temperature, the pulse becomes rapid, and there is a progressive loss of flesh and strength. It is not unusual that a large amount of pus may be raised when the abscess breaks into a bronchus; after the expectoration of such a quantity of pus there is often found amphoric respiration. The abscess often extends to the pleural surface, and finally breaks through into the pleural cavity. As the process is more chronic, pleural adhesions are more likely to occur than in gangrene of the lung; so that when the abscess breaks we have an encapsulated pleural abscess. Rarely, a neglected empyema may break into the lung and give rise to a pulmonary abscess instead of forcing its way outward through the skin.

The prognosis, in abscess of the lung, though serious, is not so absolutely unfavorable as in gangrene.

As to the general treatment, the same course may be followed as outlined in gangrene. This condition offers a better opportunity for surgical interference than does gangrene: we do not have the general septic condition to contend with. Before making a free incision into the lung the diagnosis should be confirmed by an aspirating needle, and incision should be made at the point where the pus is withdrawn.

BRONCHITIS.

BY WALTER S. CHRISTOPHER, M. D.,

CHICAGO.

BRONCHITIS is an inflammation of the bronchial mucous membrane. On account of the great number of independent causes capable of producing this condition, it should be regarded as a symptom rather than a disease.

Bronchitis may be classified from several standpoints. With reference to the parts of the bronchial tree affected, it may be classified as large tube, small tube, and capillary bronchitis. Under the first category tracheitis should be included. Capillary bronchitis, referring to the inflammatory condition of the smallest bronchioles, is probably always associated with broncho-pneumonia and does not exist as a distinct entity. The term, therefore, is an unfortunate one, and should not be used; indeed, any general classification of bronchitis with reference to the anatomical distribution of the bronchial tubes is misleading and often erroneous.

As to duration, bronchitis is classified as *acute*, *chronic*, and *recurrent*. From the standpoint of origin it is denominated *primary* or *idiopathic*, and *secondary* or *symptomatic*. It is doubtful if bronchitis ever occurs as a primary disorder, an opinion which Sutton has also expressed, although it must be admitted that it is not always possible to clinically determine the antecedent conditions. As to intensity, it is convenient to adopt the division into mild and severe cases.

Etiology.—The etiological factors which lead to the production of bronchitis are exceedingly varied, and the consideration of them is one of the most important factors in the study of this subject. Much light is thrown upon the nature of bronchitis by grouping together the various elements which go to produce the disease in its different forms. Bronchitis is a constant symptom in most of the exanthemata and in some other of the acute infectious diseases, produced no doubt by a direct action of the particular poisons present. Prominent among diseases of this type are pertussis and measles. Typhoid fever is invariably accompanied by some bronchial catarrh, and, while in the adult this symptom is frequently so slight as to be practically unnoticed, it is by no means so in children, and the younger the child the more important does the symptom become. As seen in the West, a disease which seems to be typhoid fever, and is so admitted by many practitioners, is characterized by the great predominance of the bronchial symptoms; and there can be but little doubt that some cases of so-called idiopathic bronchitis in infants, some of which have advanced even to the stage of broncho-pneumonia, are manifestations of typhoid fever. While bronchitis is one of the usual symptoms of influenza, not infrequently it is the most important and most striking; particularly is this true of infants. During the prevalence of influenza, cases of bronchitis are seen that cannot be referred positively to this infection, but which probably are manifestations of it. Rubella, rather less frequently than measles, has bronchial catarrh as a symptom. In

scarlet fever bronchial catarrh rarely occurs, but the possibility of its occurrence in this disease should not be overlooked. Pulmonary tuberculosis is a common cause of bronchitis in infants. Septicæmia, or wound infection, occasionally has bronchitis as one of its numerous symptoms. Another toxic influence of great practical importance is to be found in infection from the intestine. Several years ago Sevestre called attention to cases of broncho-pneumonia accompanied by putrid diarrhœa, from which he inferred that the cause of the pneumonia was to be found in the infection from the putrid contents of the bowel. Later, his pupil, Le Sage, determined in the lungs of such cases the presence of the bacillus coli communis. More recently, similar cases have been investigated by his pupils, Gastou and Renard, who did not find the coli bacillus uniformly, but occasionally the pneumococcus, a staphylococcus, and an encapsulated bacillus. While there is no positive research going to show that a similar condition obtains in the case of bronchitis, there is clinical evidence which confirms the idea that some cases of bronchitis are due to infection or poisoning from the intestine. That poisoning by a chemical agent alone is capable of inducing the anatomical conditions of acute bronchitis has been shown very conclusively by Hamilton, who describes the appearances found in the bronchial tubes of a healthy man dead of opium-poisoning, and proves quite conclusively that the appearances found were due to the opium-poisoning exclusively. The conditions were exactly those produced at the beginning of acute bronchitis. In Bright's disease the bronchitis which occasionally occurs is no doubt a toxic symptom, although in some instances, particularly in the acute Bright's disease of children, it is an evidence of pulmonary œdema.

In infants and young children innutrition plays a most important rôle in the production of bronchitis. It is frequently asserted that dentition is a cause of bronchitis. The coexistence of dentition and bronchitis is no doubt true; the recurrence of bronchitis in certain children with the prurption of each tooth likewise is to be admitted; but in the cases which have fallen under my own observation there has invariably been a demonstrable degree of innutrition, and to this factor, rather than to the dentition, should be ascribed the occurrence of the disease. In the presence of some nutritional deficiencies, other physiological conditions, no less trifling than dentition, may be capable of exciting a bronchitis. The particular form of innutrition present is usually shown to be rickets—that is to say, a fat-starvation, characterized by profuse sweating about the head, by delayed dentition, by restlessness at night, and later by the bony changes. No doubt exposure to cold becomes active as an etiological factor in those whose nutrition is below par, but it is more than doubtful that exposure to cold alone is capable of inducing the condition of bronchitis. Nevertheless, it must be admitted that bronchitis occurs much more frequently during the cold and damp periods of the year than during the dry and warm seasons.

Inhalations of irritating gases and the accidental introduction of foreign bodies into the bronchi are capable of producing acute bronchitis in a purely mechanical way. Obstructive heart lesions, by interfering with the pulmonary circulation, may likewise lead to œdema and some of the changes of the milder form of bronchitis. Chronic bronchitis, once established, is capable by its mere presence of being the starting-point of subsequent acute attacks; indeed, any form of lung degeneration, as has been pointed out by Sutton, is capable of inducing attacks of bronchitis.

Probably the most important cause of recurrent bronchitis is the presence of enlarged bronchial glands. And when it is remembered that any acute bronchitis, no matter how trifling, may lead to the enlargement of these glands, and that acute bronchitis, in one form or another, is probably in children the

commonest of all pathological manifestations, the importance of broncho-adenitis as a cause of recurrent bronchial catarrh, and, indeed, as an independent affection, is at once apparent. It is not at all uncommon to find children suffering through several winters with attacks of bronchitis recurring at short intervals, and in almost every instance it can be found upon investigation that enlargement of the bronchial glands is at the root of the trouble. Many cases classed as phthisis pulmonalis in younger children are instances of broncho-adenitis. It must also be noted that bronchitis may be secondary to a local extension downward of any form of laryngeal inflammation.

From the wide variety of factors concerned in the production of bronchitis it is hardly to be expected that a micro-organism should be found as a specific cause of this condition; nevertheless, E. F. Grün has noted in cases of bronchitis produced by various causes, measles, whooping-cough, etc., a bacillus which he regards as the specific cause of the catarrh.

Morbid Anatomy.—A very careful study of the anatomical changes occurring in bronchitis has been made by Hamilton,¹ whose work has been referred to freely in the preparation of the following outline. The anatomical changes in *acute bronchitis* have been found to be identical, irrespective of the cause. The bronchial mucous membrane throughout is not uniformly affected, but the inflammation is found distributed either generally, in patches of greater or less extent, or limited principally to one lung or even a part of one lung. The trouble may be limited to the tubes of large calibre or may extend into the smaller tubes. The tendency to extend into the smaller tubes is more marked in children than in adults, and particularly is this true of infants. Inasmuch as the accumulation of the catarrhal products in the smaller tubes adds a gravity of its own to the situation, it is well to emphasize this peculiar tendency of the trouble in those of tender age.

On section of the lung a muco-purulent discharge is seen to ooze from the bronchi, and by squeezing the lung the same material is forced out of the smaller tubes. To the eye the surface of the mucous membrane appears congested and vessels are seen ramifying on the surface. According to Hamilton, the first microscopic change consists in the "relaxation and distention of the abundant plexus of blood-vessels ramifying in the inner fibrous coat immediately beneath the basement membrane—that is to say, of the branches of the bronchial artery." Immediately following this the basement membrane becomes thickened and oedematous and is thrown into folds. By the end of twenty or thirty hours the columnar epithelium becomes loosened and desquamates in patches. The cast-off epithelium becomes one of the elements of the catarrhal secretion, but as these cells are not reproduced until after the process ceases, they are only found in the expectoration during the early stages. During this period the bronchial secretion is diminished and the accompanying cough is spoken of as "tight." The cells of the deeper layers of the epithelium nearly all remain attached to the basement membrane, and when freed from the overlying columnar epithelium proliferate actively, and give off into the bronchial secretion an abundant mass of small round cells. The secretion is further made up of the material poured out by the mucous glands. These elements partake of the general activity. Their secreting cells become greatly distended with mucus, and, breaking down, pour out an abundance of this material into the bronchial tubes.

Throughout the whole process, according to Hamilton, the basement membrane remains intact, except in so far as it becomes thickened, and forms a barrier between the inner epithelial elements and the outer fibrous, muscular,

¹ *The Pathology of Bronchitis, etc.* London, 1883.

and lymphatic elements. Beneath the basement membrane the inner fibrous coat of the bronchus becomes thoroughly infiltrated with small cells, and, as these cells cannot pass inwardly because of the basement membrane, they make their way outwardly and infiltrate the muscularis and the outer fibrous coat. Beyond this infiltration the muscularis and the outer fibrous coat are not involved if the process ceases in the acute stage. The cellular infiltration continues outwardly, involving the interlobular septa and even reaching the pleura. Hamilton notes that the lymphatic glands at the root of the lung, the bronchial glands, are invariably involved in the process and become enlarged. This harmonizes with clinical experience. Particularly in infants and young children does this change take place. There is no one item in the morbid anatomy of bronchitis which is of greater consequence than this. It is important to note that enlargement of the bronchial glands occurs in every case of bronchitis; that in sharp attacks or after repeated attacks the enlargement becomes considerable; and that the enlargement is not always tuberculous, but may become so. A considerable enlargement of the bronchial glands is not infrequently mistaken for pulmonary phthisis. As has already been noted, broncho-adenitis is a potent factor in the further production of bronchitis, and should always be suspected in the presence of recurrent or chronic bronchitis. It is furthermore important in that it leads to the establishment of anæmia and to delayed convalescence, for, as Rachford has shown, disease of the lymphatic system is a potent factor in the production of chronic anæmia in children, with resulting malnutrition.

When an acute bronchitis has run its course and is about to terminate in resolution, the vascular congestion and the epithelial activity ceases, the mucopurulent secretion grows less, and finally the columnar epithelium is redeveloped over the denuded spots from the now less active epithelium beneath.

During the course of bronchitis it sometimes happens that atelectasis or collapse of lobules occurs. The amount and distribution of collapse varies very greatly. It is usually associated with emphysema and with broncho-pneumonia, which supervene under the same conditions as favor the occurrence of atelectasis. Broncho-pneumonia is the most serious termination of bronchitis.

Chronic bronchitis may result from the acute form or follow obstructive heart lesions, or it may be produced by the inhalation of foreign matter. When the acute form fails to undergo resolution, the small cell infiltration of the fibrous coats continues, and results in an enormous thickening of the whole bronchus. This thickening causes a diminution in the calibre of the tube, and further leads to atrophy and absorption of the muscularis and cartilages. The diminished elasticity of the bronchia then favors the formation of fusiform dilatations. If the infiltration goes on, the formation of fibrous tissue, so-called interstitial pneumonia, ensues. The subsequent contraction of this tissue, particularly that which has been formed in the interlobular septa, draws out the bronchial walls in places, leaving irregular dilatations of the tubes. This condition, known as *bronchiectasis*, is a potent factor in the causation of subsequent acute attacks. Among the lesions of chronic bronchitis atelectasis and emphysema are always found.

Symptoms.—Acute bronchitis varies in its severity from an exceedingly mild to an exceedingly severe type. The character of its onset is largely determined by the causes which lead to it. In the milder forms the onset may be rather insidious, but sometimes it commences sharply with feelings of malaise, some elevation of temperature, cough, soreness of the chest, and at times with catarrh of other mucous surfaces, as those of the larynx, the throat, and the nose. In this form none of the symptoms become severe, although the cough

may be somewhat distressing. The fever does not reach a point to attract attention, and, if the child be young, expectoration does not occur. Such an attack usually lasts three or four days, but may be prolonged, according to the cause which has produced it, for several weeks.

In the earliest stages of bronchitis the cough is dry and rasping, and individual paroxysms are apt to be prolonged. The secretion at first is scanty, but after twenty-four to thirty-six hours becomes freer. It is removed from the bronchial tubes by the act of coughing, but in the case of infants and young children it is not expectorated; indeed, it is with great difficulty that infants can remove the secretion from the bronchial tubes into the mouth, and when once in the mouth it is swallowed and not expectorated. Expectoration is an art which has to be acquired, and usually is not learned until the sixth or seventh year of life. A cough which is sufficiently severe to cause expulsion of bronchial secretion from the mouth in children who have not yet acquired the art of expectorating is usually whooping-cough. The swallowed secretion occasionally produces some disturbance of the large bowel, and may be associated with mucous diarrhoea, but the mucus in the movements, while in part originally secreted in the bronchial tubes, is also in part formed in the intestine itself. It is to be noted in this connection that a mucous diarrhoea may be induced on the one hand by a bronchitis, and on the other hand a bronchitis may be produced as the result of a diarrhoea, or at least as the result of a putrid condition of the intestinal contents. In milder cases of bronchitis the respiration is not particularly hurried: in young infants, however, it becomes quite rapid even in mild cases. In the severer forms of bronchitis, where there is much thickening of the bronchial mucous membrane and great difficulty in the removal of the bronchial secretion, and a corresponding interference with aëration, the respirations become correspondingly rapid. But the difficult respiration of acute bronchitis cannot always be attributed to mechanical occlusion of the bronchial tubes, for not infrequently great dyspnoea will be present, and disappear suddenly without a corresponding removal of mucus from the bronchi. Difficulty of respiration is manifested in several ways: First, by an increase in the rate of respiration; second, by dyspnoea; third, by special forms of dyspnoea, particularly the grunting expiration. When dyspnoea is present the alæ of the nose dilate on inspiration, and if the dyspnoea be due to mechanical causes, the tissues above the sternum and the soft parts along the insertion of the diaphragm sink in during inspiration. These symptoms, which usually are diagnostic of broncho-pneumonia, may be occasionally found in cases in which the evidences of pneumonia are not altogether clear and in which only bronchitis can be made out. But, inasmuch as they not infrequently disappear quite suddenly in a manner that seems impossible in broncho-pneumonia, it is justifiable to assume that they are indeed the result of a bronchitis pure and simple. Even in broncho-pneumonia the dyspnoea is at times entirely out of proportion to the amount of lung-tissue invaded, and cannot be explained entirely by the mechanical obstruction to the aëration of the blood. It is simpler to suppose that such are cases of toxæmia, in which the dyspnoea is itself a toxic manifestation, in part at least.

In severe forms of bronchitis the respiration may become exceedingly rapid, but the pulse, while frequent, may not be increased in proportion to the respiration. The temperature varies greatly in different cases, but usually there is some elevation. It is hard to believe, however, that bronchitis, of itself, necessarily causes an elevation of temperature, and it is more than likely that the associated pyrexia is a distinct and co-ordinate symptom produced by the same factors which cause the bronchial catarrh. No definite temperature curve can

be ascribed to bronchitis; it follows the other conditions present, and in the severer forms runs high.

The facies of severe bronchitis resembles that of broncho-pneumonia; that is to say, the countenance is anxious, the alæ of the nose dilate, the lips may become cyanotic, and in general the countenance indicates distress. Under such conditions it is perhaps true that broncho-pneumonia is usually present to a greater or less degree, but this is certainly not always the case, as this facies is sometimes found in bronchitis which has invaded only the larger tubes. Nevertheless, the prognosis, whether broncho-pneumonia be found upon physical examination or not, is grave in accordance with the facies just described.

Nervous symptoms are often very marked in the severer forms. Great restlessness occurs not only as a result of the difficulty of respiration, but also as a toxic symptom. Ataxic features are occasionally noticeable, and drowsiness deepening into coma is at times seen. A toxic or so-called febrile dyspnœa is often met with; that is to say, a dyspnœa which is out of proportion to the mechanical conditions present, and apparently due to the same or a coincident cause as that producing the fever. The grunting expiration, noted above, is often of this type; it usually occurs when the rate of respiration is not greatly increased, and, while present during the waking hours, disappears during sleep. The bronchitis which is caused by the putrefaction of bowel-contents is essentially toxic. Often mild, it may be very severe and accompanied by great acceleration of respiration, by dyspnœa, and by marked head symptoms. An uncomplicated case of this kind is relieved by the action of a suitable purgative, the most marked symptoms disappearing at once, leaving no doubt of the toxic origin.

The cough which accompanies enlargement of the bronchial glands is usually dry and harassing, and often assumes a croupy character. Not infrequently, however, the accompanying bronchitis is severe, and may continue for weeks or even months with a profuse bronchial secretion, showing little or no tendency to recovery. This is but one phase of the condition which Dr. B. K. Rachford¹ designates by the term "scrofulous bronchitis." He describes it as follows: "It is, as a rule, recurrent, coming on during the cold and disagreeable winter months and disappearing during the summer months. It is characterized by marked anæmia, and as a rule by other well-known signs of scrofula, such as enlarged external lymphatics, chronic coryza, etc. In these cases of scrofulous bronchitis there may be extensive tubercular disease of the deep-seated lymphatics of the abdomen or chest, without any evidence whatever of external scrofulosis. In such cases the well-marked anæmia and the possible family history of tuberculosis will be of material aid in diagnosis."

This form is very often mistaken for pulmonary tuberculosis, but it may extend over a very prolonged period without the production of pulmonary phthisis, although it tends to that termination. The prognosis is about the same as in other forms of glandular tuberculosis.

Bronchitis is accompanied by a great variety of symptoms referable to other organs and variable, inasmuch as the associated features are determined by the particular causes which produce the bronchitis, and necessarily must vary with them.

Chronic bronchitis in children does not differ sufficiently from the same condition in adults, either in its symptoms or treatment, to require separate consideration.

Prognosis.—Prognosis as to duration should be guarded, as it depends upon the cause which has produced the disease. Those cases which we are com-

¹ Personal communication.

pelled to recognize clinically as idiopathic bronchitis usually, when mild, terminate in three or four days, and even when severe rarely last more than a week or ten days. A bronchitis which is caused by typhoid fever will last from ten days to three weeks, and disappear with the disease which it accompanies. In the case of pertussis the bronchitis may be prolonged quite indefinitely. In measles, while it may disappear in four or five days, it not infrequently lasts several weeks. Bronchitis of purely intestinal origin, usually disappears immediately upon the removal of the bowel-contents.

Prognosis as to severity is determined by a number of factors, but ordinarily it is good. It is customary to say that the prognosis in bronchitis of the larger tubes is more favorable than in bronchitis of the smaller tubes, and in general this is true, but by no means is it always so, as some of the most severe attacks, so far as fever, depression, and other nervous symptoms go, are those in which the large tubes only are affected. The age of the patient is always an important element in the prognosis. The infant with bronchitis is to be regarded as always in danger, as broncho-pneumonia may readily supervene. The exciting causes of the attack must also be taken into consideration. Bronchitis symptomatic of a general infection, such as measles, is very likely to be commensurate with the other symptoms so far as severity is concerned. The presence of enlarged bronchial glands is to be taken as indicating a prolongation or recurrence of the trouble, and as paving the way for a possible termination in pulmonary phthisis. The condition of the child's nutrition determines to a very considerable degree the severity of an attack. Where the nutrition is below par, particularly where rickets is well marked, the disease is apt to prove very severe, and to take upon itself suddenly severe nervous symptoms or to lead to the development of broncho-pneumonia. Marasmus and great weakness from any cause, interfering with the prompt expulsion from the tubes of the accumulating secretions, are conditions unfavorable to the satisfactory progress of the case. The cough *per se* is of but little aid in prognosis. It may be very severe in children who are evidently but slightly ill, and, again, may be nearly absent in children who are in great danger. The character of the respiration is of more importance from a prognostic standpoint. Whenever it becomes rapid, or its rhythm is interfered with, or the grunting expiration appears, or dyspnoea manifests itself, the prognosis should be guarded. With improvement of the respiration in rate and rhythm a more favorable prognosis may be made. The temperature is often an important guide: the higher the temperature, other things being equal, the graver the prognosis; the lower the temperature, the better the outlook. With a pulse that tends to irregularity irrespective of the temperature and respiration-rate, the prognosis is not favorable. But more important than all these symptoms is the condition of the brain, delirium in any of its forms having its usual grave significance. Intense cardiac depression, and sleeplessness, or, on the other hand, somnolence, all are indicative of severe and threatening conditions.

Diagnosis.—The diagnosis involves the recognition of the existence of the bronchial catarrh itself, and the determination, so far as possible, of the etiological factors. The existence of bronchitis is ordinarily recognized without any difficulty. The history of cough, with bronchial secretion of recent origin, is usually enough to establish the diagnosis. An examination of the chest, which should always be made, will decide. In the earlier stages, before the secretion has become established, sibilant and sonorous râles are heard. Not infrequently, however, these râles are very scanty, and not always heard on both sides of the chest. Later the râles become moist and more numerous. When the smaller tubes are invaded, small and even subcrepitant râles are

heard. At no time in an uncomplicated bronchitis is there any modification of the percussion note.

The severer forms are to be differentiated from pneumonia. This can only be done by the detection of the consolidated pneumonic area by percussion and auscultation. The consolidated area is expected to show dulness on percussion, and bronchophony and bronchial breathing on auscultation. But when the area is small and centrally located, these signs cannot always be made out. Fortunately, it is not of the highest importance to determine these conditions exactly, because the prognosis and treatment will not be essentially modified by the presence of a small area of pneumonic consolidation.

Pleural effusion, whether serous or purulent, does not always present specific symptoms indicating its nature, but is often shown only by a cough which may readily be mistaken for that of bronchitis. The physical examination will always differentiate these conditions.

The presence of bronchitis being once established, the search for the etiological factors begins. The existence of one of the exanthemata as a causative factor is usually readily made out by the history and appearance of the child. Pertussis, however, is difficult to determine before the occurrence of the convulsive stage. It may be suspected, however, if the cough be very severe and the disease be prevalent. Influenza usually presents its neuralgic and other nervous features. The character of the stools should always be carefully inquired into, and if there be any suspicion of putridity of the bowel-contents, the fact should be noted as a possible factor in the case. The condition of the nutrition should be carefully studied, particularly in infants, and if the history shows the occurrence of profuse sweating, especially about the head at night, with great restlessness and a tendency to lie uncovered, if there be beading of the ribs, recurrent bronchial attacks during dentition, and occasional laryngismus stridulus, rickets is to be diagnosticated.

Treatment.—The treatment of bronchitis includes attention to the local conditions in the chest, to the general constitutional disturbance, and to the removal, as far as possible, of the causative factors. It is not convenient, however, to divide the description of the treatment with strict reference to these three factors, but rather to consider the matter somewhat in the order in which the various steps are undertaken in actual practice.

The very mildest cases require no treatment whatever, but they should always be watched, particularly in infants, so that interference may be made as soon as necessary.

It is good practice to commence the treatment of every case of bronchitis in infants and young children with the use of a laxative, the reason for this being that the intestinal tract of the infant so commonly contains putrid fæces which do not always manifest themselves by special signs. In older children some signs of bowel disturbance may be waited for, but in severe cases the character of the bowel-contents should always be investigated by the aid of purgatives. Besides their action on the bowels, purgatives deplete the liver and prepare that organ to receive some of the blood which has been determined to the bronchi. The most available laxatives are castor oil and calomel.

Calomel, which is preferable in the infant, should be administered in three doses, of one grain each, at intervals of four or five hours. When putrid fæces are found, all animal food should be prohibited for one or two days, and such intestinal antiseptics as naphthaline and salol administered.

Expectorants are often of great service in the earlier stages of bronchitis, but, as a rule, they are abused. Their sole use is to cause an increase in the bronchial secretion. When the secretion is scanty, and the râles few and dry,

and the cough, in consequence, frequent and harassing, expectorants afford relief. But when the secretion has become thoroughly established, and auscultation shows the râles to be abundant and moist, then expectorants are of no further use, and it is better to withhold them. The best expectorants are ammonium chloride and potassium iodide. The following formula may be employed for an infant from three to six months of age:

R̄. Ammon. chlorid. gr. xvj.
 Syr. toltan.
 Aq. destillat. āā f 3j.—M.

Sig. One teaspoonful in a little water every two or three hours.

Ipecacuanha is widely used. It is of peculiar value because, besides increasing secretion, it tends to dilate the cutaneous capillaries. When the secretion is excessive and the efforts at coughing inadequate to remove the accumulation, emesis affords much relief. For this purpose ipecacuanha is valuable.

The modern coal-tar antipyretics have a marked effect in bronchitis. They appear to act almost as specifics, diminishing the amount of secretion, lessening the severity and frequency of the cough, and relieving pain, without acting like opium in simply covering up symptoms. Of these, the safest probably is phenacetin. For an infant from six months to two years of age the following formula will be found useful:

R̄. Phenacetin gr. xii-xxiv.
 Caffeine gr. j-ij.—M.
 Div. in chart. No. xii.

Sig. Give one powder every four hours.

The smaller dose may be used at six months and the larger at two years. For younger infants the dose should be reduced, and for older children slightly increased. These powders are advantageously alternated with the calomel powders given at first. Here, as elsewhere, phenacetin should be used cautiously, withheld entirely from weakly children, and never continued over a long period.

In severer cases the inhalation of antiseptic vapors seems at times to be useful. For this purpose it is convenient to evaporate turpentine or oil of eucalyptus from a water-bath in the patient's room.

Particularly in the bronchitis of infants and young children is the cough salutary, and it should be laid down as a cardinal rule that no effort should be made to smother it. Narcotics and antispasmodics distinctly increase the tendency to pneumonia. But it is not always possible to dispense entirely with the use of opium. In some very severe cases, where there is great restlessness, a single full dose of opium to produce sleep is occasionally necessary. Used in this way, the best results to the patient are obtained with a minimum of danger.

Certain means very commonly employed in the treatment of bronchitis and pneumonia have for their object the relief of internal congestion by the production of a dilatation of the cutaneous capillaries. These are the poultice jacket, the cotton and oiled silk jacket, local counter-irritation, and the internal use of sweet spirits of nitre, alcohol, and aconite. Redness of the chest-wall is readily obtained by thorough friction with camphorated oil or an ointment of turpentine and lard. It is rarely necessary to use mustard. The

agent selected should be well rubbed on twice each day, and the redness maintained by the use of the poultice jacket or the jacket of cotton batting and oiled silk. When poultices are used, two should be made—a smaller one to lie upon the front of the chest, and a larger and heavier one to cover the back and sides of the chest and lap over the front poultice. As their object is to keep the skin red, they must be as warm as can be borne, and changed often enough to prevent cooling. The advantage of two poultices is to be found in the changing. The one at the back does not cool as rapidly as the front, which must be the thinner, so as to embarrass the respiration as little as possible. Hence the front poultice requires changing oftener than the back. Poultices which are allowed to become cold constitute an element of danger, and therefore should not be used on patients when the nursing is inferior. They are disadvantageous also to very weak children, to whom their weight is a burden. When properly employed their action is of the greatest service, and they should always be used in properly selected severe cases. As a substitute for the poultice the chest may be enveloped in a thick layer of cotton batting, and this covered with oiled silk. This dressing, while inferior to poultices, is yet so convenient and so serviceable that it should always be employed, in conjunction with camphorated oil, even in quite mild cases.

The principal utility of alcohol in bronchitis has seemed to the writer to be due to its power of relaxing the cutaneous capillaries. For this purpose it is best administered in rather small doses at frequent intervals, and in the shape of whiskey or some light, non-astringent wine. Sweet spirits of nitre, so commonly employed in febrile conditions, is often of great service in bronchitis, particularly when there is fever. It dilates the cutaneous capillaries, acts as a diaphoretic, and by its diuretic action no doubt assists in the elimination of toxic principles.

When bronchitis is produced by any of the specific fevers the cause cannot be directly removed, but treatment directed to the amelioration of the complexus of febrile conditions relieves the bronchitis, as it does the other manifestations of the poison. In those specific fevers which are best treated by the application of cold the presence of bronchitis is not to be regarded as a contraindication of the means.

Convalescence from bronchitis is always worthy of attention, and after severe cases, where the bronchial glands are considerably enlarged, treatment of this stage is highly important. Fortunately, proper medical attention at this period produces excellent results and prevents much subsequent trouble.

In the treatment of broncho-adenitis cod-liver oil is a most important agent. It is usually desirable to administer it plain, and by most infants it is well borne. Its use should be continued for three or four weeks, and even longer if the trouble does not yield readily.

When the bronchial glands are enlarged a coexisting anæmia will usually require the use of iron. This agent is best administered as the reduced iron or the freshly-prepared saccharated carbonate of iron. In either case the dose should be large. Reduced iron in 5-grain doses three times a day to a child two years old will give better results than smaller doses. For very young infants iron is best administered in the shape of freshly-expressed beef-juice, which may be given in teaspoonful doses three times a day.

The iodides may at times be used advantageously, and of these the best are the syrup of hydriodic acid and potassium iodide. The latter should be given in small doses, $\frac{1}{2}$ grain to 1 grain, three times a day, and well diluted. The syrup of the iodide of iron is rather disappointing in its action.

It is often desirable to use creasote or guaiacol, particularly where the

glandular enlargement is very pronounced and general tuberculous infection is feared. The following is a convenient formula for a creasote emulsion :

R̄. Creasoti (beechwood) fʒj.
 Pulv. acaciæ gr. xv.
 Aq. dest. ℥xliv.
 Glycerini q. s. ad fʒss.—M.

Sig. Four to eight drops in port wine three times a day.

Ordinarily it is not desirable to commence treatment of the broncho-adenitis along these lines until after the subsidence of the acute attack of bronchitis. Cases presenting nutritional deficiencies call for treatment both during and after the attack. In most instances the innutrition in infants is due to rickets, and cod-liver oil and iron act almost as specifics. Salt baths and out-door exercise are also valuable, and should never be omitted.

In older children, the subjects of scrofulous bronchitis, the underlying nutritional deficiencies particularly call for treatment. In these cases cod-liver oil, iron, and iodine, while of service, are often disappointing, and do not yield the satisfactory results obtained by their use in less severe cases, where enlargement of the bronchial glands constitutes the principal departure from the normal. In the severer cases of this type relief can only be obtained by removal to a warm climate or to the sea-shore. In the experience of the writer the Florida coast has afforded great relief to such patients.

PLEURISY AND EMPYEMA.

BY HENRY KOPLIK, M. D.,
NEW YORK.

PLEURISY, or pleuritis, occurs in infancy and childhood usually as a secondary, and rarely as a primary, disease. There are certain forms in which the pleura is inflamed without any appreciable exudate; such are called *dry* or *fibrinous* pleurisies. Other forms combine the above with an exudate of fluid—serous, sero-purulent, or purulent—into the pleural cavity. These forms are called *pleurisy with effusion*, or sometimes, less accurately, *subacute pleurisy*. When the exudate has a sero-purulent character or is visibly purulent, the pleurisies have been called empyema. *Empyema* in this article will, for the sake of uniformity, be called *purulent* or *suppurative pleurisy*, while those pleurisies which have a protracted course and are due to neoplasms will be referred to only.

Frequency.—Pleurisy is a common disease of infancy and childhood. The greatest number of cases occur before the fifth year of life (Simmonds). The succeeding five years (five to ten years) show the next greatest frequency. Our statistics upon pleurisy in childhood are incomplete, for the reason that authors have not unreservedly exposed their material for criticism. Only favorite methods have been published, to the exclusion of unfavorable results. This has caused much confusion. Israel has tabulated 206 cases, of which 59 were purulent (29 per cent.). Mackey gives purulent cases in children 40 per cent. as against 5 per cent. of the whole number in adults. In 240 cases 140 were boys (Simmonds). On the other hand, Hofmokl, who has a great pediatric surgical practice in Vienna, tabulates 60 cases, of which 42 were females. Thus, combining both statistics, the boys would still show the greater frequency.

The left side is more frequently the seat of disease. Of 175 cases collected by Simmonds, 103 were on the left side, whereas of the 60 tabulated by Hofmokl, 33 were on the left side.

Pleurisy is generally a unilateral disease. Of 175 cases, only 7 were bilateral (Simmonds). This is fortunate in infancy and childhood, where exudates reach a large amount in a very short time. With these youthful patients the natural resiliency of the chest combines with others factors to make even enormous exudates comparatively well borne, as contrasted with a similar condition in later life. In the adult the resistant chest-wall tends to cause greater pressure-effects and displacements of important viscera.

Pathology.—The pleura is a connective-tissue structure, made up of elastic fibres in a fibrillar membrane, containing branched connective-tissue cells and covered with a layer of flat epithelium, called, in this membrane, endothelium. In inflammations of the pleura which are not dependent upon and accompanied by a neoplastic growth (tubercle or carcinoma), the changes take place at the surface. The most frequent pleurisies are those acute processes which invari-

ably accompany the several forms of acute pulmonitis. They occasion but few symptoms *per se*, and only in the event of a fatal termination of the primary pulmonary disease do they come to the autopsy table. In these forms of pleurisy the changes may be so trifling as to be indicated only by a slight injection of the surface of the pulmonary pleura and a loss of its characteristic lustre. Here and there a few fibrinous threads or adhesions may be found coursing over the surface of the membrane or running from the costal to the pulmonary pleura. This is the so-called dry pleurisy, *pleuritis sicca*. In other cases there is a more extensive formation of fibrin, which becomes diffused over the whole surface of both the pulmonary and costal pleura; and this formation may become so marked as to cause a distinct thickening of both these surfaces. In some forms in children the amount of fluid is small compared with the immense thickening of the pleuræ. Some writers have maintained that in these fibrinous exudates the primitive endothelium may be found upon the original pleural surface, beneath the exudative product; others, that the fibrinous exudation is coated with the original endothelium (Delafield). The pleura itself may be but little altered, the only change being that its lymph-spaces and blood-vessels are dilated, and there may be a diapedesis of leucocytes.

In other forms of pleurisy the fibrinous exudation at the surface is also combined with a serous exudate into the cavity of the pleura. This serum is variable in amount: it usually contains leucocytes, in many cases bacteria, as will be shown later. It may be quite clear, turbid, or opaque, yellow or greenish in color and creamy or thin in consistency. In acute processes in children large masses of fibrin may be found floating free in the cavity of the pleura (metapneumonic cases). In many instances the adhesions are so great as to bind down the lung at various places, thus enclosing the exudate in quasi-capsular formations. Even in acute cases the fibrinous coating on the surface of the pulmonary and costal pleura contains newly-formed blood-vessels. Hæmorrhages into the pleural cavity may rarely occur as a part of such conditions as scurvy and true morbus Werlhofii, and then the serous or purulent exudate becomes a so-called hæmorrhagic one.

In some cases the fibrinous coating on the pulmonary pleura may be so thick as to seriously impair the function of the lung. In children, however, this is not common, except as a sequence of tubercular processes; so that a marked pleurisy, suppurative or fibro-serous, may be followed by a complete *restitutio ad integrum*. It is rare that in acute processes the lung is in any way compromised. It is only in prolonged, unrelieved pleurisy that this occurs, and thus there may be perforation of the exudate with erosion of the pulmonary or costal pleura (*pleuritis necessitatis*). Small purulent exudates, unrecognized during the illness, may thus perforate after all fever has ceased and the patient is apparently well.

In tubercular inflammation of the pleura, besides the production of fibrin, serum, clear or hæmorrhagic and pus, there may be considerable thickening of the costal and pulmonary pleura, caused by the inflammatory exudate, which, as well as the pleura, is infiltrated with tubercle. In these cases the serous or purulent effusion may be encapsuled by adhesions, while the lung is crippled and bound down by layers of inflammatory tissue. In these forms of pleurisy the anatomical changes are progressive. In acute fibrinous pleurisy the exudative products on the surface of the pleura are organized into new connective tissue or partly disappear, but the pleura is restored to its original condition. Again, absorption takes place in those cases where the exudate does not demand artificial relief. In children the adhesions form an important part

of the process in acute pleuritis, while in other forms the pleura may remain permanently thickened by the formation of a surface layer of new connective tissue, which may persist through life. There are non-tubercular forms of pleurisy where, after the acute process has run its course, the pleura remains thickened by newly-formed connective tissue; and this not only involves the pleural tissue proper, but also continues to extend and involve, through the lymph-vessels, the interlobular tissue of the lung itself, causing a species of cirrhotic changes. In these cases, which are prolonged, the lung-tissue is seriously compromised.

In the exudates of the pleura there is a constant interchange of fluids through the vessels of this membrane (Gerhardt). Drugs may find their way from the general circulation into the pleuritic fluid. Iodine and salicylic acid have thus been found. Moreover, the amount of leucocytes, red blood-cells, and endothelial cells in the exudate is constantly varying, so that a serous effusion may result from a hæmorrhagic one, and an opaque purulent from a serous.

The amount of fluid effused in children is usually considerable, and may reach 1000 or 2000 c.cm. (Simmonds). Hofmokl in several cases evacuated as much as 2000 to 5000 c.cm.

The chemical composition of pleural exudates may be of clinical interest. The specific gravity varies from 1028 to 1032 (Bartels, quoted by Gerhardt). Some authors have attempted to formulate prognostic signs from the specific gravity of the pleural exudate, but few would accept such a line of thought to-day.

The amount of albumin varies from 0.06–2.68 per cent. in non-inflammatory to 2.40–6.90 per cent. in inflammatory exudates; extractives and salts in non-inflammatory exudates, 1.08 per cent., in inflammatory, 1.18 per cent.; the chlorides average 0.67 per cent. in both. Among the foreign substances, urea, uric acid, leucin, tyrosin, glucose, glycogen, cholesterin, xanthin, and medicinal agents have, at various times, been found, proving that the fluid in the pleural cavity is in direct touch with the general circulation and lymphatic system.

Etiology.—Primary pleurisy, occurring without any exciting cause in the chest or elsewhere, is rare in children. There are numbers of cases in which an acute effusion of inflammatory character takes place without any previous symptoms of illness or external exciting causes. Our data upon this very interesting and important question are still incomplete. Such a case came under the notice of the author in a boy aged six years, in whom a pleural effusion was present for a week without any previous symptoms. The liquid was serous in character, and did not contain any micro-organisms. There was no tubercular lung disease and no history of other illness. In these clinical cases the etiology is very obscure. The author has elsewhere published cases of infants where illness began acutely, nothing having been found except a tonsillitis follicularis. The chest showed no pneumonia or pleurisy at first. Within a week, however, a purulent effusion was found in the chest. In these cases it is impossible, inasmuch as recovery takes place, to establish the primary cause. In those cases which come to the autopsy table after the disease has existed a long time the pulmonary changes are no more conclusive.

Primary pleuritis, if it does occur in children, must be rare. There are so many avenues of infection that to satisfactorily exclude all these has as yet not been possible. Pleuritis in infancy and childhood is therefore mostly secondary to diseases of the lungs. All acute forms of pneumonitis—lobar pneumonia and broncho-pneumonia—may give rise to pleuritis. The greatest num-

ber of cases has been traced to this cause. Of 84 cases of pleuritis tabulated by Simmonds as occurring in children, 31 were caused primarily by pneumonia (meta-pneumonic pleurisy).

The infectious diseases, measles, scarlet fever, pertussis, typhus, typhoid, diphtheria, forms of tonsillitis, retro-pharyngeal or mediastinal abscess, may precede and directly cause an attack of pleurisy. In these cases a pneumonitis generally precedes the pleurisy or is present at the same time. Such a pleurisy is to be classed under the heading of complications. It may be serous or purulent, but is generally microbic in origin, as will be shown later. In the new-born the class of cases included under the heading of septicopyæmia are sometimes complicated by a pleuritis, usually suppurative and of a progressive, fatal type. In these instances the pleuritis is simply caused by the same microbic agent, which enters at the umbilicus or elsewhere. Such cases have been published by the author. The acute bone diseases, such as osteomyelitis, may be complicated by purulent pleurisy; so also may septic wounds in any distant portion of the body, as the foot (Koplik).

Tubercular disease of the lung or tuberculosis elsewhere; echinococcus (Simmonds) or abscess of the liver; any abscesses in the mediastinum; forms of endocarditis; and abscesses in the abdominal cavity or involving any of the viscera,—may cause pleuritis. A case of perityphlitis in the author's practice, in a girl eight years old, after running an acute course was followed by chronic peritonitis with multiple abscess-formations in the abdominal cavity, and was later complicated by pleuritis on the right side. As no autopsy was allowed, it was impossible here to trace a direct connection, but such has been done by other authors.

In many cases of pleuritis, as in other diseases, it is possible to find as the only exciting cause an exposure to cold or dampness. This has occurred so often, and with such apparent connection, that most authors look upon cold and dampness as undoubtedly exciting toward any pulmonary or pleural inflammation. At least they are not without influence. A reduction of constitutional resistance by these agents opens the avenues for the activity of well-known exciting agents (microbic).

Traumatism of all kinds, even without a lesion of the external surface, may act like cold in exciting pleurisy. Compression of the chest-wall or a blow may not directly cause it, but certainly many cases follow so closely upon such accidents that an intimate connection seems to be the inevitable deduction.

It is conceded upon all sides that there are evanescent forms of pneumonia in children lasting only a few days. It is easy to conceive that a pleuritis may have been preceded by such a pneumonia, the symptoms of the primary disease being masked by those of the main condition, the effusion in the chest.

The etiology of pleurisy has been greatly elucidated, in recent years, by the bacteriological studies of Weichselbaum, Fraenkel, Ehrlich, and Thue. These authors have busied themselves with the study of pleuritic exudates and their relationship to processes which affect the lung. They directed their attention to the adult cases. In 1891 the author made a series of bacterioscopic studies in children, which, with certain peculiar exceptions, bring the pleurisies of children much into the line of those of the adult as to causation. We know that when the lungs are the seat of bronchitis, broncho-pneumonia, or lobar pneumonia, a number of micro-organisms play an important rôle during the course of the inflammatory processes. Thue, in a series of studies, established beyond question that these micro-organisms (notably the diplococcus pneumoniae) can be found not only in the lung-structures, but especially in the lymph-spaces of the tissue of the pleura and on the surface of the pleura itself,

even in most evanescent inflammatory reactions of that structure. This once accepted, it is easy to explain how micro-organisms, which are *per se* capable of exciting suppuration, when they once gain the surface of the pleura will cause inflammatory response of that structure. Such is, in fact, the case. If we examine the acute pleuritic exudates in children, we find they resolve themselves into groups. The most interesting group is that in which the effusion, whether serous (clear) or purulent and full of fibrin clots and flocculi (suppurative), shows the presence of the diplococcus pneumoniae of Fraenkel or the streptococcus lanceolatus. This micro-organism is the accepted exciting factor of both lobar (Fraenkel) and lobular pneumonia (Weichselbaum). It is found in both serous and purulent exudates (meta-pneumonic pleurisies), and this in pure culture. So constant is this that we can group such pleurisies by themselves, and both clinically and bacteriologically accept the diplococcus as the connecting link between the process in the lung and the pleuritic inflammation. It is not always possible to trace clinically the pneumonia and pleurisy in sequence, for in many of these cases the pneumonia is so slight as to play but a secondary clinical rôle. In other cases the direct clinical sequence of pneumonia followed by pleurisy can be satisfactorily established.

In another group of cases the pleuritic effusion, if examined bacteriologically, is found to contain staphylococcus pyogenes aureus, and in other cases the streptococcus pyogenes. The exact etiological rôle played by these micro-organisms is not very apparent. It is true we can justly conclude that by their presence in the pleural cavity they have been direct excitants of the pleuritic inflammatory reaction. It is not clear, however, how they gain access to the pleural cavity, and whether the pleuritis was preceded by, or was concomitant with, some form of pneumonitis. These organisms are found in the lungs during a lobar or broncho-pneumonia. In certain forms of broncho-pneumonia following or complicating the infectious diseases, the streptococcus pyogenes is found as a chief exciting factor of the pneumonitis. This has been well established by Babes, Prudden, and Northrup. But there is a class of pleurisies in children which are not secondary to the acute infectious diseases, and in these the staphylococcus and streptococcus have been found (Koplik). The most probable conclusion in such cases is that there may have been some element, such as an exposure or traumatism, which favored the invasion of the pleura through the lungs. In many cases we could assume, in spite of the absence of the streptococcus lanceolatus or Fraenkel's diplococcus, that a broncho-pneumonia might have existed, and the staphylococcus or ordinary streptococcus, which always exists in these cases in the lung as a mixed infection, may have gained access to the pleural cavity to the exclusion of the primary excitant, the diplococcus pneumoniae.

In many pleuritic effusions, both serous and purulent, the most careful examination of the exudate fails to give any microbial elements, and in these we are left to surmise the etiology. The serum and pus of such cases have been injected into animals without arriving at any satisfactory conclusion. It is possible that a proportion of these cases are tubercular, but it would be a very extreme view to assume that all those cases of pleuritic effusion in which no micro-organisms are found are tubercular. For this is at variance with clinical experience. Many of these negative exudates have been assumed to be due to acute primary pleurisies brought about by cold, exposure, or trauma. The clinical regularity with which an exposure or traumatism can be shown to have been followed by pleurisy leads us to assume that, though of itself it may not be able to produce inflammation of a structure, it can so devitalize a part or organ as to make the latter a ready prey to the action of microbial

agents. On the other hand, we know that in the healthy individual the upper air-passages are the seat of micro-organisms which, isolated from their habitat, are pathogenic (the streptococcus of sputum). Yet in the healthy unexposed individual these micro-organisms are harmless. We thus have that class of pleurisies in which the staphylococcus of various kinds and the chain coccus have been found, as well as part of the class in which no micro-organisms have been established, as still to be more satisfactorily elucidated.

The question of *primary pleurisy* in children is also very difficult to approach. We know of pleurisies which, clinically, are very acute in onset, and in which the effusion within twenty-four hours reaches such an extreme gross quantity as to cause by its presence alone quite serious symptoms. In these cases the effusion may be serous, or it may from the outset be purulent. In many of them no previous history of lung trouble or any traumatism or exposure has preceded. These are the cases which have been described as *acute primary pleurisy*. While allowing the former classification to stand, the writer must express his conviction that future work will reveal some primary etiological factor outside the pleura itself. The pleural cavity is such an isolated space, much like the joints, that it is difficult, in the light of our present knowledge, to conceive of its primary inflammatory reaction similar to that taking place in the lung in pneumonitis.

In the septic pleurisies the micro-organism which has been found in children is the streptococcus, probably the streptococcus pyogenes (Koplik). In the tubercular pleurisies, whether the effusion be serous or purulent, the tubercle bacillus can be found, but only with great difficulty. In many cases, as has been shown by Ehrlich, it is absent. In the purulent exudates the staphylococcus and streptococcus may be found as mixed infections, or they may be absent.

Symptoms.—There are two distinct sets of cases in children: those with an acute and those with an insidious onset. If the invasion be acute, we have a picture which differs but little from the onset of a pneumonia, and as in the majority of cases such a pulmonary process is coexistent, it is easily seen how the symptoms of one condition may be masked by the other. A chill is the rule only in older children, while in infants cerebral symptoms, convulsions, or stupor may usher in the disease. The fever is quite high—103° to 105° F.; and the pulse very much increased—to 140, sometimes 180 beats. There is marked dyspnoea, and even in infants the face has an anxious expression. The urine is diminished, and in the course of a few days we have all the symptoms—dryness of tongue, loss of appetite, and prostration—which accompany any acute disease with fever. The cough, which may be present from the beginning, is distressing, for the infant cries whenever it coughs: but, as is the rule in infants and children of all ages, there is no expectoration. After the acute symptoms have subsided a slight elevation of temperature may persist, with a *remittent* curve, sometimes only about one-half degree above the normal, with an evening rise of one or two degrees, but never quite reaching the normal. This, with dyspnoea and pain, though less than at first, and more infrequent cough, continues the clinical picture during the sub-acute stage. The effects of the illness are shown by pallor instead of the febrile flush of the onset, and, if the case continue without relief, even for two or three weeks, by marked emaciation, especially in those patients suffering from a purulent exudate.

In the other class of cases the onset is more insidious. The child may have at first a marked febrile movement for a few hours, and as this passes away it is apt to disarm suspicion. The child is not quite well; it has a remittent

curve of febrile movement, and, if older, will complain of occasional pain in the side. The cough may be so slight as to be unnoticed. Yet the increasing pallor, languor, and evident illness will bring the patient to the physician, who will not suspect a pleurisy unless a systematic physical examination reveal fluid in the chest.

The fever is, in most acute cases, high in the beginning, and, though it is not uniformly so from day to day, it still reaches in some cases a maximum of 105° , and then may remit a degree or two. When pleurisy is accompanied by pneumonia, the temperature, as in this disease, continues uniformly high, 103° – 105° F., until the eighth, ninth, tenth, or thirteenth day, when a fall will occur with an attempt at crisis. At this period the axillary temperature may reach 99° – 99.5° , but it will not fall to the normal level. In the following days, should the pleurisy continue, as in most of these cases it does, the curve begins to rise gradually to 101° or 102° , and will remit in the morning. These cases are quite characteristic. In dry pleurisy without effusion there is scarcely any fever.

The pulse is accelerated, being sometimes as high as 180, and especially so in paroxysms of coughing. The tension varies, but in children the heart, though pressed upon by effusion, generally is equal to the new condition in the chest. It is only in fat, flabby children and those suffering from dyscrasie that, with a rapidity and threadiness of pulse, even from the outset, we notice instead of the usual flushed appearance a pallor of the skin and a cyanosis of the mucous surfaces, as of the lips.

Dyspnœa is generally the most apparent symptom in children. The dilated nostrils and the drawing inward of the infrasternal region both indicate a disturbance of the respiratory function. When the chest is touched, pain is evinced by uneasiness and greater dyspnœa. The mother will say that the child cries when taken hold of under the arms in the usual way. The babe will favor the side affected by lying upon it, and suckling the left breast, if the right side be the seat of trouble (Henoeh). Older children will sometimes indicate the portion of the chest in which the pain is located; in other cases they will mislead by indicating the epigastrium or abdomen as the seat of pain (diaphragmatic pleurisy).

The cerebral symptoms not only mislead, but may puzzle the physician for days, until the effusion becomes large enough to detect. These symptoms resemble those in pneumonia—convulsions, somnolence, vomiting, in older children cephalalgia and epileptiform seizures.

Physical Signs.—*Inspection* of the chest in children who suffer from any form of pleurisy, whether effusion be present or not, reveals a lack of movement on the affected side. This is quite apparent in even very young infants, and is in striking contrast to the motion of the opposite side in all the various grades of dyspnœa which may be present in individual cases. If there be a quantity of exudation or fluid in the chest, there is, in addition to lack of motion, a very marked bulging of the affected side. By this is meant bulging as a whole. The individual intercostal spaces do not always bulge in infants. On the contrary, the chest may be full of fluid, and a retraction of the spaces, increasing on inspiration, may exist. It is of little practical value to calculate the amount of increase in circumference of the affected side. This will vary with the amount of fluid present.

Palpation reveals but little if the form of pleurisy be dry and the effusion slight. On the other hand, if the effusion be considerable, a most valuable sign is furnished by the complete absence of vocal fremitus in older children. In infants the absence of the cry-fremitus gives evidence of the same con-

dition. This is one of the most constant signs of pleurisy with effusion in children, where, above all other things, the physical signs to be detailed are constantly varying. It has been the practice of the author to rely largely upon fremitus and a certain resistance to percussion, which will be noted later, in deciding upon the presence of an effusion. If the healthy side be the seat of bronchitis, a peculiar râle-fremitus may be felt on this side, but this is only of negative interest.

Percussion.—The percussion-note over thickened pleura is dull; over fluid, flat. But, as has been hinted, in children these signs show the most marked variation. There is nothing characteristic in the signs obtained by percussion. The chest in an infant is so resilient that much depends upon the force used and the skill of the examiner to bring out the requisite note. A layer of fluid may exist between the lung and the chest-wall, and skilful percussion will reveal dullness, while more forcible percussion brings out the pulmonary note of the underlying lung. If the chest be filled with fluid, the note will be flat; and this is another reliable sign. In chests where the fluid fills out the lower portion of the pleural cavity the pulmonary resonance will be obtained above, while below there will be noted dullness varying to flatness, depending upon the thickness of the layer of fluid between the lung and the percussing finger. *The resistance to the percussing finger is peculiarly wooden in character, especially in children.* The resonance upon the unaffected side of the chest is increased, and sometimes tympanitic.

Auscultation may reveal râles or friction-sounds, bronchial voice, and bronchial breathing, or all these may be absent, the breathing being simply puerile and the voice but little changed. Nothing is so deceptive as the auscultatory signs in pleurisy. If no effusion be present, we hear friction-sounds in children resembling for the most part the fine crepitations of pneumonia, and even when the chest is full of fluid these crepitations may be quite loud. These may be confined to small areas in dry pleurisy, or in pleurisy with effusion may be diffused over the whole chest. This is what tends to confuse the examiner. The voice in dry pleurisy is not changed. In pleurisy with all varieties of effusion the voice may be *normal*, even when the chest is full of fluid. Again, as stated, it may be bronchophonic. The breathing may be heard above the level of fluid, and be diminished, absent, or bronchial, below. Again, breathing may be heard with equal distinctness over a side which is full of fluid, as over the unaffected side. In most cases we must rely mainly upon fremitus and percussion.

In children sometimes, though rarely, the fluid will not appear in front of the chest, though it exists over the whole side posteriorly. The lung seems to have been pushed up and forward, instead of against the spinal column. In such cases increased respiratory murmur and tympanitic resonance will be obtained over the apex of the lung in front.

It is quite common to see the routine remark that displacements of viscera, notably of the liver and heart, are common in children suffering from pleurisy with effusion. This is not strictly true. In young children, where the chest is very easily expanded by the accumulated fluid, the effusion must be exceedingly large before downward displacement of the liver will be appreciated. Older children also may carry large amounts of fluid without marked displacement of the liver, though it can, in some cases, be distinctly noted. In younger children effusion upon the left side may displace the apex of the heart toward the sternum, but this is not apt to occur, except as the result of very large effusion. In the adult the displacement of the liver in right pleurisy, and of the heart in left, is quite a constant sign.

In conclusion, the author would lay stress upon the immobility, bulging of the affected side as a whole, lack of fremitus, and flatness, combined with a peculiar resistance to the percussing finger, as the leading reliable signs of acute chest effusion, which may be corroborated by change in the voice and breath-sounds. In children, as in adults, the effusion of pleurisy accumulates in the most dependent part of the thorax, behind, adjacent to the vertebral column. In children 100 grammes of effusion can be thus discovered by percussion at the lower and inner portion of the chest-wall, adjacent to the spine (Gerhardt; Pirry). Accumulation of the fluid takes place thus in an oblique area, growing deepest toward the median and tapering at the axillary line. Small effusions in meta-pneumonic pleurisies may be encapsuled and give a localized area of dulness or flatness. In tubercular pleurisies this is also very often the case. In infants and young children the fine distinctions of change of position of small exudates can hardly be made out, as in the adult, on account of the restlessness of the patient.

Diagnosis.—The diagnosis of pleuritis in children is not difficult in the majority of cases, but there is a percentage in which care must be exercised before diagnosis can be positive. Dry pleurisy is diagnosed by the presence of pain and the physical signs of local dulness and friction-râles. Localized encapsuled pleurisies must be diagnosed by the circumscribed dulness or flatness and the change of fremitus over a circumscribed area, with perhaps a change in the voice and respiratory sounds.

If an effusion be of considerable size, the diagnosis is difficult when the layer of fluid is so thin as not to mask the pulmonary resonance and give only dulness; but even here the fremitus will be absent. In marked effusion the complete loss of fremitus, immobility of the affected side, and flatness, with a certain wooden resistance to the percussing finger, are quite characteristic. It is well not to rely too much upon vocal resonance or respiratory murmur. In order that an effusion may not be overlooked, it is important to think of the possibility of its existence in every case, and to exclude it only after careful examination. It is of little moment if a delay of twenty-four or forty-eight hours occur when the symptoms are not of a pressing character. But every practitioner sees cases in which fluid must have been present for weeks without being recognized. In children the exudate at a very early period, even from the onset, is likely to be purulent, and it can be easily seen how important it is to discover the character of an exudate as soon as possible. Aside from pressure effects, the presence of a purulent exudate is dangerous on account of its tendency to burrow inward toward the lung, eroding the pleura, or to rupture externally.

If there be doubt as to the presence of fluid or as to its nature, these facts should be determined as soon as possible. For this purpose a hypodermic exploring needle should be used in the following manner: The mother holds the babe in her arms in the usual way, the posterior part of the chest is bared, and the area of most complete dulness or flatness is determined. This part is first washed carefully with alcohol, and then with corrosive sublimate (1:5000). A long exploring needle, a little larger than the ordinary hypodermic needle, but stronger and stouter, having been attached to a well-cleansed hypodermic syringe, is rapidly driven into one of the intercostal spaces, the higher the better. On the right side, where the liver will present itself to the entering point of the needle if too low, the puncture should not be lower than the eighth space, in line with the angle of the scapula. The chief point, however, is to enter at the area of greatest dulness or flatness. Having pushed in the needle about one-half an inch, the piston of the syringe should be drawn.

The whole operation should be rapidly done, and the mother should be warned to hold the child firmly, for any sudden movement might cause the needle to impinge against the rib and break off—an accident which has occurred. This little operation should be over before the child has ceased to experience the pain of the entry of the needle. If no fluid be found the needle is rapidly withdrawn and a piece of rubber plaster placed over the point of puncture. The author has never had an accident in many such operations, and it requires but ordinary cleanliness and care. It secures to the patient the benefit of an absolute diagnosis.

Sometimes we may be absolutely certain of fluid, and yet be unable to prove it with the needle. In such cases the needle has entered an adhesion of the pleura, and at the next sitting, if still in doubt of the diagnosis, the needle should be entered at another point. It is unwise after inserting the needle to thrust it up and down the chest-wall or pleural space. In this way the lung may be wounded, and emphysema, hæmorrhage, or irreparable injury be caused. While the needle is in the chest it should be held so lightly that any sudden unexpected movement on the part of the child will not afford leverage to the needle against the rib, for if this occur the needle is apt to break. When fluid is obtained its character should be carefully determined, and the presence and significance of contained bacteria should be investigated. The busy practitioner may not have time to do this, but the author has devised a very simple bulb¹ for the withdrawal and transportation of such fluids.

As far as prognosis and even treatment are concerned, it is of self-evident importance to determine as early as possible whether an exudate is pneumonic, tubercular, or doubtful. The presence of chain cocci, staphylococci, or the diplococcus pneumoniæ in a serous exudate will prepare the physician for the advent of a purulent effusion, and the practical knowledge thus gained may be of vital importance to the patient's future happiness.

In the presence of a suspected effusion it was previously, and still is among some, the custom to temporize. It was argued that an exploring needle was likely to cause a serous fluid to become purulent through the entrance of air or some few micro-organisms. But the most ordinary cleanliness will render this almost impossible. The author doubts very much if an effusion was ever changed in character by careful hypodermic exploration. A slight amount of air, or a few staphylococci, if through some carelessness introduced into a serous exudate on the point of a needle, can scarcely change the character of fluid filling the chest. The serous portion of exudates, like those in joints, hydroceles, etc., is actually capable of annihilating the life of micro-organisms in fixed ratio (Buchner; Prudden). Moreover, serous effusions, formerly thought to turn purulent through some accident, are really purulent and contain the microbic element of pus from the outset, although they appear serous to the eye. While advocating caution, the author recommends a fearless resort to so valuable a guide as the hypodermic exploring syringe.

The tubercular cases alone offer the greatest difficulties of diagnosis, for, as has already been shown, some serous and purulent exudates which contain no micro-organisms may be tubercular, as may even those that contain staphylococci or streptococci. But, fortunately, in children tubercular pleurisy is not the most common forms. Hæmorrhagic pleuritic exudates are very rare in children. They are generally caused by grave disease—tuberculosis, sarcoma, carcinoma, or morbus Werlhofii.

The cases of pneumonia which are complicated with pleurisy are the most trying to the practitioner. Here on the eighth, ninth, tenth, or thirteenth day

¹ *American Journal of the Medical Sciences*, 1892.

no complete crisis takes place. The temperature falls to within even one-half of a degree of the normal in the axilla, but dulness persists in the lower part of the chest or flatness appears over its whole extent. This condition is frequently mistaken for so-called unresolved pneumonia.

Prognosis.—In children the prognosis in pleuritis is good. In the form occurring after pneumonia or that caused by the staphylococcus or streptococcus (non-septic), with effusion into the chest, recovery is rapid as soon as the fluid is evacuated, and much depends upon early diagnosis. In suppurative pleurisy, if allowed to remain unrelieved the pus will burrow, usually externally. The effusion then may infiltrate the soft tissues of the thorax, after eroding the pleura, and point as an abscess at the side anteriorly or posteriorly. Sometimes such an exudate, when on the left side, may receive an impulse from the heart, and thus is occasioned the so-called *pulsating pleurisy*. Such effusions have been mistaken for aneurisms, but lack of expansile pulsation and the history of the case will guide in the diagnosis. The tumor disappears when the chest is aspirated. If the pulmonary pleura becomes eroded by a purulent exudate, the perforation takes place into the lung, and the pus is more or less quickly expectorated. Even in such cases, though unrelieved by any additional measure, recovery has taken place, as in a case elsewhere recorded by the author. Tubercular pleurisies do not recover completely in children; fistulous suppurating cavities with retraction of the chest result. In some cases the pleurisy has been so extensive as to cause retraction of the lung, its utility being impaired by the binding of thick pleural plates, which leave behind a large suppurating pleural sac. The septic cases are, as a rule, fatal, though in fortunate instances recovery takes place.

Hofnokl treated by resection 60 cases, in which recovery was complete in 26. Twenty-eight cases were fatal; 13 of these were tubercular, 6 were complicated with pneumonia, 3 died through pericarditis, 3 with peritonitis, 1 with amyloid degeneration of the organs, 1 with heart failure, and 1 with neoplasm. These cases were evidently more unfavorable, as to general character of the pleuritis, than is common.

Complications.—The most dangerous complication of pleuritis is pericarditis, which in most cases is fatal. The occurrence of lobar or lobular pneumonia as a complication has been dilated upon elsewhere. The septic cases may be complicated by endocarditis or suppuration of other serous surfaces, such as the peritoneum or that of the joints. Gangrene of the lung may cause severe putrid inflammatory reaction of the pleura, and thus the pleural cavity may contain gases with purulent exudation (pyopneumothorax). In these cases a peculiar physical sign, known as the succussion sound, may be elicited by shaking the patient.

Sudden death from heart failure may occur, but this must be rare. The right heart, however, may become weakened to such an extent as to allow the formation of thrombi, and their entry into the circulation may cause sudden death.

Contraction and retraction of the chest-wall always follow, to a certain extent, in those forms of pleuritis which have been left to nature. Many of the deformities of the chest observed later in life are due to pleuritis in childhood.

The perforation of an empyema into the lung, with its evacuation through a bronchus, has already been referred to as having rather a favorable prognosis, even when not relieved by operation. As a rule, however, such cases are best treated by external incision, although evacuation may be expected by the bronchus. Again, perforation may take place through the chest-wall;

here a large boggy infiltration of the tissues of the chest or adjacent abdominal wall takes place, constituting the condition known as *empyema necessitatis*.

Treatment.—It is difficult to formulate methods of treatment of pleuritis, a disease in which the successful issue depends greatly upon judgment founded upon experience. Those cases of pleuritis in which the process is circumscribed, and in which the effusion in the pleural cavity is but slight, have pain as the main symptom. The fever is generally marked, and requires, as a rule, but ordinary methods. In children the pain is best relieved by some mild opiate, like Dover's powder in proportionate dosage, or in combination with phenacetin and salol. The latter has the advantage of controlling to a degree the febrile movement. The author has seen but little advantage from the time-honored application of iodine to the chest, nor has he seen much result from the internal administration of the iodide of potassium. The latter is apt to disturb the stomach, which at this time has largely to be depended upon to maintain nutrition. The author would also advise against the use of external blisters of all kinds, if for no other reason than the unnecessary pain which these agents cause, and from the danger of infection in a weakened constitution if the skin be broken.

When there is a moderate effusion of a serous character, even though this effusion contain *micro-organisms*, yet if there is still no tendency to turbidity, it is quite proper to make an attempt to favor absorption. Therefore, without weakening the patient, care should be taken that the bowels are freely opened from day to day, while the strength of the heart must be maintained. The most useful combination of drugs in these cases is one of digitalis and calomel. There is undoubtedly a very firm foundation for the belief that activity of the kidneys will diminish a pleural effusion which is not due to renal or cardiac disease. The fluid extract of digitalis should be used, in proportionate dosage, in a separate mixture, whereas the calomel may be used in powder form. The author generally gives both together. The supporting effect of digitalis upon the circulation is aided by the diuretic effect of the calomel. Large doses of the latter drug are unnecessary; small doses should be used at first and increased, given at three-hour intervals. Salivation, or even dosage to its limit, is injurious.

Where the chest is full of an exudate which is quite clear, but which causes few symptoms of pressure, absorption may be hastened by aspiration of a small quantity to begin with, trusting to drugs and nature for the rest. In children this is rarely necessary, so quickly does the circulation, if supported, respond to the demands made upon it. There are cases of pleurisy in which a clear serous exudate of a pneumonic character may increase so rapidly and cause such dangerous dyspnoea and pressure effects, that within a short space of time it may be necessary to relieve the patient by aspiration. Even when aspiration is effectually carried out, in some cases reaccumulation at once occurs. Such exudates are not turbid, but clear, and may contain micro-organisms. If reaccumulation occur in spite of diuretics, the question of a radical procedure always presents itself. The author must support the view founded upon experience, that such cases can be most effectually treated by permanent drainage. The operations which are at our disposal for this end will be taken up later.

From this it will be seen that the author regards aspiration as a palliative measure, after the performance of which the little patient must be watched as closely as before the operation. In children aspiration does not bear the same relative therapeutic value in pleuritis that it does in the adult. Its immediate performance entails as much care, causes as much anxiety, as a more radical

procedure, and with less satisfactory results. In most cases not only does reaccumulation occur, but the effusion, at first serous, becomes purulent—not because it has been infected by aspiration, but rather through the progress of the pleuritis, as previously explained. Radical procedure may therefore be required in rapidly reaccumulating serous exudates, causing pressure effects, whether these contain micro-organisms or are free from such.

In small and large purulent exudates absorption rarely occurs spontaneously. To temporize with a purulent exudate is to harm the patient. With purulent exudates we include also those serous exudates which were formerly treated expectantly: they are slightly turbid, and contain, to the eye, a few flocculi, but, if examined bacteriologically and microscopically, will be found to contain leucocytes and micro-organisms. To temporize with such so-called serous exudates is to be finally disappointed in finding them more distinctly purulent after a short period. In formulating diagnoses we must remember also that exudates which are in part purulent tend to separate into a serous layer above and a thick purulent layer below. Our needle may withdraw serum from a chest which contains a fully-developed purulent exudate.

In the *simple aspiration* of the chest we should be guided by the case, and with our needle avoid the proximity of vital organs. The sixth space in front, the seventh in the axillary line, and the eighth behind are those generally selected. Yet sometimes, fluid being low in level, a change may be demanded. The point of the needle should enter near the upper border of the rib, and should not be passed too deeply into the chest for fear of wounding the lung.

The operative procedures which may be considered to be radical in their nature, and which now have the confidence of clinicians are—incision, with insertion of drainage-tubes; siphonage of the pleural sac; excision of the ribs with insertion of drains.

Incision.—This operation is practised in the fifth space if in front, in the sixth in the axillary line, and if behind, the ninth space is chosen. König advises the higher point. Behind and on the right side we consider the presence of the arch of the liver. The incision is made near the upper border of the rib, 5 to 8 cm. long.

This operation is popular with the practitioner, because it involves but little technical skill, and once the incision is made, a drainage-tube is easily inserted. In children, however, where the intercostal spaces are narrow, surgeons do not look with great favor upon simple incision, for the reason that it is difficult to retain a tube of any great size in the wound. The opposing ribs are constantly pressing the sides of the tube together, and in this respect the drainage is imperfect. Moreover, the constant movements of the patient and the chest are apt to dislodge the tube completely, and in the intervals of dressing the wound the opening into the pleural cavity becomes distorted, so that attempts to replace the tube give much pain or even fail completely. Many cases will, however, do well with simple incision; yet the fact remains that in other cases a secondary operation, which has for its object the removal of a piece of rib, has to be performed in order to obtain drainage. The author has seen cases treated by incision, and thought to have recovered, in which reaccumulation occurred after removal of the tube, and necessitated a secondary resection of the rib.

Resection.—In all cases of purulent exudation it saves much of the strength of the patient if efficient drainage be obtained from the outset. This is secured by the operation of resection of one of the ribs of the affected side. In this way sufficient space is obtained for the insertion of a drain of considerable size, but

this drain is not pressed upon by the adjacent ribs, and is not generally displaced, or, if displaced, is easily readjusted.

The seventh, eighth, ninth, or tenth rib is chosen, as demanded by the individual peculiarities of each case. The skin incision is made about 10 cm. long, and 4 to 6 cm. of the rib is taken away with the bone forceps, after carefully reflecting the periosteum. The opening is then made into the pleural space—through the periosteum, or by a separate incision which passes through the intercostal space below. The latter saves the whole periosteum intact, and ensures reproduction of the bone without the least deformity. As in simple incision, the opening may be made in the axillary or post-axillary line, or behind in line with the angle of the scapula. On the right side the incision for resection should not be made too low, as the arch of the liver will eventually interfere with the retention of the drainage-tube. After the rib has been resected and an opening made, some operators introduce the finger and break up adhesions between the lung and chest-wall to free any encapsuled collections of pus which may be present. This is to be deprecated, because in unskilful hands the lung itself is apt to suffer injury.

Irrigation of the cavity is not necessary either at or after the operation. Such a procedure may cause fatal syncope, or, if not attended with accident, certainly does tend to prolong inflammatory processes going on in the chest. Moreover, on account of the retention of some of the irrigating fluid, an exudate at first of good character may become putrid.

In those suppurating pleurisies which, from various causes, such as the perforation of a gangrenous or tubercular pulmonary focus, become putrid, or have from the first been putrid, irrigation at long intervals with Thiersch's solution or simple boric-acid solution or permanganate of potash is admissible.

Resection of the rib has of late been confounded with Estlander's operation. The latter operation is one undertaken to secure retraction of the chest-wall against a crippled lung, and should not in any way be associated with the comparatively simple procedure of removing an inch or so of one rib to give space for the insertion of a drain in ordinary acute purulent pleurisies.

Though much has been said on the subject of valvular drains (Phelps), which prevent the entrance of air into the pleural cavity, and are supposed to favor expansion of the lung while securing complete drainage, there seems to be little gained by their use. In the ordinary suppurating pleurisies the customary surgical dressings seem to answer very well in taking up and keeping aseptic any purulent discharge from the pleural cavity. The free filtration of air into the pleural sac is not attended with any ill effects. It is difficult to conceive how a discharge can become putrid from the admission of air alone into the pleura. There must be other elements present to cause such a bad result; and these will be found in ineffectual drainage with retention of old discharges in the pleural sac, or in some necrotic focus adjacent to the pleura and opening into it.

It was formerly customary to make counter-openings in the chest to favor drainage, but this has been found to be undesirable.

Siphonage.—To some the operation of resection will always be a grave procedure, and there has been a constant effort to find some substitute which would be more satisfactory than simple incision, yet not so complicated as resection. This has resulted in perfecting an operation which depends on the principle of siphonage, through negative pressure, to drain the pleural cavity. The Buelau operation, to which reference is made, consists of the introduction of a drain through an opening in the intercostal space; this

drain is connected with tubing which empties into a siphon-bottle, under the surface of an antiseptic fluid.

The operation requires (*a*) a trocar exactly 6 mm. in calibre, fitted with a canula; (*b*) a new disinfected Jacque catheter, fitted accurately to the canula, and passing through its lumen with ease, yet not loosely; (*c*) attached to this catheter, by means of glass tubing, a rubber tubing 75 cm. long.

A small incision is made in the skin of the intercostal space, where the trocar is to enter. The trocar and canula are then inserted, the trocar withdrawn, and the Jacque catheter, with its blunt extremity cut squarely off, is introduced for about 15 centimetres into the chest. The canula is now withdrawn over the Jacque catheter, escape of chest-contents being for the time prevented by pinching the catheter. The catheter is now connected with the tubing, which is led into a bottle filled one-third with an antiseptic fluid. The pleural exudate thus escapes into the bottle beneath the layer of antiseptic fluid, and air is prevented from entering the chest. Among the advantages claimed for this operation by its advocates are its simplicity and the prevention of entrance of air into the pleural sac. The negative pressure in the pleural sac is also maintained, and the siphonage favors expansion of the lung. The siphoning exudate is under constant observation through the glass tubing and bottle, and when recovery sets in its advent can be noted by the cessation of the discharge. There are no dressings except the adhesive plaster, which retains the catheter in the chest. The results of this operation, especially with children, in the hospitals of Hamburg have been so gratifying as to make certain surgeons there its enthusiastic advocates. Scheede, on the other hand, fears that unruly children will displace the tube in the chest. The advocates of the siphon method maintain that this is not likely to happen. Their results are certainly equal to those of surgeons using other methods, and should bring the operation into favorable notice.

PULMONARY EMPHYSEMA.

BY JOHN DORNING, M. D.,

NEW YORK.

PULMONARY EMPHYSEMA is an abnormal accumulation of air within the vesicles or in the extravascular connective tissue of the lungs.

The varieties of this malady are—I. Interstitial, interlobular, or extravascular emphysema. II. Vesicular or alveolar emphysema, subdivided into *a*, compensatory or vicarious emphysema; *b*, substantive, idiopathic, or hypertrophic emphysema. III. Atrophic emphysema. As this last form occurs only in advanced life, no further allusion will be made to it here.

I. INTERSTITIAL EMPHYSEMA.—In this condition there is an accumulation of air in the connective tissue of the lung. It is usually the result of some violent expiratory effort, such as would occur in a severe case of pertussis. When the escaped air extends beneath the pleura, small air-bubbles appear on the surface of the lung, showing the outlines of one or more lobules. Sometimes large bullæ are seen. In unusual cases the air may burrow along the larger bronchi into the mediastinum and up into the subcutaneous tissue of the neck. Interstitial emphysema, as a rule, gives rise to no symptoms, and unless it extend to the neck is not a serious malady.

II. VESICULAR OR ALVEOLAR EMPHYSEMA.—*a*. COMPENSATORY EMPHYSEMA.—As the term would imply, this is a condition in which the vesicles of one portion of the lung are abnormally distended in consequence of the crippling or non-expansion of some other part of the organ.

Etiology.—It is this form of emphysema rather than the substantive form that is to be observed in young children. Indeed, cases of typical substantive emphysema are extremely rare in early childhood. In the genesis of compensatory emphysema there probably exists in most of the cases as a predisposing factor a defect in the nutrition of the pulmonary tissue. Thus with the same exciting causes in operation it is much more likely to occur in rachitic subjects than in children whose nutrition is perfect. The immediate causes include any mechanical obstruction to free respiration that would give rise to increased pressure within the vesicles. In protracted bronchitis, particularly when the finer bronchial tubes are affected, the swollen mucous membrane and the accumulation of viscid mucus interfere with the entrance of air into the corresponding lobules, causing a partial or complete atelectasis of the parts involved. This will leave an unoccupied space in the chest-cavity which becomes filled by the hyperdistention of adjacent lobules. This is the inspiratory theory. Again, as is so often observed in pertussis, in consequence of obstruction to the free egress of air through the glottis with extra-violent expiratory efforts, the retained air is forced in the direction of the least resistance, the apices and anterior borders, causing an over-distention of the vesicles in these regions—the expiratory theory.

In the vicinity of solidified areas of lung-tissue, as in pneumonia or tuber-

culosis, emphysema is usually discernible. When one lung is compressed by fluid in the pleural cavity, the other lung by reason of its increased function becomes over-expanded. Pleuritic adhesions that prevent the normal expansion of the apex and posterior border of the lung necessitate over-distention of other parts of the organ, especially the anterior and inferior borders.

In addition to other complications, emphysematous distention of parts of the lungs is to be found in membranous croup. In advanced rachitis the pliability of the ribs and costal cartilages favors the development of emphysema in the anterior margins of the lungs.

Inflation of the lungs in the asphyxiated new-born child by blowing into its mouth has been said to give rise to emphysema. Such a cause must be quite exceptional, judging from the manner in which lungs that have been removed from the body collapse after forcible inflation.

Pathology.—In the majority of cases of compensatory emphysema complicating acute bronchitis and pertussis recovery evidently takes place. In these cases there has undoubtedly been simply a hyperdistention of the pulmonary air-vesicles without any structural changes in their walls. The same may be said of the inordinate inflation of the lung of the non-affected side in acute pleurisy with effusion, where there has been a rapid absorption of the accumulated fluid. Where the affection is associated with tuberculous infiltration or old pleuritic adhesions, dilatation of the air-vesicles, with thinning of their walls and other structural changes characteristic of substantive emphysema, may be found to exist. From this we may conclude that the longer the duration of the immediate causes of compensatory emphysema, the more likely is a true emphysema to develop.

Symptoms.—A diagnosis of compensatory emphysema cannot, in most instances, be made either from the symptoms or by physical exploration of the chest. In fact, there are no distinctive signs of the affection unless considerable of the lung be involved, and its existence is generally assumed. Bulging of the supraclavicular space during the severe expiratory efforts of coughing, and a falling-in during inspiration, have been regarded as indicative of an involvement of the apices. Where one side of the chest is filled with fluid the hyper-resonance of the opposite side with the exaggerated vesicular murmur would suggest the belief that the one lung is performing the work of the two, and that the vesicles are abnormally distended. If extensive pleuritic adhesions exist, a prolonged low-pitched expiratory murmur may be heard over certain portions of the lung, but especially at the anterior border. In this latter situation the same character of respiration may be detected in rachitic subjects with marked chest-deformity.

Treatment will be considered under Substantive Emphysema.

b. SUBSTANTIVE EMPHYSEMA.—This is a chronic and generally incurable malady, characterized by an abnormal distention of the pulmonary vesicles, with structural changes in their walls.

Etiology.—Well-marked substantive emphysema in young children—that is, under the age of ten years—is extremely rare. After this age it is occasionally observed, but not until adolescence is it encountered with any frequency. Authorities differ materially in their views regarding the causation and nature of this disease. From the frequency with which it is found to run in families it would, in a measure, appear to be of an hereditary nature. Jackson investigated 28 cases, and found that 18 were born of parents one or the other of whom had suffered from emphysema. Greenhow collected 42 cases, 23 of which appeared to be of an hereditary tendency. The histories of many cases of emphysema in the adult show that there have been frequent respiratory

affections from early life; still, in other instances where the disease has been extensive, no account of previous attacks of bronchitis can be elicited.

Increased air-pressure within the pulmonary vesicles, due to forced and long-continued inspiration or expiration, is by some investigators considered at least the exciting, if not the primary, cause of emphysema.

According to the inspiratory theory of Laennec as modified by Hutchinson, Traube, and Gairdner, emphysema is a result of bronchial catarrh. The presence of a tumefied mucous membrane and viscid mucus in the bronchioles prevents the entrance of air into the corresponding lobules, giving rise to areas of collapse, and to fill up the deficiency so caused the neighboring lobules become hyperdistended.

The theory of expiration as maintained by Jenner and Mendelsohn would seem to afford a more adequate explanation, than does the inspiratory theory, of the part mechanical distention of the air-cells plays in the production of substantive emphysema. During forced expiratory efforts with a closed glottis, as occurs in violent attacks of coughing or severe straining, the air is driven in the direction of the least resistance—namely, the apices and anterior borders of the lungs. It is in these situations that the greatest degree of dilatation is usually found. There are cases, however, where the disease is diffused throughout the lung, without a history of previous cough or increased expiratory pressure.

C. J. B. Williams claimed there was a fatty degeneration of the lung-tissue that aided in bringing about the pathological changes observed in emphysema. Fatty matter has been found in only a small number of cases. Jenner taught that the most frequent anatomical change in the lung was fibrous degeneration resulting from slight but long-continued congestion.

Delafield believes substantive emphysema to be a chronic inflammation of the lungs, a pneumonia, and the dilatation of the air-vesicles a mere result of this inflammation, and not the essential lesion: the inflammation, he states, is of the same type as that which so often attacks the endocardium, the inner coat of the arteries, the liver, and the kidneys—a chronic inflammation attended with the production of new fibrous tissue, and at the same time with atrophy and disappearance of normal tissue. It is quite evident that increased air-pressure within the vesicles does not exclusively account for the presence of substantive emphysema. Indeed, it seems doubtful if it can be considered as anything more than an exciting cause or as aggravating the disease when it has already been established. We think it may reasonably be inferred that children who suffer with frequent prolonged attacks of bronchitis are likely to become the subjects of emphysema later in life, not only because of the pulmonary disturbance induced by the increased intralobular pressure, but on account of the existing condition which predisposes the child to the repeated bronchial catarrhs; for in such children there is unquestionably a vulnerability of the tissues the outcome of some defect in the nutrition.

Pathology.—In the rare cases of substantive emphysema that occur in early life most of the changes that are to be observed in the adult are present, only in a less degree. On opening the thorax the lungs do not collapse. They have a peculiar cushiony feel and pit on pressure. The color is pale grayish or yellowish gray. The air-vesicles present varying degrees of dilatation. Their walls are in some parts of the lung thinned, in others thickened. Coalescence of neighboring vesicles and obliteration of the capillaries occur in some instances. The epithelium of the air-cells presents degenerative changes. In the bronchial tubes may be seen evidence of chronic bronchitis, with dilatation of the bronchioles in some advanced cases. There may be some hyper-

trophy of the right ventricle, and less frequently a secondary dilatation. The secondary lesions of emphysema do not usually occur until long after childhood.

Symptoms.—Substantive emphysema not infrequently is present in the adult without giving rise to any subjective symptoms. This being the case, the more abundant reason there is why, with its less extensive development, it may exist in the young subject without thus manifesting its presence. When rational symptoms are present, they resemble, in a milder form, with the exception of those dependent upon secondary lesions, which are absent, those observed later in life.

Dyspnoea is probably the most marked symptom. At first it may be experienced only during unusual exercise; later, it becomes more constant, and is aggravated by even slight exertion, attacks of bronchial catarrh, and by distention of the stomach by a hearty meal or by the accumulation of gas from indigestion. Asthmatic attacks are of not infrequent occurrence. Off and on during the winter there is more or less cough.

Physical Signs.—*Inspection.*—The typical barrel-shaped chest of emphysema is seldom observed in children. There may, however, be a slight increase in the antero-posterior diameter. This will be more noticeable when associated with rachitic deformity of the thorax. Posteriorly, the curve of the spine may be increased, giving the back a rounded appearance. This must not be confounded with rachitic curvature of the spine. There is some increased exertion in respiration, but the rigidity of the chest, due to ossification of the costal cartilages, seen in advanced adult cases is absent. There may be some retraction of the upper abdominal region, owing to the powerful action of the diaphragm on the lower ribs. Jenner has observed falling in of the supraclavicular region during inspiration in cases where the apices were affected. Fürst considered expansion of this region during severe cough as a characteristic sign.

Palpation is negative.

Percussion.—Pulmonary resonance may remain unaltered. In older children, when it is changed, it is of a vesiculo-tympanitic quality. In young children the great elasticity of the thoracic walls and the smallness of the organs to be examined favor the transmission of resonance from the distended intestines, so that, unless there be very marked distention of the thorax, sufficient to displace the liver downward, percussion will be of little value. Thus it is the extent, and not the intensity, of the pulmonary resonance that is to be considered.

Auscultation.—The respiratory murmur is usually feeble and of a low pitch. Expiration is prolonged. When bronchitis is present sonorous, sibilant, and mucous râles are heard. The heart-sounds are generally clear; the second sound may be accentuated in older cases.

Prognosis.—Recovery from compensatory emphysema, if the malady has not existed for too long a time, may be expected. Perfect restoration of the lungs, however, when substantive emphysema has once become established, is not to be looked for. It never of itself proves fatal; still, it may be a complicating factor in bringing about a fatal issue. It is claimed by some that in cases of short duration with but limited involvement of the lung, under favorable circumstances recovery may take place. Not infrequently, improvement, even to the extent of an apparent cure, may be observed, but later in life, in most instances, it will be found to have been only temporary. At one time it was erroneously believed that emphysema protected the subject against tuberculosis.

Treatment.—In children the treatment should be mainly prophylactic. As malnutrition is evidently a predisposing factor, everything pertaining to the

diet and hygiene, even from early infancy, should receive due consideration. In this way the exciting causes of the disease may be prevented, or, should they develop, the patient will be in a better condition to withstand them.

When the affection is present it is infinitely necessary that measures be adopted toward the improvement of the general health. The whole body should be protected by woollen underclothing. The cold sponge bath, used only to an extent that will produce a proper reaction, is a general tonic of unquestionable value. By maintaining a healthful condition of the skin it lessens the liability to repeated bronchial catarrhs. An abundance of out-door air, with exercise regulated to suit the physical endurance of the patient, is an essential part of the treatment. An equably dry climate with an altitude of not over a thousand feet is very desirable. The diet should be principally nitrogenous. The value of milk is too well appreciated to need more than mere mention. The quantity of food taken at one time should not be great enough to cause any embarrassment of the respiration. Cod-liver oil, particularly if rachitis be present, should be administered. When the pure oil is given, begin with small doses, five to ten drops three times a day, and increase gradually until a full teaspoonful is reached. The emulsion of cod-liver oil, either simple or in combination with malt extract, is in some cases preferable to the plain oil.

In the way of medicinal treatment iron in some form should be used when there is any evidence of anæmia. Of the different preparations, the tincture of the pomate is for children one of the most acceptable both to the palate and the stomach. A child three years of age may be given from five to eight drops in a little plain or sweetened water three times a day; at ten years, ten to twenty drops. The citrate or the tincture of the chloride may also be used. In older children either Basham's mixture or the ethereal tincture of the acetate of iron can be recommended.

Strychnine has been thought to possess some specific virtue in the treatment of this disease. That its action is anything more than that of a general tonic seems doubtful. Care should be taken in prescribing the drug for young children. Tincture of nux vomica is a safer preparation, and may be administered in from one-half to two-drop doses at six years of age. Arsenic in the form of Fowler's solution, in from one-half to two-drop doses at eight years of age, is a general tonic of some value.

The mechanical treatment by compressed air, while valuable in certain cases in the adult, is less practicable, and may be positively harmful, in children.

All the exciting causes of compensatory emphysema or those that aggravate the substantive form, if not preventible, should be mitigated as much as possible.

For the chronic bronchitis that so often coexists with substantive emphysema iodide of potassium is generally recognized as a drug of great worth. In many cases favorable results may be obtained by combining it with linseed oil, as follows:

R̄.	Potassii iodidi	ʒij.
	Ol. lini	fʒiij.
	Pulv. acaciæ	ʒiij.
	Ol. gaultheriæ	gtt. viij.
	Syrupi	fʒij.
	Aq. dest.	q. s. ad fʒvj.—M.

Ft. emulsio.

Sig. Teaspoonful three or four times a day at ten years of age.

Another drug of marked excellence where there is much bronchial secretion is terebene. At eight or ten years of age it may be given thus:

R̄. Terebene fʒij.
 Tinct. opii camph. fʒss.
 Ol. menth. pip. gtt. vj.
 Syr. acaciæ q. s. ad fʒiij.—M.

Sig. Teaspoonful every four hours.

The treatment of the complicating asthmatic attacks will be considered in the article on Bronchial Asthma.

BRONCHIAL ASTHMA.

BY JOHN DORNING, M. D.,

NEW YORK.

ASTHMA is a peculiarly distressing form of paroxysmal dyspnoea, accompanied by wheezing respiration and characterized by a freedom from all manifestations of the affection in the intervals of the attacks.

Etiology.—It seems to be generally conceded by writers on the subject that those who suffer with asthma inherit a tendency to the disease. In many cases there is an ancestral history of gout instead of asthma. According to the statistics of Théry and Hyde Salter, asthma is more common among males than females. It is of frequent occurrence during childhood. Of Hyde Salter's 225 cases, 71 developed the disease during the first decade. It is said to be more common in the upper than in the lower walks of life. In a certain class of cases the cold season seems to exert some predisposing influence on the malady.

The exciting causes may be divided into those which act directly upon the nervous mechanism of the lungs, and those which are reflected from more remote parts or organs.

It is to be borne in mind that the exciting causes are only operative when there is a predisposition to the disease. In some instances no definite exciting cause can be discovered. Uræmic, cardiac, gouty, saturnine, and mercurial asthma are thought to be the result of an irritation of the respiratory centre in the medulla oblongata by vitiated blood. Irritation of the pneumogastric nerve along its course, as by the pressure of enlarged bronchial glands, may give rise to paroxysms of asthma. Eustace Smith has rarely failed to find evidence of swelling of the bronchial glands in the cases he has seen of asthma in the child. The enlargement of these glands is a result of bronchial catarrh. The asthma observed in the subjects of congenital syphilis, the so-called syphilitic asthma, can very likely be explained by a syphilitic enlargement of the bronchial glands. Bronchitis, either alone or associated with emphysema, is generally recognized as an exciting cause of asthma. Such cases may be accounted for either by a direct irritation of the terminal filaments of the pneumogastric nerve or by the concomitant swelling of the bronchial glands.

The inhalation of various irritants, as dust, the pollen of plants, smoke, gases, certain vapors, and the emanations from certain animals, are well known to excite asthmatic attacks. In this connection idiosyncrasy plays a prominent part. Some individuals are susceptible to only a few or perhaps but one of such irritants, and what will excite a paroxysm in one patient will have no influence on another. Thus, one patient cannot bear the perfume of some particular flower, as the rose, Easter lily, or heliotrope; another cannot tolerate the presence of a cat, horse, or dog; and a third dare not

encounter the air of certain localities. It is a well-known fact that a change of residence may either bring on the attacks or entirely prevent them. Sudden changes in the barometrical pressure, with strong easterly or northerly winds, are particularly detrimental to some asthmatics. Indigestion, overloading the stomach, or the ingestion of certain articles of diet not infrequently precipitates a paroxysm. In some rare instances intestinal worms are said to be an exciting factor. Asthmatic attacks may be induced by polypi in the nose. Voltolini of Breslau was the first to direct attention to this fact, and his observations have been confirmed by later investigators. Hypertrophy of the mucous membrane over the turbinated bones and nasal septum has been shown by Daly, Harrison, Roe, Allen, Hack, and others, to be a source of reflex irritation in provoking paroxysms of asthma, more especially hay asthma. Skin eruptions, notably eczema and urticaria, have been included in the category of exciting causes. West has "never known eczema to be very extensive and very long continued without a marked liability to asthma being associated with it." Cases have been observed where asthma and eczema have coexisted or alternated with each other, and the cure of one has been coincident with recovery of the other. It would seem not unreasonable to assume that where urticaria or eczema and asthma coexist or alternate with each other, instead of there existing a reciprocally etiological relation between the two, both are dependent upon some common cause.

Pathology.—Thus far, no well-defined post-mortem alterations have been discovered that would place the pathology of bronchial asthma, if it really be a distinct affection and not merely a symptom, without the domain of speculation. There is a number of theories regarding the nature of this affection, the most plausible of which are:

1st. That it is due to spasm of the bronchial muscles—the most popular theory at the present time. This theory is based upon the experiments of Williams and Longet, who, after the discovery of muscular tissue in the walls of the finer bronchi by Reisseisen, found that electrical irritation of the lungs and pneumogastric nerve produced contraction of the bronchial tubes. Among the advocates of this theory are Romberg, Bergson, Trousseau, Hyde Salter, Paul Bert, and Biermer.

2d. The next theory, and one having many supporters, is that the dyspnoea is due to a sudden tumefaction of the bronchial mucous membrane with exudation, the result of turgescence of its blood-vessels caused by the action of the vaso-motor nerves (Weber), fluctuatory hyperæmia (Traube). Stoerck adopted this theory from having, during the paroxysm, observed with the laryngoscopic mirror an acute hyperæmia of the laryngeal and tracheal mucous membrane, which disappeared after the attack had subsided, and he consequently inferred that the same condition existed in the smaller bronchial tubes.

3d. Another view regarding the nature of this malady is that it is dependent upon a catarrh of the bronchioles (bronchiolitis exudativa). This theory is based on the presence in the sputum of certain peculiar spiral structures described by Curschmann (Fig. 1).

Leyden discovered in the sputum of asthmatics certain elongated octahedral crystals (Fig. 1), which he believed, by their irritation of the terminal nerve-filaments in the bronchial mucous membrane, induced bronchial spasm. These crystals have been found in pneumonic expectoration, and hence, while not pathognomonic, they may be of some diagnostic value in differentiating bronchial asthma from other forms of dyspnoea.

Symptoms.—In the majority of instances the asthmatic attack occurs without any premonition whatever; sometimes, however, certain sensations are

experienced which to those who have previously suffered are pretty sure evidence of an approaching paroxysm. The premonitory symptom may be a depression or exaltation of spirits, a chilly feeling, a sense of constriction of the chest or throat, flatulent distention of the abdomen, itching of the skin,

FIG. 1.

Curschmann's Spirals and Leyden's Crystals (Strümpell).

the voiding of a large quantity of clear urine, or some other functional disturbance peculiar to the individual. Not infrequently an acute catarrh of the upper air-tract precedes the attack.

The paroxysm generally comes on after the patient has retired for the night; still, it may occur at any hour of the day. It commences with the characteristic wheezing, and soon the patient is awakened by a distressing sense of lack of breath, which becomes more and more urgent until he is finally compelled to assume a position that will facilitate an easier entrance of air into his lungs. He may sit up in his bed or in his chair, with his hands grasping his knees, his shoulders elevated, and his head thrown backward, so that all the muscles of respiration and their auxiliaries may act to greatest advantage; or, he may find greatest relief by kneeling before his cot or chair with his head resting on his hands or a pillow. Often the desire for breath is so pressing that the sufferer will rush to an open window in the hope of obtaining relief. The face assumes an anxious expression, pallid at first, and as the dyspnoea increases changing to a dusky bluish hue. The eyes are prominent and have a staring expression, the nostrils are widely dilated, and the mouth is partly open. The skin becomes moistened with perspiration as the distress increases. The respiration, particularly expiration, is noisy and wheezing, and may be heard in the adjoining apartment. Inspiration is short and jerky, expiration very much prolonged. The number of respirations is seldom much increased, and may be even less than normal. Speech, beyond monosyllables, is impossible. Notwithstanding the laborious efforts in breathing there is merely an up-and-down movement of the ribs, with but little or no expansion, the thorax being fixed in the position of full inspiration. The pulse is small, rapid, and thready in proportion to the intensity of the dyspnoea. There is no elevation of the temperature. If the attack be prolonged, the surface temperature falls below normal, the extremities become cold, clammy, and bluish, and death seems imminent.

As the paroxysm subsides there is more or less cough and expectoration, whether they have previously existed or not. In some cases the expectoration consists of rounded masses of tenacious mucus; in others it is profuse and watery. Sometimes streaks of blood are found. In some rare and severe cases hæmoptysis has been known to occur.

After the paroxysm there is usually considerable exhaustion, and the patient soon falls asleep. On awakening, with the exception of a little soreness of the respiratory muscles, no discomfort is experienced, and the patient afterward enjoys his usual health.

The duration of the attack may vary from a few hours to several days, with remissions and exacerbations. The paroxysms vary in frequency. They may recur as often as once a week or there may be an interval of months between them. Ordinarily there is no regularity in the recurrence of the attacks. A periodicity, however, is sometimes noticed, and is probably due to some condition operative only at particular times.

PHYSICAL SIGNS.—During the paroxysm inspection shows an expanded and barrel-shaped thorax, with but little respiratory motion. Inspiration is short and quick, expiration prolonged and violent. On percussion more or less hyper-resonance is obtained; in mild cases it is slight, but when the attack is severe and of long duration it is usually quite marked. Auscultation reveals, in severe cases, diminution or suppression of the vesicular murmur.

In mild attacks the respiratory murmur may be exaggerated and jerky. All over the chest may be heard an ever-changing variety of sonorous and sibilant râles. They are piping, cooing, wheezing, and often musical in their nature. They are louder during expiration. Toward the close of the paroxysm moist râles are to be heard, or, if bronchial catarrh exists, they may be detected from the beginning of the attack.

Prognosis.—Uncomplicated asthma is, *per se*, rarely if ever fatal. In general the prognosis is better in young subjects than in adults. Hyde Salter makes the statement that “in young asthmatics the tendency is almost invariably toward recovery.” The prognosis may be said to be favorable when the attacks are dependent upon some removable cause, when mild and occurring at long intervals, when there is no hereditary predisposition, and when there is freedom from complications.

Diagnosis.—The rational and physical signs of an uncomplicated paroxysm of asthma are so distinctive that, if properly appreciated, there should be little or no difficulty in reaching a correct diagnosis.

The affections which it is thought may possibly be mistaken for bronchial asthma are the various forms of obstruction in the upper air-passages, as foreign bodies in the throat; retro-pharyngeal abscess; diphtheritic and false croup; œdema of the glottis; neoplasms of the larynx; spasmodic contraction of the adductors of the larynx or paralysis of the abductors; tracheal stenosis or foreign body in one or the other of the main bronchi; bronchitis, pneumonia; emphysema; pulmonary œdema; pleuritic effusion; cardiac disease; uræmia, and spasm of the diaphragm.

In obstructive dyspnoea from any cause the difficulty in breathing is during inspiration, while in asthma it is during expiration. There is also inspiratory recession at the episternal notch and epigastrium not observed in asthma. In the former there is the absence of wheezing in the chest, and the dyspnoea is continuous instead of paroxysmal, as in asthma. Changes in the quality of the voice will exclude the latter affection. Examination of the throat with the finger or mirror will enable one to determine the exact nature of the obstruction. Occlusion of a main bronchus will cause a diminished intensity or absence of the respiratory murmur on the affected side. The dyspnoea of bronchitis and pneumonia comes on gradually and is attended with some degree of fever; the respirations, particularly in pneumonia, are rapid and often short and catching. In asthma the onset is

more sudden, there is no elevation of temperature, and the respirations are either but slightly or not at all increased in frequency.

Some difficulty may be experienced in distinguishing between emphysema and asthma on account of their frequent coexistence. Each may induce the other. Emphysema more often exists without asthma than does the latter affection without some degree of the former. In emphysema the dyspnoea is remittent rather than intermittent as in asthma. It is aggravated by physical excitement, and hence is more likely to occur during the day than at night. In pulmonary œdema the increased frequency of the respiration, with perhaps some dulness on percussion, the presence of large and small moist râles all over the chest, the profuse and watery expectoration, and the absence of wheezing will ordinarily distinguish it from asthma. In pleuritic effusion the usual dulness on percussion, the limitation of the diminished respiratory murmur to the area occupied by the fluid, the detection of ægophony, and the absence of the characteristic dry râles of asthma will suffice for a diagnosis.

Cardiac asthma is not very common in children. It, however, resembles bronchial asthma in that it may be paroxysmal in nature, intense in degree, and may come on at night. It generally follows cardiac excitement. The absence of the varied musical sounds in the chest and of the prolonged expiration, and the presence of a cardiac lesion capable of inducing dyspnoea, will be of some assistance in distinguishing the one from the other.

Dyspnoea due to uræmia need never be confounded with bronchial asthma if the precaution is taken to examine the urine of every case coming under observation.

Spasm of the diaphragm may be distinguished from asthma by the sudden, abrupt inspiration, the hiccough, and, after a few seconds, the quick, violent expiratory effort.

Treatment.—The treatment of asthma comprises the management of the paroxysm and the treatment of the patient in the intervals between the attacks. If possible, the exciting cause should be discovered and removed. For instance, if clearly dependent upon an overloaded stomach or the presence of some indigestible substance in the alimentary canal, an emetic or an enema will afford prompt relief. To relieve the patient during the attack, in the absence of any apparent and removable cause, it generally becomes necessary to have recourse to some sedative or depressant. The numerous drugs recommended vary so in their action upon different subjects that not infrequently a number have to be tried before the one is found that gives the greatest relief. The one drug that is most frequently successful in cutting short the paroxysm is morphine administered subcutaneously. In young children, however, it is rarely necessary to use it, as some one of the remedies to be mentioned will usually be found to be sufficiently effective. In later childhood, if given, the greatest caution should be observed, as children are markedly susceptible to the toxic influence of morphine. To a child ten years of age from $\frac{1}{8}$ to $\frac{1}{2}$ of a grain of the sulphate, combined with $\frac{1}{250}$ of a grain of atropine sulphate, may be given hypodermatically. Next to morphine in abating the asthmatic paroxysm comes chloroform. The relief is speedy, but often only temporary, so that repeated inhalations are usually required. In the writer's experience chloral hydrate is superior to chloroform at any period of childhood, in that its effects, though less prompt, are more lasting. At five years of age 5 grains dissolved in at least 1 drachm of some simple menstruum, may be given, and repeated in forty minutes if there be no abatement of the dyspnoea. If it cannot be taken by the mouth, 10 to 15 grains dissolved in half an ounce of water may be injected into the rectum.

The fumes of nitre-paper (*charta potassii nitratis*), a very popular remedy, will often cut short a mild attack and give considerable relief in a severe one; sometimes it has no effect at all. The remedy is prepared by dipping a sheet of absorbent paper into a saturated solution of nitrate of potassium and afterward drying it; the dried paper is then cut into pieces of the required size and is ready for burning. The patient should be placed in a small room or in some kind of an extemporized tent, so that he can inhale the fumes of the burning paper. It acts promptly if at all, at first exciting some cough, but in a few minutes alleviating the distress.

Inhalation of the smoke of *Datura stramonium* and *Datura tatula* is often serviceable. In young subjects it must be used with care, and the inhalation stopped as soon as the sight or intellect becomes confused. *Lobelia* and *belladonna*, either separately or combined, are beneficial in some cases.

Tobacco, while an excellent remedy in adult cases, is too powerful a depressant to be recommended in children. The nitrite of amyl and nitro-glycerin do good, but they have not yielded such results as would be expected from our knowledge of their physiological action. If used at all in children, they must be given with due caution. *Quebracho* and *Grindelia robusta* have been advocated, but their action is uncertain.

Iodide of ethyl is thought to be efficacious (*Germain Séé*). Eight to twelve drops by inhalation is a fair dose at eight years. *Pilocarpine*, $\frac{1}{8}$ to $\frac{1}{10}$ of a grain hypodermatically at five years, has been advocated by *Berkart*. Coffee and alcohol are useful in the adult; but it is questionable if it would be wise to have recourse to them, particularly the latter, in children.

Intense mental emotion, as a sudden alarm or a pleasurable surprise, will frequently at once check an asthmatic paroxysm.

During the intervals of the attacks every effort should be made to discover and remove the exciting cause. Hypertrophied turbinated bodies should be reduced, nasal polypi extirpated, adenoid growths in the naso-pharynx removed, and catarrh of any part of the respiratory tract relieved by appropriate measures. Particular attention should be given to the diet, especially when the asthmatic attacks bear any relation to the state of the digestion. As a rule, it is best to allow only a light and easily-digested supper, and that early enough in the evening to be digested and passed from the stomach before retiring.

When there is no apparent exciting cause the general condition of the patient requires attention. The value of an out-door life, in the open country if possible, the daily cold sponge-bath, the protection of the body by suitable clothing, and a nutritious diet in the asthmatic subject is too well appreciated to require more than mere mention. All those affections that directly or indirectly cause enlargement of the bronchial glands are to be most sedulously guarded against. Cod-liver oil, beginning with small doses and gradually increasing, should be administered in most cases. Iron is frequently indicated. The tincture of the pomate of iron in from 5- to 10-drop doses at five years of age is an acceptable and easily-digested preparation for children. The tincture of the chloride or the syrup of the iodide may be given if the digestion be good. In many cases arsenic renders good service. It is best administered in the form of liquor potassii arsenitis (*Fowler's solution*), beginning at the age of five years with 1 drop in water three times a day, and increasing gradually to 4 or 6 drops. On the supervention of toxic symptoms the drug should be discontinued for a time.

Iodide of potassium is lauded as possessing some special beneficial action in asthma. If given to the point of tolerance and continued for a long period of time, it often yields good results. In some cases, however, it utterly fails.

Quinine and strychnine have their respective advocates. The former will prove valuable where there is a malarial complication. In small doses they are both tonics.

Change of climate or locality will relieve some patients. Asthma is such a capricious malady that it would be next to impossible to select any particular locality and guarantee immunity from the attacks. Some city patients are benefited by removal to the country, those living in the country by going to the city, dwellers at the sea-coast by a change to the interior, and those living inland by a residence at the sea-board. The fact of the matter is, each patient must select his own climate.

FIBROID PHTHISIS.

BY FREDERICK C. SHATTUCK, M. D.,

BOSTON.

THIS affection—otherwise known as chronic pneumonia, interstitial pneumonia, cirrhosis of the lung, or fibroid induration of the lung—is a process not uniform in origin, generally unilateral, very chronic in course, resulting in the substitution of connective for pulmonary tissue in a more or less considerable area, usually associated with bronchial dilatation, and often, at some period in the case, with tuberculosis.

Etiology.—This condition—for, in the great majority of cases at least, it is a condition rather than a disease—is not very common at the best, and is, in its fully-developed form, very rare in children, though its origin may date back to childhood. Of 30 fatal cases with autopsy collected by Bastian in Reynolds's *System of Medicine*, only 2 were under fifteen years of age, 3 from fifteen to twenty, while more than one-half of the cases succumbed between twenty and forty. The age of both children was seven years, and one of them was reported by Sir D. Corrigan in his original paper on "Cirrhosis of the Lung," published in 1838 in the *Dublin Journal*. In Wilson Fox's great posthumous work on "Diseases of the Lung and Pleura" will be found references to other cases in children.

That the affection should be rare in children is not surprising, inasmuch as inflammation, like nutrition, in the young is a more active process than in adults, and is less likely to lead to the formation of organizable products than in later life. The power of complete repair is also greater in children, and in them, if recovery takes place, it is less likely to leave permanent or progressive changes behind. The literature of the subject would seem to show that in children pneumonia and broncho-pneumonia are the affections which are most apt to be followed by fibroid changes in the lung. Of the two, the latter is probably the more frequent antecedent. That simple bronchitis may pave the way to connective-tissue growth seems probable. It is certain that pleurisy may do so, though this origin is probably more frequent in adults. The thick false membranes may then serve as the starting-point for a growth of connective tissue into the contracted lung itself, while bronchiectasis gradually comes about as a result of frequent cough, and also as a means of equalization of the atmospheric pressure within and without the chest. Other things being equal, the older the person the more rigid the chest-wall and the less can it collapse. The space which the firm adhesions prevent the lung from reoccupying must thus be filled in a measure by dilatation of the bronchi, of some of the air-vesicles, and even of the blood-vessels and lymphatics.

There is another sequence of events which is certainly more common in adults, if indeed it ever occurs in children. The arrest of an ordinary ulcerating pulmonary tuberculosis, with the formation of abundant connective-tissue growth in which the bacilli are, as it were, bottled up, is here alluded to. The writer has seen some conspicuous examples of this. The report of one of them,

with autopsy, may be found in the *Boston Medical and Surgical Journal*, 1880.

The fibroid phthisis which results from irritation by particles of dust, as in miners, grinders, painters, and the like, is not apt to be encountered in children, and is a bilateral affection.

The view is expressed by Strümpell, Osler, and other recent writers that most cases of fibroid phthisis either are or have been tuberculous. That this is true of some cases there can be no question; but further investigation is needed to enable us to determine how large the proportion is, or whether, indeed, such destructive processes ever go on without the aid of the tubercular bacillus. That many of the inflammations of serous membranes, including the pleura, formerly believed to be simple or due to exposure to cold, are really tubercular, seems now to be well established. And the origin of some of these cases of fibroid phthisis in pleurisy has been already alluded to. The discovery of the true criterion of tuberculosis is still too recent to permit the accumulation of sufficient positive evidence to establish the relation of fibroid phthisis and pulmonary tuberculosis. In the older reports, if no miliary tubercles or caseous masses were found after careful search, the case was classed as non-tubercular. I have not met with any reports of thorough microscopic examination of these cases of late years. But we have learned since Koch's great discovery more than we knew before as to the multiplicity of the lesions following the local and general action of his bacillus, and also more as to their frequent self-limitation, and, indeed, curability.

Pathological Anatomy.—The striking morbid feature of this affection is the presence of connective tissue in the lung with corresponding destruction of the true parenchyma. The changes are generally unilateral, and may be so even when the primary process—broncho-pneumonia, for instance—is essentially bilateral. The lower are more frequently affected than the upper lobes. Bands of fibrous tissue may traverse the affected part, and these bands are, for obvious reasons, less likely to be pigmented in the young than in adults. Or the distribution of the connective tissue may be more uniform, producing an appearance which has been compared to that of the uterus after delivery. Peribronchitic thickening is practically always present to a greater or less degree, as is also bronchial dilatation, resulting in the formation of cavities of greater or less size.

Another mode in which cavities are formed or increased in size is through ulceration, the accompaniment of the growth of tubercular bacilli or the result of the irritation of retained and decomposing secretion, or both at once. Miliary tubercles, caseous masses, or calcified deposits may be seen by the naked eye. The microscope may reveal tubercular bacilli in active growth in the secretion or the tissues, or safely imprisoned within the connective tissue. Here and there within the diseased portions there may be macroscopic or microscopic islets of relatively normal or of emphysematous lung-tissue. The microscope may also demonstrate within the indurated lung or the thickened pleura dilated blood- and lymphatic-vessels.

The affected lung may be moderately or very greatly diminished in size, with corresponding contraction of the chest, approximation of the ribs, droop of the shoulder, and twist of the vertebral column.

The pleura is rarely if ever spared; it may contain an encapsulated collection of fluid, more probably sero-fibrinous. Adhesions vary considerably in thickness and density; they may be cartilaginous, and so firm that the lung must be cut out of the chest at the autopsy. It seems reasonable to suppose that when the process started in the pleura the thickening of that membrane is more con-

spacious than when it started in the lung itself and secondarily affected the pleura, as does every inflammatory process of the lung or of the chest-wall which approaches one or the other layer of the serous cavity.

The sound lung, or sound portions of both, is the seat of compensatory hypertrophy; perhaps of emphysema, either confined to the edge or more widely distributed. Adhesive pericarditis is common as a result of extension of inflammation from the pleura, especially when the left lower lobe is the seat of the disease. The heart itself is often more or less drawn out of place, and the right chambers are apt to be dilated and hypertrophied in extensive disease of long standing, in consequence of the augmented internal pressure to which the cavities are subjected by reason of the increased resistance in the pulmonary circulation. If compensation has failed in the right ventricle, the common secondary results of such failure are shown by general and visceral venous stasis.

Symptoms and Course.—Cough and expectoration are practically constant, though they vary widely in degree and severity in different cases or in the same case at different times. The character of the expectoration is not distinctive. If notable cavities of bronchiectatic or other origin are present, their existence may be suggested by a more or less periodically profuse expectoration, by profuse expectoration in certain positions of the body, or by the separation of the sputum on standing into an upper frothy, a middle serous, and a lower layer of purulent masses. The presence of tubercle bacilli is suggestive of a recent infection from without or of a fresh outbreak from within. If ulceration is going on, elastic fibres may be found. Hæmoptysis is extremely common, is often repeated, and usually moderate in amount. It may, however, as in ordinary phthisis, arise from a good-sized vessel traversing the wall of a cavity, and then be so profuse as to be the immediate cause of death. Dyspnoea may be absent while the patient is at rest, but very marked after but slight exertion.

Constant fever, with its attendant emaciation and constitutional disturbance, is absent. The process in itself is not a febrile one, and a rise of temperature which may be found at any time is attributable to some secondary or complicating affection. General nutrition may be excellent, and the fat layer notable. Clubbing of the tips of the fingers and toes and incurvation of the nails may be more marked in this than in any other condition, save, perhaps, congenital heart defects; this is an infallible indication of chronicity. In a word, the appearance of the patient may be, in the main, that of one in perfect health, from which a wide deviation is found to exist when the clothing is removed from the chest and a physical examination is made.

It does not seem advisable under the circumstances to enter here into a detailed account of the physical signs, which are so similar to those of a case of chronic tuberculosis. I shall therefore briefly touch only on those which are most striking and distinctive.

Inspection is apt to show a disparity in size and mobility between the sides of the chest; unilateral shrinkage, the droop of a shoulder, and curvature of the spine reaching their highest expression in those cases originating in or complicated by extensive pleural changes. Palpation, auscultation, and percussion reveal the presence of consolidated lung containing secretion, perhaps of cavity formation. As contrasted with ordinary phthisis, these changes are more apt to be found at the base than at the apex. Cardiac pulsation may be visible over unusually large or in unwonted areas, according as retraction of the lung away from the heart, or adhesions to the pericardium and retraction of the heart itself, or both together, may happen to have operated in the case in

hand. Sometimes, however, the heart is unduly overlapped by the hypertrophied healthy lung, and its pulsations may then be obscured. Although the right heart is apt to be, often markedly, hypertrophied and dilated, the fact that it is so must be often a matter rather of inference than of direct signs furnished by the examination of the organ itself. The explanation of this fact lies in the altered mutual relations of the lungs and heart under the influence of the disturbing factors mentioned above. Cardiac murmurs bear no constant relation to the condition.

If, for any cause, the compensatory hypertrophy of the right ventricle fails, the characteristic evidences of stasis in the pulmonary and systemic veins are superadded to those of the underlying condition—cyanosis, distention or pulsation of the jugulars, anasarca, ascites, enlarged or tender liver, the urine of passive renal congestion, and the like.

The course of the affection is essentially chronic, and, on the whole, progressive, though apparently stationary periods, perhaps of considerable duration, seem to occur. Intercurrent attacks of bronchitis are not rare, and certainly do nothing to retard progress. Death may occur from failure of the cardiac compensation, hæmoptysis, exhaustion, or from intercurrent disease.

Diagnosis.—This can seldom present any great difficulties, provided that a good history can be obtained and a careful physical examination be made. The combination of a history of chronic cough and expectoration, with repeated hæmoptysis; the physical signs of pronounced lung destruction, usually unilateral, often with cavity-formation; and hypertrophied and dilated right ventricle, with the maintenance of a surprisingly good condition of general nutrition, presents a picture which is perfectly characteristic. The very small respiratory margin is also noteworthy. Chronic pleurisy with great thickening of the membrane and contraction of the side is perhaps more liable to give rise to error than any other affection. The history of the case, but, above all, the signs of pronounced pulmonary changes, and the occurrence of hæmoptysis, are the chief aids in the differentiation. The good general nutrition, the absence of fever, and the duration and mode of onset of the trouble are sufficient to exclude ordinary pulmonary tuberculosis. The thoracic physical signs of cancer of the lung or pleura might be similar; but the course and duration are quite different. Congenital syphilis of the lung is of pathological rather than clinical interest. Acquired syphilis of the lung is very rare in children: it is also rare in adults, but resembles clinically ordinary phthisis more than the fibroid variety, which, moreover, is not amenable to mercury and the iodides.

Prognosis.—There can be no question that the expectation of life is curtailed by this condition. Probably Dr. Oliver Wendell Holmes did not have it in mind when he said that the way to ensure length of days is to acquire an incurable disease. And yet its owners may live many, many years. The danger is rather from intercurrent disease than from the fibroid induration of the lung itself. If the patient's circumstances permit, he will naturally lead a more careful life than if he were sound in all parts. In a case of the writer's, proving fatal at twenty-eight years of age, the onset dated back presumably to measles at the age of seven, and yet the patient worked as a shoeblack in a damp, narrow, and sunless alley in all sorts of weather until shortly before his death from hæmoptysis. Had he been able to take care of himself, it is probable that he might have lived many years longer.

Treatment.—It is obvious enough that little can be done to repair damage already done. Therapeutic effects must, therefore, in the main, be directed to staying the progress of the affection as far as possible, and to warding off intercurrent diseases, which may either promote the extension of the

fibroid growth or carry off the patient. Hygienic measures are thus vastly more important than medicinal agents. The limitation of the respiratory capacity is such in most cases as to preclude residence in high altitudes. Climatic change has for its object an abundant supply of fresh, pure air with lessened risks of colds and bronchitis. The amount and character of exercise are to be determined by the peculiarities of each case. Tonics and stimulants are to be given if the appetite and digestion seem to require them. Expectorants may be needed from time to time. Narcotics and hypnotics, except occasionally and in the last stages, are to be avoided as far as is possible. Iodide of potassium may render good service in promoting recovery from bronchitis, but cannot be expected to have much influence on the connective tissue growth. Failure of compensatory hypertrophy of the right heart calls for cardiac tonics, as when it occurs under other circumstances.

In a word, it should be our aim to keep our patient in the highest possible condition of health, treating him rather than his disease.

PART IX.

DISEASES OF THE HEART.

CONGENITAL AFFECTIONS OF THE HEART.

BY BARTON COOKE HIRST, M. D.,

PHILADELPHIA.

CARDIAC anomalies of pre-natal origin, like other developmental abnormalities, cannot be easily classified in a thoroughly satisfactory manner. Osler gives an etiological division into (1) those affections due to defective development, (2) those resulting from intra-uterine endocarditis; and (3) those that are caused by a combination of both causes. The same author employs, however, the following general classification: I. Conditions in which structures normal to the fœtus persist during extra-uterine life, such as open foramen ovale, persistency of the Eustachian valve, and patency of the ductus arteriosus. II. True anomalies of development, as absence or imperfection of the ventricular septum, absence of the auricular septum, anomalous division of the truncus arteriosus, transposition of the great vessels, and numerical variations in the valve segments. III. Conditions caused wholly or in part by endocarditis, as extreme stenosis of the cardiac orifices, puckering, thickening, and adhesion of the valve segments.

The writer will employ Baginsky's classification, somewhat modified, as follows:

1. Patency of the foramen ovale.
2. Defect of the ventricular septum.
3. Anomalies of the right and left auriculo-ventricular orifices.
4. Stenosis and atresia of the pulmonary artery.
5. Persistence of the ductus arteriosus.
6. Stenosis of the aorta.
7. Transposition of the arterial trunks.
8. Numerical anomalies of the valve segments.
9. Ectopia cordis.

1. **PATENCY OF THE FORAMEN OVALE.**—Much attention—more than it deserves—has been bestowed upon this affection of the heart. Of itself, it does not entail, as a rule, any disadvantage upon the individual. A patent foramen ovale has been discovered in many persons dying of a variety of diseases, in whom, during life, there was no evidence of heart embarrassment. Unless there be associated anomalies, congenital or acquired, increasing the pressure in the right auricle, the blood will not flow in any quantity from right to left auricle, even though the foramen be open, and consequently the arterial blood

will not be vitiated to any appreciable extent. If pressure be increased in the right auricle by a contracted auriculo-ventricular septum or by an obstacle to the escape of blood from the right ventricle, then the stream may be deflected into an abnormal course, the heart be embarrassed by extra work, and the blood in the aorta become mixed. The child will be cyanotic, and its life will very likely be cut short.

If the size of the patent foramen is increased by a defect in the anterior muscular septum between the auricles, as well as in the membranous septum, the anomaly is a very serious one. I have had an opportunity to make a post-mortem examination in two such cases. In both the children lived but a few hours after birth, and they were intensely blue. In one the cyanosis reached a grade I have never witnessed before or since.

The cause of a patent foramen ovale is either an absence or defective development of the *membrana fossæ ovalis* or a defective institution of respiration. Normally, the opening is closed by the increased blood-supply to the auricles incident to the beginning of respiration. Should the latter act be imperfectly performed, as in atelectasis, the mechanical force to close the foramen by pressure upon its valve—with the subsequent adhesion of its free edges to the rim of the oval fossa—is lacking. More frequently, however, in infants that survive birth the *membrana fossæ ovalis* is lacking or ill developed, and the foramen consequently cannot be closed. It is claimed by Sansom that patency of the foramen can be diagnosticated during life by cyanosis without heart murmur, or by cyanosis with systolic and presystolic murmurs over the cartilages of the third and fourth ribs. But if one remembers that there are many other causes of cyanosis in the new-born infant besides heart defects, and that an open foramen uncomplicated by other anomalies may very likely present no symptoms at all, the difficulty of making this diagnosis may be appreciated. As interesting anatomical conditions under this head, but without clinical significance, are to be noted perforations of the valve of the foramen ovale and small slit-like openings under the valve where it has not adhered to the rim of the opening. The last are very common.

2. DEFECT OF THE VENTRICULAR SEPTUM.—This anomaly is most frequently associated with other abnormalities of the heart, as stenosed orifices and vessels, or defect of the auricular septum. It is not at all uncommon in its lesser degrees, but total defect is rare, and, when present, is associated almost always with defect of the auricular septum, constituting the so-called reptilian heart or *cor biloculare*. The defect is most frequently found in the anterior muscular portion of the septum, as shown by Rokitansky, and not in the median membranous portion, where it formerly was believed to be most frequently situated, but is in reality very rarely found. The effect of an unnatural opening between the ventricles is a propulsion of some of the blood from the left ventricle into the right during the former's contraction. Should the latter sufficiently hypertrophy to dispose of the extra amount of blood thrown into it, there need not necessarily be striking symptoms of heart defect. But should the hypertrophy not be sufficient, there results an embarrassed respiration and an obstructed venous circulation, with cyanosis and transudation of serum into connective tissue and body-cavities. As Baginsky points out, the cyanosis is due to this cause, and not to the mixing of arterial and venous blood.

The diagnosis of defect in the ventricular septum can be made, it is asserted by Roger and Sansom, by a loud systolic murmur over the præcordial region and between the shoulders, not transmitted to the vessels. The existence of a ventricular septum defect is unfavorable to the life of the infant, mainly on account of the associated anomalies. Sansom, however, records a case in a

child that lived eight and a half years, and Johnstone another that lived seven years.

3. ANOMALIES OF THE RIGHT AND LEFT AURICULO-VENTRICULAR ORIFICES.—These consist in stenosis and valve defects, mainly, the result of an intra-uterine endocarditis of the right and left heart-cavities. Osler claims that the endocarditis is secondary to developmental anomalies and is almost always of the chronic, sclerotic type, and very rarely of the verrucose or warty variety. He describes a typical specimen as presenting thickened valve segments, which are shrunken and smooth. In the case of the auriculo-ventricular valves the cusps become united and the attached chordæ tendineæ are thickened and shortened. In the semilunar valves all trace of the segments usually disappears, leaving a stiff, membranous diaphragm perforated by an oval or rounded orifice.

Valve defects from endocarditis are more commonly found upon the right than upon the left side. We shall first, therefore, glance at the anomalies of the right auriculo-ventricular orifice.

There is usually a thickening of the tricuspid valve as well as of other portions of the endocardium. The right ventricle is small. If the disease leads, as is not very uncommon, to complete atresia of the orifice, the circulation is only possible in a roundabout way, and then only when there is a defect in the ventricular septum. The blood flows from the right to left auricle, and from the left ventricle, in part, into the right, and so into the pulmonary artery. The left ventricle, from the additional work thrown upon it, is dilated and hypertrophied. In case of associated stenosis and insufficiency the right heart is dilated and hypertrophied. Cardiac murmurs, systolic and diastolic, with a thrill imparted to the thoracic wall, are loud and distinct, the heart's action is labored, the cyanosis is marked, and passive congestion everywhere is pronounced, leading on slight provocation to hæmorrhages.

In addition to the abnormalities resulting from disease in the tricuspid valves, developmental anomalies may be found, as an imperfect separation of the cusps, so that there is a circular opening between auricle and ventricle, with an annular diaphragm surrounding it. On the other hand, there may be four cusps instead of three.

The most common cause of abnormality in the left auriculo-ventricular orifice is a left-sided endocarditis. If stenosis of the orifice is well marked, the blood in the distended left auricle flows back through the patent foramen ovale into the right auricle, thence into the right ventricle, and so, by the ductus arteriosus, into the aorta. The left ventricle, becoming functionally more or less useless, undergoes atrophy, sometimes to a very marked degree. When the child is born the determination of blood to the lungs, and the increased amount flowing to the left auricle, embarrass the heart extremely. Congestion of the lungs, extreme cyanosis, and an early death is the result. As in the right orifice, there may be the developmental anomalies of imperfect differentiation of the cusps or their division into three instead of two segments.

4. STENOSIS AND ATRESIA OF THE PULMONARY ARTERY.—Osler divides the anomalies of the pulmonary orifice into stenosis, atresia of the orifice and of the artery, and stenosis of the conus arteriosus.

Stenosis of the pulmonary artery is one of the commonest and most important congenital defects of the heart. A child may live some length of time—may, in fact, reach adult life—with a serious narrowing of the pulmonary orifice and with enormously dilated and hypertrophied heart-cavities and muscles, without special symptoms until some extra strain is imposed upon the heart, especially by congestion of the lungs, when sudden death is likely to

occur. On the other hand, intense cyanosis and embarrassed respiration and circulation may be manifested from the first, and the infant may live but a few hours. The continued existence and development of the infant depend upon the hypertrophy of the heart. If this be truly compensatory, the child may thrive surprisingly well, even in grave cases. The prognosis as regards duration of life is better than in any other form of congenital heart defect of serious character. One individual reached the age of fifty-seven, and 16 per cent., according to Assmus, survive the twentieth year. But the tenure of life is always uncertain, for any sudden call upon the heart for extra work may prove fatal. And these cases are particularly liable to have grafted on them, at some time after birth, a fungous or infectious endocarditis that may be the immediate cause of death. Moreover, individuals affected with a contracted pulmonary orifice are peculiarly liable to tuberculous disease.

The cause of this anomaly is almost invariably an intra-uterine endocarditis, but it may possibly be a developmental defect. The symptoms are cyanosis, with signs of embarrassed circulation and respiration. The body warmth is likely to be very imperfectly preserved. The slightest exposure of the extremities leads to a remarkable frigidity, and the infant manifests signs of discomfort or suffering in consequence, unless it is too apathetic to take note of its surroundings. A mental and physical apathy very likely characterizes the individual throughout life.

As already stated there may be no special symptoms, even in bad cases, or at most, attacks of dyspnoea, lividity and heart palpitation from time to time.

On auscultation a loud systolic murmur is heard over the second and third ribs to the left of the sternum, and at the apex, which is not transmitted to the carotids. A thrill is imparted to the thoracic wall, the area of cardiac dulness is much increased, and the anterior wall of the thorax is protruded in later life.

Complete atresia of the pulmonary orifice and of the artery, while rarer than stenosis, is not very uncommon. The condition is due to defective development, and not to disease. If the atresia is of early appearance in embryonal life, there is a wide opening between the auricles and advanced atrophy of the right ventricle. The blood flows from the right auricle to the left auricle, and in part to the lungs by the medium of the ductus arteriosus. If, as is likely, there is a defect in the ventricular septum, the aorta may arise equally from both ventricles, or even belong more to the right; in which case the latter is much hypertrophied and dilated. The symptoms are more pronounced and the prognosis much worse than in stenosis. There is intense cyanosis, great dyspnoea, the child becomes very often convulsed, and dies usually in a few hours.

Stenosis of the conus arteriosus forms, according to Assmus and Osler, a considerable portion of the cases of obstruction at the pulmonary orifice. The former collected 47 cases of the kind. The condition is due to faulty development. By a constriction of the lower portion and dilatation above, a sort of accessory auricle may be formed. There are almost always other defects of development, as a defective ventricular septum. The symptoms are those of stenosis of the pulmonary orifice.

5. PERSISTENCE OF THE DUCTUS ARTERIOSUS.—By the fourteenth day, or within the first four weeks at least, the ductus arteriosus is closed by an overgrowth of the cells in its inner wall. Occasionally, in consequence of puerperal infection of the new-born with infected thrombi, or on account of defects in cardiac development, or as a result of the imperfect institution of respiration and an anomalous pulmonary circulation, the duct remains patent. It has been my experience, in making post-mortem investigations upon the

bodies of young infants, that a slight degree of patency is by no means uncommon during the first year of life. It is frequently easy to pass a small probe through the duct or to squeeze a drop or two of blood through, but in such cases the duct, of course, plays no part of practical importance in conveying the main-stream of the blood. The clinical symptoms of an efficient patency of the ductus arteriosus are rapid hypertrophy and dilatation of the right ventricle, dilatation of the pulmonary artery, increase in area of cardiac dulness, long-continued systolic murmurs, thrill of the anterior chest-wall, protrusion of the upper part of the sternum, attacks of dyspnoea, cyanosis or, perhaps, an almost cadaveric hue, a disposition to bronchitis and congestion of the lungs, and anasarca. Atheromatous processes in the pulmonary artery are common in individuals who live some years.

The prognosis is not favorable. Of sixteen cases 7 died in childhood, 5 lived from nineteen to thirty-four years, and 4 to between forty and fifty.

6. STENOSIS OF THE AORTA.—Obstruction at the aortic orifice is the result of developmental defect or of endocarditis, as in the case of obstruction at the pulmonary orifice. Stenosis is rarer, while atresia is relatively more common, at the aortic than at the pulmonary orifice. As in the right side of the heart, the conus arteriosus may be narrowed, but the condition is rare. Stenosis of the aortic orifice is a much more serious condition than narrowing of the pulmonary orifice. Of 33 cases, only 1 survived the first month. Stenosis of the conus arteriosus, on the other hand, does not seem so serious, for the majority of cases have been observed in adults. The aorta itself may be narrowed at the insertion of the ductus arteriosus. In this case the blood current finds its way to the lower portion of the trunk and the lower extremities by a roundabout course through the dilated subclavian arteries and by their branches anastomosing with the intercostal and epigastric arteries. The arteries of the upper portion of the body may be demonstrated to be much larger and fuller than in the lower, as in a comparison between the radial and crural pulses. The prognosis of this developmental defect is good. The individual may live to advanced old age.

7. TRANSPOSITION OF THE ARTERIAL TRUNKS.—This anomaly is not of great interest to the practitioner, for it is usually associated with other grave developmental defects that make extra-uterine life unlikely, and, of itself, it leads to an early death. The vitiated blood flowing from the right auricle into the right ventricle is distributed by the aorta springing from this ventricle again to the body, while the aerated blood from the left auricle is conveyed back again to the lungs. Continued existence at all is usually explained by an open foramen ovale or by a communication between the pulmonary veins and the right side of the heart. Osler describes an example in an eight-months' foetus, in which there was a partial transposition, the right ventricle giving off a small branch to the lungs, and the major part of its stream into the thoracic aorta, while from the left side sprang an arterial trunk that divided into the innominate and left carotid arteries. Children thus affected are deeply cyanosed, have dyspnoea, are prone to hæmorrhages and rapid cooling of the skin and the extremities. They are apathetic and die early. Twenty out of twenty-five cases did not survive the first year. A number of cases has been collected by Rauchfuss and Von Etlinger.

8. NUMERICAL ANOMALIES OF THE VALVE SEGMENTS.—The valve segments may be diminished in number by failure of development or as a result of endocarditis. Of itself this anomaly has little importance clinically, but it is often associated with other defects, as in the ventricular septum, and is commonly followed by sclerotic changes in the valves. Supernumerary valves are

not uncommon. As many as five semilunar valves have been observed. This is not likely to be accompanied by other abnormalities of the heart, and may have no clinical significance.

9. *ECTOPIA CORDIS* is the result usually of fissured sternum and thorax, and is commonly associated with a congenital fissure of the whole anterior body-wall. The heart may also be displaced upward into the neck or downward into the abdominal cavity. Other rare congenital malformations of the heart are found in *acardia*, ill-developed heart, double heart, bifid apex, and absence of the pericardium.

Symptoms.—The symptoms of all congenital heart defects have a certain general resemblance, as has been noted in their description under the appropriate divisions. Cyanosis is common, more or less, to them all. Indeed this term was long regarded as practically synonymous with congenital anomalies of the heart, but in the writer's experience the following conditions, arranged in the order of their frequency, have all been responsible for it: Pneumonia (often syphilitic); premature birth; asphyxia; atelectasis; degeneration of the blood; malformation of heart and blood-vessels; interference with the nerves of respiration; malformations of respiratory tract; congenital pleurisy, and partial occlusion of the trachea.

Treatment.—The treatment of congenital heart defects comprises hygienic management, protection from cold and physical exertion, and the administration of the heart tonics to tide over attacks of threatened cardiac failure and to help the development of a compensatory hypertrophy. Medicinal treatment alone, however, is of little avail, except to meet temporary indications. If compensatory hypertrophy is not soon established to a satisfactory degree, the prospect of life is bad.

ORGANIC DISEASES OF THE HEART.

BY FLOYD M. CRANDALL, M. D.,

NEW YORK.

DISEASES OF THE HEART during childhood present, in their general outlines, conditions very similar to those seen in the adult. In their details many and important differences occur. In the following pages these differences receive the chief attention, it being taken for granted that the reader is conversant with the diseases of the adult heart and their methods of detection. The following peculiarities are observed in the normal heart:

I. The apex lies higher in the chest and more to the left than in the adult, being outside the nipple line.

II. The apex-beat in the infant is usually difficult of detection; in the child it is more clearly visible, and can be detected by touch more readily than in the adult.

III. The area of dulness is comparatively large, so that the normal heart may, without caution, be considered hypertrophied.

IV. Murmurs are heard over a comparatively wide area, being frequently audible over the entire chest.

V. The rate may be increased and the rhythm disturbed by slight causes, so that rapidity and irregularity are of but little importance.

VI. In rachitic children, owing to deformity of the chest, the apex may appear in an abnormal position.

VII. Prominence of the præcordia is sometimes marked.

Cardiac disease during early life is also modified by the fact that the heart is undergoing numerous changes in growth and development. These are not constant, but occur chiefly at certain periods. The relative weight of the heart is greatest at birth, the right side predominating slightly over the left. During the first seven years there is an increase in volume of about 80 per cent. Between seven and fourteen the increase in actual volume is barely 10 per cent. There is then a very rapid increase of almost 100 per cent. These changes necessarily modify to a marked degree any diseased condition which may be present, and are of especial importance as regards prognosis and treatment.

I. PERICARDITIS.

Inflammation of the pericardium during childhood presents but few peculiarities pathologically. At this period of life inflammation of the serous membranes is more frequently marked by effusion than in the adult, and the pericardium presents no exception to the rule. Fluid forms with great rapidity, and is prone to be purulent. Endocarditis is a common accompaniment of pericarditis, and the walls of the heart are always more or less weakened. Not infrequently pericardium, endocardium, and muscle are all involved. Sturges, in extensive post-mortem observations, invariably found acute rheumatic endo-

carditis accompanied by more or less pericardial inflammation or adhesion, and believes that endopericarditis is the most common cardiac affection of early life. It is quite possible, however, that conditions present in cases so grave as to permit of post-mortem observation may not be as frequently present in the less serious cases which survive.

Etiology.—Pericarditis is seldom a primary affection. It may result from injury or the extension of inflammation from a neighboring organ, but more commonly occurs in the course of rheumatism or one of the infectious diseases. While rheumatism causes by far the greater number of cases, rheumatic pericarditis is not as common proportionately as in adult life. Scarlet fever, empyema, and pneumonia are frequent etiological factors. In young infants purulent pericarditis sometimes occurs as a result of septicæmic conditions at the umbilicus. Rheumatic pericarditis develops early, and sometimes precedes the articular symptoms. In scarlet fever the pericardial inflammation commonly develops during the second or third week.

Symptoms.—The subjective symptoms of pericarditis are usually obscure, and vary with the different stages of the disease. The early stage is frequently insidious and passes unrecognized. The most frequent symptoms are pain and palpitation. Pain may be confined to the præcordial region, or may be reflected into the shoulder or referred to the region of the stomach. It varies in intensity from a simple uneasiness to a sharp, lancinating pain. The patient sometimes assumes a characteristic position, with the head elevated and the body thrown somewhat toward the left. The trunk is held rigidly quiet, while the legs are moved freely. The pulse is full, and there may be slight fever and a hacking cough.

When effusion occurs the pain gives place to a sense of oppression. Respiration becomes labored, and the countenance assumes an anxious expression or a look of actual suffering. The face is livid or ashy pale. Dyspnœa is marked when the head is lowered. The pulse is weak, irregular, and intermitting. In fatal cases, as the effusion increases, attacks of syncope occur, hiccough develops, and delirium appears, followed by coma and death. In less severe cases præcordial heaviness and dyspnœa may be the only symptoms.

Physical Signs.—In the early stages the heart's action is usually forcible, but irritable, and often irregular. Percussion shows nothing except, perhaps, tenderness. A friction-sound is heard upon auscultation, the point of greatest intensity being, as a rule, under the fourth rib, just at the left of the sternum. This point varies with the position of the patient and with full inspiration. The sound is superficial, and has but a slight area of diffusion. It is frequently double, and usually creaking or rubbing in character, but may be crackling or even blowing. It sometimes so closely simulates the mitral regurgitant murmur as to be indistinguishable from it. Friction-sounds are more frequently absent in children than in adults, and rarely, when present, remain more than one or two days. The early detection of pericarditis in children is often one of the most difficult problems in the domain of physical diagnosis.

In the stage of effusion the difficulties in diagnosis are but slightly diminished. Owing to the thinness and yielding character of the chest-wall both the apex-beat and the normal heart-sounds may be readily detected when considerable fluid is present. In some instances the pulse is full and fairly strong, while the apex-beat is feeble or imperceptible. Occasionally an undulating impulse may be felt under the palm when the actual point of impact cannot be determined. Prominence of the præcordia is sometimes extreme. The area of percussion dulness is enlarged, but it is impossible to make definite statements as to its exact shape and extent. It is modified by the shape of the

chest, by pleuritic adhesions, and by pulmonary consolidation. If no adhesion or other lesion be present, the area of dulness assumes a somewhat pyramidal shape, being broad laterally at the lower portion and extending well up to the first rib. There is danger of mistaking an extremely dilated heart with feeble impulse for a pericardial effusion. Rotch, who has made a most careful series of observations upon the subject, calls attention to the fifth right interspace as a region of great importance in deciding between these two conditions. While with a dilated heart partial dulness may extend to the right of the sternum in the second or third interspace, it rarely appears in the fifth, and absolute dulness never. Even a small amount of effusion, on the other hand, finds its way into the fifth interspace, causing absolute dulness. Upon the left of the sternum the area of dulness in the two conditions is almost identical.

In the late stages, when recovery takes place, there are no physical signs by which pericardial adhesions may be positively detected. Intermittent or disturbed cardiac action following a pericarditis without evidence of an endocardial lesion offers strong presumption that such adhesions exist. According to Sturges, a rubbing exocardial sound does not preclude the possibility of pericardial adhesion.

Prognosis.—In infancy pericarditis is a serious and usually fatal disease. During childhood the tendency is to recovery. Not infrequently the course is rapid, complete resolution taking place within ten days. In other cases, while ultimate recovery is complete, it is long delayed. In still others adhesions remain which seriously cripple the heart. When the formation of fluid is rapid, embarrassment of the heart's action becomes alarming and sudden death may occur. Myocarditis is a frequent and serious source of danger. The longer the effusion is present the greater this danger becomes. The dilatation resulting from myocarditis is sometimes extreme, but if the child is in fair general condition hypertrophy follows, and is usually fully compensatory.

Treatment.—Any constitutional condition to which pericarditis may be secondary should be brought under control as quickly as possible. Pain and cardiac irritability should be at once relieved. For this purpose opium stands without a rival, and is the most important agent in the treatment of pericarditis. Sufficient should be given to relieve pain and maintain a mild continuous effect through the early stages. Though it may be administered more freely than in endocarditis, the condition of narcotism should never be induced. Stimulants are indicated when the pulse becomes feeble and weak. In attacks of syncope quickly-acting stimulants like Hoffman's anodyne are demanded. Digitalis aids materially in maintaining the integrity of the heart-muscle, and in most cases is a drug of much value. Occasionally, when there are extensive adhesions, it causes palpitation and increased irregularity, and must be discontinued.

Locally, poultices or large hot anodyne applications are preferable to the ice-water coil. Blisters should never be employed. Absorption is sometimes hastened by mercurial ointment applied upon flannel over the præcordia.

Nutrition should be maintained at the highest possible point, but overloading of the stomach must be carefully guarded against. After the acute stages tonics are usually indicated, for pericarditis is eminently a disease of the weak, anæmic, and feeble. Absolute rest cannot be too strongly insisted upon. Care in this direction should not be relaxed while the slightest evidence of impaired cardiac action remains. In no other condition is weakening of the heart-muscle so common. Weeks, or even months, must sometimes elapse before active exercise can be safely permitted.

When the amount of fluid becomes so great as to seriously threaten life,

paracentesis is demanded. Death, however, very rarely results from pressure. Urgent symptoms are often transient, and disappear without mechanical interference. Much has been said regarding the harmlessness of the operation, but it is not without serious dangers. It should be resorted to, however, when the fluid is found to be purulent or so excessive in quantity as to endanger life. Dieulafoy's or Potain's aspirator should be employed with a Fitch needle, which has a protector to be pushed over the point after it is introduced, thus avoiding the danger of puncturing the heart-wall. The fluid should be completely removed. The fifth intercostal space, just to the left of the sternum, is the point usually advised as the seat of puncture. Rotch, however, proposes the fifth intercostal space of the right side as preferable, since it would here be impossible to puncture a dilated heart—an accident which might occur on the left side.

II. ACUTE ENDOCARDITIS.

Inflammation of the endocardium is a frequent disease of early life. During foetal life the right side of the heart is usually involved, after birth the left side. During childhood the serous membranes are especially sensitive, and there is a marked tendency in the connective tissue to cell-proliferation. Morbid changes are chiefly confined to the valves and chordæ tendineæ, but in some instances the whole endocardium is implicated. As a rule, the fibrous structure of the valves bears the brunt of the attack. The valves are simply folds of serous membrane bound together by fibrous tissue. Inflammation is attended by proliferation of cells within the endocardium, pushing it up into papillary elevations, and also by proliferation of the fibrous tissue itself. This latter change is the most characteristic and important process in endocardial inflammation. The whole valve becomes thickened and stiff, and the chordæ tendineæ are affected in a similar manner. Nodules are most numerous along the edges of the valves, where they form rows of reddish semi-translucent beads. As they lie directly in the blood-current, fibrin is gradually deposited, forming the so-called vegetations. They may become so large as to cause serious mechanical interference with valvular action, or portions may be detached and swept into the circulation. Even when these vegetations are quite numerous they may undergo resolution and disappear, but when marked hyperplasia of connective tissue has occurred, the almost inevitable result is contraction, with consequent puckering, thickening, and distortion of the valves, shortening of the chordæ, or narrowing of the valvular openings.

Etiology.—Sex cannot properly be called an etiological factor of endocarditis, although twice as many girls suffer from heart disease as boys. A boy who has rheumatism is as liable to a cardiac complication as a girl, but girls are more subject to rheumatism than boys. Of my own cases, 38 per cent. were boys, 62 per cent. girls, the preponderance of girls being greatest under eight years.

Age is a more important factor. Endocarditis occurs in infancy, and even in intra-uterine life, but it is rare under five years. It is probably more common during the three years between eight and eleven than at any other similar period of life.

Rheumatism is by far the most important exciting cause of endocardial inflammation, but in children that disease is so uncertain in its manifestations that it is readily overlooked. In the majority of cases it appears in a form which in the adult would be designated as subacute. But the mildest and most transient attacks are not infrequently accompanied by inflammation of

the endocardium, which would be overlooked without physical examination. No attack of joint-pain in a child is too mild to preclude the possibility of an accompanying endocarditis. I have seen it develop during the course of torticollis in a child of rheumatic parentage. Among 117 cases of cardiac disease, I found rheumatism, either antecedent, concurrent, or subsequent, in 82 per cent. A definite family history of rheumatism was obtained in 57 per cent., excluding grandparents. Attention has been directed to the importance of subcutaneous fibrous nodules in the diagnosis of rheumatism, and it is believed that similar nodules form at the same time on the cardiac valves. While they are strongly suggestive of endocarditis, they give no positive evidence of that condition. I have seen a profuse crop of nodules develop without the slightest evidence of cardiac disturbance.

While the intimate association of chorea and heart disease is well known, the exact etiological relationship is still uncertain. Occasionally endocarditis developing during a choreic attack disappears as the chorea subsides; more commonly it leaves a permanent lesion. In the great majority of cases the murmur is not functional, but organic, and is due to well-defined pathological changes in the valves. Thirty per cent. of my cases of cardiac disease suffered at some period of their lives from chorea, but 24 per cent. gave also a clear history of rheumatism. Although in the remaining cases no positive history of rheumatism could be obtained, there is ground for belief that the endocarditis of chorea is, in fact, rheumatic.

Scarlet fever is occasionally complicated by endocarditis. In rare instances it appears early in the disease, but more commonly develops during the stage of desquamation. It usually appears in patients showing evidence of nephritis, and is probably due more to uræmia than to the poison of scarlatina. Diphtheria, measles, erysipelas, and septicæmia are occasionally complicated by inflammation of the endocardium.

Symptoms.—Endocarditis is a very obscure disease. The symptoms are few in number and occur in no fixed order. They may be wholly wanting, and the disease may run its course without presenting any appreciable symptom. The symptoms of the acute disorder during which it develops often mask or wholly obscure those of the cardiac complication. When accompanying a rheumatic attack there is frequently an increase in temperature, or slight fever appears if none has previously been present. The child seems more ill than the arthritis would account for. There may be a peculiar restless, anxious expression, with a tendency to cyanosis. The heart's action is disturbed and the pulse becomes very rapid. The symptoms depend largely upon the amount of myocarditis present. If the muscular tissue is much involved, palpitation, præcordial distress, cyanosis, and dyspnœa will be marked. In milder and more common cases none of these symptoms are present to draw attention to the heart. Anæmia is a very constant accompaniment of endocardial inflammation, and develops rapidly. The appearance of subcutaneous fibrous nodules should always lead to a physical examination of the heart.

The tendency to recurrence is a marked feature of endocarditis. An endocardium that has once been inflamed is far more sensitive thereafter to irritating blood-conditions. Fresh attacks are readily lighted up by slight causes.

The occurrence of an embolism first directs attention to the heart in some cases. The spleen is the organ most frequently affected. The most distinctive symptoms result from embolism of the brain, the middle cerebral artery of the left side being commonly the seat of lesion, with resulting hemiplegia and aphasia. Embolic pneumonia occurs in the child as in the adult.

Physical Signs.—The signs obtained by physical examination are the

only means of positive diagnosis. An endocarditis may, in rare instances, be present for several days, or even run its course, without developing a murmur. Occasionally abnormal sounds, as roughness, muffling, or prolongation of the first sound, precede an actual murmur. In most cases the murmur is heard only at the apex. It is systolic, soft, and blowing, differing from the ordinary mitral regurgitant in its limited area of conduction. It is more intense at the apex, but it is not transmitted far to the right, and is rarely audible behind. It usually appears early in an attack of rheumatism, and is organic. It sometimes disappears, leaving no valvular lesion. A similar murmur occasionally appears late in the course of typhoid fever, and is probably due to muscular insufficiency the result of anæmia or myocarditis. The murmur of scarlatina, chorea, and rheumatism is usually entirely different in character.

Other sounds are heard at the apex much more frequently in children than in adults. Of these reduplication of the second sound is most important. Reduplication of the second sound at the base is frequently heard in Bright's disease of the adult, but as heard at the apex in children it is probably due to asynchronous action of the mitral and tricuspid valves, the result of stiffening of the mitral. It is almost a certain forerunner of a mitral obstructive murmur. Sometimes a soft blowing murmur is heard immediately after the second portion of the double sound. This gradually increases in length and intensity, and develops the well-known rumbling murmur of mitral stenosis. In very rare instances an aortic murmur develops early in endocardial inflammation, either alone or in connection with a mitral murmur. The same is also true of tricuspid regurgitation.

When acute endocarditis is engrafted upon an old valvular lesion, its diagnosis is especially difficult. If the patient has been under observation and the character of the murmurs is known, diagnosis is easy. Marked enlargement of the heart is strong proof of an old lesion. Extreme subjective symptoms of cardiac disease, especially œdema, are rarely seen in primary endocarditis, but in chronic heart disease the symptoms are all aggravated by a fresh endocardial attack. The character of the murmur may furnish some aid in diagnosis, but cannot be relied upon. A soft blowing murmur is usually recent; if harsh, musical, or rough, it is probably old.

Prognosis.—As endocarditis is not an idiopathic disease, the prognosis depends largely upon the condition with which it is associated. A first attack is rarely the direct cause of death. It is extremely variable in its course. It may pass away, leaving no lesion or murmur, but more frequently a valvular lesion is left behind. If the pulse becomes feeble, and the child loses strength and grows rapidly anæmic, the prognosis is bad. It is bad if recurring attacks of rheumatism appear or if fibrous nodules recur in successive crops. Endocarditis appearing during the course of a septic disease is usually ulcerative in character, and the prognosis is extremely unfavorable. Early involvement of the aortic valves is also unfavorable. It is not wise to give a too favorable prognosis at first, especially as to duration, for exposure or lack of rest will materially prolong an attack. Duration is more uncertain in children than in adults. Loudness of the murmur is of but little importance, but the greater the number of murmurs the more serious is the condition. The murmur appearing during chorea occasionally disappears as the choreic movements subside. This is sometimes apparent rather than real. After a time a murmur which has almost disappeared may return and continue permanently—a result that is probably due to the lighting up of a fresh valvulitis, consequent upon the occurrence of a mild rheumatic or choreic attack. On the whole, the ultimate prognosis is rather better in children than in adults. Tissue-growth is so

rapid and compensation becomes so complete that an endocarditis of not excessive severity may produce but little permanent injury.

Treatment.—The constitutional disease with which endocarditis is associated should receive prompt attention. In the treatment of rheumatism it is not sufficient to direct our efforts simply to the control of the arthritis and relief of pain. The possibility of endocarditis must also be considered. The ideal treatment is that which controls the arthritis, reduces fever, relieves the pain, and, above all, prevents cardiac complications. In my experience the ordinary treatment with salicylate of sodium has not fulfilled these requirements, for it has not perceptibly removed the danger of endocardial inflammation. A patient fully under the influence of the salicylate will not infrequently develop a cardiac murmur—an accident which occurs much less frequently under the alkaline treatment. In view of the great susceptibility of the endocardium in childhood a judicious combination of the salicylates and alkalies offers the safest and most efficient treatment. If endocarditis develops, the salicylate should be dropped or administered with the utmost caution.

Treatment for the purpose of affecting the endocardium directly is of but little avail, yet much may be accomplished by drugs. It is important that the rapidity and irritability of the heart be lessened, and that a condition of cardiac rest be attained as far as possible. Aconite lessens the rapidity, but it also weakens the force, and with children is an unsafe drug. Digitalis must be used cautiously. In acute endocarditis developing in an old cardiac case it is often of supreme value. When the heart's action is tumultuous, but rapid and weak, it may be given with the most satisfactory results, as it reduces the frequency, increases the force, and corrects the irregularity. A child of six years may take four drops of the tincture every four hours for one or two days, when the dose should be diminished. Opium is also of great value in rheumatic endocarditis. It not only relieves the articular pain, thus rendering general bodily quiet possible, but it has a most happy effect in steadying and quieting an irritable, irregular, and rapid heart. Two minims or more of the deodorized tincture may be given every four to six hours at six years. When pericarditis is also present opium is the sheet-anchor. Stimulants should be avoided until definitely indicated. When dilatation is marked they are demanded, and must be administered freely. When the fever has abated a tonic is indicated, for anæmia appears early, and is frequently persistent and extreme. Citrate of iron and quinine is admirably adapted to these cases, and may be given in doses of three to four grains three times a day. The bitter wine of iron is also an excellent preparation. One or two drops of Fowler's solution may be added, but full doses of arsenic are inadvisable. When the fever ranges high during the acute stages, quinine may be given in moderate doses, but antipyrine and acetanilide are too depressing to be employed with safety. Phenacetin is, perhaps, admissible. Administered in small doses it is an excellent analgesic.

Absolute rest and protection of the surface from cold and dampness are of far more importance than medicinal treatment. Without these precautions treatment is of little avail in preventing permanent valvular lesions. The child should wear a flannel jacket or night-dress, and be placed between flannel blankets instead of the usual sheets. Even in mild cases of acute endocarditis strict rest should be enjoined and insisted upon long after every rheumatic and cardiac symptom has disappeared. If a permanent murmur results, it is often difficult to determine when it is safe for the child to leave the bed and resume play, but it is wise to err on the side of caution. This enforced rest is, perhaps, the most difficult of accomplishment of any measure in the treatment

of children, particularly in families where discipline is lax. It can be obtained with almost any child with determination and patience, and when the importance is so great these qualities should certainly not be lacking.

Local applications, while less efficacious than in pericarditis, are of considerable value. Poultices sometimes give marked relief from præcordial distress, but caution must be exercised to prevent chilling of the surface. The application of a weak chloroform liniment upon flannel held in position by a flannel band is safer and accomplishes fully as much. The chest should always be closely protected with flannel.

III. CHRONIC HEART DISEASE.

Chronic valvular disease is the sequel of acute endocarditis. The lesions in childhood do not differ materially from those of the adult. Thickening and distortion of the valves are the changes most frequently observed, but vegetations occasionally appear. They are most common on the auricular surface of the mitral valve. Adherent pericardium, the result of previous pericarditis, is very common, while hypertrophy of the cardiac wall is more frequent and extensive than in later life.

Etiology.—Acquired valvular lesions result from acute endocardial inflammation. The causes of such inflammation are considered in detail in their appropriate place.

Clinical History.—Cardiac disease presents three conditions or periods :

1. Period of acute inflammation.
2. Period of compensation.
3. Period of heart failure.

It must not be supposed that these conditions always follow each other in the order mentioned, or that the disease runs a course through three definite stages to a fatal termination. This may occur, but more frequently the first condition is several times repeated, and the third is often transformed into the second by rest and treatment. Compensation occurs with great rapidity and completeness in children. Failure of compensation never occurs without cause. The most frequent causes are anæmia and impaired general nutrition ; acute intercurrent diseases, particularly rheumatism with endocarditis ; and sudden heart-strain from excessive muscular exertion.

Symptoms.—When compensation is perfect there are no symptoms. It not infrequently happens, therefore, that a murmur is discovered when there is nothing whatever in the child's history or appearance to direct attention to the heart. Dyspnœa is by far the most frequent symptom, with palpitation but little less common. They are most marked when the aortic valves are involved, but dyspnœa on exertion is usually present with mitral stenosis. Pain as an urgent symptom is not common, and is more frequently associated with mitral stenosis than with any other cardiac lesion. Cyanosis and œdema are rare, and do not appear until other symptoms become urgent. Œdema rarely pursues a typical ascending course. Epistaxis is not uncommon. Persistent cough and subacute bronchitis are frequent accompaniments of mitral stenosis. The condition often observed in the adult, marked by dyspnœa so extreme as to prevent sleep, by tumultuous palpitation and extreme cardiac distress, cyanosis, and dropsy, is rarely seen under twelve years.

MITRAL REGURGITATION.—Imperfect closure at the mitral orifice is the most common cardiac defect during childhood. It usually results from pathological change in the valves, but may be due to dilatation of the ventricle causing a failure of coaptation of the edge of the valves. The murmur is systolic, is

heard with greatest intensity at the apex, and is conveyed to the left. Such a murmur developing during the course of a rheumatic endocarditis is organic and probably permanent. If developed under other conditions it may quickly disappear. The great relative frequency of this murmur is shown by the following table, compiled from my own history books:

Mitral regurgitation in 131 cases (94.7 per cent.), alone in 99 cases.					
Mitral obstruction	17	11.8	“	“	4
Aortic regurgitation	9	6.3	“	“	0
Aortic obstruction	28	20.1	“	“	3

MITRAL STENOSIS.—The frequency of the presystolic mitral murmur in childhood is comparatively great. In my cases it occurred in relation to mitral regurgitation as 1 to 7.71. Rheumatism was a factor in its production, but was less strongly marked than in either of the other murmurs, confirming the statement of Sanson that mitral stenosis is intimately associated with rheumatism, but most frequently with insidious varieties. Symptoms are somewhat more marked than in simple mitral regurgitation. Pain is more common than with any other lesion, and dyspnoea on exertion is the rule. Palpitation is also common, while bronchitis and cough are frequent and obstinate. The mitral obstructive murmur is very rare in infancy. I have never seen it under five years. It is slow in its appearance, never developing suddenly, as does the mitral regurgitant. The character of the abnormal sound is subject to change from time to time—more so than any other murmur. It may become very faint or even imperceptible, but it is very sure to return, and hopes based on its disappearance are almost certain to be disappointed. Frequently there is no perceptible cause for this changeability.

The mitral obstructive is probably more frequently overlooked than any other murmur, yet it is quite distinct and characteristic. It is, as a rule, harsh and of a rattling, blubbery character. It differs decidedly from other murmurs in one particular: instead of rising to a maximum, and then gradually decreasing or shading off into silence, it rises rapidly to a maximum, and suddenly ceases as the apex strikes the chest-wall. Its area of diffusion is limited. As the stethoscope is carried from the apex a point is quickly reached at which the murmur suddenly and completely ceases. If a regurgitant murmur is also present and the heart is acting rapidly, the two murmurs may run so closely together as to be with difficulty separated. In this case the first portion, or obstructive murmur, suddenly ceases at a given point, while the regurgitant remains unchanged. If the second sound is reduplicated at the apex, the certainty of mitral stenosis is increased. A thrill is by no means so common as in the adult. It is sometimes absent in well-marked cases, and is occasionally present when the murmur is faint and uncertain. The left auricle is dilated and hypertrophied in cases of long standing, and the right side of the heart is engorged and frequently dilated. Right-side enlargement, however, cannot always be determined by physical examination.

AORTIC STENOSIS.—Aortic murmurs are much more definitely associated with rheumatic histories than are the mitral, and indicate a more extensive endocarditis. An aortic obstructive murmur may permanently disappear. This has occurred in my own experience twice, two years being required in one case and over three years in the other. A change in character is not uncommon, a loud, harsh murmur becoming soft and blowing or even disappearing temporarily. While symptoms are in many cases obscure, they are, as a rule, somewhat more distinctive than when mitral regurgitation alone is present, it being remembered that a mitral murmur is almost invariably an accompaniment of the aortic. Dyspnoea is frequent, and with a double aortic

murmur dyspnoea and palpitation upon exertion are almost constant. Both symptoms are more continuous, and depend less upon exertion than in the case of mitral disease. Anæmia is very common; it is persistent and often extreme. Physical signs differ but little from those observed in the adult.

AORTIC REGURGITATION.—This is the most infrequent left-side valvular lesion. It rarely, if ever, occurs alone in childhood, and in but one instance have I heard a double aortic murmur without an accompanying mitral. The symptoms are somewhat more marked than those of simple aortic stenosis, for it appears only after extensive endocardial inflammation, and is an additional burden to an already disabled heart.

TRICUSPID REGURGITATION.—This condition is more frequently detected by the pathologist than by the clinician, because in the young it is extremely difficult of differentiation from mitral regurgitation. In early infancy a murmur heard with greatest intensity at or just to the right of the apex is presumably tricuspid. If the lesion is serious, right-side enlargement will be present, which may be detected by an area of dulness at the right of the sternum and by epigastric pulsation. When added to mitral and aortic disease the symptoms are distinctive. Visceral enlargements and dyspepsia are invariably present, but jugular pulsation is not constant. Palpitation, dyspnoea, cough, pain, cyanosis, and œdema develop to form the last stage of a fatal malady.

Prognosis.—The elements of prognosis are numerous and complicated. Murmurs alone usually furnish insufficient evidence upon which to base an opinion. The action of the heart, the condition of hypertrophy or dilatation, the completeness of compensation, and the general physical condition of the patient must all be taken into account. The social condition, surroundings, and mode of life are important factors and must be duly considered. Parental discipline is also an element of great importance. In a wayward and uncontrolled child the prognosis is decidedly worse than in one under firm and judicious discipline. On the whole, the prognosis may be said to be better in the child than in the adult.

The period from ten to fifteen years is a critical one. The remarkable increase in the volume of the heart at the time of puberty has already been referred to. A patient sometimes progresses satisfactorily till this age is reached, when the whole aspect of the case is changed. Compensation becomes imperfect, the child grows anæmic, and gives evidence of impaired nutrition. Development is retarded, though there may be growth in height, the child being thin and without strength or vigor. Sometimes he develops into a fairly healthy youth, but in other cases, going from bad to worse, finally succumbs. Fortunately, the majority of patients pass safely through this trying period, often without perceptible inconvenience. Such children, if a mitral regurgitation only is present, usually develop into healthy men and women and never show symptoms of cardiac disease.

The etiology aids somewhat in prognosis. The more distinctly rheumatic the patient, the worse the prognosis, for recurring attacks of endocarditis are to be feared. Failure of compensation resulting from an attack of rheumatism or scarlet fever is of far greater importance than that developing from muscular strain, anæmia, over-study, or nervous excitability. Among symptoms cyanosis and œdema are of the most serious import.

If mitral regurgitation alone is present and the child is strong and well-nourished, the probability of maintaining compensation is good, provided recurring attacks of endocarditis can be prevented. The prognosis turns almost entirely upon this last contingency, and this, in turn, depends in large measure upon the personal and family history as regards rheumatism. Hence

the history is a matter of decided importance in prognosis. Mitral stenosis is always a grave condition, but is somewhat less serious in young children than in adults, largely because the pulmonary arteries adapt themselves more readily to the abnormal strain placed upon them. Compensation sometimes becomes perfect, and remains so, but when the lesion is extreme, it does not admit of complete and permanent compensation. When pulmonary symptoms are marked the prognosis is especially bad. In aortic disease, if obstruction alone is present, without rheumatic history, the prognosis is very favorable. The murmur may entirely disappear. If, on the other hand, it is associated with a mitral murmur and a rheumatic history is obtained, the case is a grave one: the disease is the result of an extensive endocarditis, which will probably recur to cause more and more distortion of the valves. Aortic regurgitation is a far more serious condition than aortic stenosis, and when both murmurs accompany a mitral the prognosis must be very guarded. Tricuspid regurgitation is always a serious condition, and the prognosis is unfavorable.

Treatment.—The successful management of cardiac disease requires, on the part of the physician, a clear conception of its various stages and an understanding of the exact condition of his patient. If the compensation is perfect, there will be no symptoms of heart disease and nothing to treat. All that can be accomplished in any case not suffering from acute inflammation is to establish compensation. If that is already accomplished, it is the height of impropriety to treat the patient for heart disease. The error must not be made upon the other extreme, however, that the physician has no duty in the case. The child should be kept under observation, for the condition of compensation may be at any time changed to that of heart failure. Nutrition should be maintained at the highest possible point by diet and properly regulated outdoor exercise. The child should be especially guarded against exposure to the exanthematous diseases, and, above all else, should be protected from conditions which tend to precipitate an attack of rheumatism. If that disease does develop, it should receive prompt and vigorous treatment. Anæmia is a condition full of peril in heart disease, for when it is extreme compensation is not long maintained. It should be combated by iron, arsenic, cod-liver oil, the vegetable bitters, and a generous but simple and digestible diet. The question of exercise is one of the greatest importance. Violent games may do irreparable harm, while, on the other hand, if the child be debarred from reasonable outdoor exercise, heart failure may develop from anæmia and impaired general nutrition. Quiet games and plays are to be definitely prescribed, with the strictest injunction against football, baseball, and all games requiring violent muscular exertion and running. The clothing should also receive the physician's attention, flannels being prescribed for both summer and winter.

If failure of compensation appears, absolute rest should be rigidly enforced. The cause should be sought and removed if possible. The appetite usually disappears utterly, and the stomach becomes irritable and enforced alimentation is necessary. If the stomach rejects milk and lime-water, animal broths, or koumyss, it may retain milk peptonized for two hours, to which a little lemon-juice may be added. If this is rejected, nutritive enemata of completely peptonized milk must be given every four to six hours. Medical treatment will prove of little avail if the child is permitted to lose strength from lack of nourishment.

Among drugs digitalis still holds its position as first and most important, but it must be employed judiciously. Much harm may result from lack of judgment and nice discrimination in the use of the cardiac stimulants and sedatives. By increasing the force of the systole, prolonging the diastole, and contracting

relaxed arterioles digitalis restores the balance of the circulation when deranged by valvular lesions or weakness of the heart-muscle; in other words, it re-establishes compensation. Its use is indicated when the heart's action is rapid, feeble, and irregular and the pulse shows low arterial tension. Rational symptoms offer more reliable indications for its use than do the physical signs, but both should be duly considered. Dyspnoea, cough, cyanosis, œdema, and scanty urine are indicative of failing heart-power, and call for a cardiac stimulant. Mitral regurgitation is the valvular lesion for which digitalis proves most generally useful. With mitral stenosis irregular heart action is sometimes aggravated by its use. In that case convallaria may prove efficient. When an aortic murmur is present digitalis is not so frequently efficacious as in mitral disease alone. If compensation is good, its use may cause alarming symptoms, and in any case it should be prescribed cautiously at first. Iron, strychnine, and the alkalies are, as a rule, more efficacious. In tricuspid regurgitation digitalis must be used with extreme caution. The tincture is the preparation most commonly employed, the dose varying according to the age and cardiac condition from one to five or six minims. It is often very badly tolerated by the stomach. The solid preparations cause far less gastric disturbance, and may be usually continued for weeks without trouble. The dose of the powdered leaves is from one-fourth grain to one-half grain, and of the extract one-fourth of these amounts.

In case of great restlessness on the part of the child, with palpitation and cardiac distress, a sedative may be required. Bromide of sodium should be first tried in doses of three to ten grains every six hours. If this be unavailing, opium may be cautiously administered, paregoric being selected for younger children, and the deodorized tincture for those of more advanced years. Excessive palpitation, with dyspnoea appearing in paroxysms, is often quickly relieved by a few drops of compound spirits of ether combined with a small dose of opium.

If the urine becomes scanty and œdema appears, a hot digitalis poultice should be applied across the loins. This is made by boiling two ounces of digitalis leaves in a pint of water, and then stirring in sufficient linseed meal. Digitalis should be administered freely, and in this condition the infusion is most effectual. At the same time the bowels should be freely acted upon by calomel. The compound diuretic pill for children who can swallow it often relieves the symptoms with marvellous rapidity. It consists of equal parts of calomel, digitalis, and squill; one-third to one-half grain of each may be given at twelve years. For younger children the tincture of digitalis and tincture of squill may be combined with spirit of nitrous ether or citrate of potassium.

THE FUNCTIONAL AFFECTIONS OF THE HEART (THE CARDIAC NEUROSES).

BY J. C. WILSON, M. D.,

PHILADELPHIA.

THE functional affections of the heart include those motor and sensory derangements which occur in the absence of demonstrable anatomical changes in the organ.

The qualifying adjective "functional" is used in its ordinary sense, to denote the absence of anatomical lesions demonstrable during life or after death. It is appropriately employed in this connection to designate disorders not primarily of the heart itself, but rather of its innervation. Hence these affections are also properly spoken of as cardiac neuroses.

It is important to note that all the morbid phenomena observed in functional disorders may and frequently do attend the structural diseases of the heart.

The functional affections of the heart which occur in childhood are—

A. MOTOR :

1. Derangements of rhythm.

a. Arrhythmia.

b. Rapid heart—tachycardia.

c. Slow heart—bradycardia (brachycardia).

2. Momentary arrest—syncope.

B. SENSORY :

Subjective sensations referred to the præcordia.

a. Heart-consciousness.

b. Distress.

c. Pain.

C. MOTOR AND SENSORY COMBINED :

Palpitation.

Etiology.—The influences which predispose to affections of the heart are the same in childhood as in adult life. They consist in (*a*) a weak and delicate organization associated with an impressionable nervous system; (*b*) anæmic conditions; (*c*) lithæmia and allied derangements of metabolism and excretion; and (*d*) morbid conditions directly affecting the nervous system, as organic diseases of the brain and cord, chorea, epilepsy, and the acute and chronic infections. To this list must be added adenoid hypertrophies of the pharyngeal vault.

Certain of these conditions are inherited, others acquired. Thus the children of nervous or insane parents, those begotten of elderly persons, those born prematurely, those who have in infancy been exposed to privation and neglect, or who have suffered from serious or protracted disease, are especially prone to functional disturbances of the heart. To a less extent is this true of the

children of gouty families and of the offspring of tuberculous and syphilitic parents. The tendency to functional cardiac trouble, rarely observed in early infancy, usually shows itself at the approach of the seventh or eighth year.

The exciting causes include (A) those acting upon the nervous system; (a) directly, as intense mental emotion, fever, anger, passionate grief; or (b) reflexly, as dentition, gastro-intestinal irritation from indigestion, intestinal worms, foreign bodies in the intestinal canal; and (B) those acting, by means of mechanical disturbance of the circulation, upon the heart, as violent exercise or exertion, especially after meals.

Functional derangements of the heart are much less frequent in childhood than in adult life, for the reason that the Pandora's box of vicious habits, the brunt of which the heart must sooner or later bear, is only opened by degrees, and, happily, not often early in life.

Symptoms.—In general terms the symptoms of the functional disorders of the heart in childhood, as in adults, consist in derangement of the motor functions and abnormal sensations referred to the præcordia. These motor and sensory derangements are not always associated. More commonly the movement of the heart is deranged, its action being accelerated, retarded, or irregular, without abnormal sensations; occasionally deranged rhythm of frequency occurs in connection with præcordial distress or pain or a sense of oppression, and in comparatively rare instances præcordial pain occurs in the absence of perturbation of the movements. Angina pectoris is not a disease of childhood, nor is it common to encounter the agonizing pains of pseudo-angina early in life.

When the functional disorder is paroxysmal or of a high grade of intensity, it is usually accompanied by increased frequency and shallowness of respiration, and very often by pallor of the face and slight cyanosis. Especially is pallor associated with the temporary arrest of the heart's action known as fainting, a condition also usually preceded by momentary nausea.

The child, ignorant alike of the existence of his heart and of its functions, uncomfortable as he may be in other respects, escapes the anxiety and mental distress which in the adult forms so important an element in the paroxysmal functional affections of this organ.

When the derangement is not paroxysmal, but persistent, the rhythm of the respiration is not usually disturbed.

It is to be borne in mind that in childhood both the respiration and the action of the heart are normally far less constant in rhythm than in adults, that they are more readily deranged by slight causes, and that the action of the heart is often irregular during sleep and much influenced by inspiration and expiration. The *pulsus paradoxus*, in which the heart-beats during inspiration are more frequent, but less full, than during expiration, may often be observed in perfectly healthy children during sleep.

Physical examination yields a limited number of definite signs. The frequency of the heart's action and the degree and character of the arrhythmia are recognized upon palpation. By this method of examination we also detect, especially on palpation, the change in the character of the impulse, which is increased in force. We observe also by this means and by inspection that the impulse is extended. We determine by the position of the apex-beat, and may confirm by percussion, the observation that the heart is not enlarged. Upon auscultation the first sound is found to be sharp and valvular and shortened in duration, while the second sound remains distinct or is accentuated. In very rapidly-acting or very irregular hearts transient murmurs, usually mitral systolic, sometimes develop.

ARRHYTHMIA.—The various forms of arrhythmia are encountered in the functional cardiac affections of childhood. The paradoxical pulse, as has been mentioned, is frequently observed in healthy children during sleep. When encountered during the waking hours it is more frequently a manifestation of organic than functional derangement of the heart.

The rhythm of the foetal heart, embryocardia, a condition in which the acoustic properties of the two sounds are almost identical and the pauses nearly equal in duration, frequently occurs when the heart's action is rapid. Other forms of arrhythmia, as the alternate heart-beat in which strong and weak contractions occur with regular alternation, the bigeminal and trigeminal pulsation in which the ventricular contractions occur in series of two or three separated by an interval or by feebler contraction, the gallop rhythm and dicrotism, are rarely observed. The disturbances of rhythm in which with rapid action there is irregularity, not conforming to definite type, are the most common. This condition in its more marked degrees has been described under the term *delirium cordis*. With less rapidity of action there may be recognized, upon physical examination, short series of three or four forcible heart contractions followed by great irregularity and feebleness of action, this succession being irregularly repeated. True intermission or the missing of a cardiac beat—"heart dropping," as it is frequently called, a condition common in adult life—has not come under my observation in childhood.

RAPID HEART (*Tachycardia*).—The action of the heart, normally 130 to 140 per minute in the new-born, gradually decreases in frequency until the end of the third year, when it ranges about 90. It is readily accelerated by slight causes. Great increase in the rapidity of the heart's action is encountered in fevers. Rapidity of the heart is also induced by violent emotion and undue exercise. The rapid action thus induced may sometimes persist for hours or days. The paroxysmal tachycardia occasionally encountered in adults does not occur in children.

SLOW HEART (*Bradycardia, Brachycardia*).—This condition is not common in childhood. Slowness of the pulse, the rate falling to 60 or somewhat below it, is, however, occasionally encountered during convalescence from the acute infectious diseases, in acute rheumatism, in disorders of the digestive system, in jaundice, and in anæmia. Slowness of the heart's action has been observed in post-epileptic coma.

SYNCOPE occasionally occurs in nervous and impressionable children. It may result from sudden shock or intense excitement. On several occasions I have known children of six or seven years of age to faint at the sight of blood. I have seen a boy of seven faint at the sight of the denuded spot upon his arm caused by vaccination. A healthy girl eight years old, of shy and timid disposition, fainted at the dinner-table upon being suddenly addressed by a person whom she did not know. For some hours she remained quiet upon the sofa, the pulse-rate not exceeding 60. Actual loss of blood, even when slight, profuse diarrhœa, extreme fatigue, and severe pain are capable of producing syncope in impressionable children.

HEART CONSCIOUSNESS is fortunately extremely rare in children. The most tumultuous action of the heart may take place apparently without subjective sensations. It occasionally happens, however, that older children complain of the beating of the heart without pain under conditions of excitement or fatigue and in the absence of over-action amounting to palpitation.

PRÆCORDIAL DISTRESS is occasionally encountered. It is usually reflex in character and caused by gastro-intestinal irritation. As a rule it is transient.

PRÆCORDIAL PAIN is rare. A remarkable instance of distressing præcordial

pain in a lad has come under my notice. The patient was the feebler one of twins, and suffered in various ways from the reflex nervous disturbances due to adenoid vegetations in the pharyngeal vault. Among these were attacks of pain in the region of the heart, unaccompanied by disturbances of rhythm or over-action, and occurring in paroxysms repeated on several successive days.

PALPITATION may be defined as over-action of the heart with abnormal præcordial sensations. These sensations are always distressing and very frequently amount to actual pain. Palpitation is attended by increased rapidity of respiration and a sense of oppression. It is among the more common of the functional heart affections of childhood, usually induced by over-exertion or violent emotions, and sometimes occurring without recognizable cause. The condition of convalescence from acute disease, debility, anæmia, and lithæmia are predisposing influences.

Course.—The course of the functional affections of the heart in childhood is in the main transient. If recurrences take place, they gradually cease as the general health improves. This is especially true of the attacks which occur as the result of reflex gastro-intestinal derangements, of anæmia, or during the convalescence from acute disease. The attacks which are met with in constitutionally feeble children, in those who are lithæmic or who have habitually an abundance of calcium-oxalate crystals in the urine, yield less readily and more slowly to treatment. The mere "impressionable heart" is likely to be functionally deranged by slight causes throughout life. It is not, however, incompatible with fairly good general health and a reasonable expectancy of life.

Diagnosis.—The diagnosis rests upon the presence of the symptoms and signs which have been described, in association with the constitutional or local conditions in which functional derangements of the heart are known to occur, or the history of a direct exciting cause. The absence of the physical signs of organic heart disease, and of the rational symptoms of transference of blood-pressure from the arterial to the venous side of the circulation, must further be established.

Prognosis.—The prognosis is as a rule favorable, both as regards the separate attack and the ultimate recovery. I have not seen organic disease of the heart develop as a sequence of either frequently-recurring or long-continued functional disorder.

Treatment.—In the paroxysmal forms the treatment must be directed to the immediate condition. The child must be placed at rest in the recumbent or sitting posture, the clothing loosened, every effort made to allay fear and calm excitement. The face and hands should be bathed, and by degrees the attention diverted. If necessary, ammonia may be inhaled or a few drops of the aromatic spirit of ammonia in water administered.

In the case of syncope the recumbent posture should be maintained for some time and a current of air admitted. The face may be sprinkled with cold water, and the venous circulation in the limbs favored by centripetal frictions.

Efforts should be made to correct those conditions which act as predisposing influences. Attention to hygiene is of the first importance. Systematic feeding and a diet at once nutritious, easy of digestion, and abundant, are imperative. Fresh milk, eggs, broiled and roasted meats, bread-crusts, fresh vegetables and fruits, selected and regulated according to the age of the child, constitute the dietary. Quality is of supreme moment; variety is not necessary. A spoonful of preserves or jam occasionally should be regarded as a treat. The breakfast should be taken early, the dinner at midday, supper at five or six o'clock, and bed-time should not be later than eight. The bath should be given in the morning, cold or at most only tepid, and followed by

brisk towelling till the skin glows. By day and night the clothing must be warm, light, and loose. Exercise in the open air should be systematic and regular. Even in changeable climates delicate children, when properly clad, may go out to walk, except in extremely cold weather or in actual storms, almost every day—not only without injury, but even with positive gain.

Anæmic conditions require prompt and careful attention. Among the drugs most useful in their management are alcohol, cod-liver oil—which, in well-made emulsion, children take very well—syrup of iron iodide, and the various preparations of mercury and of arsenic in minute doses.

Lithæmia, whether inherited or acquired, demands very careful study and management. Here a milk diet is especially useful, and an occasional laxative. Where the fault lies with the nervous system, long hours of rest, especially rest in the middle of the day, and the bromides, are of advantage. Adenoid vegetations of the pharyngeal vault must, when discovered, be forthwith removed.

Wholesome moral influences and discipline at once gentle, affectionate, and firm are of untold value in the care of delicately organized and impressionable children. Those who have the care of the young ought to possess in a high degree that rare greatness which shows itself in the ruling of one's own spirit—said to be beyond that which enables one to take cities.

If disturbances of the cardiac function occur during dentition, the stomatitis which often arises must be promptly treated, and if the gum over a presenting tooth be tense, livid, and tender, it may be freely incised.

Derangements of digestion are best managed by withholding ordinary food for a time, giving small amounts of milk and lime-water, a calomel purge, and the subsequent administration of an efficient pepsin.

If intestinal worms be present, they are to be expelled by appropriate treatment.

The functional derangements of the heart which occur in acute disease and during convalescence disappear with returning health, and as a rule demand no especial treatment.

It remains to speak of the group of drugs familiarly known as heart tonics. They are rarely indicated, often used with no good effect. What the heart most needs for its best nutrition, both in childhood and afterward, is well-oxygenated, healthy blood and moderate and fairly regulated work; and these constitute the greatest need also of the nervous system, which controls and regulates the heart.

Digitalis, *nux vomica*, and *belladonna* are often required. They must, however, be given only in response to clear indications. Their employment in short courses under proper circumstances is highly beneficial; as a matter of routine they are not only generally useless, but also often hurtful.

PART X.

DISEASES OF THE GENITO-URINARY SYSTEM.

HÆMATURIA, PYURIA, CHYLURIA, ANURIA, AND INCONTINENCE OF URINE.

BY E. M. BUCKINGHAM, M. D.,

BOSTON.

HÆMATURIA.

BLOOD reaches the urine from any part of the urinary passages. Its quantity varies within the widest limits, and the color of the urine containing it ranges from bright red to smoky red, dark greenish-brown, or almost black. The longer it remains in contact with urine, and the more thoroughly mixed with it, the darker it becomes, especially if it be in small quantity. A very large hæmorrhage is more likely to be from the bladder, and a small one from the kidney. It has therefore been assumed that the presence of bright blood shows a vesical, and of dark blood a renal, hæmorrhage. This is not necessarily true, for in individual cases large hæmorrhages have been seen by means of the electric light to issue from the ureters, and small ones may certainly come from the bladder. If blood is fresh and in sufficient quantity to render the urine alkaline, it may settle to the bottom of the containing vessel, leaving a clear upper layer of urine. Clots occur only when the blood is in tolerably large quantities, and especially when not thoroughly mixed with urine. They may be large enough to cause pain from consequent retention, and they may decompose and give rise to cystitis. By their shape they sometimes give evidence of their place of origin, but moulds of the ureters may resemble those formed in the prostate. It is possible for urine to be discolored like that of hæmaturia without containing blood. Icteric urine has this appearance if sufficiently charged with bile, and red stains of uric acid upon the diapers are occasionally taken for blood. In hæmoglobinuria no red corpuscles are present, but the urine is nevertheless stained with blood-pigment. When urine contains any appreciable amount of blood, it also contains albumin in appreciable quantity. Blood-cells are probably found by the microscope, but they become swollen and disintegrated in very dilute or ammoniacal urine.

If the blood has its source in the urethra, its appearance is usually confined to the beginning of micturition. The cause may be traumatism, including the passage of small ragged calculi. There is a case on record of hæmaturia in a child from urethritis depending upon decomposition of urine the result of malposition of the meatus, and entirely and quickly relieved by operation. Blood from prostatitis—rare in children—precedes the urine if the seat of inflammation be in the anterior part of the gland, or it flows backward into the bladder

and mixes with urine if it comes from the posterior part. Generally the last few drops contain most of the blood. In either case micturition is frequent and painful, and is generally followed by tenesmus. Rupture of a vessel at the neck of the bladder might cause similar symptoms. If pain and frequent micturition are both absent, this region can with tolerable certainty be excluded as the source of hæmorrhage. If cystitis or pyelitis causes hæmaturia, the urine contains pus. The pain of cystitis is more likely by far to be referred to the bladder, and that of pyelitis to the back, but this distinction is not absolutely diagnostic. Both conditions are rare in childhood, but either may be excited by calculus, tubercle, or acute disease.

Calculi in any part of the urinary tract may occasion hæmaturia, and renal calculi may do this without causing other symptoms. Vesical calculi are not uncommon in children, but do not, as a rule, give rise to much bleeding. This is more likely to come from a calculus impacted in the ureter, in which case there is probably severe pain.

The symptoms of tubercular bladder resemble those of cystitis. In making this diagnosis one should eliminate the more common causes of bleeding, and examine elsewhere for tuberculosis, which is seldom if ever primary in the urinary organs. Bacilli in the urine would help the diagnosis, but they are stated by Osler to be scanty in pyelitis; and this would be expected where the tubercular surface is constantly washed with urine. Therefore, their absence would not exclude this disease.

Prolonged bleeding with intermissions very probably comes from one kidney or its pelvis, intermissions being due to plugging of the ureter. Exacerbations of pain during intermissions increase this probability. Chill or vomiting may accompany them. Generally, however, hæmorrhage starting above the bladder is not painful.

Blood from the kidney generally contains enough renal casts and epithelium to suggest its source, but one should inquire further. Bloody urine is a symptom of acute nephritis. There is generally the history of an exciting cause, and often much œdema. The urine not only contains blood, but is at first scanty and of high specific gravity, with albumin and numerous renal casts. Hyperæmia, not amounting to nephritis, also causes bleeding. The difference is one of degree. Passive hyperæmia from a weak heart may produce it. It may occur in the course of chronic parenchymatous and of interstitial nephritis, especially toward the close, but is by no means universal in them as in acute nephritis, nor are these diseases so common in childhood. Some drugs cause hyperæmia or nephritis, and therefore hæmaturia. Among them are turpentine, cantharides, potassium chlorate, carbolic acid, and amyl nitrite. Rhubarb is said to invariably cause it in certain persons.

Neoplasms occasionally cause hæmaturia, but less frequently in children, because carcinoma, which often bleeds, is rare with them, while sarcoma, which is more common, bleeds less. Villous growths in the bladder give rise to serious hæmorrhage. If in the prostatic region, there may be pain at the end of micturition, owing to the tumor being squeezed by the empty bladder. Berkeley Hill writes that we may infer that blood comes from a villous growth if bleeding is profuse at first and painless, and lasts from a few days to a week or more. It stops as suddenly as it begins, and is uninfluenced by rest or exercise. Fragments are occasionally washed out in the urine. Such growths have been removed by the écraseur, but bleeding often stops of itself. Harrison reports the removal of a small fibroid from the bladder of a boy of seventeen, giving complete relief to a hæmorrhage which recurred at intervals of two weeks. There was severe pain in the penis.

Certain parasites occasion hæmaturia. The rhabditis genitalis, as described by Scheiber, was found by A. Baginsky in the urine of a child three and a half years old with hæmoglobinuria, and by Peiper and Westphal in the urine of a feeble child of nine, who had had scarlatinal nephritis four years before. In the latter patient, pleuritis occurred in October, and in November severe hæmaturia, followed by negative urine; then for a short time there was much blood and pus in the urine. A month later a less severe hæmorrhage occurred, at the beginning of which the amount of urine was temporarily lessened. In two days the microscope detected worms, hardly half as large as trichinæ, which on comparison appeared to be the Scheiber worms. Many were found, but all were dead. None were detected in the blood, stools, or preputial secretion. Soon hæmaturia ceased, but slight albuminuria lasted six weeks, when more, but degenerated, worms were passed. Albuminuria then ceased. Meanwhile, marked improvement in enuresis of two years' standing occurred. The authors are cautious about assuming relation between these worms and this symptom.

Berkeley Hill mentions the filaria sanguinis hominis as causing hæmaturia: this sometimes occurs in chyluria, believed to be generally due to this parasite.

The Bilharzia hæmatobia, first described by Bilharz of Cairo, is found in streams in Africa from the Mediterranean to the Cape of Good Hope. The mature worm is too small to be seen by the unaided eye. Eggs have been found in various parts of the body. The view of Bilharz, that it is swallowed in unfiltered drinking-water, is commonly accepted. Allen of Pietermaritzburg, South Africa, reasons from its greater frequency in boys, who bathe in rivers, and from the urethra being a favorite residence for it, that it may also enter by the meatus. He states that he can sometimes feel a colony in the upper urethra by means of a metallic catheter, and reports relief from urethral injections. Hæmorrhage occasionally causes retention from clots, and may be serious from prolonged oozing, but patients may recover after years of suffering. Davis reports that the use of kamala appeared to limit the number of embryos passed.

Malarial hæmaturia is found in many parts of the world. In the United States it is confined to severe cases, and generally to highly malarial regions. It is not uncommon in the South, but seems less frequent in cities than in the country, which apparently emphasizes the need of a high degree of malarial poisoning to produce it. Cases are reported in children as young as four years; these were of a distinct adult type, marked with severe chills and fever, rather than of the partly masked form. Castle states that malarial hæmaturia is not invariably accompanied by chill. Some cases are remittent and some pernicious. The presence of blood-pigment may be continuous, or the urine may become entirely clear between paroxysms. It may contain many blood-corpuscles or only a few with much hæmoglobin, or blood-corpuscles may be entirely absent, although the urine is colored with blood-pigment. Day states that the urine of comparatively mild cases is more likely to contain red corpuscles than that of severe ones. It has been urged that they are present at first and decompose, but there is reason to believe that they become altered in the vessels, allowing the escape of free hæmoglobin. Various theories have been advanced to account for malarial hæmoglobinuria: (a) the action of bile on the blood while still in the vessels, supported by the fact that injection of bile or bile acids into the blood has produced bloody urine; (b) the general disturbance of the spleen and liver, organs which have a part in the formation and destruction of red cells; (c) the effect of external cold on the stagnant blood of the extremities during paroxysms; (d) the direct destructive action of the

plasmodium malariae upon the red cells. Malarial hæmoglobinuria is more or less combined with real hæmorrhage, therefore the name hæmaturia is probably the better one. It is a grave condition at best, and is probably often fatal despite every method of treatment.

Some writers of the Southern States assert that malarial hæmaturia is not due directly to malaria, but to quinine. This causes congestion in other organs, and, considering the enormous doses used in the South,¹ it possibly sometimes excites nephritis; but there is a malarial hæmaturia not due to quinine. Hæmaturia sometimes precedes any treatment. Owen has suddenly put a stop to it, together with other malarial symptoms, by the subcutaneous injection of quinine, and a series of 286 cases collected by Howell shows that those treated with quinine and calomel made the best recoveries.

There is a considerable English literature relating to cases of paroxysmal hæmaturia, in which evidence of malaria is absent or so slight as to cause doubt if it be a factor in the etiology. Herringham reports the cases of two sisters of four and a half and three and a half years; and four other cases of his were under five. These sisters were observed from November to May during several attacks. They were at first coincident with exposure to cold, but one occurred while the child was kept in bed. There was generally no albuminuria, except a trace before some paroxysms, showing that it was mostly hæmoglobin rather than blood that entered the urine. It was reported that both children had been syphilitic, and he states that Muri of Bologna believes paroxysmal hæmaturia to be syphilitic. Berkeley Hill also states that hereditary syphilis gives rise to this symptom. Verco reports the case of a man who could produce hæmaturia whenever he pleased by merely going into the cold. It was accompanied by chill and a temperature of from 101° to 103° F. There was no albuminuria in the intervals, and no periodicity. He was not known to have had malaria. Rosenbach is quoted in the *American Medical Journal* (vol. iii, p. 544) as reporting a case excited by a cold bath in summer. Other patients have paroxysms only in winter. In considering the etiology, it must be remembered that malaria once contracted may give rise to symptoms without fresh exposure, and may be irregular in its course. On the other hand, the reports from the South, where it is common, show malarial hæmaturia only when accompanied by well-marked malarial symptoms. Some cases of paroxysmal hæmaturia have lasted for long periods and have recovered.

Paroxysmal hæmaturia may result from physical exercise, being perhaps analogous to the so-called physiological albuminuria of soldiers after forced marches. Herringham also mentions mental exercise as a cause, and reports a case where it was brought on many times in an adult by worry or excitement. Lannois reports the case of a patient whose first attack was at the age of nine years, and who had not recovered at thirty-two. Paroxysms were excited by gymnastics, railroad travelling, light work, and especially by long walks. They always disappeared with rest and light diet. At first there was but little blood, and that disappeared the next day. At one time albuminuria persisted a few days. During the height of paroxysms the microscope showed red blood-cells, many leucocytes, and renal epithelium. The peculiarity of this case is its long duration. There were no malarial phenomena nor any history of malaria or syphilis, nor had the patient been in the tropics. Since childhood he had occasional pain in the side, which led Lannois to suspect some obscure disease of the kidney.

Among badly-fed children scurvy occasionally causes hæmorrhage into the

¹ I am not criticising the doses in question: no one has a right to do that without the experience in malaria that Southern physicians have.

urine as well as elsewhere. The diagnosis of scorbutic hæmaturia includes the diagnosis of scorbutus. (See article on Scurvy.) It is conceivable that hæmaturia may occur in natural bleeders, but I cannot find the report of a case within ten years.

The treatment of hæmaturia will be indicated by the exciting causal condition.

PYURIA.

Pus may enter the urine at any point. When it occurs it results from some underlying cause, but it is seldom found in the urine of children, because they seldom have the diseases that cause it. It is said, indeed, that boys may have a non-venereal urethritis from debility. Mild vulvitis and vaginitis from this cause are rather common. Cystitis and pyelitis are very occasional sequelæ of several acute diseases. They may be occasioned by the irritation of drugs and of saccharine urine. The presence of calculi is possibly the most frequent cause of this rather uncommon symptom.

CHYLURIA.

Chyluria is especially a disease of certain tropical and subtropical regions, but enough cases of European and North American origin have been reported, particularly in the southern parts of the United States, to prevent our considering it absolutely tropical. As it lasts a long time and does not absolutely disable the patient, it may be imported anywhere. Prout reports a case at eighteen months. Cases are either parasitic, apparently the most common, or non-parasitic. Hunt reports a traumatic case, probably due to rupture of a lymphatic in the kidney. The urine remained chylous but a short time. At first it smelt of milk, afterward of sour milk. The same and also a putrid odor have been observed in other cases. Parasitic chyluria is due to the presence of a minute parasite, the *filaria sanguinis hominis*, itself the product of a parent parasite, the *filaria Bancrofti*. The *filaria sanguinis hominis* probably establishes a fistula between the lymphatics and the urinary organs. It is found in the blood, but, as a rule, only in the late afternoon and night, though by changing the meal hours it may be found at other times. Although usually a parasite of warm countries, it was found by Weiss in the urine of a child who had never been out of Illinois.

Patients are not generally very ill, but chills and abnormally high or low temperatures are reported, and the disturbance to nutrition from prolonged and occasionally profuse hæmorrhage leads to debility. Attention is generally first attracted by the presence of chyle, which may merely make the urine turbid or as white as milk. Blood may precede it. The presence of urinary casts is the exception. Elephantiasis may be a complication, and chyle may exude from swellings in various parts of the body. Cases may last continuously for years or may intermit. Suzuki, by limiting diet, and especially by omitting meat and fat, decidedly lessened the chyle in the urine. Grimm found that he could regulate the amount of chyluria by regulating the fat ingested. In his case there was enough coagulation to cause pain in the bladder, but no renal colic. He therefore concludes that chyle entered the urine between the ureter and the urethra. Sigmund mentions a case in which advantage was taken of a prolapsed bladder to see clear urine issuing from the left ureter.

ANURIA.

Complaint is sometimes made that the urine of a little child, generally a baby, is suppressed. This may depend on congenital malformation or an acute

renal disease, but usually it is a symptom of short duration and no danger. There is often slight fever and a history of imperfect digestion, possibly of difficult dentition. A liberal supply of drinking-water is the only treatment required.

INCONTINENCE OF URINE.

After a time, differing with the intelligence of the child and the pains taken with its education, probably also with muscular development, children learn to use the chamber-vessel. The age when this takes place averages about eighteen months, but is sometimes much later. An undetermined proportion lose control of the bladder after acquiring it; this occurs before the age of six or seven. Incontinence is not uncommon in any class of society, and patients often come incidentally under observation after suffering for a long time, the delay being due to the prevalent belief that spontaneous recovery occurs about puberty. Some patients have incontinence of feces as well as of urine. In some this condition prevails both by day and by night, in some few by day only, but by far the most numerous class is that which has nocturnal incontinence of urine alone. Occasionally patients pass from one class into another. Among nocturnal cases urine is passed while absolutely unconscious, or the child dreams of the act and wakes to find itself wet. This happens once in the night or oftener. Temporary recoveries sometimes occur, to be followed by relapses, and incontinence is far more troublesome in winter than in summer. These considerations should make us careful about claiming results for treatment unless the patients are watched a long time, especially so if recovery occurs in the spring. Many remedies have been proposed, and papers written to show the brilliant results of one or another treatment, yet the number of cases that do not improve continues large. The failure of some practitioners where others seem to succeed is due partly to hasty generalizations at the bottom of many enthusiastic papers, partly to the after-history of patients being obtained for too short periods. But, with all allowances, a study both of the literature and of our individual patients should convince us that we are not dealing with one condition, but with a symptom common to many conditions. Unfortunately, we cannot always find this underlying cause, and with our present knowledge many patients must be treated empirically. When we do find it, we sometimes accomplish much more than can be done by blind groping.

A few cases occurring in the day-time depend on postponement of micturition owing to the demands of play, yet there are cases of day-time occurrence that are unavoidable. I have notes of the case of a lady who is never troubled at night, but who wets her under-clothing so often by day that she always wears a guard. This condition has lasted since early girlhood, and is increased by excitement. Large doses of strychnine, continued for some weeks, gave temporary relief. I do not think nocturnal cases are due to carelessness in any appreciable number. Children are generally mortified at this failing, and would be only too glad to avoid it.

Profound sleep, if not a cause, is often at least an accompaniment. This fact, first noticed by Trousseau, receives more attention from French than from English-speaking or German writers. I have often found that the one child of a family that wets its bed is also the soundest sleeper. Therefore waking the child when its parents retire for the night may be something more than a palliative, and here may be the explanation of some recoveries as patients grow older, when sleep becomes less sound than in early childhood. Recovery at puberty is more often attributed to some obscure influence of maturity on the genitals. In favor of this view it may be said that some women recover at

the time of their marriage. Whatever the reason, however, many recoveries do occur about the time of puberty.

Many patients are debilitated, and debility often, if not the only causal factor, is nevertheless one so powerful that on its removal the child recovers. A large proportion of such patients in my former dispensary service were anæmic, and recovered as soon as given enough iron. These cases were not sufficiently followed up for me to speak as to relapses; but patients, after long and varied treatment without result, do sometimes get well, and stay well, on proper attention being paid to the general health. Such attention does not, of necessity, exclude other treatment. I have notes of the case of a boy treated with belladonna, strychnine, and electricity many times during some years, but with no permanent result, he being always in poor health. When eleven years old, while at the seashore, as badly off as ever and without treatment, he learned to swim, and returned permanently relieved, and with a taste for athletics for which he had been formerly too weak. Whether such incontinence as this is caused simply by a weak sphincter, itself a part of a generally weak system, or whether by a neurotic condition due to anæmia, is a matter upon which one may speculate. Certainly, some of the subjects are neurotic. Possibly both explanations hold good—sometimes one, sometimes the other, and sometimes both together.

Nux vomica and its equivalent, strychnine, are often used successfully. They have a good effect on many neurotic people and are general tonics. They are especially indicated when we know the sphincter to be weak. This may occur if the child has been compelled to hold its water too long, as sometimes happens at school. Cold douches to the perineum are probably local in effect, and the same is true of electricity and massage. Good results are claimed for all of them. Electricity is generally used in the form of faradization, with one pole on the lumbar part of the spine and one in the urethra, the vagina, or on the perineum, the sittings lasting a few minutes each day or every other day and the current being as strong as the child will bear. I object to introducing the electric or any other sound into the child's urethra or vagina—especially in girls approaching puberty—if it can be avoided, and therefore prefer the perineum. This care, perhaps excessive, combined with a possible bad selection of cases, may partly account for my non-success with this treatment. Certainly, I in common with others have not obtained the good results claimed.

Local massage has its advocates. Some good results have been reported, but this method, like all others, has its failures. Sanger massages the sphincter by introducing a probe into the bladder and exercising gentle pressure backward and from side to side. The danger of teaching masturbation is, I think, to be considered.

There is a class of cases in which the urine is sometimes passed with great force, evidently from some other factor than a weak sphincter. There are grounds for believing many of them to be hereditary; many are neurotic. I have met in one family of three children, one case of somnambulism, two of chorea, and one of nocturnal incontinence, the last ejecting the stream violently by day. Chorea is itself supposed to be a cause. It is assumed that there is want of co-ordination between sphincter and detrusor. In other words, such cases are choreic. Such considerations lead to treatment designed to allay irritability of the bladder, by the use of belladonna, potassium bromide, and ergot. Belladonna, originally given by Trousseau in a single night dose, has since been administered in three daily doses. Baruch gave it in the late afternoon and early evening in a series of cases, thus avoiding the probably unnecessary morning dose, and better graduating that in the evening. This is of

some importance, as it is often necessary to approach a poisonous dose; that is, to get some effect on the pupil; and also because the continued use of this drug is not always innocuous. At least, I believe that I have seen gastric disturbance and general malaise result from its prolonged use. It is, however, in many cases the most efficient treatment known, and is perhaps to be preferred where we can make no probable diagnosis of the underlying cause. Relief is sometimes temporary, sometimes permanent.

Epilepsy is responsible for a certain number of cases. So is the general disturbance attending the onset of acute disease. Ergot, by lessening congestion in the spinal cord, is sometimes of use where there is a very irritable bladder.

Children whose mode of life affords frequent opportunity for micturition, make use of it, and thus accustom the bladder to contract when not very full. In such cases a dry bed can sometimes be secured by gradually training the bladder to contain greater amounts, thereby educating the sphincter. This plan must not be carried out too heroically, or a strained instead of a strengthened sphincter will result. It is said that sleeping on the back, by causing urine to press upon the most sensitive part of the bladder, is an exciting cause, and may be relieved by elevating the foot of the bed.

Urine loaded with uric acid, urates, oxalates, or phosphates may cause incontinence, as well as an irritable bladder; hence the urine should always be examined. Albuminuria is said to be a cause. I have met with diabetes in a child, where the real diagnosis would have been overlooked but for the routine examination for sugar in this affection. Possibly the effect of ptomaines on the brain may be to produce incontinence in some children, as it does night-terrors in others. Whatever the explanation, attention to the digestive organs is sometimes of great use.

The influence of phimosis is exaggerated. I have met with several cases in circumcised Jews, while half of Townsend's cases were in girls. Furthermore, patients have been operated on without relief. Yet phimosis is sometimes a cause. Patients previously carefully treated without result do sometimes get well immediately after circumcision or even after breaking up adhesions between prepuce and glans. Phimosis is merely one of several conditions giving rise to reflex incontinence. Among others are a small meatus, rectal polypi and fissures, pin-worms, hardened fæces, and even, in one reported case, a brass button in the nose. Masturbation is said to sometimes result in incontinence.

Davenport reports a case, and refers to another, in which malposition of the orifices of the ureters was the cause.

Among palliatives is avoidance of drinking large quantities of liquid late in the day. This must not be overdone, for a too concentrated urine may be as irritating as one too abundant. Regular habits of life seem of some use. I had opportunity to observe a boy admitted to the hospital on the day that an epidemic of measles began there. As he had been exposed, it was not thought desirable to begin treatment until he had had the disease. He had regular diet and hours with no excitement. Before the incubation period was over the incontinence had ceased. He did not contract measles, and after a reasonable time of observation was discharged.

This symptom, then, arises from the most varied causes and repays careful study of the individual. The general health is never to be lost sight of. Hopes of relief are reasonable, but it is never to be promised, and we are not justified in assuming treatment to be successful until after a long lapse of time.

DIABETES MELLITUS, DIABETES INSIPIDUS AND LITHIASIS.

BY JAMES TYSON, M. D.,

PHILADELPHIA.

I. DIABETES MELLITUS.

DIABETES MELLITUS is a constitutional disease especially characterized by the secretion of an abnormally large amount of urine charged with sugar. While in adults there is good ground for admitting at least two forms of diabetes mellitus, a mild and a severe form, in children I have as yet met only the latter, of which the course is more rapid than in adults.

Etiology.—The etiology of diabetes in children is even more obscure than in adults. In both heredity is an acknowledged influence, but with this exception the cause of diabetes in children may be said to be unknown. In adults, while in the majority of cases a sufficient cause is sought in vain, there are certain well-recognized influences, such as prolonged overwork, anxiety, and grief, which favor its causation: these agencies cannot operate in children. The sex-relation of diabetes is reversed in children as compared with adults, it being more common in girls than boys.

Morbid Anatomy.—In the matter of morbid anatomy, too, we are unable to find lesions which can be held responsible for the disease. Rather are they the result of it. It is true that recent studies have shown an increasingly close relation between diabetes and pancreatic disease, originally pointed out by Lanceraux a number of years ago. Extirpation of the pancreas, according to Von Mehring, Minkowski, and Lepine, is invariably followed by diabetes if the extirpation is complete; and although De Dominicis, to whom we are indebted for the original experiment, and De Renzi and E. Reale deny this, it is still true that this operation is followed by glycosuria in a vast majority of cases, while every year furnishes autopsies in which pancreatic lesions are far more common than any other. At the same time, typical cases of diabetes are constantly occurring in which there is no pancreatic disease.

Among anatomical lesions—in addition to those of the pancreas—which are found in connection with diabetes, may be mentioned enlargement and hardening of the liver, cirrhosis, dilatation of its capillaries, amyloid changes in its cells; hyperæmia, and even slight grades of parenchymatous inflammation, of the kidney; tuberculous foci and cheesy degeneration of the lungs; and a variety of lesions of the nervous system, especially in the neighborhood of the medulla oblongata, among which tumors and traumatic lesions are the most common.

Symptoms.—In children, as in adults, a frequent desire to pass water, with increase in quantity, intense thirst, and sometimes great appetite, are the symptoms which commonly first attract attention. Examination of the urine discovers the presence of grape-sugar or glucose, and a specific gravity

usually higher than normal, 1030 and upward, although a lower specific gravity does not preclude the presence of sugar in considerable amount. Rapid emaciation, shrinking and dryness of the tissues, and constipation are early associated. If we add the peevishness and restlessness which grow out of these conditions, and occasional intense itching of the genitalia, we include most of the symptoms which occur in children. The neuralgic pains and rheumatic complications, the lung involvement so often seen in adults, are not commonly present in children. Cataract I have met in a single case, a boy of sixteen. It was double.

The state of the urine, which contains sugar and is increased, varies as it does in the adult. In a little girl four and one-third years old, under my care for some time, whose case may be considered a fair example, the quantity ranged from 65 to 200 ounces (1950 to 6000 cc.) in the twenty-four hours, and the proportion of sugar from 13 to 34 grains to the ounce (3 to 7.5 per cent.); the specific gravity 1018 to 1040. Toward the close of the disease diacetic acid and aceton are found in the urine, and death by diabetic coma is not unusual. Concurrent with the diaceturia and acetonuria are a diacetæmia and acetonæmia.

Albuminuria occurs in a certain number of cases of diabetes in children, as in adults, from two causes: first as the result of irritation of the tubular structure of the kidney by the sugar-charged urine, and second as a coincidence.

Pneumonia is prone to occur, as in adults, tuberculosis to a less degree, but gangrene I have not met in children. The suggestion that in a large number of these cases the albuminuria is due to the excessive quantity of eggs consumed in the diabetic diet I do not consider sustained by the facts.

Diagnosis.—With such a train of symptoms as those noted there should not be much delay in recognizing diabetes mellitus, even without an examination of urine. All cases, are not, however, so clear, and such examination is always necessary to a proper study of any case. The occasional confusion due to the reducing effect of uric acid on the proto-salts of copper should be borne in mind. The darker hue and scantiness of the uric-acid urines should excite suspicion, while the absence of all other symptoms of diabetes should protect against error.

The tests for sugar at once most delicate and to be relied upon are the copper tests, and of these the most satisfactory is the solution known as Fehling's.¹ In using Fehling's solution for qualitative testing take 1 cc. of the solution and dilute with four times its bulk of water; boil the mixture thus obtained, and, if it remain clear, it is fit to be used in completing the test. If, however, there should be a precipitate of the red suboxide on boiling before any urine is added, the solution is spoiled and a fresh one should be obtained. If the fluid remain clear after the first boiling, the urine should be added, drop by drop, until a bulk equal to the original mixture of Fehling's solution and water is obtained; and if no yellow or red precipitate takes place, the urine may be said to be free of glucose. It is scarcely necessary to say that the gray floccu-

¹ Fehling's solution is thus made: Dissolve 34.639 grams of pure crystallized sulphate of copper in 200 cc. of distilled water; 173 grams chemically pure crystallized neutral sodic-potassium tartrate in 480 grams of solution of caustic soda of sp. gr. 1.14; and into this basic solution pour the copper solution, a little at a time; then dilute the resulting mixture to 1 litre with distilled water. The tendency of Fehling's solution to deteriorate is well known. This may be obviated by substituting glycerin or mannite for the tartaric acid, but more effectually by dissolving the sodic-potassium tartrate in 480 grams of solution of caustic soda and diluting to 500 cc.; the copper in 500 grams of distilled water; and keeping the solutions separate until such time as they are wanted, when 1 cc. of each will furnish 2 cc. of Fehling's solution.

lent precipitate of phosphates which sometimes occur should not be mistaken for a precipitate of suboxide of copper.

A sufficiently accurate quantitative test may be made with Fehling's solution thus used if it be remembered that it is of such strength that if the cupric oxide be exactly reduced—that is, if the *color is exactly removed* by an equal bulk of urine—that particular specimen of urine contains *one-half of 1 per cent.* of sugar; if the color is removed by half of the bulk of urine, the sample contains 1 per cent.; and if twice the bulk of urine is required, the sample contains $\frac{1}{2}$ of 1 per cent.; and so on. Moreover, if, as is usually the case, it is necessary, by reason of the large percentage of sugar, to dilute the urine, the proportion should be 1 to 9 of water. Then we proceed as before, multiplying the result by 10. When it is remembered that it is *impossible to judge accurately of the progress of any case of diabetes mellitus without a quantitative analysis for glucose*, the importance of having an easy clinical quantitative method will be appreciated.

In the absence of Fehling's solution the original form of the copper test suggested by Trommer may be thus used: The urine is first alkalized by about one-fourth its bulk of liquor potassæ, and then a drop or two of a preferably weak—say 1 to 30—solution of cupric sulphate should be added. A precipitate ensues, but if sugar be present the first drop or two of the copper solution is redissolved on shaking. The addition should therefore be continued until a slight excess remains, when heat is applied, and in a few seconds a precipitate of the yellow cuprous hydroxide occurs. This subsequently loses its water and becomes the red cuprous oxide.

Of the remaining tests for sugar it will be sufficient to give the *fermentation test*, which is easy and serves a *quantitative* as well as a *qualitative* purpose, while it has fewer sources of error than any of the other tests. The objections to it are that it requires several hours for its operation, and that quantities less than a half of 1 per cent., or $2\frac{1}{2}$ grains to the ounce, cannot be detected. The simplest method of its application is as follows: Having taken the specific gravity of the sample to be tested, fill a four-ounce bottle with the urine, to which add a small piece—say the size of a pea—of German yeast or a teaspoonful of brewer's yeast, after which shake thoroughly; put aside in a warm place, temperature 60° to 80° F., for at least twelve hours. At the end of this time, sugar, if present, will have been converted by fermentation into carbonic acid and alcohol, and the specific gravity proportionately lowered. For practical purposes it may be allowed, as originally ascertained by Dr. Roberts, that for every degree of reduction of specific gravity on the urinometer there is *1 grain of sugar to the fluidounce*. Thus, if the original specific gravity is 1040, and the specific gravity after fermentation 1020, there are 20 grains to the fluidounce. From this the percentage may be ascertained by multiplying such difference by .23. Thus in the illustration named the percentage would be 4.6.

The matter of the selection of a specimen of urine for analysis is of the greatest importance. It goes without saying that the most suitable sample is a portion of the whole twenty-four hours' urine collected for the purpose. But it is evident that it is often—indeed, almost always—impossible to do this. Then my practice is to take two samples for analysis—one a portion of that passed on rising in the morning, the other a portion of that first passed after the evening meal, usually that passed at bed-time. If pains be taken always to examine samples thus selected under the same conditions, comparisons may be made from day to day or week to week which suffice for clinical purposes.

Prognosis.—The prognosis is unfortunately very bad in children. The

only case of a child I have ever known to recover was a girl of twelve under the care of a friend. Life may, however, be prolonged for a time by careful attention to dietetic, hygienic, and medicinal treatment. The course is, however, always much more rapid than with adults, and the fatal termination comes sooner.

Treatment.—In children, as with adults, the most efficient treatment is the dietetic, and the greatest difficulty is that of getting a substitute for bread. Of the various so-called gluten flours and breads, so far as I know, the only ones made in this country which contain so little starch as to justify the name pure gluten or almost pure gluten are the gluten flour of Theodore Metcalf & Co., of Boston, Mass.,¹ and the No. 1 gluten biscuit and No. 1 gluten meal of the Sanitarium Food Company of Battle Creek, Mich. No new preparation of gluten should be accepted for what it claims to be unless the claim is sustained by analysis. In England and France diabetics are more fortunate, as they can secure flour, bread, and biscuits containing a minimum amount of starch. The great objection to all pure gluten preparations is that they are more unpalatable than the bread made of flour from which the starch has not been removed. But it should be made clear to the friends of the patient that he must make his choice of the two evils.

It is not always necessary that the purest attainable gluten preparations should be used in mild cases, as in these a certain amount of starch is assimilable; but such latitude must be based on trial of fixed quantities of the given breads associated with careful quantitative analyses of the urine selected as directed. To such the so-called "bran bread" made out of unbolted flour, in which the ratio of starch is of course less, and oatmeal gruel with cream, may be allowed. Unfortunately, mild cases of diabetes are not commonly found in children.

Among the substitutes for the white flour so much used is almond flour, and it is totally without objections, so far as its composition is concerned. The patient is apt to tire of it as of anything else from exclusive use, and fair digestive capacity is required.

Various other flours have been suggested. One of these is the flour of the soya bean (*Soya hispida*), a native of Japan, but now extensively grown in Europe, said to contain only 4 per cent. of starch. It is, moreover, very rich in nitrogenous substances. From this are made bread and biscuit. A flour known as *poluboskos* contains a small quantity of starch, and is a suitable food for most diabetics. *Fromentine* is another of these flours made from the embryos of wheat, which, so far as I know, is not yet obtainable in this country. Like the soya flour, it contains a considerable quantity of oil, which not only renders pannification difficult, but disposes to early rancidity. Efforts are also being made to isolate for the same purpose legumine, the caseine of the leguminous vegetables. The substance so isolated is known as embryonine.

¹ The following are the directions suggested by Dr. John A. Jeffries in common use for making gluten biscuit out of the Metcalf flour:

Gluten flour	1 cup.
Best bran, previously scalded	1 cup.
Baking powder	1 teaspoonful.
(Or the equivalent of bicarbonate of soda and cream tartar.)	
Salt	to taste.
Eggs	two.
Milk or water	1 cup.
Mix with a spoon.	

The appended table is one which has been my guide for many years, and I believe it includes most of the articles admissible :

FOOD AND DRINK ADMISSIBLE IN DIABETES MELLITUS.—*Shell-fish.*—Oysters, mussels, and clams, raw and cooked in any way, without the addition of flour.

Fish of all kinds, fresh or salted, including lobsters, crabs, sardines, and other fish in oil; fish-roe, caviar.

Meats of every variety except livers, including beef, mutton, chipped dried beef, tripe, ham, tongue, bacon, and sausages; also poultry and game of all kinds, with which, however, sweetened jellies and sauces should not be used.

Soups.—All made *without* flour, rice, vermicelli, or other starchy substances, or without the vegetables named below as not allowed; animal soups not thickened with flour, such as bouillon, beef-tea, and broths.

Vegetables.—Cabbage, cauliflower, Brussels sprouts, broccoli, green string beans, the green ends of asparagus, spinach, tomato, dandelion, mushrooms, lettuce, endive, coldslaw, olives, cucumbers, fresh or pickled, radishes, sorrel, young onions, water-creesses, mustard and cress, turnip tops, celery tops, artichokes, gherkins, okra, parsley, or any other green vegetables.

Fruits.—Cranberries, plums, cherries, gooseberries, red currants, strawberries, acid apples, lemons, oranges sparingly, all without sugar. Acid fruits may be stewed with the addition of bicarbonate of sodium instead of sugar.

Bread and cakes made of gluten, soya, almond flour, inulin, "poluboskos," fromentine, or embryonine, with or without eggs and butter. Griddle-cakes, pancakes, biscuit, porridges, etc., made of these flours. In cases requiring less stringency the so-called "bran bread," made of unbolted flour, the *crust* of bread, and oatmeal porridge with cream.

Eggs in any quantity, and prepared in all possible ways, without sugar or ordinary flours; butter and cheese.

Nuts.—All except chestnuts, including almonds, walnuts, Brazil nuts, hazelnuts, filberts, pecan-nuts, butternuts, cocoanuts.

Condiments.—Salt, vinegar, and pepper in moderate quantities.

Jellies.—None but those unsweetened, except by saccharin. They may be made of calf's-foot or gelatin and flavored with wine.

Drinks.—Coffee, tea, and cocoa-nibs, with milk or cream, but without sugar; also Vichy, Vals, and Carlsbad waters, carbonated waters, and all mineral waters freely; lemonade without sugar, acid wines, including claret, Bordeaux, Rhine, and still Moselle wines, diluted with Vichy or similar waters, very dry sherry; unsweetened brandy, whiskey, and gin. No malt liquors, except those ales and beers which have been long bottled and in which the sugar has largely been converted into carbonic acid and alcohol. Saccharin may be used for sweetening.

To be Especially Avoided.—Potatoes, white and sweet, rice, beets, carrots, turnips, parsnips, peas, and beans; all vegetables containing starch or sugar in any quantity; sweet wines, including sherry, Madeira, port, and champagne.

The hygienic treatment of diabetes mellitus is important. The patient should be bathed frequently, and brisk friction should succeed the bathing in order to stimulate the circulation. Out-door life and muscular exercise, short of that sufficient to excite fatigue, should be insisted upon, the idea being to stimulate every process which may result in the oxidation of sugar. For a like reason the sleeping-room should be well ventilated and the purest air supplied to it.

The medicinal treatment of diabetes is limited, as there are few drugs

having power to control the defective assimilation resulting in sugar excretion. The most efficient of these is undoubtedly opium and its preparations and alkaloids, any one of which possesses this power. Codeine is, however, the preparation usually selected, because it is less apt to produce the harmful effects of the other chief alkaloid, morphine. It is, however, much more expensive. While generally better borne than morphine, it does sometimes nauseate as well as constipate. That it controls the sugar output is abundantly proven. Moreover, I have reason to believe from my own experience that it occasionally happens that where sugar has disappeared during treatment by codeine, it does not return after discontinuance. It is desirable, however, to put off the use of opium, as a rule, until other measures and drugs fail. If the efficiency of opium in diabetes be based upon its sedative action, then the bromides should also be useful, and it does occasionally happen that they serve a good purpose; but in my experience they are of limited utility.

After opium, arsenic is perhaps the drug which has longest maintained its reputation as a remedy in diabetes mellitus, but its usefulness, like that of most drugs, is limited to the milder cases. There is no better preparation than Fowler's solution, of which the dose is so easily regulated. The action is unexplained, although a reasonable theory has recently been advanced by Cuthbertson of Chicago, who says it is partly local upon the stomach, bowels, or respiratory organs, and partly on blood-cells, increasing their activity, and therefore the oxidation of sugar. The dose must be regulated by the age, from a drop to five drops three times a day, increased until slight œdema of the face results. It is often combined with lithium carbonate, 1 to 5 grains, by which its effect is sometimes increased. The bromide of arsenic, originally recommended by Clemens, is sometimes given, but I have not found it more efficient than Fowler's solution. The preparation commonly used is Clemens's solution of bromide of arsenic, of which the dose is 2 to 5 minims, the smaller dose for children.

Ergot is a drug which is sometimes efficacious, but I value it less highly than I used to. That it sometimes exerts a controlling effect I have not the least doubt. The best form is the fluid extract in doses of five minims to a drachm.

That the coal-tar series of antipyretics, including antipyrine, antifebrin, phenacetin, and sulfonal, prominently brought forward by the French school of physicians, have in the milder forms of diabetes a controlling influence, I can also assert from my own experience. As claimed by the French school, their efficiency is increased by combinations with alkalies, sodium carbonate being commonly used in the proportion of twice the dose of the antipyretic. Thus, if 15 grains of antipyrine are given, 30 grains of sodium bicarbonate are added, and these doses are recommended by Dujardin-Beaumetz and Germain-Sée for adults. They are bulky and apt to derange the stomach, and they should not be given after meals. My method has been to give the combined drugs in equal doses before meals. For children they should be much smaller— $\frac{2}{3}$ to 10 grains of the drug, with an equal quantity of sodium bicarbonate. If the antipyretic is given alone, it may be given after meals, although a somewhat larger dose is then required.

Salicylate of sodium has some reputation, and may be used, especially when the diabetes is associated with rheumatism.

Alkalies alone, doubtless, have an effect in the diabetic process, and it is this constituent to which the alkaline mineral waters of Vichy, of Vals, and of Carlsbad owe their chief efficiency. None of the negative mineral waters in this country, so much vaunted by their owners as specifics, have in my expe-

rience any effect whatever. Persons visiting the sources of these waters may be benefited, but the associated diet, and not the waters, is the efficient agent.

A great many remedies have from time to time been suggested as useful in diabetes, and I have tried most of them as opportunity presented, generally with negative results. One of the most recent of these is jambul (*Syzygium jambolanum*). A careful and systematic trial by myself in three cases has resulted in signal failure. The dose given is from ten drops to a drachm.

The latest of these remedies is creasote, which I have not yet tried. It is recommended by Audibert as producing excellent results where diet did not seem in any way to influence the intensity of the glycosuria. The quantities used were: first 2, then 4, and finally 6, grains daily *for adults*. The glycosuria steadily diminished in one case in spite of the fact that the patient, despairing of any results, deliberately neglected all dietetic rules.

II. DIABETES INSIPIDUS.

DIABETES INSIPIDUS is a nervous affection, mainly functional, characterized by the secretion of a large amount of urine of low specific gravity.

While diabetes insipidus is a much rarer disease than diabetes mellitus, it is believed to be relatively more frequent in children than the latter. Out of 70 cases collected by Roberts, 22 were under ten years of age, and 13 between ten and twenty; out of 85 by Strauss, 21 were under ten; and of 87 by Von der Heijden, 7 were under ten and 19 between ten and twenty.

Etiology.—Nervous influences, such as those which produce hysteria—viz. shock, fright—are the principal causes of diabetes insipidus. Thus a boy of ten years, recently treated by myself, was choreic at various times prior to the attack of polyuria, and was very nervous throughout the illness, from which he recovered.

Morbid Anatomy.—No definite morbid anatomy has been found associated with simple polyuria. The kidneys have been found sacculated in various degrees, more likely as a consequence of the enormous accumulation of liquid filling the bladder and pressing backward through the ureters upon the kidney structure, causing its atrophy. Tubercular and gliosarcomatous tumors in the neighborhood of the floor of the fourth ventricle have been found.

Symptoms.—The chief symptom is a profuse polyuria associated with a proportionate thirst. The quantity of urine exceeds that of all ordinary cases of diabetes mellitus. The boy of ten referred to would pass a quart at a single sitting, while the frequency of the desire to pass water made it impossible to attend school. The specific gravity is proportionately low, generally 1002 to 1006, and I have known it to be scarcely above 1000. For the twenty-four hours' urine the other constituents remain usually normal, while albuminuria is much more rare than in diabetes mellitus.

As a natural result of such a condition there is great dryness of the skin and mucous membranes. On the other hand, there is never that extreme emaciation seen in children with diabetes mellitus, and the patients are often fairly well nourished. This is favored by the fact that the appetite is apt to be increased, from which, indeed, derangements of digestion may result.

Other nervous symptoms frequently attend or precede diabetes insipidus, such as chorea, restlessness, and sleeplessness.

Diagnosis.—The diagnosis of diabetes insipidus is easy. The enormous quantity of urine passed, its low specific gravity, and the absence of sugar, if maintained for any length of time, can mean nothing else. It is barely

possible that the milder forms might be confounded with chronic interstitial nephritis in adults, but in children this seems impossible. The presence of a trace of albumin should, however, lead to an exhaustive examination of the urine for casts and other signs of interstitial nephritis—a very rare disease in children.

Prognosis.—The prognosis in my experience is generally favorable, the patient sooner or later getting well.

Treatment.—Cases under my care have usually yielded sooner or later to ergot or gallic acid, the former in beginning doses of 10 minims of the fluid extract, or less according to age, and increasing until results are obtained or full doses reached without effect. Gallic acid may be given in 5-grain doses at the beginning and increased. For antipyrine and antifebrin great efficiency in the treatment of this affection has recently been claimed. While I have as yet had no opportunity to try them, my experience with these drugs in diabetes mellitus leads me to expect that they will be even more efficient in diabetes insipidus. The same reasoning leads me to expect that bromide of potassium would be useful, as it sometimes is.

Valerian is one of the older remedies for simple polyuria, and it can be easily understood why it should be useful in nervous cases. The older physicians used powdered valerian and valerianate of zinc, but at the present day the more elegant preparation of elixir of the valerianate of ammonium, in doses of half a drachm, a drachm, or more according to age, should be substituted. The exceedingly disagreeable smell of the substance is in the way of its general use. Opium is also recommended in diabetes insipidus, but has made for itself no reputation like that it has attained in saccharine diabetes.

A blister at the nape of the neck or on the epigastrium was suggested by Roberts, and might be expected to be of service by its impression on the nervous system. The constant galvanic current would be reasonably useful from the same standpoint, and is recommended by Seidel and Kuelz, the former of whom applied daily one pole of a strong battery over the loins near the spine and the other as deeply as possible over the hypochondrium.

In the matter of drinking water a moderate restriction should be exercised in diabetes insipidus, but to cut down the amount of water largely is a cruelty unjustified by the results. The cry for water is a demand to make up a loss from the economy by the kidneys. It is an effect, and not a cause. Yet it is possible to carry drinking to excess after a habit is once acquired, and for the effect thus to become the cause. To prevent this a reasonable oversight should be exercised.

III. LITHIASIS.

LITHIASIS is the deposition of certain solids of the urine in the urinary tract, any portion of which, from its beginning in a Malpighian capsule to its terminal expansion, the bladder, may be the seat of such deposit. The sediments thus precipitated include, in the order of frequency, first, uric acid and its compounds of sodium, potassium, and ammonium; second, oxalate of lime; and, third, the phosphates of calcium, magnesium, and ammonium. A clot of blood or fragment of foreign matter may be the nucleus of calculi thus formed. They may be so minute as to be barely visible to the naked eye, constituting *sand* or *gravel*, or they may be a couple of inches or more in diameter, when they are spoken of in common language as *stones* in the kidney or bladder.

As stated, the most frequent sediments are uric acid, which are often found in the shape of red sand in the very first urinary discharges of the new-born

infant. Calculi may form, consisting of pure uric acid or its compounds, but they are seldom large. Less common are small stones of pure oxalate of lime. More commonly large stones consist of nuclei of uric acid or oxalate of lime, around which phosphates are deposited in concentric layers. Phosphates rarely form the nuclei of stones. The alkaline reaction of urine, which is necessary to the deposit of phosphates, is not common in children fed on milk. It is not until vegetable substances are added to the diet that the alkaline reaction becomes conspicuous. More frequently the alkalinity necessary to the precipitation of phosphates is the consequence of organic matter generated in inflammatory processes, especially those excited by calculi themselves. This occurs as soon as they reach a sufficient size to act as irritants producing local

FIG. 1.

Calculi impacted in the Ureters. From a boy of 5 years (Tyson).

inflammation. They thus become surrounded by alkaline urine, whence phosphates are deposited in concentric layers around the uric-acid or oxalate-of-lime nucleus.

It has been said that calculi may form in any part of the urinary tract. Hence they may be found imbedded in the kidney, circumscribed and encapsulated in the centre of the organ. Thus situated, they may grow by accretion until they have almost destroyed the entire organ, filling up its pelvis and calyces, converting the entire kidney into a pus-sac; or they may even make their way through the capsule of the kidney into the perinephric tissues, and thence

down into the pelvic cavity. Appended is a drawing of a remarkable specimen occurring in the practice of the writer in a boy of five years, twice successfully operated upon for stone in the bladder, the first time when but three years old. He perished finally of exhaustion. The necropsy only revealed the extent of the mischief. The stone in the left ureter was spirally spindle-shaped, and measured 5.5 cm. long and 1.5 cm. wide in the thickest part. The stone in the right ureter was 10.5 cm. long and 1 cm. through at its thickest part. The bladder also contained a small stone 2.5 cm. long and ranging in diameter from .5 to .75 cm.

Etiology.—It would scarcely be profitable to attempt to discuss the causes why in one child there is a tendency to deposit uric-acid sediment, or why in another under apparently the same conditions an oxalic-acid lithiasis should exist. The conditions which favor phosphatic deposits have been mentioned. Whatever may be the cause of each, there can be no doubt that in every case the deposit of sediments is favored by a reduction in the amount of water separated by the kidneys—a condition which depends largely on the amount of liquid ingested. The reaction of the urine, whether acid or alkaline, also plays an important rôle. Phosphatic sediments are never spontaneously deposited from an acid urine, nor uric acid from an alkaline urine. The law cannot be so sharply laid down with regard to oxalate sediments, crystals of oxalate of lime being deposited in alkaline as well as acid urines, although I believe the reaction of urine containing them is most frequently acid.

Calculi may present themselves at any age, and probably begin their formation sometimes even before birth. At any rate, large stones have been removed from the bladders of children in the first year after birth—too large, it would seem, to have been produced in the short time which had elapsed since birth.

Symptoms.—The symptoms of lithiasis in the child vary very greatly according to seat and degree. For convenience, such symptoms may be divided into those caused by sand or gravelly deposits, those caused by calculi in the bladder of such size as to justify the term “stone,” and those caused by calculi impacted higher up in the urinary tract, in the pelvis of the kidney and in the ureters.

Sand or Gravel in the Bladder.—A simple peevishness or fretfulness or other evidence of pain in an infant, with retractions of the limbs, may be caused by gravel, evidence which is confirmed by red-pepper-like sediment on the napkin or an unusually dark staining of the latter by urine. The same condition in an older child may give rise to more intelligible manifestations of discomfort, which may be located in the lumbar region, in the groin, or in the urethra. A very common mode of manifestation of discomfort in the latter situation and in the neck of the bladder is traction upon the prepuce, which often becomes elongated in consequence. At this early age a frequent desire to pass water, and especially wetting the bed at night, should lead to examination of the urine, the presence wherein of uric-acid or oxalate-of-lime sediments would, together with dark color and high specific gravity, add further probability of the presence of such a cause.

Stone in the Bladder manifests itself by very much the same symptoms, though intensified, especially the disposition to draw upon the prepuce and frequency of micturition. Tenderness in the region of the kidney will be found where the pelvis is the seat of detention of the calculus, and not infrequently bulging, and even fluctuation from the presence of pus, may be detected. Abdominal palpation should not be neglected, as enlargements of the kidney are very apt to be anterior in direction. Examination of the urine may give negative

results, or it may show the presence of the crystals already mentioned; more frequently the secretion contains evidence of irritation of the bladder in the presence of mucus or pus, while a trace of albumin will attend the presence of pus. When mucus or pus is absent, the microscope may still discover mucus threads or so-called mucus-casts, which always mean irritation of the genito-urinary passages short of what is sufficient to produce mucus or pus in the urine. Such urines, if not already alkaline when passed, readily become so, and the alkalinity thus produced tends to make the urine viscid and glutinous. Where the alkalinity takes place in the bladder in the presence of pus, this glairy material is formed in the viscus, and micturition becomes difficult or impossible.

Such a set of symptoms will of course suggest the use of the bladder-sound, by which a stone is commonly readily recognized.

The continuance of symptoms of such severity as are caused by the larger stones soon affects the general health of the patient, as attested by feverishness and gradually growing emaciation, which may terminate in death.

Diagnosis.—This is successful according as the lines of investigation may be thorough or otherwise in the examination of urine, palpation, and the use of the sound.

Prognosis.—This is generally favorable, the use of appropriate solvent medicines and diet being sufficient to correct the states wherein only gravelly sediments are present; while the surgeon's knife even more promptly removes the stone from the bladder or kidney, nephrotomy to-day saving many lives which would have formerly been lost. It is only, for the most part, those cases which have advanced too far, or which present the peculiar conditions presented in Fig. 1, which are beyond the reach of any remedy, and gradually wear out the patient.

Treatment.—As soon as a stone of size sufficient to be recognized by a sound, or by localized pain or tenderness in the kidney itself, is discovered, there is but one course to be pursued. The case must be handed over to the surgeon. At the present day no intelligent physician expects to dissolve away a stone by medicinal treatment.

From the physician's standpoint, treatment is therefore limited to such cases in which the lithiasis is confined to gravelly sediments. Of these there can be no rational treatment except after a thorough chemical and microscopical study of the urine, and, although symptoms may be relieved without such study, the success attained is accidental, and reflects no credit on him who employs it. The management demanded by different conditions is often diametrically opposite.

If, on examination, the urine is found highly acid in reaction, depositing uric-acid sediments, the treatment is pre-eminently by alkalies. It does not much matter what alkalies are used. They should, however, be associated with an abundance of liquid, in order the better to furnish a solvent for the uric acid. The liquor potassæ of the U. S. Pharmacopœia is an excellent remedy in doses of 5 to 20 minims, the dose being adapted to the age of the patient and administered three or four times a day. The object should be to alkalinize the urine, and in testing it a time of day should be selected when the urine is most likely under ordinary circumstances to be acid. Such a time is the early morning before food is taken. Milk is an admirable medium for liquor potassæ. The salts of potash are also useful, and there is less danger of an overdose. The citrate and carbonate are equally efficient in doses of 5 to 15 grains three or four times a day, or oftener if necessary to secure an alkaline reaction. With alkalinity established, uric acid cannot be precipitated. On the other hand, care must

be taken to avoid the opposite extreme—having escaped Scylla, to steer clear also of Charybdis. If the urine be made too highly alkaline, the phosphates will fall and the sediments of these urinary constituents arise. The alkaline mineral waters, of which the imported Vichy waters are the type, and even negative mineral waters, are useful in the uric-acid lithiasis.

The new substance, piperazine, is an admirable solvent for uric acid in doses of 3 to 5 grains for children.

On the other hand, if we have an alkaline urine to contend with and persistent phosphatic deposits, we must seek to make the urine acid. This, unfortunately, is not so easy. There are very few medicines which have this tendency. Benzoic acid and boric acid are the only ones, and neither of them is well borne in large doses by children. But they should be given in doses of 1 to 5 grains every three hours, or often enough to secure the acid reaction sought for.

Oxalate of lime, unfortunately, is insoluble in both acids and alkalies. At the same time, it is sometimes formed under the same conditions as uric acid. The same general plan of treatment may be carried out.

Oxalate-of-lime sediments frequently attend dyspeptic states, which are successfully treated by acids, especially nitromuriatic, which should be cautiously administered in combination with suitable doses of tincture of nuxvomica, or even strychnine, with pepsin or pancreatin.

Where the composition of gravel cannot be determined, it is a great deal better to give an abundance of distilled water than the alkalies and alkaline mineral waters, by which we only add fuel to the flame if it happens that we are dealing with phosphatic gravel.

As to diet, if the gravel be uric acid, meats and albumens should be limited, as they tend to produce an acid urine and uric-acid sediments. On the other hand, milk and vegetables tend to alkalize the urine. Abundant experience has taught me that not only during childhood, but also during infancy, parents are too indifferent about giving their children pure water to drink. Children should be encouraged to drink water between meals, and infants should be given pure water to drink two or three times a day. They soon grow fond of it, and in this way liquid is furnished to flush out the excretory channels of the economy, and to dissolve the solids which can only be removed in solution.

In children, no less than in adults, pain must be relieved by appropriate anodynes. The milder preparations of opium, as paregoric, should be made to suffice, because of the danger of the stronger preparations. The suppository is a convenient and effectual medium. Phenacetin will often relieve the milder, and sometimes even quite severe, degrees of pain, especially if it be renal. Five to ten grains may be given at a dose.

ACUTE AND CHRONIC NEPHRITIS, AND AMYLOID DISEASE OF THE KIDNEY.

BY I. N. DANFORTH, M. D.,

CHICAGO.

I. ACUTE TUBAL NEPHRITIS.

Synonyms.—Acute catarrhal nephritis; Acute desquamative nephritis; Acute croupous nephritis; Acute parenchymatous nephritis; and Acute Bright's disease.

Etiology.—In adult life exposure to cold and wet is the most common cause of acute tubal nephritis, but it is a curious and interesting fact that the disease is very rarely produced in children in this way. My experience quite accords with that of Ralfe, who says, "I have never yet succeeded in obtaining a history of exposure to cold and wet in a case of acute nephritis occurring in childhood." The usual causes are acute febrile diseases, especially the exanthemata; septic diseases, like diphtheria and erysipelas; and traumata, such as burns, scalds, and injuries involving the nervous centres. Certain drugs in use among children, notably cantharides and turpentine, are capable of inflaming the kidneys, and I have known the extravagant use of highly-flavored confections produce the same result.

Symptoms.—The symptoms of a well-marked case of acute nephritis are always pronounced and aggressive. The patient is sometimes seized with an initiatory chill, but if this is absent pyrexia is always present, the temperature ranging from 100° to 103°, or even 104°F., and maintaining this altitude for from six to twelve days. The pulse is frequently tense, and has a peculiarly quick, short, nervous beat, thus giving expression to the cardiac irritation characteristic of the uræmic state. The tongue is coated, the appetite lost, and the bowels constipated. There is generally deep dull pain in the lumbar region, due to the swollen condition of the kidneys. Headache is a prominent symptom, vertigo is not uncommon, transitory strabismus sometimes occurs, and if relief is not promptly obtained uræmic convulsions supervene, to be followed by partial or perhaps profound coma, with probably dilated, but certainly uncontracted, pupils. If the coma is not complete, obstinate nausea with violent retching will probably occur; that is, the vomiting of uræmia.

The urine is diminished in quantity from the first, and this significant symptom progresses until complete suppression may occur. The reaction is usually acid; the specific gravity increases from 1.025 to 1.040, in the early stage, but diminishes later; the color varies from pink to a vivid red, the intensity of the color denoting roughly the quantity of blood present, for it rarely happens that acute nephritis is not attended by well-marked hæmaturia. Albumin is always present in large quantities, at least one-quarter, and frequently three-quarters, by volume; that is, when a specimen of urine is

tested by heat and nitric acid in a test-tube and allowed to stand for twelve hours, the albumin will occupy from one-quarter to three-quarters of the space. A copious sediment will fall when the urine is set aside; this is made up of hyaline, epithelial and blood-casts, free blood-globules, many of them crenated, renal epithelium, granular urates, and amorphous matter. In the early stage blood-casts will predominate; later on, epithelial and hyaline casts are more abundant, and before convalescence is established some fatty or granular casts may appear, although they are usually few and far between, unless the case falls into a chronic condition.

Dropsy appears very early in the case, generally manifesting itself first in the lower eyelids, cheeks, or the loose tissues of the neck; it then invades the feet and travels upward, reaching the scrotum or labiæ, then the abdominal cavity, and it may be the pleural or pericardial cavities. Œdema of the lungs may occur; the glottis may be distended with fluid, threatening or even causing death by asphyxia, although this can generally be avoided. As already intimated, the heart's action is rapid and the systole is quick, powerful, and "angry," because of uræmic irritation and increased arterial tension.

The foregoing account of symptoms relates to a well-marked typical case. Of course mild cases occur, when the symptoms are much less pronounced; but it is also true that cases of greater severity and more rapid progress are occasionally seen, which generally prove rapidly fatal from acute uræmia.

Morbid Anatomy.—The kidney is swollen, not hypertrophied, but distended with blood and also by the contents of the convoluted tubes. Dickinson relates a case in which the capsule of both kidneys was ruptured by the intense distention caused by congestion, but this is a very exceptional occurrence. The color of the kidney is much darker than normal, and the stellate veins stand out with great distinctness. If the organ be laid open lengthwise, blood will drip freely from the cut surface, and it will be seen that the cortical substance is apparently much increased. The Malpighian bodies sometimes project above the level of the incised cortex, and may be felt as little rounded bodies under the finger. Microscopic section shows the small vessels much dilated, especially those of the glomeruli; in fact, these are in many instances ruptured. The convoluted tubes are much distended by casts, blood-globules, cast-off epithelia, and granules or crystals of urinary salts, and the straight tubes are in less degree distended by similar contents. If the disease passes into the chronic stage, of course the kidney will show granular or fatty degeneration.

Diagnosis.—The diagnosis of acute nephritis can scarcely be said to present any difficulties. The rapid invasion, early occurrence of dropsical effusion, arterial tension, and especially the scantiness of the urinary secretion, together with its pink or red color, at once indicate the nature of the illness. Of course an examination of the urine will at once remove all doubts. Acute nephritis may be complicated with, or rather preceded by, chronic nephritis, but a microscopic examination of the urinary sediment will at once reveal the characteristic fatty or granular casts, which will establish the real facts in the case. Moreover, a careful inquiry into the history of the patient will result in the discovery of symptoms indicating pre-existing renal disease. Cyanotic induration of the kidneys may possibly be mistaken for acute nephritis, but a careful examination of the heart will clear up the doubt, since this disease is almost invariably associated with some obstructive lesion of the cardiac valves, especially the mitral. Careful inquiry will also develop the fact that the disease has existed for a length of time which rules acute nephritis out of the question. As cyanotic induration is not very uncommon in children,

PLATE XXI.

TUBE-CASTS AND URINARY SEDIMENTS.

it should always be borne in mind when renal symptoms are under investigation.

Prognosis.—Acute nephritis is always a grave disease, and is by no means free from danger. Yet, if recognized early and treated appropriately, there are few serious diseases that yield better results. Of course, I am now speaking of uncomplicated diseases. But the danger is greatly increased if the child has cardiac insufficiency, bronchitis, tuberculosis, or any other organic affection. If proper treatment be not instituted until inflammatory exudation has been poured into the tubes and capsules of Bowman, the chances of recovery are diminished, although the case is not hopeless. Suppression of urine and uræmic convulsions indicate a condition of extreme danger, but I have seen several perfect recoveries even after these untoward symptoms have appeared. Children are more apt to recover than adults; in fact, granted an otherwise healthy child, an early diagnosis, and prompt and vigorous treatment, the great majority of cases will recover without damage to the kidneys.

Treatment.—Promptitude without precipitation and vigor without rashness should guide the physician in the treatment of acute nephritis. It is frequently the case that a judicious blow at the right time saves a life, and, on the other hand, it is equally true that hesitation and delay cost the life or blight the future of many a child. If the child be strong and vigorous and the attack be violent, it will be wise to apply three or four leeches over each kidney, or, if the leeches cannot be obtained, blood should be taken by means of cups. The amount must of course depend on the age and strength of the child, but two ounces would be none too much to take from each renal region if the child be from six to eight years of age and in vigorous health at the time of the attack. Immediately following the bleeding a large hot linseed cataplasm should be applied, so as to entirely encircle the body at the level of the kidneys. If the poultices be covered with rubber cloth or oiled silk, they need not be changed oftener than every six hours. It is very important that they be made to “fit” the body closely, and if a little powdered mustard be incorporated in each poultice, it will be an improvement. But no stimulating applications, like turpentine stupes, should be employed in the early stage of the disease.

The practitioner should next turn his attention to the all-important necessity for securing elimination of the urinary factors by other agents than the kidneys. Fortunately, the alimentary tract and the skin afford ample means for accomplishing this. A vigorous cathartic should be given, and I am much in favor of administering from one to three grains of calomel, and following it in three or four hours with an appropriate dose of solution of citrate of magnesium. The bowels should be kept loose for several days or until the danger from the acute invasion has passed; and this for two reasons: first, for the purpose of compelling the bowels to take up a portion of the work of the kidneys, so that the latter may have the benefit of a season of physiological rest; secondly, for the purpose of using the vast alimentary area as a “derivative” surface. Cathartics produce more or less hyperæmia of the intestinal mucous membrane, and if the circulatory current is “determined” toward the intestine, it is proportionally drawn away from the engorged kidneys—a result that is very desirable. I have many times seen the good results of this practice, and am therefore confident that it is something more than a mere theory. Of course the most useful cathartics are those which produce free watery evacuations. The skin is also a vast eliminating organ, and the reciprocal relations existing between the skin and kidneys are well known to physiologists. The physician should take full advantage of this fact in the treatment of acute nephritis, and

encourage copious as well as constant diaphoresis. For this purpose jaborandi, or its alkaloid pilocarpine, and the hot-air or vapor bath are both prompt, efficient, and certain. I have seen such excellent results from the use of hot dry air that I do not hesitate to urge its employment in every severe case of acute nephritis. My method is as follows: The patient, all but his head, is placed in a "tent" (made by supporting the bed-clothes upon arches or semicircles of half-hoops or bent wire) and the bed-clothes are drawn closely about the neck, so as to exclude cold air and include hot air; the perforated tin box (1) is then placed under the bed-clothes by the side of the patient

FIG. 1.

Apparatus for the Administration of the Hot-air Bath. The top and inner side of the box are made of perforated tin.

and about six inches away from him; a current of hot air from a spirit lamp (3) is now conducted into the perforated tin box (which acts as a "register" or "radiator") through the tin pipe (2), as shown in the figure. The result is usually very copious diaphoresis, which may be maintained for many successive hours, or even days in cases of emergency. In one case which seemed well-nigh hopeless, the hot-air apparatus was kept in action almost constantly for ten days, and the patient made a perfect recovery. In some cases the hot dry air evokes sensations of "faintness" or "smothering;" when this happens the heat should be increased very slowly, so as not to alarm or excite the patient. Now and then a case will be encountered which will not bear dry heat at all, while moist heat will be tolerated with both comfort and benefit. A few heated bricks, wrapped in wet cloths and placed around the patient under the tent, will produce active diaphoresis. This method, however, is less efficient than dry heat, and the latter will almost invariably be tolerated after a few trials.

In jaborandi we have a most powerful and certain diaphoretic, and one which is entirely safe if used at the proper time and place. In practice the

alkaloid pilocarpine, the active principle of jaborandi, will be found the most convenient and efficient and by far the easiest of administration. In cases of unusual danger, where copious or excessive diaphoresis is imperatively necessary, pilocarpine in connection with the hot-air bath is invaluable. But a proportionally larger dose must be given to a child than to an adult. To a child of seven or eight years one-eighth of a grain of the nitrate of pilocarpine will be a medium dose, and if copious sweating does not commence in half an hour the dose should be repeated. It may be given either by the mouth or hypodermatically, although in an urgent case the latter method should be adopted, and it is always preferable. In a given case experience will soon determine what dose should be employed. When bronchial catarrh is present, pilocarpine is said to have produced profuse and even fatal transudation of fluid into the bronchial tubes, so that patients have been "drowned" in their own secretions. I have seen no such results, and I believe the danger of this accident has been overestimated; but where any considerable pulmonary or bronchial lesion exists I place the patient in the hot-air bath ten or fifteen minutes before giving the pilocarpine, so that the flow of blood shall be predetermined toward the surface of the body. Three very desirable results follow the use of pilocarpine in acute nephritis: namely, the reduction of arterial tension, the reduction of the temperature, and the free elimination of urea by the skin, as shown by its enormous increase over the normal amount in the perspiration (Bartholow). In cases of danger, where dropsical effusions threaten the heart or lungs, or where uræmic symptoms are imminent, or where progressive coma indicates transudation into the intracranial cavities, the hot-air pilocarpine sweat should be repeated daily, or even twice in the twenty-four hours, until the immediate peril is averted. Here and there a case will be encountered in which the hot-water bath—placing the patient in the bath-tub with the water at the temperature of 95° to 105° F.—will answer best, because both the dry air and steam are equally repugnant. When this is the case, by all means let the hot bath be employed, but let it also be remembered that the hot dry air is therapeutically the most efficient, because it produces the most copious diaphoresis; the steam-bath is next best, while the hot-water bath possesses the least eliminative power.

It would be a waste of time to discuss the older and now wellnigh obsolete diaphoretics in view of the certainty which follows the use of those already mentioned.

While the above methods of treatment are being pushed, certain internal remedies may be used as adjuncts for the purpose of lowering temperature, lessening arterial tension, calming nervous excitement, and unloading the kidneys of the products of exudation and waste. These various indications may be met by such remedies as aconite, codeine, or the bromides, and the potassic salts, especially the acetate or citrate, or the acetate of sodium. I frequently prescribe some such mixture as the following:

R. Tr. aconit. ℥ss.
 Codeine gr. ij.
 Potass. citrat. ℥ij.
 Glycerini ℥ij.
 Aquæ cinnamom. q. s. ad ℥viiij.—M.

Sig. A dessertspoonful every two hours in half a glass of pure water.

This formula is intended for a child of seven or eight years of age; of course the quantities must be increased or diminished according to age. In some

cases it will be found that the codeine provokes nausea; when this happens, sodium bromide or potassium bromide may be substituted. In other cases the potassic citrate will cause gastric eructations or troublesome flatulency; this will call for the use of potassic acetate or sodium acetate in its place. The above formula is given simply as a suggestion; it must be varied so as to suit the indications as they arise. The practitioner should first have a clear and definite comprehension of what he wishes to accomplish; then, and then only, can he set about an intelligent adaptation of means to ends.

If the foregoing measures are promptly and vigorously carried out, it is not probable that uræmic convulsions will supervene; but if they do, the physician must be prepared to act, as it were, by instinct. He must *act*, and deliberate afterward. Place the child immediately in a bath at the temperature of 100° F.; administer chloroform by pouring 10 to 20 drops upon a napkin and holding it very *near*, but not in *contact with*, the nose until the spasms are controlled; if the child be vigorous, healthy, and plethoric, apply a couple of leeches to each temple, and allow the bites to bleed until the temporal arteries soften and cease throbbing; administer 5 to 10 grains of sodium bromide every hour till its effect is manifested; give a brisk cathartic—and I know none better than a full dose (say 5 grains) of calomel; after the convulsions cease remove the child from the hot bath to the hot-air tent (as before described), and administer hypodermatically $\frac{1}{8}$ grain of pilocarpine.

It will be of very little use to administer diuretics at this time, as the kidneys are not at all likely to respond under such circumstances, but it will be entirely in order to administer 10 grains of the acetate or citrate of potassium every two hours, dissolved in a liberal quantity of water.

It will generally be found, however, that the renal congestion will be so much relieved by the action of the cathartic and diaphoretic that the kidneys will resume their functions spontaneously. For several days after a uræmic convulsion, or until the kidneys resume their action, the child should be carefully watched, should be kept in bed, and given a milk diet, and the action of the diaphoretics and cathartics should be kept up in a moderate degree. While uræmic convulsions in children seem frightfully dangerous, it is nevertheless true that in most cases the danger is more apparent than real, and recoveries are by no means unusual.

The treatment above given is that which is adapted to the first stage of acute nephritis only. It is now incumbent upon us to consider what should be done after the violence of the first attack is past and convalescence has fairly commenced.

The problem before us is to restore to their structural integrity kidneys which have been intensely congested, which have suffered laceration of many of their minute blood-vessels, whose glomeruli and tubules have been invaded by copious fibrinous exudation, which is still taking place, although in a comparatively slight degree.

In all cases of albuminuria with scantiness of urine the temptation to administer diuretics is very great, and yet in the great majority of cases no more unwise measure could be adopted. It is always true that stimulating or irritating diuretics should be carefully avoided unless some very imperative demand for their employment exists. In fact, diuretics bear the same relation to inflammation of the kidneys that cathartics do to inflammation of the alimentary canal. A mild aperient for a specific purpose may be proper in a case of enteritis; so, under similar conditions, a mild diuretic may be proper in a case of nephritis; but in neither case can the remedy be regarded as curative of the lesion. In nephritis, as we have seen, the renal tubes become occluded

by fibrinous casts, and experience has demonstrated that these casts are soluble in the alkaline salts of potassium. It is therefore advisable to administer 10 grains of the citrate of potassium, dissolved in half a glass of water or lemonade, every three hours, it being well known that citric acid and the citrates are converted into alkalies after ingestion. If there be any serious indication of cardiac exhaustion, digitalis may be combined with the potassium, but not unless it is clearly indicated. I am persuaded that the indiscriminate and ill-judged use of digitalis and other cardiac tonics is productive of more harm than good. It should be remembered that digitalis and other cardiac tonics are not direct but indirect diuretics, acting by virtue of their power of increasing arterial tension. But the potassic salts are "direct" diuretics; that is, they actually increase elimination of the factors of the urine, especially urea, the most important of them all. Thus they subserve two useful purposes: they remove from the occluded tubes the plugs of fibrin and other material, and they rouse the dormant epithelia of the convoluted tubes into action without unduly exciting them. The vegetable potassic compounds, more particularly the citrate or acetate, may very properly be continued in medium doses until the albumin has disappeared from the urine.

One of the constant results of nephritis is anæmia, frequently of a very pronounced type. This is due to loss of blood, loss of albumin, but perhaps quite as much to the body waste which attends pyrexia and the cessation of assimilating power. No acute disease produces such rapid and extreme anæmia as acute nephritis. It is important that it be recognized *early*, before the anæmic or "run-away" heart is developed, which is so prone to result in valvular disease and a life of suffering. The remedies are rest in the recumbent position, appropriate food (of which I shall speak presently), and the chalybeate tonics. Of the latter, the "mistura ferri et ammonii acetatis" (otherwise known as "Basham's mixture") or the ferri et potassii tartras, or the ferrum dialysatum have given me the best results, and I have mentioned them in the order of their comparative value. Basham's mixture is an elegant diuretic tonic, usually very well borne and easily assimilated. It can be given as soon as the temperature falls to the normal point, and thus the practitioner can anticipate and prevent the extreme anæmia so sure to follow if the case be allowed to drift on. When the urine is scanty and the sediment abundant, it is an excellent plan to combine equal parts of a saturated solution of potassium citrate with Basham's mixture, of which a teaspoonful every three hours may be given to a child eight years old. A very good formula is the following:

R. Sol. potassii citratis (sat.),
 Mist. ferri et ammonii acetatis $\bar{a}\bar{a}$ f $\bar{5}$.j.
 Glycerini f $\bar{5}$.j.
 Aquæ q. s. ad f $\bar{5}$ iv.—M.

Sig. A dessertspoonful every three hours in water.

I am much in the habit of adding glycerin to diuretic formulæ, because it seems in some unexplained manner to promote their action. At a later period, when the kidneys no longer require any specific medication and a stronger tonic is desirable, the potassic tartrate of iron may be substituted in doses of from 3 to 5 grains three times a day. No other therapeutic measures will be required unless special complications arise: if this be the case, they must be met according to the indications in each particular instance.

The diet of a child suffering from acute nephritis, or, in fact, *any* lesion inducing renal inadequacy, is of the utmost importance. Both theory and

experience concur in the necessity for excluding a nitrogenous dietary. In the early stage of acute nephritis all solid food should be cut off. This exclusion should extend also to broth, beef-tea, soups, and all forms of liquid diet of which beef or mutton forms the basis. The ideal food is milk, and during the period of invasion this should be taken sparingly. Milk and water (half and half) is an excellent combination, as it combines nutrition with a natural diuretic. As the kidneys regain their activity and fever subsides pure milk may be given, together with bread, oatmeal, or crackers. A little fruit, as a baked apple or the juice of an orange, may also be allowed, but the diet should be increased slowly and cautiously, and flesh food must be prohibited until the casts and albumin have been absent for several consecutive weeks, and even then it should be given only in small quantities once a day.

A few general suggestions may not be improper. The patient—be he child or adult—should not be discharged as “cured,” but should be kept under observation long after all signs and symptoms of trouble have disappeared. If frequent examinations of the urine are kept up, as they should be, the practitioner will be surprised every now and then to find a little albumin and a few small structureless hyaline casts appearing, even after they have been absent for many weeks. So long as this is the case there is great danger of a sudden return of the acute symptoms with a fatal result, or of the supervention of chronic nephritis, with equally sad, although less sudden, consequences. It is therefore the duty of the physician to warn parents of the lurking perils, and to exercise a personal supervision over the patient until health is fully restored.

Again, muscular exercise is dangerous to a patient recovering from acute nephritis, because it strains the heart and loads the urine with nitrogenous products of disassimilation, thus throwing work upon the kidneys which they cannot safely do. The patient should therefore be kept quiet for a much longer time than seems necessary to parents and friends. Lastly, the patient should be warmly clad and carefully guarded from exposure to wet and cold. Woollen garments and confinement within doors should be insisted upon until the child's symptoms and the weather give concurrent testimony that gentle exercise in the open air may be cautiously entered upon. To some these suggestions may seem superfluous, but to observe them will do no harm, while if they are neglected the lives of helpless children may pay the fearful penalty.

II. CHRONIC TUBAL NEPHRITIS.

Synonyms.—Chronic diffuse nephritis; Chronic catarrhal nephritis; Chronic croupous nephritis; Chronic parenchymatous nephritis; and Chronic Bright's disease.

Etiology.—Acute nephritis is the most common cause of chronic nephritis in children. Scarletina stands next in order; then comes exposure to cold and wet, especially when combined with malarious or other unhealthful surroundings, as is so frequent among the children of the neglected poor. Long-continued suppuration, although more likely to produce amyloid degeneration of the kidneys, may cause chronic tubal nephritis, probably, as Bartels suggests, because “something is developed in these collections of pus which is taken up into the blood by absorption and excreted by the kidneys, and which, during its excretion, excites an inflammation of these excretory organs.” Nearly twenty years have elapsed since these words were written, and we do not yet know what that “something” is, but in the light of modern pathological research we can easily understand that the toxic derivatives of chronic suppuration might easily worry the kidneys into chronic inflammation.

Diphtheria must certainly be regarded as a cause of chronic as well as of acute nephritis, and so must measles, but less frequently. Few cases of diabetes mellitus terminate without the supervention of chronic tubal nephritis. Finally, anything which demands constant overwork of the kidneys, or which results in a slight but long-continued irritation of them, may prove the groundwork of chronic tubal nephritis.

Symptoms.—The symptoms vary very much in different cases, being modified by the rapidity with which the disease progresses. When the progress is rapid the symptoms are more pronounced, and *vice versa*. In a typical case of chronic tubal nephritis the first symptom attracting attention is likely to be great debility and well-marked anemia. The pulse is small, rapid, and feeble, and anæmic cardiac murmurs are common. There will probably be no rise of temperature, or, if any, very slight and inconstant. The digestion is impaired, the tongue coated, and the bowels torpid or loose and irregular. Following these symptoms, and frequently coincident with them, is dropsy, generally first manifested on the dorsum of the foot and around the ankle-joints, or perhaps it is first seen in the swollen and transparent eyelid. There is also a marked pallor or waxy appearance of the face, which is quite characteristic. The dropsy extends up the lower extremities, invades the abdomen, may reach the chest and oppress the lungs and heart, so as to become a source of serious danger, although this can generally be avoided.

The disease is usually divided into three stages; this division, though somewhat arbitrary, is convenient. During the first stage the urine is generally scanty, dark, and turbid; of variable, but with a tendency to high, specific gravity (1020 to 1025), and heavily loaded with albumin (2 grams or more to the litre), as determined by Esbach's "albuminometer"—the best, because the simplest, apparatus yet devised for the practical quantitative estimation of albumin. After standing, the urine deposits an abundant precipitate composed of hyaline and epithelial casts, with occasionally a blood-cast, renal epithelia, and granular matter of indeterminate origin. Chemical examination will show the percentage of urea to be much less than normal, while the chlorides, sulphates, and phosphates, though diminished somewhat, are nearer the normal point.

With the development of the second stage the urine increases in quantity, but becomes pale in color, sometimes all but colorless, of low specific gravity (1005 to 1010), less turbid, but not quite clear, and the sediment diminishes very much in quantity, and also becomes nearly colorless. But the quantity of albumin remains large, rarely falling below $1\frac{1}{2}$ grams to the litre, and the solid excreta are still markedly deficient. The casts also change. The blood-casts disappear entirely; the hyaline casts increase in number, and many of them are large and somewhat distorted, showing that they are formed in tubes which have shed their epithelium. The epithelial casts present a granular cloudy appearance, and their borders are eroded or "nibbled," showing that fatty change has commenced in the epithelia and that the walls of the tubes have become roughened and irregular. As the disease progresses an occasional wave of renal hyperæmia may occur, when the urine again becomes scanty, dark, and cloudy, and the casts characteristic of the first stage reappear, but intermingled with these will be found the granular casts which belong to the second stage, so that no serious confusion as to the diagnosis need occur.

With the commencement of the third stage the urine again becomes scanty and cloudy, but is still pale and watery. The albumin does not diminish, but is more likely to increase. The casts now become "fatty;" that is, they are large, short, irregular, with rough borders, and contain fine fatty granules, minute drops of fat, and epithelial cells in an advanced state of fatty degenera-

tion. During this stage periods of partial or incomplete suppression of urine are apt to occur, followed by uræmic convulsions, succeeded by coma, or perhaps sudden death without coma; or drowsiness may gradually steal over the patient, until it becomes coma ending in death. Meantime the dropsy becomes general, the limbs swell almost to bursting, the abdomen becomes distended with fluid, the thoracic cavity gradually fills, pulmonary œdema with impeded respiration occurs; the heart labors violently until it suddenly fails from exhaustion, and death ensues. It must not, however, be inferred that all cases present these distressing symptoms. In the majority they are either not witnessed at all or are easily anticipated and prevented.

Diagnosis.—Chronic tubal nephritis may be confounded with (*a*) chronic interstitial nephritis; (*b*) amyloid disease of the kidney; (*c*) cyanotic induration of the kidney.

(*a*) Chronic interstitial nephritis is very rare in children, but it is not difficult to differentiate it from tubal nephritis. Chronic interstitial nephritis (renal cirrhosis) is characterized by its slow and insidious development; by the increased volume of urine; by its low specific gravity and small amount of albumin; by the absence of dropsy, except in the last stage; by the early development of cardio-vascular tension; and, generally, by well-marked lithæmia. None of these symptoms are present in chronic tubal nephritis.

(*b*) Amyloid disease of the kidney is most likely to occur in children, and, as it sometimes occurs in connection with tubal nephritis, a certain diagnosis may be impossible. The distinctive features of amyloid disease are an increased quantity of urine with a comparatively large amount of albumin; absence of leucocytes and epithelial cells, but the presence of numerous small hyaline casts which are perfectly structureless, but some of which are likely to give the characteristic reaction with iodine. There is usually considerable disturbance of the digestive tract, with hypertrophy of the liver and spleen, and this disease is almost always caused by and associated with syphilis, tuberculosis, or some chronic disease involving suppuration. These diagnostic points are quite sufficient to distinguish an uncomplicated case of chronic tubal nephritis from an uncomplicated case of amyloid disease.

(*c*) Cyanotic induration of the kidneys only occurs where there is some obstructive lesion of the organs of circulation which retards the movement of blood through the kidneys and produces venous stasis. There is little albumin in the urine; the casts are few, generally small, and of the hyaline variety; dropsy is generally limited to the lower extremities; respiration is difficult; much exercise is impossible; and the circulation is much embarrassed. None of these peculiar features belong to chronic tubal nephritis. But careful attention to the history and constructive symptoms of the latter almost invariably enables the practitioner to arrive at a correct diagnosis.

Morbid Anatomy.—In a given case the morbid appearances will depend entirely upon the stage at which the examination is made. I shall briefly describe the macroscopic and microscopic changes which are peculiar to each of the three stages, which are themselves founded upon the anatomical changes so uniformly present.

During the first or hyperæmic stage the kidney is either of normal size or only slightly enlarged; the capsule is somewhat cloudy, but strips off easily, leaving the surface of the kidney smooth and red or purple. On section blood oozes from the cut vessels, and the cortex is seen to be relatively increased. The vessels in the "boundary layer" are turgid and frequently tortuous, and the vasa recta stand out as well-defined red lines running toward or into the apices of the cones. Between the straight vessels numerous white or grayish

lines will be seen; these are the straight tubes occluded and distended by casts and epithelia. Microscopic study of a section of the cortex will show that the blood-vessels are dilated and tortuous—that the convoluted tubes are stuffed with fibrinous casts, perhaps blood-globules, and enlarged epithelial cells, some of which are in a state of “cloudy swelling.”

The second or hypertrophic stage results in considerable, and sometimes extreme, enlargement of the kidney; the capsule is but little changed and strips off easily, leaving the surface generally smooth, but with here and there a slight cicatrix-like depression. Its color is variable and mottled, showing pale grayish or whitish spots or islands surrounded by interlacing groups of “stellate” vessels, which are beautifully displayed. The pale spaces are the distended fatty convoluted tubes lying near the surface. On laying the kidney open longitudinally it will be seen that the cortex is increased, but pale or yellowish, and that it is anæmic rather than hyperæmic. The Malpighian bodies are not enlarged and prominent as in the stage of hyperæmia. The vessels in the boundary-layer are thickened and enlarged, but not distended with blood. The cones or pyramids have undergone no essential change. This is the so-called “large white kidney” or “large fatty kidney.” The microscope shows the convoluted tubes distended with epithelia in an advanced state of fatty degeneration; they also contain granular casts and fine fatty granules which have not fused into drops. The Malpighian bodies are somewhat enlarged, and the space between the glomerulus and the capsule of Bowman is apt to be occupied by exuviated epithelial cells in a state of fatty transformation. The walls of the blood-vessels may be somewhat thickened, but not markedly so. It will be seen that the “hypertrophy” is more apparent than real, and that it is mainly due to the distention of the tubuli contorti, each one of which occupies far more space than it does normally. The connective tissue is not materially increased.

The third or last stage is very appropriately known as the stage of “atrophy.” The kidney is small, shrivelled, mottled, but the predominant color is gray or grayish yellow. *It is never red.* The capsule is generally slightly thickened, but strips off easily, except that here and there it may bring a small bit of the kidney with it. The surface of the organ is no longer smooth, but broken by alternating elevations and depressions. On section it is seen that the cortex is wasted or atrophied, while the medullary portion is not materially changed. The cut surface is frequently oily to the touch, and if it be scraped with a scalpel, drops of oil will appear upon the blade. Microscopic sections show many of the tubules shrivelled and wasted—many others distended with fatty casts, free fat-drops, and epithelial cells in complete fatty degeneration. The walls of the blood-vessels are much thickened, and the connective tissue is somewhat increased, but has not entered upon the contractile process which produces cirrhosis. It should also be observed that the kidney is pale throughout its entire extent, which fact differentiates it from the “cirrhotic kidney,” to be considered presently.

Prognosis.—During the first or inflammatory stage recoveries are common. They ought to be more so. An early and correct diagnosis and an appropriate line of treatment, administered with some faith in its efficacy, are indispensable to the successful treatment of chronic nephritis. Unfortunately, the impression is quite too general among the profession that chronic Bright’s disease is always incurable, and impressions ingrained for years are apt to become dogmas. Nevertheless, chronic tubal nephritis, at any time up to the actual development of the second or degenerative stage, is a curable disease, and especially so in children, in whom the constructive forces are at their best.

After the development of the second stage, or that of pseudo-hypertrophy, the prognosis is far less favorable, yet not absolutely hopeless. I have seen recoveries take place when all the symptoms indicated the inception of fatty changes in the kidney. Each day's delay renders the prognosis less hopeful, and as the hyaline casts diminish and the fatty casts increase in numbers the prognosis increases in gravity.

With the development of the third stage, or that of atrophic wasting, all hope of recovery ends. As functional organs the kidneys are now practically destroyed. Distressing symptoms may be relieved and life may be prolonged, but that is all. Yet the physician must be sure of his diagnosis before he abandons hope, and in the practice of medicine it is far better to err on the optimistic than on the pessimistic side. The disappearance of hyaline casts or their very infrequent appearance, the prevalence of large irregular fatty casts, which are short, broken, and loaded with fatty epithelium and fat-drops, together with progressive diminution in quantity of the urine, are the most reliable diagnostic factors.

Treatment.—The treatment of every case of chronic nephritis should stand by itself, and should be carried out in accordance with a well-digested plan founded upon an accurate determination of the stage of the disease.

During the first stage, where the condition of the kidneys is something similar to that in acute nephritis, the chief object is to place the inflamed organs at rest. The patient should therefore be kept as quiet as possible and carefully guarded from exposure to cold. The bowels should be kept freely open by means of saline cathartics. The skin must be actively stimulated and made to do vicarious duty by means of hot air and pilocarpine. The kidneys should be relieved of tube-casts and other obstructive material by the use of the potash salts, much as indicated in the article on Acute Tubal Nephritis. In fact, the general indications are practically the same, and the same measures should be employed, only less vigorously. The diet should be the same—namely, milk in some form with a little fruit—and the patient should be urged or tempted to drink water freely. A little fish, a bit of broiled quail, or a chicken's wing may occasionally be allowed for the purpose of varying the monotony, but grills and roasts must be forbidden. The child should be kept warm and the inner garments should be of wool. I particularly insist on woollen stockings—a point that will surely be neglected by mothers and nurses unless insisted upon by the medical adviser. As the case progresses toward recovery chalybeate tonics are indicated, and I advise the employment of those already mentioned in the article on Acute Nephritis, to which reference may be had for details.

During convalescence the patient should be carefully watched, and it must not be forgotten that convalescence is not perfect recovery. Albuminuria will disappear slowly, and will reappear after long intervals of absence, thus showing that the renal vessels have not yet recovered their tonus; the heart will remain irritable and weak for a long period; and the hæmogenetic power of the little patient will be recovered slowly. Hence careful but not ostentatious or over-officious watching will be required for several months after all symptoms have disappeared.

When the disease becomes chronic, as indicated by the symptoms denoting "fatty kidney," the treatment will be somewhat different. The kidneys must now be relieved as much as possible by bringing the skin and intestinal tract into play. Minute doses of pilocarpine— $\frac{1}{40}$ of a grain for a child of six or eight years—may be given four times a day. A warm salt-and-water bath three times a week, followed by smart friction, is a very useful adjunct to the

pilocarpine, the bath of course being given in a warm room. If the skin is rough and dry, it is a very good plan to rub the child with fresh and well-warmed olive or sweet almond oil after each salt bath. These measures may be continued indefinitely.

Cathartics must be employed frequently, but wisely. Violent catharsis is rarely required; gentle stimulation of the bowels is frequently needed, and is very useful, both for its derivative and its eliminant effect. The saline cathartics are most useful, but an occasional cholagogue, like the following, will not be amiss:

R̄. Resin. podophylli gr. j.
 Hydrarg. chlorid. mit. gr. x.
 Sodii bicarbonatis gr. xxx.—M.

Ft. chart. No. X.

Sig. One powder to be given every third night.

Diuretics should be used sparingly, and not with any expectation of "curative results." The acetate or citrate of potassium, and the bitartrate in the form of "imperial drink" [U. S. P.], are the safest and most efficient. They should be given freely diluted. Cardiac tonics will doubtless be required as the case progresses, but they should be reserved until they are actually needed, as their premature employment exhausts the heart-muscle unnecessarily. Of the various heart tonics, digitalis and strophanthus are the most reliable. The chalybeate tonics will be indicated, and the mixture of the acetate of iron and ammonia, the potassio-tartrate of iron, and the newer preparation called "ferum dialysatum," have my preference in the order written. Special symptoms will require attention. Dropsy, if excessive, demands active diuretics, as squill, apocynum cannabinum, or that excellent preparation, "Trousseau's diuretic wine," which consists of—

Junip. contus., ʒx; Pulv. digitalis, ʒij; Pulv. scillæ, ʒj; Vini Xerici, Oj; macerate for four days, and add potass. acetatis, ʒiij; express and filter. Dose, one teaspoonful in water every three hours for a child of six or eight years, (Tyson's *Bright's Disease and Diabetes*).

Hydragogue cathartics and active diaphoresis must be employed in conjunction with the diuretics; among the former, calomel and jalap, concentrated solutions of salines, and elaterium are the best, in about one-third the dose of an adult for a child from six to eight years old. As to diaphoretics, the hot-air apparatus (see page 986), with pilocarpine, stands first always; but the hot bath or warm pack, aided by pilocarpine, may be employed for the want of something better. It may be found necessary to make minute punctures through the skin of the ankle or dorsum of the foot, so that the dropsical fluid may drain away. I prefer the point of a sharp tenotomy blade for this purpose. If uræmic symptoms appear, they must be treated as already indicated. Uræmic asthma is likely to arise; it may be temporarily relieved by nitrite of amyl, spirits of chloroform, elixir of valerianate of ammonium, or any other antispasmodic at hand, but it is a consequence of uræmia and calls for increased elimination. Insomnia may be relieved by sulphonal, chloral, somnal, or any of the newer hypnotics. I am accustomed to giving paregoric to children with chronic Bright's disease who are kept awake by distressing symptoms, and with the happiest effects, although the practice is not in strict accordance with therapeutic orthodoxy.

III. AMYLOID DISEASE OF THE KIDNEY.

Synonyms.—Waxy kidney; Lardaceous disease; Depurative disease.

Etiology.—The most common causes of amyloid kidney are syphilis; exhaustive and long-continued suppuration, especially if associated with necrosis of the vertebrae, as in Pott's disease, or of disease of the large joints, as in coxalgia; phthisis pulmonalis; chronic ulcerative disease of the bowels; and chronic albuminuria. As some of these affections are not uncommon in children, it follows that they are liable to amyloid disease of the kidney. The most perfect or complete specimen that I have ever seen occurred in a girl of ten years, who was fairly worn out with repeated abscesses due to Pott's disease. Amyloid disease rarely occurs in a child under five years, for the reason that the above-named causes rarely exist prior to that age; yet Dickinson cites a case of amyloid spleen in a boy two and a half years old who had an exhausting abscess of the thigh.

Pathological Anatomy.—In the early stage the kidneys are about normal in size and present little change except to the experienced observer, who will note a peculiar paleness, together with a translucent appearance, when thin sections are held between the eye and a strong light. The capsule is non-adherent. When the kidney is laid open no essential change in the relative proportion of cortex and medulla is seen, but all parts appear pale and comparatively bloodless. If a few drops of an iodine test-solution be applied, multitudes of mahogany red or reddish-brown points will appear, thus locating the infiltrated Malpighian bodies.

At a more advanced stage the kidneys are enlarged, sometimes considerably, though not to an extreme degree, unless amyloid disease and chronic tubal nephritis coexist. The pale waxy or bacony appearance will now be very apparent, and the iodine reaction will extend to the convoluted tubes, the vessels of the labyrinth, and the vasa recta.

In the last stage the kidney is atrophied, contracted, and deformed. The capsule is thickened and adherent, the cortex is wasted, and one is reminded of the cirrhotic kidney, except that the latter is red or brownish red, while the one under discussion still preserves its pale waxy appearance. Microscopic sections show the glomeruli, the capillaries of the labyrinth, the vasa recta, and most of the tubules infiltrated with the characteristic waxy material. The application of the iodine test-solution¹ enables the observer to accurately differentiate the infiltrated from the normal structure.

Prognosis.—As a clinical fact, amyloid disease is incurable. In a given case, if the cause can be effectually and permanently removed before the kidneys are damaged beyond the power of carrying on their functions, life may be prolonged indefinitely. Moreover, if the patient be a child of six or eight years, subsequent growth and development may practically restore the structure and function of the diseased organs. So much for theory. In practice we generally find that the cause cannot be removed: that the liver is almost sure to be infiltrated with amyloid deposit to quite as great an extent as the kidneys; and that in most cases the spleen suffers as well. In other words, we are taught that, under certain conditions, amyloid disease is curable, but in practice these fortunate conditions are hardly ever met with: hence the disease is scarcely ever cured.

¹ I recommend the following formula:

R. Iodi	gr. iij.
Potassii iodidi	gr. vj.
Glycerini	fʒj.
Aque dest.	ad fʒj.—M.

Treatment.—Obviously the most important thing is the discovery and removal of the cause. As I have already said, if this can be accomplished, the progress of the disease may be arrested and the patient may live out his days. In clinical experience this can rarely be done. The next best thing is to reduce suppuration to the minimum, and secure free drainage and asepsis for suppurating cavities; to remove dead bone if it exists, and encourage the process of repair if possible; to adopt the most approved treatment for tuberculosis if present, including change of climate when it is necessary and practicable; to institute antisyphilitic treatment when indicated; and, in fine, to search out and remove the cause if possible. We possess no specific agents for the cure of amyloid disease. The iodides—especially of iron and potassium—have been highly recommended and much employed, but I have never seen any positive results follow their use. Theoretically, I should expect more from arsenic or the chloride of gold and sodium. Diuretics must be given if symptoms of suppression show themselves. Diarrhœa, which is likely to be troublesome, must be treated on general principles. Anæmia—always pronounced in amyloid disease—should be combated by iron, malt, cod-liver oil, arsenic, and especially by a liberal diet, which may be safely given unless nephritis should complicate matters. If dropsy becomes troublesome, the diaphoretics, diuretics, and cathartics already recommended will answer every purpose. Uræmia is not likely to occur, as the functional power of the kidney is destroyed so slowly that the system acquires “toleration;” but if it occurs it must be treated promptly and vigorously as already indicated. If nephritis arises, it will require the prompt employment of the measures recommended in a previous article; it is of course a dangerous complication and one of not very infrequent occurrence. Other complications may arise, just as they may in the course of any other chronic disease, and must be met and treated according to the indications presented in each individual case; but the physician should remember that the eliminating power of the kidneys is more or less damaged, and he must exercise due care in the use of certain drugs, like digitalis, which have a cumulative tendency.

IV. CHRONIC INTERSTITIAL NEPHRITIS.

Synonyms.—Renal cirrhosis; Gouty kidney; Granular degeneration; Contracted kidney; Renal sclerosis, etc.

Etiology.—Among the most frequent causes of interstitial nephritis are rheumatism and gout (more correctly called lithæmia), alcoholism, lead-poisoning, valvular disease of the heart, malaria, mental strain, heredity, and chronic lesions of the genito-urinary tract. As these causes are hardly ever active in childhood, it follows that cirrhotic kidney is exceedingly rare under puberty. All authors to whose writings I have access agree that it is not a disease of childhood. I have never seen a case in a patient under thirty. Bartels records one case at eighteen years, and Dickinson one “between eleven and twenty years.” Suppurative interstitial nephritis, pyelo-nephritis, or “surgical kidney,” may occur in children, but it does not fall within the scope of this work. It is of course possible that heredity or cardiac disease may cause contracted kidney in childhood, but in clinical experience we rarely meet with such cases.

Symptoms.—The following are the four classic symptoms of interstitial nephritis, and I may mention them in the order of their occurrence: (1) increased arterial tension, with a sharply accentuated second sound of the heart: the increased arterial tension is easily recognized by examining the pulse; (2) the

small amount of albumin present (rarely more than 1 to 2 per cent. by volume) or its entire absence for considerable periods of time; (3) the small number of casts, their small size and structureless or hyaline appearance, and their form, which is in many instances twisted or distorted; (4) the appearance of albuminuric retinitis, which is a late and very characteristic symptom.

These four symptoms are so nearly always present in interstitial nephritis, and so uniformly absent in other forms of renal disease, that they may be regarded as pathognomonic. Early in this disease the urine is pale and watery, increased in quantity, and of low specific gravity (1005 to 1010).

Pathological Anatomy.—Chronic interstitial nephritis results in the production of the "small red," "contracted," or "cirrhotic" kidney. The kidneys are contracted, atrophied, rough or nodulated, and dark red or brownish red. The capsule is thickened, and when pulled off tears away portions of the kidney with it. On section it is observed that the cortex is very much wasted, and the medulla somewhat so. The arteries are enlarged, tortuous, prominent, and unyielding or inelastic. The organ is indurated and condensed. Microscopic sections show a great increase of the connective tissue, with wasting and distortion of the tubules and the smaller blood-vessels. Broad bands of connective tissue will be seen between the remaining tubules and surrounding the Malpighian bodies. Many minute cysts will be seen which are due to dilations of the tubuli mainly, but partly to dilated Malpighian bodies.

Prognosis.—Chronic interstitial nephritis is incurable. The damage done by overgrowth of connective tissue cannot be repaired. Yet it is quite possible to arrest the further increase thereof, and thus practically arrest the disease and prolong life indefinitely. Much depends upon the patient's habits, environment, temperament, age, and social condition. Under favorable circumstances so much can be accomplished that, so far as the patient is concerned, a practical cure may be expected. But the physician must not forget the inveterate tendency of connective tissue toward mischief when once aroused, and he must regard the disease, although latent, as still present and ready to break forth at any unusual provocation.

Treatment.—I reaffirm and refer to all that I have said in the foregoing pages regarding habits, dress, exercise, and food and drink, except that the dietary may include a little fish or fowl or a small allowance of almost any kind of game once a day. Medical treatment should be directed to the arrest of the further development of pathological connective tissue in the kidney. For this purpose the remedies most efficient in my experience are bichloride of mercury, iodide of potassium, and chloride of gold and sodium, in small doses long continued. I use but one of these remedies at a time, but alternate them at intervals of two or three weeks. If the kidneys falter, diuretics are indicated, and I have found the lactate of strontium a prompt and efficient diuretic in this form of Bright's disease. It may be given in doses of 5 grains three times a day to patients from six to eight years old. Diuretic sometimes answers very well, but is quite likely to fail altogether. Of course the potash salts may be given with every expectation of good results. Chalybeate tonics are indicated in most cases, and the tincture of the chloride of iron is particularly adapted to our wants. If combined with syrup of lemon (℞. Tr. ferri chloridi, fʒj; syr. limonis, ad fʒij.—M.) it makes a very palatable mixture, and will be readily taken by children. Heart failure, uræmia, and other complicating symptoms must be met and treated as already indicated in the foregoing articles.

TUMORS AND OTHER ENLARGEMENTS OF THE KIDNEY.

BY THOMAS R. NEILSON, M. D.,

PHILADELPHIA.

TUMORS of the kidney are met with in infancy and childhood with sufficient frequency to make the subject one of great importance from a clinical point of view. In the allotted space the different varieties of these tumors, or those diseases of the kidney which may constitute tumor, will of necessity be considered somewhat briefly. But, while no extended discussion of the subject can be attempted, the effort will be made to present as compactly as possible the essential facts.

In addition to solid growths—neoplasms—certain other affections, cysts, hydronephrosis, pyonephrosis, and perinephritic abscess, may give rise to enlargement in the renal region. These will be first taken up.

RENAL CYSTS.

CONGENITAL CYSTIC DEGENERATION OF THE KIDNEY.

This condition may cause tumors of considerable dimensions. It sometimes results in destroying the life of the fœtus or in premature birth, and so great may be the size of the tumor that delivery is impossible and embryotomy is required. In less-marked cases the child may live a few months or even a year or two, and may not give evidence of the affection by the presence of tumor, but sooner or later is likely to perish either from uræmia or from exhaustion. In this disease the kidney is studded with or changed into a conglomeration of cysts of varying sizes, filled with a fluid usually clear, but sometimes turbid, and containing urea and urinary salts. Both kidneys are, as a rule, affected.

The condition is generally accompanied by defects of development of the urinary apparatus, such as absence of the pelvis of the kidney or the ureter, exstrophy of the bladder, and malformations of the genitalia, as well as vices of conformation of the extremities, hare-lip, cleft palate, etc. The origin of the affection has been explained by Virchow as due to an imperforate condition of the straight tubes of the papillæ, resulting from a prenatal inflammation caused by impaction of the ducts with uric acid and the urates, and leading to retention of secreted urine and dilatation of the uriniferous tubules. Another view of the etiology has been taken by Köster, who considers the condition to be due to defective development. The accompanying abnormalities of the urinary organs, as well as of other parts of the body, would seem to favor this theory, at least in some cases.

Cystic degeneration is not likely to call for surgical treatment. Even

though there should be marked symptoms caused by the dimensions of the tumor, the strong probability of both kidneys being affected and the fatal tendency of the disease would interdict any radical interference, and even aspiration could offer but slight temporary relief, if any at all.

PARANEPHRIC CYST.

Another variety of renal cysts which may be met with in children is one which grows in the cellulo-adipose tissue surrounding the kidney, the cyst not being primarily connected with the kidney. Morris, in his work on *Surgical Diseases of the Kidney*, mentions an interesting case of this kind reported by Mr. Cæsar Hawkins, observed in a boy six years old. In this instance the cyst developed from an imperfect third kidney, and reached great proportions, extending from the lower border of the thorax to Poupart's ligament. The cyst seemed to be like the simple renal cysts met with in adults, and was filled with a clear fluid which contained neither albumin nor urinary salts.

Paranephric cysts may be of congenital origin, as in the case just referred to, and sometimes they may be due to traumatism. They may communicate secondarily, by a fistulous tract, with the pelvis of the kidney or the ureter. The diagnosis of the tumor from other forms of renal cyst and from hydronephrosis must be difficult, if not sometimes impossible.

Treatment.—These cysts should be evacuated with the aspirator, and the procedure repeated if the fluid should reaccumulate. If, after this has been tried, the cyst should rapidly fill up again, it would be better to cut down upon it and incise it, securing it to the margins of the wound in the integument, thus maintaining drainage.

HYDATID CYSTS OF THE KIDNEY.

The ova of the *tænia echinococcus*, a diminutive species of tapeworm infesting some of the lower animals, notably dogs, sheep, and swine, are sometimes transmitted to man in food and drinking water, and give rise to what are known as hydatid cysts. In the kidney hydatids are not so frequent as in the liver, the statistics of Davaine, quoted by Roberts, showing the proportion to be 1 to about $5\frac{1}{2}$.

Pathology and Symptoms.—Hydatid of the kidney may be met with at any age, although less often in children than in adults, and is unilateral, involving the left oftener than the right kidney. Palpable tumor is produced in somewhat less than one-half of the cases. The cyst, surrounded by a capsule of fibrous tissue and having in its interior the characteristic daughter cysts, usually develops in the parenchyma of the kidney, but sometimes between the organ and its capsule, and, as it grows, encroaches on the kidney tissue, causing more or less atrophy. Sometimes several hydatids are found in the same kidney. These cysts tend to rupture and discharge their contents, and this may take place into the pelvis of the kidney, which is the usual place, into the intestine, or into the lung. The peritoneum is generally pushed forward by the tumor, and rupture into its cavity never occurs.

Unless the cyst has attained proportions sufficient to constitute a tumor, or unless it should rupture and discharge its contents in the urine, there may be no evidence of its presence. The tumor generally occupies the loin, is globular in outline, and more or less fluctuating. The thrill or fremitus supposed to be peculiar to hydatids is a very uncertain symptom of the disease in the kidney, having seldom been observed in recorded cases. Rupture of the cyst into the

pelvis or ureter is manifested by pain in the lumbar region, together with a sensation of something having given way. Then, as the vesicles descend through the ureter, symptoms similar to those caused by the passage of a renal calculus will be provoked. The vesicles may become impacted and obstruct the ureter, giving rise to distention of the kidney with urine; or, reaching the bladder and escaping into the urethra, they may obstruct that channel and cause retention of urine. The escape of the hydatid vesicles, or of portions of the laminated cyst-wall, or of the peculiar hooklets of the echinococcus in the urine positively establishes the presence of the affection. In some cases pus has been noticed in the urine during the discharge of the cyst. After once evacuating itself the tumor may subside, or, on the other hand, it may fill again and empty itself as before, and this may happen at greater or less intervals for a long time, even many years. Should the cyst undergo suppuration, fever and other evidences of constitutional disturbance will result.

Diagnosis.—A renal tumor is easily recognized as an hydatid cyst when vesicles, particles of cyst-wall, or hooklets appear in the urine. In the absence of this evidence the tumor may readily be mistaken for hydronephrosis, other varieties of renal cyst, or pyonephrosis. Hydatids differ from malignant tumors of the kidney in their slow development and the absence of constant pain and cachexia.

Prognosis.—The disposition of these cysts to rupture and discharge their contents by the urinary channels or to disappear without evacuation makes the prognosis usually good. If, however, the tumor continues to increase in size, it may lead to serious, sometimes fatal, results from destruction of the parenchyma of the kidney or from pressure upon other organs. Suppuration, either in or about the cyst, is a grave complication, and death may follow rupture into the pleural cavity or the bronchi.

Treatment.—With the object of destroying the life of the parasite certain anthelmintics, such as oil of turpentine, male fern, and the like, have been exhibited, but there is no evidence of their efficiency. When hydatids are discharged in the urine, alkaline diluents should be freely given for the purpose of increasing the secretion of urine, and thereby favoring the washing out of the pelvis and ureters. Beraud is mentioned by Roberts as having had a case in which the administration of nitre caused an increase in the discharge of vesicles. Renal colic induced by the escape of hydatids into the pelvis and ureter should be treated as when due to other causes.

If the cyst does not discharge, but continues to increase, or if it should suppurate, or if, from obstruction of the ureter, sudden distention of the kidney should occur, surgical interference will be called for. Under these circumstances, while aspiration may afford relief, the best prospect of success is offered by cutting down to the tumor, opening the cyst, and suturing its edges to the external wound.

HYDRONEPHROSIS.

The term "hydronephrosis" signifies dilatation of the kidney and the ureter from some hindrance to the outflow of urine. The affection may be either unilateral or bilateral. Its causes may be divided into congenital and acquired. When the cause is congenital, it does not necessarily follow that the hydronephrosis is present at birth; it may not develop for some years later. In extreme cases the condition has caused dystochia, necessitating embryotomy.

Etiology and Pathology.—The obstacle which leads to the formation of hydronephrosis may be any one of several. Thus an excessive angulation of

the junction of the ureter with the pelvis of the kidney, a twisting contraction, imperforate condition, or valvulation of the ureter, compression of that duct by an abnormal supernumerary renal artery, and obstruction of the urethra by a septum of mucous membrane, are all recognized causes, falling under the congenital class. As acquired causes may be named obstruction of ureter from injury due to the passage of a calculus or from traumatism from without, stone in the bladder, vesical tumors, stricture of the urethra, phimosis, and habitual frequent micturition. Floating or movable kidneys are sometimes hydronephrotic.

The proportion of cases in which there is tumor is small, but the distention sometimes reaches enormous dimensions. The appearance of the sac varies, sometimes being quite thin and pellucid, while at others it is thick and opaque. The accumulation of urine first distends the pelvis of the kidney; then the calyces becomes dilated, and by degrees the resulting compression causes absorption of the renal substance, until none, or but a mere trace, of it remains. The tumor thus formed is a cyst, sometimes, but not always, subdivided by fibrous septa. Its contents differ in the majority of instances from normal urine. Often a fluid resembling water is found; in other instances it may be brownish; and, again, colloid material may fill the sac. The fluid may contain no salt but chloride of sodium; or uric acid and its salts, oxalate of lime, and the phosphates may be present, as may albumin, pus, muco-pus, and epithelial cells in some cases.

Symptoms.—When the affection is limited to one kidney, and the sac so small as not to produce tumor, it may give rise to no definite symptom; on the other hand, occasionally there may be lumbar pain, thirst, frequent micturition, or intermittent anuria. When both kidneys are hydronephrotic, uræmia may result. When tumor is present, it is situated in the first place in the loin or flank; later it becomes more prominent in the abdomen, and may even reach such a size as to extend from the median line in front to the vertebral column behind, and from the hypochondriac region above to the iliac region below. A very large tumor will by its presence create considerable pain, and in those cases in which the trouble results from an obstruction in itself painful there will naturally be much suffering. The tumor on percussion is dull, and on palpation is soft and fluctuating, and sometimes a lobulated condition of its outline may be noticed. The abdominal viscera may be variably displaced according to the size as well as the direction in which the cyst extends, and symptoms referable to its pressure on the different organs or the diaphragm may result. Sudden subsidence of the tumor, either complete or partial, may occur synchronously with the passage of a large amount of urine. The urine under these circumstances is of a lower specific gravity than normal, and may occasionally contain pus, muco-pus, or even blood. Hydronephrosis is sometimes intermittent.

Diagnosis.—In the few cases in which the abdominal tumor subsides during the discharge of a large quantity of urine the diagnosis presents little difficulty. Under other circumstances hydronephrosis may resemble renal, ovarian, hepatic, or splenic cysts, pyonephrosis, perinephritic abscess, and ascites. There may be considerable difficulty in making the diagnosis from renal cysts, except in the case of hydatids, when vesicles appear in the urine. Ovarian cysts may be distinguished by their relation to the colon, which is generally behind them, and by the absence of dulness on percussion of the loin. In ascites the area of flatness on percussion changes on alteration of the patient's position, while in hydronephrosis it remains fixed. Pyonephrosis and perinephric abscess present a history of pyuria or the constitutional signs of sup-

uration, and œdema and redness of the integument of the lumbar region not characteristic of this affection. Hepatic and splenic cysts are affected by the movements of respiration rather more than the hydronephrotic enlargement, and tend to become prominent anteriorly rather than toward the loin.

Prognosis.—When the condition is unilateral, and the other kidney is equal to carrying the burden of sufficient urinary excretion, there is no immediate risk of life. Even if the cyst be large the prognosis is not unfavorable if it be evacuated early. But if the tumor increase to a great extent, fatal consequences may result from its pressure upon other organs, from rupture into the peritoneal cavity, or from uræmia. In bilateral cases death will sooner or later be caused by the diminution of kidney tissue induced by pressure of the accumulated fluid.

Treatment.—When there is no trouble from the size of the tumor hydronephrosis requires no treatment. Massage is sometimes recommended with the idea of removing the cause of obstruction, but if practised the danger of rupturing the cyst should be borne in mind. Large tumors, accompanied by much pain or by urgent pressure symptoms, call for evacuation of the fluid, which is most easily accomplished by aspiration. This may be repeated if the sac fills again. In inserting the trocar a spot should be chosen where there is no risk of wounding the peritoneum, for if this should happen the escape of some of the cyst fluid into the peritoneal cavity would be attended with great danger. If after repeated aspirations the sac refills, lumbar nephrotomy should be performed. The cyst, having been exposed and emptied, should be secured to the margins of the wound, and after exploring with a probe for calculus in the pelvis or ureter a large drainage-tube should be inserted. The after-treatment consists in antiseptic irrigation of the cyst, for which purpose either boric-acid solution or Thiersch's fluid may be used. If a persistent fistula should follow this operation, and if it be known that the amount of renal tissue remaining is insignificant, nephrectomy is to be recommended.

PYONEPHROSIS.

Distention of the kidney with pus or with urine and pus is called pyonephrosis.

Etiology and Pathology.—The condition may originate from any of the causes which give rise to hydronephrosis, provided that pyelitis be developed. Also it may result from injury, from tuberculosis, or from diphtheria and other zymotic diseases.

Distention of the pelvis and calyces and wasting of the renal parenchyma from pressure occur just as in hydronephrosis, and the kidney is eventually replaced by a mere lobulated pouch. The tumor is whitish in color, with walls of variable thickness, and the sac-contents are purulent urine or pus mixed with blood and, in some cases, phosphatic material. The mucous membrane of the pelvis is pale in color and much thickened. A large pyonephrotic kidney causes displacement of other organs, and, especially if due to impacted stone, may ulcerate, discharging its contents into one of the hollow abdominal organs or into the peritoneal cavity, or, becoming adherent to the abdominal wall, it may discharge externally, establishing a fistula.

Symptoms.—While in some cases there may be no perceptible swelling, pyonephrosis usually gives rise to a fluctuating or elastic tumor in the renal region. It is generally accompanied by pain, the character of which depends on the cause of the obstruction. Sometimes it is very severe. It originates in the lumbar region, and is increased by pressure from in front, but relieved

by pressure in the loin. Chills, fever, sweating, diarrhoea, and vomiting are present, together with marked loss of flesh. In cases in which the obstruction is not complete the urine voided, although containing pus, may be normal in reaction, being mixed with that secreted by the sound kidney; later it is liable to become alkaline. When the obstruction is complete, pyuria will not be observed. In pyonephrosis resulting from stone there will be a history of pyuria and hæmaturia extending over a considerable period.

Diagnosis.—Pyonephrosis may be confused with the same conditions as hydronephrosis. The constitutional symptoms which, on the one hand, establish the diagnosis from hydronephrosis, on the other hand render the affection liable to be mistaken for perinephritic abscess.

Prognosis.—The prognosis is more grave than in hydronephrosis, and is manifestly more serious if the condition be bilateral than when only one kidney is affected. The nature of the cause of the pyonephrosis, and whether the accumulation has been gradual or sudden, materially influence the chances of life. If it has been gradual, the opposite kidney may become hypertrophied and do duty for the diseased one. Spontaneous removal of an obstructing calculus is a favorable occurrence, as is the discharge of the cyst into some part of the urinary organs below the seat of obstruction. A fatal termination may be reached by the sac rupturing into the peritoneum, from the results of pressure upon other organs, from pyæmia, septicæmia, or amyloid disease induced by prolonged suppuration, even though the pyonephrosis has discharged its contents externally or into the intestines.

Treatment.—In cases where the obstruction is not complete the treatment may be expectant. The patient should be kept at rest with warm applications to the abdomen and lumbar region. The condition of the digestive organs should be carefully seen to, and light, easily-assimilable nourishment given. When obstruction is complete and the tumor rapidly increases in size, causing marked pain, and the constitutional effects of the suppuration are severe, or symptoms consequent upon pressure become urgent, interference is indicated and lumbar nephrotomy should be performed. When the cyst has been opened a finger should be inserted, not only to explore for a stone, but to feel for and to break down any septa which may subdivide the sac, so that all parts of it may be well drained. The cyst should be drawn up into the wound and sutured to its edges, a drainage-tube left in, and the cavity washed out daily with antiseptic fluids, as in hydronephrosis.

In cases where the kidney tissue is ascertained to be destroyed, or where the health is seriously impaired, or where prolonged suppuration continues in spite of thorough drainage, nephrectomy should be the operation selected.

PERINEPHRITIC ABSCESS.

Perinephritic abscess, resulting from inflammation of the fatty and areolar tissue surrounding the kidney, may be met with at any age from the earliest weeks of infancy.

Etiology and Pathology.—Perinephritis may be either a primary or a secondary condition. Primarily, it may arise from traumatism, exposure to cold, or as a sequela to the zymotic diseases; secondarily, it may result from renal calculus, pyelitis, pyelo-nephritis (or "surgical kidney," so called), pyonephrosis, cysts, tumors, and tubercular disease of the kidney, vesical calculus, stricture of the urethra, and phimosis. Again, the suppuration may be traced to disease of the vertebræ, to abscess resulting from perforative ulceration of the colon or ileum, or to retrocæcal abscess. In some instances, accord-

ing to Steven, infection from inflammation originating in the bladder may extend by means of the lymphatics of the ureter to the capsule of the kidney and the tissue surrounding it, the kidney itself escaping. In the same way it is possible that the source of the inflammation might be traced to other remote points.

When suppuration occurs the abscess is generally at first limited by a well-defined wall of lymph, but the nature of the tissue, like that in the ischio-rectal fossa, is such as to favor extension of the suppurative process, and the pus soon works its way in various directions through the loose cellular and fatty tissue. From its original situation it may burrow through the lumbar muscles and point in the loin, or it may travel downward and appear in the thigh, like a psoas abscess, or, getting beneath the pelvic fascia and passing through the sacro-sciatic notch, it may point in the buttock. Extending upward, the pus may pass through the diaphragm and cause pleurisy, empyema, pneumonia, or may discharge into the bronchi. Again, the abscess may rupture into the peritoneum, the colon, small intestine, stomach, bladder, or prostatic urethra.

In the primary cases the kidney may be found macerated or broken down by the action of the surrounding pus, while in secondary cases of renal origin there will be found the special morbid conditions to which the abscess is due.

Symptoms.—The patient will usually first complain of pain in the lumbar region, extending forward, generally severe, and aggravated by motion as well as by pressure. At the same time it will be observed that the trunk is bent toward the affected side, and the thigh is kept slightly flexed upon the abdomen and rotated outward. On assuming the erect posture the patient assists in supporting his weight by bearing with his hand upon the thigh of the affected side. Examination will reveal more or less fulness or prominence of the loin instead of the normal concavity, and in marked cases palpation and percussion will map out a well-defined tumor. This latter symptom may not be present for any great length of time in consequence of the tendency of the pus to burrow. The integument of the part is œdematous, waxy, red or congested, and hot to the touch.

The constitutional symptoms are prominent, consisting of decided elevation of temperature, reaching as high, perhaps, as 104° F., chills, sweating, anorexia, and diarrhœa. Pressure of the abscess upon the lumbar plexus of nerves excites pain in its various branches, which, together with the attitude assumed, may lead to error in diagnosis. The urine, except in those cases in which the abscess is the result of violence, and in which there may be hæmaturia or pyuria, presents no especial characteristics. In some primary cases there may be a little albumin, resulting from high temperature, or, when the abscess is large and produces congestion of the kidney from pressure, some blood may be found.

Diagnosis.—The local and constitutional signs of a fully-developed perinephritic abscess are generally sufficiently clear to leave little room for doubt as to the diagnosis. It may, however, be confused with hydronephrosis, pyonephrosis, cysts and tumors of the kidney, lumbago, disease of the vertebræ, coxalgia, psoas abscess, and perityphlitic abscess. It is not possible here to point out the distinguishing features of these affections. Careful and exact examination, together with the accurate history of the case in question, will usually easily remove any difficulty that may be in the way of establishing the diagnosis.

Prognosis.—The prognosis depends upon the cause of the abscess, although the condition should always be regarded as a serious one. When the abscess

results from pyonephrosis or from disease of some other organ, the outlook is more grave than when it is primary. The prognosis is most favorable when the pus is evacuated early, while in unrelieved cases a fatal termination is to be apprehended from the discharge of the pus into other organs—into the peritoneum, the pleural cavity, lungs, or bronchi. Amyloid disease is imminent when the suppuration is long continued.

Treatment.—At the onset attempts may be made to induce resolution of the perinephritis, for which purpose cupping or leeching of the loin and the application of an ice poultice may be tried. The patient should be kept upon a liquid diet, a simple fever mixture should be prescribed, the bowels kept freely opened, and opium given for the relief of pain. If these measures fail to ameliorate the local and constitutional symptoms, warm flaxseed poultices should be applied, quinine added to the medicinal treatment, and the patient closely watched. Increased elevation of temperature or the occurrence of chills and sweating, being tokens of suppuration, call for prompt resort to the knife. Delay is dangerous, since it renders possible burrowing of the pus. Therefore, in spite of the absence of fluctuation, a free incision in the lumbar region should at once be made down to the perirenal tissue. Then with the finger this should be carefully explored or teased apart until the abscess, which is sometimes deeply seated, is found. The opening made with the finger should be enlarged by inserting a pair of long-bladed hæmostatic forceps and separating the blades. This being done, the abscess-cavity should be washed out and a good-sized drainage-tube inserted. Later, strips of iodoform gauze may be gently pushed into the cavity beside the tube, and the packing gradually lessened and the tube shortened as granulation progresses.

In cases in which the abscess is secondary to disease of the kidney, nephrotomy or nephrectomy may be called for, according to the condition found at the time of operation.

TUMORS OF THE KIDNEY.

New growths of the kidney, as met with in children, are for the most part, if not entirely, of the malignant class. While it is possible that benign growths may occur, investigation of statistics has failed to find any case which has been the subject of surgical operation. Malignant tumors may involve the kidney either primarily or secondarily, but it is only with the primary tumors that we are here concerned.

Etiology and Pathology.—Some of these growths are congenital. In other cases their origin is attributed either to the irritation of a renal calculus or to injury, such as contusions or falls upon the loin, although it is not very easy to understand how this latter cause can be operative.

Unlike similar formations elsewhere in the body, malignant tumors of the kidney are met with more frequently in the first ten years of life than during the period of life generally recognized as that of malignancy. They may occur at any age in childhood, although the greater number of cases have been observed in children under five. Thus, in 54 cases references to which the writer has obtained, 9 were under one year old, 17 between the ages of one and three, 18 between three and five, 6 between five and eight, and 4 between eight and twelve years of age. As to sex, in 40 cases in which it was stated 22 were females and 18 were males. The tumor is unilateral as a rule. When both organs are the seat of growths, except in cases of congenital myosarcoma, the involvement of one organ is secondary to the disease in the other. Of 30 cases, the right kidney was the seat of the neoplasm in 14, the left in 12, and both were involved in 4.

The great majority of these renal tumors in children are sarcomata. Out of 52 cases, 43 were instances of sarcoma, while 9 were designated as encephaloid carcinoma. The variety of sarcoma most often found is the round-celled, both large and small, the spindle-celled variety being less frequent. These growths, which are first usually encapsuled, but which, owing to their rapid development, soon extend through their capsule, may begin at the hilum and either spread around and envelop the kidney, or they may extend into the kidney, which ultimately becomes stretched out as a thin layer over the tumor. More often they originate in the cortex, being separated from the surrounding renal tissue by a capsule until the latter gives way, when the sarcoma extends throughout the kidney. In addition to the round-celled and spindle-celled, other varieties of sarcoma which have been found are adenomo-sarcoma, in which the sarcomatous tissue and that of the glandular substance of the kidney are combined; myxo-sarcoma, in which the elements of mucous tissue are combined with sarcoma; alveolar sarcoma; and myo-sarcoma and rhabdo-myoma. Tumors of the last-named kind are of congenital origin, and consist of a mixture of striped muscle tissue and sarcoma tissue. They may be either unilateral or bilateral, sometimes reach a very large size, and are rapidly fatal. Owing to special characteristics, certain sarcomata have been described as fibrous and fibro-fatty tumors.

Sarcomata of the kidney grow rapidly and are highly vascular, extravasations often taking place into them. They frequently break down in places and form cysts containing blood and clots.

The variety of carcinoma which has been most frequently met with is the encephaloid, although any of the varieties may be found. Encephaloid cancer of the kidney has sometimes attained immense proportions. The growth may invade the entire kidney, being disseminated throughout it and producing a tumor possessing the general outline of the organ, or it may develop from one part of the organ and have an irregular outline. The origin of the growth is traced to the intertubular connective tissue, its epithelium being derived from proliferation of the normal renal epithelium. Like sarcomata, carcinomata grow rapidly. It is doubtful whether some of the tumors specified in the older classification as encephaloid cancer would not now be placed under the heading of sarcoma.

Lymphadenomata have been occasionally observed in the kidney, but are secondary to disease in the lymphatic system. It is possible that a growth of this kind might be mistaken for a round-celled sarcoma.

Malignant growths of the kidney spread by means of the lymphatics and veins. Carcinomata are particularly apt to involve and extend by the veins. Secondary formations soon take place. The lumbar glands are early infected. The tumor may by pressure cause erosion of the vertebræ, and, opening the spinal canal, involve the meninges, and even the cord itself, by direct extension.

Symptoms.—In addition to tumor, which is the symptom most invariably present, malignant disease of the kidney causes pain, emaciation, cachexia, frequent perhaps involuntary micturition, hæmaturia, and various symptoms resulting from pressure of the growth.

The tumor, if detected early, will be found confined to the loin, where it causes more or less fulness or prominence. In some recorded cases the growth has attained an immense size, occupying the whole abdominal cavity, pressing upward the diaphragm and embarrassing the thoracic organs. Again, in other cases it may be very difficult, if not impossible, to detect a palpable tumor, even though metastasis has taken place. Pain in the lumbar region is an early indication, but while in older children, as in adults, it is an important

sign, it is very doubtful if in very young subjects it could be relied upon, as it is not likely that it would be intelligently located. It is dull in character and usually constant, although occasionally paroxysmal, differing, however, from the pain due to renal calculus in not being either aggravated by motion or relieved by rest. Hæmaturia is not always noted as a symptom. When it does occur it is constant, and although in some cases it may not be alarming, the bleeding may, on the other hand, be very severe. Sometimes clots may obstruct the urethra or may distend the bladder, or, again, may become wedged in the urethra. The hæmorrhage may be due to the calculus from which the tumor may have arisen, or it may result from the neoplasm involving and extending into the pelvis of the kidney and then ulcerating.

The tumor, as it grows, may encroach upon and compress the nerves of the lumbar plexus, giving rise to pain, and even to paralysis in the parts supplied by its branches. From pressure upon the veins within the abdomen œdema of the lower extremities and engorgement of the superficial abdominal veins are produced. Other symptoms due to the pressure of the tumor are constipation, jaundice, anorexia, and vomiting.

The urine will be found normal unless the growth has involved the pelvis of the kidney, when it may contain blood, blood-casts, albumin, epithelium, pus, or portions of the ulcerating tumor. Although convulsions have taken place in a few cases, uræmia rarely, if ever, occurs.

Diagnosis.—The salient symptoms of renal neoplasms are rapidly-increasing tumor and pain. If to these hæmaturia be added, the diagnosis should not be difficult. If the tumor be large, however, there may be some difficulty in deciding whether on the right side it is not a cyst or enlargement of the liver, or on the left whether it is not an enlarged spleen, particularly as renal tumors, as well as those of the liver and spleen, are affected by the movements of respiration. The examination will usually be more satisfactory if the child be under ether or chloroform anæsthesia. The relation of the ascending colon on the right side and the descending colon on the left to these tumors is an important point. Unless the growth be very large or has extended in one particular direction from the kidney, the colon should be found in front of it. In cases where the tumor is very large the bowel may be pushed aside, either inward or downward. Another point of distinction is that renal tumors can usually be traced deeply into the loin. Other affections with which these growths may be confounded are cysts of the ovary, fecal accumulations, and perityphlitic abscess. Ovarian cysts should have the bowel behind them and not in front, and are generally easily made out by rectal or vaginal examination; and perityphlitic abscess will usually present constitutional symptoms, which, together with the history, will clear up any doubts that may exist.

Prognosis.—Malignant disease of the kidney can of course terminate in only one way. The child may live but a few weeks after the appearance of the growth, or he may live a year perhaps, the average being six or seven months. In children these neoplasms are usually softer, grow faster, and exhibit their malignant nature more speedily than in adults.

Treatment.—The question as to whether operative treatment should be resorted to in malignant renal growths is one that can be answered only after considering the merits of each particular case. Nephrectomy is of course to be thought of only in those cases in which, so far as examination can determine, the disease is in all probability confined to the kidney, under which circumstances there may be some possibility of the removal completely eradicating it, or, if it fails in that, of somewhat prolonging life.

A review of the literature of the subject shows the results of nephrectomy

for renal tumor in children to be not very flattering. The late Prof. S. W. Gross collected 16 operations upon children between sixteen months and seven years of age. Of these, 9 died and 7 recovered from the operation. Of the latter, 5 were known to have died from recurrence of the disease at times varying from five to sixteen months after the operation, while in the remaining 2 the result was not ascertained. Dr. Gross considered nephrectomy to be positively contraindicated in sarcoma in children.

Dr. Marie B. Werner has tabulated 31 operations, including some of those collected by Gross. An additional case is mentioned by Newman in the table in his "*Lectures to Practitioners on the Surgical Diseases of the Kidney.*" Of these 32 cases, 16 survived and 16 perished from the operation. Recurrence is known to have taken place in 8 of the 16 cases which recovered from the operation, the shortest time before death occurred being two months, and the longest eight months. In the other eight cases the ultimate result was not ascertained. One of them died a year and a half after the operation, but the cause of death is not stated.

Butlin, in his work entitled "*The Operative Surgery of Malignant Disease,*" says of nephrectomy for sarcoma in children that "not one thoroughly successful case can be claimed, and it is probable that the operation will fall into disrepute."

Judging by the ultimate result in those cases of operation in which it was ascertained, there can be no doubt that the weight of evidence is unfavorable to nephrectomy for malignant disease in children. If there be any hope of success from the operation as a radical measure, it must be when it is performed at a very early period of the disease. Each case, however, must be judged on its own merits. If the operation is to be undertaken, there should be absence of evidence of dissemination of the disease, and the general condition of the child should warrant so severe a procedure. If resorted to, nephrectomy should be performed by the abdominal incision, since the space in the loin in children is insufficient to permit the safe removal of a tumor even if it be of moderate size. The risks of the operation are very considerable, hæmorrhage, shock, collapse, and peritonitis being the imminent dangers encountered. Owing to the high degree of vascularity of these growths the danger of profuse bleeding during their removal, especially if adhesions have to be broken up, is very great.

In cases which do not permit of operation all that can be done is to attempt to afford some palliation for the symptoms to which the tumor gives rise. Pain should be subdued by the administration of opium and the local use of belladonna plaster, or opium, chloral, chloroform, aconite, and belladonna in liniment. Hæmorrhage will call for the employment of hæmostatic remedies, such as gallic acid and ergot. Morris speaks highly of ferric alum for this purpose.

VESICAL CALCULUS.

By J. WILLIAM WHITE, M. D.,

PHILADELPHIA.

VARIETIES OF CALCULUS FOUND IN CHILDREN.—The *uric-acid* calculus is by far the most common kind found in children. Statistics by different authors variously place it from two-thirds to five-sixths of all stones. It was first described by Scheele in 1776. It may be composed exclusively of uric acid, or it may be mixed more or less with oxalate of lime and the urates of ammonium and sodium either in its intimate structure or in alternating layers. It is generally oval, rarely very large, and sometimes quite smooth, though more often granular or slightly tuberculated. The color varies from a light fawn—almost white—to a brownish or blackish red. There are two forms—the laminated and the amorphous—although a stone may contain layers of both. The laminated variety, when cut through the centre and polished, resembles an agate; but, besides the concentric curved lines, radiating lines may often be seen extending from the centre to the periphery. This variety is very hard, and when broken splits into angular and often sharp-pointed fragments. The amorphous uric-acid calculus is structureless or sandy on section, and generally of a dirty reddish-yellow color. It is sometimes quite soft and breaks into irregular fragments.

Next in frequency to the uric-acid stone comes the *oxalate-of-lime* or mulberry calculus, first described by Wollaston in 1797. It is generally round, covered with blunt points or spicules, very hard, and varies in color from a dark gray to a brownish black.

Urate of ammonium occasionally occurs as a calculus, but is usually in combination with uric acid. When it does occur it is flattened, oval, smooth, or granular, brittle, and of a clay color.

The *mixed or fusible phosphate*, the *ammoniaco-magnesian phosphate*, *phosphate of calcium*, *carbonate of calcium*, *cystic oxide*, *xanthic oxide*, *fibrinous*, *fatty* (urostealith), and *indigo* calculi are extremely rare, or never occur in children as pure calculi, although some of them may enter into the composition of a stone with uric acid.

Stone in children may be *small* or *large*, from a few grains¹ to an ounce or more; *soft* or *hard*, depending upon its composition and the length of time it has taken to form; *single* or *multiple*; *free* or *attached* to the bladder-walls, either by a band of lymph or by being caught in one of the folds of mucous membrane. It almost always has its origin in the kidney, unless it be formed around some foreign body which has been introduced into the bladder. The

¹Sir Henry Thompson objects to giving a concretion of less than 20 grains in weight the name of "calculus" or "stone." While there may be some practical advantage in this limitation in the case of adults as regards especially the significance of statistics, there can be none in children.

experiments of Rainey, Ord, Vandyke Carter, and others have shown that "urinary calculus is not an accidental agglomeration of solids, crystalline, and amorphous, in a cement of mucus," but that it is a "massive crystallization of urinary ingredients in a colloid substance," the formation of which occurs in obedience to a fixed law. Although the frequency of the uric-acid calculus is doubtless due to the excess of uric acid in the urine of children and to the presence in the kidneys of infarctions which are almost entirely composed of uric acid, and which Virchow has shown to be very common, almost constant, during infancy, yet it must be remembered that some colloid substance, as mucus, albumin, pus, etc., has to be present or no stone will be formed, and the crystals will pass out with the urine in the well-known cayenne-pepper or brick-dust deposit.

Etiology.—As just stated, the two chief causes of stone are crystals in the urine and the presence of a colloid substance. How far the production of these two causes is influenced by heredity it is very difficult to state.

That stone is occasionally found with exceptional frequency in certain families there can be no doubt, but before its occurrence is assigned to *heredity* it should be remembered that there may be some local cause equally affecting all the members of a family and peculiar to their place of residence, not to their physical condition.

Cadge, some years ago, made the following interesting remarks as to this point: "In five instances I have operated on brothers, and in four other instances I have operated on one brother, and other surgeons on another. Mr. Clubbe of Lowestoft has given us a curious history of a stone-family: Three brothers were cut for stone by Mr. Clubbe; a fourth passed a stone; a fifth child died, aged three months, with every symptom of stone; a female child now has vesical irritation and bloody urine. The father and mother are constantly passing large quantities of lithic acid; the grandfather passed one stone, and the grandmother seven; a great-uncle was cut for stone, and six uncles and four aunts all suffer either with fits of gravel or from lithic deposits; and, to finish, a cousin passes calculi. There is considerable historical testimony in favor of this hypothesis. We know that Montaigne and his father both died of stone in the bladder, and we remember how he moralizes on the incomprehensible wonders of the hereditary transmission of mental and bodily resemblances and infirmities. The celebrated minister Sir Robert Walpole and his brother Horace (who once represented this city in Parliament) were both afflicted with stone; and their mother also had stone."

It is probable that *gout* and *rheumatism* increase any tendency to the formation of stone, as they are usually accompanied by acid urine, with an increase in uric acid and the urates. As gout is hereditary, the tendencies to stone, which it produces, may also be hereditary. But gout, as a rule, is an inheritance of the rich, brought on by generations of over-eating and drinking, and yet it is a remarkable fact that the children of the rich are singularly free from calculus, while the children of the poor make up more than one-half of the cases of stone in the tables of statistics. Deschamps, at the close of the last century, said that during the thirty years in which he treated people afflicted with calculus, he had yet to see the child of a rich man affected with stone. Sir William Fergusson is quoted as saying that he had but once received a fee for operating on a child. Of the 863 cases of stone which Sir Henry Thompson treated in private practice, but 3 were under sixteen years of age, and only 8 from sixteen to twenty-four. In explanation of this Sir Henry Thompson says: "Insufficient food, clothing, and fresh air, the necessary accompaniments of poverty, appear to encourage calculous formations among children, but not

among adults. Habits of self-indulgence, in relation chiefly to diet, and indolence, encourage calculous formation in elderly adult males, but the children of such parents are not so affected. Hard physical labor and a regimen which necessarily contains simple diet, largely cereal, with animal food in small proportion, even although often associated with intemperate habits and with unhealthy dwellings, discourage calculous formations among all classes of the community alike."

It is a well-known fact that stone occurs much more frequently in certain districts than in others, but a satisfactory explanation of this has not been given. It is possible that *climate* may have some slight influence over the production of these affections, as in very changeable regions calculous diseases are more common than in those localities where the temperature is more uniform. This may be due to a lack of proper clothing and insufficient protection of the skin, whereby its functions become disturbed and the kidneys are required to perform an excess of labor. In the United States stone is much more common in Kentucky, Tennessee, Ohio, Virginia, and North Carolina than in any other portions of the country, and yet we have a vast area of territory which is similarly located, geographically, geologically, and climatically, in which stone is rarely if ever encountered. In England calculus is common around Norfolk and Manchester, while in other regions, which are in the same latitude and subject to the same temperature, it is almost unknown. Neither can it be attributed to hard water alone, as Mastin shows that in parts of Kentucky and Tennessee, where the water is soft, calculous diseases are common, and just as frequently met with as in the limestone districts. Again, Mr. Dudgeon of Pekin informs us that at Canton in China stone is frequently met with, while around Pekin it is hardly ever seen; yet the water of Pekin is full of lime, while the Canton water is soft.

It would seem that *race* has some influence over stone formation. The negro in America is said to be remarkably free from calculus, and Rayer says that in Egypt he escapes, while the Arab suffers.

Diet and regimen, at least in the cities, have much more to do with the production of stone than heredity, climate, water, soil, etc.; and I believe that Mr. Cadge has come nearer the cause when he says that the frequency of calculus in children will be found in strict accordance with the difficulty in procuring milk. He adds: "A few years ago, after removing a stone from a child of well-to-do parents, I was remarking to one of my assistants that this was the first instance in my practice, and that I attributed the general absence of stone in such persons to the free use of milk: the mother volunteered the statement that in a large family this was her only child who never could take milk, and who, therefore, never had any."

Sex undoubtedly has an influence upon the frequency of vesical but not of renal calculus. There is no reason why the female is not as liable to the formation of calculous concretions within the kidney as the male; but, the nucleus having once descended to the bladder, the large size and shortness of the urethra, the absence of the prostate, and the comparative freedom from urethral diseases and vesical catarrh are almost sufficient to secure immunity. Giraldès asserts that vesical calculus happens twenty-four times more frequently in boys than in girls, while Neubauer found but 5 girls in 100 cases.

Relative Frequency of Calculus.—Most of the statistics of cases of calculus agree in that children make up one-half or a little more than one-half of the number. In a collection of 1103 cases by Prout, 594 were under fourteen years of age. In Cheselden's series of 213 cases, 115 were under ten and 62 were from ten to twenty years old. Robert Smith's 543 cases from

Leeds and Bristol show 253 to be under sixteen. Sir Henry Thompson's elaborate table of 1827 cases shows that 1001 were under sixteen years of age. In Dolbeau's collection of 5376 cases, 2416 were under the age of puberty. No period of life is exempt from the liability to stone. Langenbeck found a calculus in the bladder of a male fetus of six months, and Jacobi has reported a case in which the child was only ten days old when symptoms of difficult micturition were noticed, and another case of an infant who passed blood soon after birth, the first urine being voided forty-eight hours later, and a reddish, gritty mass being found in the diapers. He has detected six cases of congenital renal calculi in forty autopsies, and believes that many cases of so-called intestinal colic occurring in children are in truth cases of renal colic. The passage of a calculus is frequently accompanied by hæmorrhage and followed by secondary nephritis.

In Thompson's table the frequency of stone rapidly increases from birth to the fourth and fifth years of life, after which it gradually decreases to the age of puberty. The fallacy of depending upon these figures has, however, been shown by various writers, and Sir Henry Thompson says that after investigating the old statistics of stone and those collected prior to 1850, he found them misleading. He adds: "So far from the stone being more common in children than in adults, according to the universal belief at the period referred to, justified as it was by the records of hospital practice, I was soon in a position to affirm that stone was more common among men of sixty years of age and upward than at any other period of life. For let it be remembered that all existing records of practice, whether found in museums or reported by the operators themselves, from all sources previous to the middle of the present century, showed that half the total number of operations for calculus occurred in childhood and youth. The truth, nevertheless, is that a very large majority of calculous cases was then, as now, to be found in persons above fifty years of age, but the fact was then unknown: the calculi were simply overlooked, not being suspected to exist; and one obvious reason of the oversight is to be found in the fact that the early symptoms in elderly subjects are extremely slight—a rule with only few exceptions—contrasting strongly with the marked and painful symptoms rarely absent in the young."

Agnew, after quoting the figures of Gross, Civiale, and Thompson, showing 62.33 per cent. under twenty years of age, adds: "These estimates, however, are calculated to mislead, from the disparity which must necessarily exist between the different classes of patients when the number of each is contrasted with the entire population living at the same ages. Were the statistics based on this principle, a result the reverse of that exhibited would be shown. In other words, the tendency to calculous disorders would be found to increase with advanced age. The inaccuracy of all statistics with regard to the age of calculous patients will be further shown by the fact that the date has been fixed at the time the patient was operated on, though the disease may have existed several years previously."

Mr. Coulson has made a similar remark, viz. "that an error has crept in from not using the proper precaution to distinguish between absolute and relative numbers. To determine liability the absolute numbers should be corrected by the number of persons living at the several periods of life enumerated. Thus, if all persons under twenty were affected with stone and all over seventy were affected with the like complaint, it is evident that the liability would be the same, though the absolute number of persons attacked would be very different." Mastin says: "To enable us to determine the liability of children of a certain age to stone, we must correct the absolute numbers by the

numbers of persons of all ages living at the several periods of life enumerated. Corrected in this manner statistics would most probably show that young persons are much less liable to calculous affections than is generally believed."

Symptoms.—The symptoms of vesical calculus in children are for the most part the same as in adults, but they present certain peculiarities due to the age of the patient. If the child be not old enough to appreciate when he is sick, and to describe the character and locality of the pain, the surgeon has to rely almost entirely upon objective symptoms for his diagnosis. But if the child be old enough, in many cases, before the development of vesical symptoms, the descent of the nucleus from the kidney will be announced by a group of symptoms known as *nephritic colic*. While feeling perfectly well he is suddenly seized with a violent pain, felt first in the lumbar or hypochondriac region, and rapidly extending down the line of the ureter toward the scrotum and end of the penis. The testicle is drawn upward by spasm of the cremaster muscle. The pain follows the branches of the lumbar plexus into the groin, thigh, and hypogastrium. Vesical irritation and tenesmus are frequent. Faintness, cold sweating, convulsions, and even collapse, may be present. These symptoms may cease as suddenly as they began, but the relief will not be permanent until the stone has passed into the bladder. As long as the stone is in the ureter, the attacks of colic succeed each other at intervals of a few minutes to an hour or more. The urine is high-colored, scanty, and may even be almost suppressed. A history of this kind is an important indication in cases of suspected stone, and should lead the surgeon to make repeated examinations if the following group of symptoms or the majority of them be present:

(1) *Frequent micturition or incontinence of urine*, more marked by day than by night; also more marked if the stone has an irregular surface than if it is smooth, and increased by active motion while at play or driving over rough roads. This symptom is more marked and more common in children than in adults.

(2) *Pain*.—The characteristic pain of stone is darting and burning, and is felt during urination, but is most severe at the termination of the act, when the irritated mucous membrane of the empty bladder comes in contact with the calculus. The pain is rarely referred to the bladder, but is felt on the under surface of the penis a short distance behind the external meatus. It is so severe as sometimes in children to cause convulsions, and often continues for a long time or until sufficient urine has collected to remove the walls of the bladder from close contact with the stone. In cases of encysted stone pain may be almost entirely absent. Handling of the penis and traction on the prepuce to relieve the pain gradually stretch the foreskin until it becomes abnormally long, and induce priapism, which, owing to the congestion of the vessels of the prostatic-vesical region, often leads in children to the habit of masturbation.

(3) *Sudden Interruption of the Stream during Urination*.—In the early period of the stone, while the calculus is still small and movable, it is often swept into the neck of the bladder and acts as a ball-valve, completely obstructing the vesical orifice of the urethra. The child soon learns the best method of obviating this difficulty, and will assume some peculiar or unusual position which experience has taught him will dislodge the stone and permit the completion of the act.

(4) *Hæmaturia* is rare as a symptom in children. It is due to the wounding of the congested mucous membrane by contact with the calculus, hence it is aggravated by exercise and is most noticeable at the end of urination.

(5) *Evacuation of the bowels during urination*, with prolapse of the rectum, is a frequent symptom when the vesical tenesmus is great on account of the violent straining to void the last few drops of urine.

(6) *The presence of muco-pus in the urine* is a corroborative symptom due to the concomitant cystitis, and is of no special diagnostic value.

(7) *Reflex pains* in different parts of the body are sometimes associated with stone. In many cases the pains will be referred to the rectum or perineum, but sometimes to portions of the body far removed from the seat of the trouble, as in the upper extremities, the back, lungs, stomach, thighs, and feet.

The principal symptoms, then, are frequent desire to urinate, with incontinence or very rarely retention; pain referred to the end of the penis; sudden stoppage of the stream; tenesmus; prolapse of the rectum; and priapism, with occasionally more or less cystitis and hæmaturia.

But the existence of this group of symptoms cannot justify a positive diagnosis of stone unless further it is felt and heard by the surgeon with the aid of the sound. The stone may be in the kidney or under the prepuce. Rectal troubles, prolapse from various irritations, as worms, ulceration, etc., may, by reflex irritation, affect the functions of the bladder apparently as seriously as though it were the principal organ involved. Diseases of the kidneys, phimosis, adherent prepuce, irritating smegma, etc. may also produce analogous symptoms, and, on the other hand, there is no ordinary symptom which may not be absent in a case of stone.

Diagnosis.—The diagnosis of stone is therefore to be made with the sound. Many different forms of vesical sound have been recommended, but the best and simplest has a straight steel shaft with a short curve near the tip and a smooth flattened handle. The tip should be blunt and of slightly larger calibre than the shaft, so that the walls of the urethra may not grasp the shaft so tightly as to interfere with the delicacy of the movements. The curve at the tip should be shorter than in the adult sound, owing to the anatomical difference of the parts in children. Sounding should always be done with the patient under ether unless there is a good reason for not doing so in the special case. The patient should be in a recumbent or semi-recumbent position, the abdominal walls well relaxed by slight elevation of the shoulders, the knees drawn up, and the thighs somewhat separated. During the exploration the bladder should be moderately distended with water. The sound being warm and well oiled, it is held lightly but securely by the handle, and the surgeon should allow it to glide along the upper surface of the urethra, more by its own weight than by using any pushing force. Once in the bladder, the cavity should be explored in a systematic manner. The sound should be partially withdrawn and reinserted in a straight line, the handle being slightly raised and depressed from time to time. The beak of the sound should then be turned toward one side of the bladder, and should be made to traverse the arc of a circle, sweeping transversely through the bladder from above downward. It should then be turned to the opposite side, and the same manœuvre repeated. If the stone is not found in this manner, the searcher should again be introduced to its full length, and the tip turned gently toward the floor of the bladder, and then rotated from side to side, while the instrument is gradually withdrawn until it comes in contact with the vesical neck. If the stone be of moderate size, in nine cases out of ten it is struck and heard at once, and its mobility in the bladder is recognized. So positive are these sensations that the nature of the case is determined even by an inexperienced examiner. A few surgeons consider it sufficient to feel the stone with the tip of the instrument, but the majority prefer to demonstrate its presence by eliciting the characteristic click. The latter is certainly by far the most definite and satisfactory symptom it is possible to obtain, and, although even that does not entirely exclude the possibility of error, it reduces

it to a minimum, especially in children, where tumors with calcareous incrustations are exceedingly rare.

Among the *sources of failure* in the detection of stone are (1), the sound may be pushed through the delicate urethra immediately anterior to its undeveloped prostate, when it would at once enter the ischio-rectal space, where, in the very loose tissues of the child, it may be moved about almost as freely as if it were in the bladder; or (2), without breaking through the urethra, the loosely-attached bladder may be pushed before the sound. This is especially likely to occur in children as compared with adults. (3) A more or less completely encysted condition of the calculus, leaving little or nothing of its surface exposed to immediate touch. This is exceedingly rare in young persons. (4) The presence of a diverticulum containing a stone and communicating with the bladder by a small aperture, the calculus in such a case being practically extra-vesical. This is a condition usually associated with long-continued obstructive disease, and is almost never found in children. (5) The stone may be suspended by a thread of lymph from the summit or the anterior wall of the bladder. (6) The surface of the stone may be covered with a blood-clot or with lymph, so as to prevent the characteristic sound from being elicited.

It is a curious fact in the history of stone in the child, as well as in the adult, that one surgeon may detect the calculus and another of equal experience may miss it.

The examination for stone *in female children* does not differ materially from the same procedure in the male. Owen quotes Holmes's remark: "I hope it may not be impertinent to point out that at very early ages the vagina may be mistaken for the urethra," and adds, "This caution is extremely pertinent: if there be any doubt, a second sound may be deliberately passed into the vagina to prove that the first has entered the bladder; or the finger may be passed into the rectum to show that the vagina is free; or the beak of the sound may be felt for above the pubes."

Preventive Treatment of Stone.—As we have seen, most of the cases in children belong to the ignorant and poorer classes, subjects of improper diet and unfavorable surroundings. If such cases could be treated in the early formative stage, there is no doubt but that much might be done to prevent the formation of stone. In the preventive treatment of calculus the avoidance of catarrhal conditions of the urinary tract is of the greatest importance. The main colloid for acid stone is probably mucus, and a little scratching of the mucous membrane by the points of the crystals or irritation by concentrated urine is sufficient to call out enough mucus to act as a colloid. Our object should then be to make the urine as bland and abundant as possible, and for this purpose there is nothing better than milk and the free use of water as a beverage between meals. The particular kind of water to be used is of minor importance, as the most noted waters in the treatment of stone seem to have purity as their chief recommendation. A proper diet for such a case should be chosen from the following articles: fish, poultry, bread, all cereals, green vegetables, salads, fruits, and eggs. Sugar and the different kinds of fats are harmful, as is an excess of the dark meats. Over-eating is especially and particularly to be avoided. Highly-seasoned articles of food are even more objectionable with children than with adults, as they tend to excess in eating, and in addition often cause acute indigestion or, worse still, a chronic acid dyspepsia.

The *solvent treatment of stone* has but little to recommend it. Brodie tried injections of dilute nitric acid; Roberts has experimented with potassium citrate and acetate; Garrod, with the lithia salts; Vogt, with piperazine;

Beale, with ammonium carbonate, etc. Electrolysis has also been tried even more unsuccessfully.

All these procedures are more objectionable in children than in adults. Vesical injections of all kinds are relatively more irritating on account of the greater delicacy of the mucous membrane. The administration of large doses of alkalis and diuretics by the mouth are almost certain to interfere with digestion, and thus do more harm than good. In the presence of excess of uric acid or urates or oxalates in the shape of crystals, the free use of water, and of small doses of lithia with potassium carbonate, is of great value in prophylaxis; carbonated "lithiated Vichy" water, a commercial product, is often agreeable and useful, but is sometimes disliked by children on account of its effervescence.

Anatomy of the Urinary Organs in Children.—This may be briefly alluded to before describing the operative treatment of stone. In the infant the *bladder* is egg-shaped, having the larger end resting in the pelvis. There is no marked fundus or base to the bladder in the young child, and it is situated mainly in the abdomen. As the pelvic cavity increases in size the bladder gradually descends into it, and the infant about this time assuming the perpendicular attitude, it has been thought that the weight of the urine tends to make the lower part more capacious. Observations upon the dimensions and position of the bladder will naturally vary with the empty or distended state of the organ. Through childhood until toward puberty, when the organs of generation are developed and the neighboring parts assume their normal adult relations, the urinary bladder is always so loosely attached to the pelvic walls that, although it may have settled into the pelvis, it will require very little force to push it upward into the abdomen. This lax condition of the bladder-attachments is of great importance in the consideration of surgical interference in this region. In the young child the anterior wall of the abdomen, from the symphysis pubis almost to the umbilicus, is in close relation to the bladder, and the neck of the bladder and urethral orifice are about on a level with the upper border of the pubic symphysis.

The peritoneum is reflected entirely over the posterior surface of the bladder in the child. The recto-vesical pouch usually embraces the prostatic region very closely, and is liable to injury in children during the operation of lithotomy, causing peritonitis, the most frequent fatal termination in that operation.

The anterior surface of the bladder is always uncovered by the peritoneum in children. The capacity of the bladder in infancy is smaller than in after years, and this may account for the frequency with which young children micturate.

The *prostate gland* is very small in children. According to Sir Henry Thompson, this gland "at the age of seven years weighs only about thirty grains, and between eighteen and twenty years it weighs two hundred and fifty grains, or nearly nine times as much."

The *urethra*, in males, appears to increase slowly in length from birth until puberty is reached. Its canal is more dilatable than was formerly supposed in both adults and children. The meatus is often constricted, so that only a small-sized catheter or sound can be introduced, but if the orifice is incised quite a large instrument will readily pass. The membranous part of the urethra in children is relatively very long, owing to the smallness of the prostate gland at that period of life. In sounding the bladder in a child it should be remembered that the urethra lies close to the rectum, and that its walls are exceedingly thin and delicate.

The degree of curvature of the urethra is greater in the child than in the

adult, but there are variations in this respect naturally following, as do those pertaining to the contiguous parts, upon growth or immature development.

In the *female* the urethra is imbedded in the anterior wall of the vagina, which is sometimes of large size in childhood, and corresponds to the upper part of the prostatic portion of the male passage. It is very distensible.¹

The Operative Treatment of Stone.—Three methods for removal of stone from the bladder of male children are open to the operator: 1. Suprapubic lithotomy; 2. Perineal lithotomy; 3. Litholapaxy.

The statistics of these operations (see next page) indicate unmistakably the rejection of the first as a routine method in children. It should be reserved for those calculi which are both too large for the perineal operation and too hard for crushing—a very rare combination.

A comparison of the two other methods is, however, of much practical importance at this time, the statistical evidence having only recently justified positive conclusions.²

Until comparatively recent times the very low mortality of perineal lithotomy in children in the hands of skilful operators made it seem a work of supererogation to seek for a better method of operation. A safer could scarcely be found. A high rate of mortality after lithotomy was almost always due to deaths among elderly adults. Fergusson and Velpeau, and, later, Freyer, Thompson, and others, objected to the crushing of stone in boys on account of the undeveloped condition of the genito-urinary organs, the smallness of the bladder, the narrowness of the urethra, and the liability to laceration of the vesical and urethral mucous membrane. No instrument had been invented by which litholapaxy could be performed with safety in male children.

Other objections were advanced from time to time, mainly, however, relating to the same anatomical points, and (before the introduction of litholapaxy) to the difficulty of getting rid of the fragments, but the majority of them are now, in the light of the modern improvements in lithotripsy, without applicability.

Anæsthesia has made the "extreme sensibility" of the part and the "indolence" of the patients of little moment. Otis has shown that in children, as in adults, the "small diameter of the urethra" may be greatly increased with entire safety. He says that the proportionate relation between the circumference of the urethra and that of the penis, which he has already demonstrated in adults, holds good in children. Thus, with a circumference of penis of one and a half inches, as in a child from two to three years of age, the size of the urethra would not be less than sixteen millimetres in circumference; and this urethral calibre increases or diminishes about two millimetres for every quarter inch added to or subtracted from the penile circumference. It is but fair to mention that Morelli has called attention to a fact upon which some of the success of the Indian surgeons may depend—viz. the very early age at which the children of tropical and Eastern countries reach full sexual development. This may permit the use of larger instruments on an average at a given age than would be possible in Europe or America, and would facilitate and extend the possibilities of litholapaxy.

Antisepsis during and after the operation has minimized the danger of laceration of the mucous membrane; instruments have been made which are at the same time small enough to permit of their introduction into the urethra

¹ For further information I may refer to McClellan's Anatomy, from which the above account has been condensed.

² As my opinion, arrived at a few years ago (*Medical News*, May 17, 1890), remains unchanged, and has indeed been strengthened by later experience, I may be excused for summarizing here the views then expressed and making such additions as seem important.

and bladder of young infants, and strong enough to deal with very large and very hard calculi; Bigelow has overcome the difficulty of getting rid of the fragments; and the argument from statistics is at least neutralized by the records of Keegan and Freyer.

Cabot has given the most recent statistics of the three operations, made up from a series of published cases and from others obtained by him. As all the cases were operated upon after 1878, and as they are classified according to age, they are especially valuable for the purpose of this paper. They may be compared as follows for children under fourteen: *Suprapubic lithotomy*, 591 cases; 74 deaths; 12.52 per cent. of mortality. *Perineal lithotomy*, 539 cases; 16 deaths; 2.96 per cent. of mortality. *Litholapaxy*, 241 cases; 4 deaths; 1.66 per cent. of mortality.

Recurrence.—In the face of these figures and of the foregoing facts there is but one argument remaining which, to my mind, has any weight as urged against the operation of litholapaxy in children, and that is the alleged greater probability of recurrence.

As regards the two great classes of operative procedures for the removal of calculus—the cutting and the crushing operations—all forms of lithotomy as compared with all forms of lithotripsy and at all ages, there can be little doubt that the statistical evidence in relation to recurrence is at present in favor of lithotomy. But it should not be accepted without reservation. Many of the tables, notably those of Sir Henry Thompson and of Mr. Cadge, are based on an experience extending over many years and antedating the introduction of litholapaxy. Those tables make the proportion of recurrence after lithotripsy about 1 in 7 or 1 in 8, and after lithotomy about 1 in 20; but, like so much of the statistical matter which our text-books and journals contain, they are useless or misleading at the present day. The two principal causes which lead to recurrence are—*a.* The failure to remove every portion of stone at the first operation; *b.* The new formation of stone in the kidney and its descent into the bladder. In the tables of Mr. Donald Day, based on the records of the Norwich Hospital, the first class includes two-thirds of all the cases of recurrence. But circumstances have altered. The employment of a large-sized evacuating-tube, the immediate and thorough emptying of the bladder, the minute pulverization usually possible with completely fenestrated lithotrites, the increased knowledge of the great tolerance of the bladder to prolonged manipulations if they are gentle and skilful, have all combined to place the question of recurrence upon a very different level, and to make the collection of a new set of statistics as to recurrence absolutely necessary before venturing to draw any positive conclusions.

But if, for the sake of argument, we investigate existing statistics on this subject, we find that the great majority of cases of relapse or recurrence have taken place in patients past middle life, and especially in very old persons with enlarged prostates and feeble or atonic bladders. It will be recognized at once that these conditions do not prevail in children. The prostate is undeveloped; the bladder is almost an abdominal organ; no pouch exists at the fundus; sacculation is nearly or quite unknown;¹ cystitis is a comparatively manageable complication; the expulsive power is proportionately greater than in the male adult, in whom a "physiological atony" is not at all infrequent. In addition to the reasons above given for not anticipating the formation of new calculi in children around nuclei of vesical origin, it may be reasonably expected that the conditions favoring the development of renal calculi

¹ Fergusson said that even in adults "sacculated stones" were generally met with by young lithotomists.

will be more easily treated and controlled in children than in adults. Certainly among well-to-do people who can carry out a proper system of diet and medication it is fair to suppose that the lithic diathesis, of whatever variety, will be more readily combated in children whose diet and drugs and mode of life can be rigidly administered than in adults with fixed and often very prejudicial habits. Mr. Cadge expressly states that this was true in his own cases, and adds that he has no personal experience of lithotripsy in children.

Jacobson at one time asserted that this important matter—the percentage of recurrences after litholapaxy—had been left undealt with by Keegan, then the chief advocate of this operation in male children.

Keegan, in reply, says that in his monograph on the subject (1886) he did not deal with this point, because then he had only had 58 cases in male children and boys. Later (1890), the operation having been on trial for more than seven years, and he having collected 145 cases, 110 of which he had performed himself, he felt competent to consider the question, and said: “As to the outcome of this practice and experience, I have arrived at the conclusion that recurrence of stone does not follow litholapaxy in male children any oftener than it does lateral lithotomy, provided that the former operation be skilfully performed. It will be conceded that recurrence of stone after litholapaxy, when performed on adult and aged male patients, is less than that which in former days followed the now obsolete lithotripsy of many sittings. But it must be admitted that recurrence of stone does occasionally follow litholapaxy in old patients. When, however, we come to investigate the causes of this recurrence, we find that the main factors which bring it about in aged patients do not exist in the case of male children and boys.” He states that he began in 1881 to use litholapaxy, and that of the 145 cases operated on since but one boy has returned with a second calculus.

Freyer records 3 cases of recurrence in 65 children, the average age of whom was seven and a half years.

For these reasons, while admitting that the question of recurrence is still *sub judice*, I am distinctly of the opinion that there is little probability that there will be enough difference between the proportions of relapses in children after lithotomies and after litholapaxies to justify any decided preference on that ground alone.

The position of litholapaxy in children is moreover strengthened by a review of the history of lithotomy, which, unlike the operation with which we contrast and compare it, has undergone but little change for many years.

The improvements in *suprapubic lithotomy* have, it is true, rendered it applicable to a much wider range of cases, and it is equally true that its most favorable results have been attained in children; but thus far, as we have seen, the statistics of suprapubic lithotomy in children do not compare favorably with those of either litholapaxy or lateral lithotomy. This is probably due to the fact that in a large proportion of cases the operation was selected only after litholapaxy had been attempted and failed, or else was originally chosen on account of the unusual character of the calculus.

It is true that MacCormac has reported 33 cases of suprapubic lithotomy without a death, but they were from scattered sources and did not constitute a consecutive series. There is no means of knowing how many unsuccessful, and therefore unreported, cases occurred during the same period.

It will probably always be employed in preference to lateral or median lithotomy in cases of extremely large or exceptionally hard stones; but when we remember that Freyer has removed by litholapaxy a calculus weighing 808 grains from a boy of nine, and Keegan one of 700 grains (and of uric acid)

from a boy nine and a half, it is evident that neither size nor hardness offers an insuperable bar to the latter operation.

Median lithotomy in children, although advocated by some surgeons, is objectionable on account of the greater danger of wounding the bulb or the rectum, and the difficulties in obtaining space through which to pass the finger into the urethra and the bladder. It is indeed true that the passage of the finger is not absolutely necessary, although it has always been one of the time-honored rules of lithotomy not to withdraw the staff until the finger is in contact with the stone. I have, however, frequently seen Dr. Agnew, when operating on young children, introduce a pair of very small lithotomy forceps along the groove of the staff, separate them, and seize the stone, and then, after the removal of the staff, extract the calculus, the finger never having been in the bladder. I have used the same manœuvre myself with success. I supposed it was original with Dr. Agnew (and believe he was of the same opinion), but I found that Mr. Cadge recommended almost precisely the same method as both safe and efficient, adding, "I dare say it has been adopted by others, but I do not find it alluded to in modern text-books." It must be remembered, however, that its adoption places the surgeon in almost the same situation in regard to the possibility of leaving débris or unnoticed stones in the bladder as he occupies after a litholapaxy. If the stone is soft and breaks down under the forceps, or if there are multiple calculi, he will be dependent on the touch and sound elicited by the vesical explorer, just as after the other operation.

If, then, the introduction of the finger be dispensed with in either median or lateral lithotomy in children, these operations lose one of their alleged advantages—viz. the assurance of the absolute removal of all calculous fragments. If it be insisted upon, it constitutes in a small proportion of cases an unavoidable source of both difficulty and danger. Sir William Fergusson, Keith, Thompson, Cadge, and many others have recorded occasional trouble with this step of the operation. The latter surgeon remarks, apropos of Fergusson's case: "He was a master of the art of operative surgery; if the difficulty occurred to him, we may conclude that it is not unlikely to occur to any of us."

Lateral lithotomy in children, in addition to the special difficulty due to the smallness of the parts, the high position of the bladder above the pelvis, the delicacy and mobility of the deep urethra and the vesical neck, has one possible contra-indication which should not be lost sight of. If the incision be prolonged a little too far backward, the left ejaculatory duct can hardly escape division and subsequent obliteration; and although this may not be a serious accident in cases in which the integrity of the opposite half of the genitals, the testicle, duct, etc., is unimpaired, yet it leaves the patient entirely dependent on that one side for fertility if not for potency. Mr. Teevan has reported four cases of sterile husbands among lithotomized patients. Langenbeck and Sir William MacCormac have called attention to the same danger, and Keegan believes the lateral operation to be frequently followed by emasculation. Dennis quotes Dr. Charles Leale in relation to several cases coming under his own observation, in which such patients grew up with shrill voices, atrophied testicles, absence of hair upon the face, etc.; in fact, with all the characteristics of eunuchs. The evidence as to this point is as yet fragmentary and inconclusive, but is of sufficient importance to deserve careful consideration, although Ehrmann characterizes the fear of sterility as a "bugbear."

The objections to perineal lithotomy in children are, however, at least as weighty as any that have been urged against litholapaxy.

The ease and satisfaction to both patient and surgeon with which the latter

operation may be performed I can best illustrate by a brief abstract of one of the earliest of my own cases :

C. W——, a small boy, aged five and a half, was brought to me by his father in October, 1889, on account of nocturnal incontinence of urine. He had a long, tightly-adherent prepuce with pin-point aperture. It "ballooned" at each act of urination. I circumcised him, gave small doses of belladonna and bromide of sodium, and dismissed him, apparently cured, in November.

In January he was brought to me again by his nurse, who told me that his symptoms had returned. I then sounded him for stone, but failed to find it. Insisting (according to my invariable rule in such cases) upon a second examination before giving a positive opinion, I easily found a calculus. I recommended crushing, and after a little delay the parents consented. On February 20th, the child being etherized, I drew off the urine and injected three ounces of warm boric-acid solution (fifteen grains to the ounce) into the bladder. I then enlarged the meatus¹ and introduced a Weiss fenestrated lithotrite, No. 16 French. This went in with ease. The stone was readily seized and broken. I spent twenty-five minutes in pulverizing it, paying especial attention to gentleness of movement and to the avoidance of rude or unnecessarily wide separation of the jaws of the instrument. A No. 16 tube was then introduced and a Bigelow evacuator employed. In about eighteen minutes,² as no more fragments or dust could be perceived, the tube was withdrawn and the bladder carefully explored with a vesical sound. Nothing was discoverable.

The time of operation was forty-three minutes; weight of dried calculus, 170 grains. The child was sitting up in bed on February 22d, and was out of bed, playing about the room, on February 25th. The nocturnal incontinence persisted for a week or ten days, and then disappeared entirely. There was no fever, bleeding, chill, or other alarming symptoms.

The parents were nervous, consented reluctantly to this operation, and would certainly have postponed a lithotomy for a long time, much to the child's detriment.

This is a typical case of litholapaxy in a young boy. I have now had many such cases, and have never had a moment's anxiety about the little patients. It can scarcely be wondered at that after his experience Keegan writes that he would as soon think of cutting an old man for the removal of a small stone as of performing lateral lithotomy on a boy whose urethra would readily admit the passage of a No. 8 (No. 15 French) lithotrite, and whose stone was neither abnormally large nor hard. Nor is it surprising that Freyer says that, lithotomy in the adult having been practically blotted out of his practice, he looks forward confidently to lithotomy in children meeting with a similar fate. Freyer says: "When, in 1885, Keegan first showed that Bigelow's operation was capable of successful extension to the case of male children, I lost no time in procuring the necessary instruments and applying the operation to such cases. In two papers I placed before the profession full details of

¹ Otis recommends performing the meatotomy long enough before the litholapaxy to allow the parts to heal. This is certainly desirable for some reasons, but in nervous children its advantages are counterbalanced by the need for two fixed appointments, two operations, etc. I have never found any harm resulting from the plan I here followed.

² The pressure on the rubber bulb during the process of evacuation should be slight and frequent rather than slow and vigorous. Prof. Bigelow himself called my attention to the much greater value of the former method, and I have repeatedly verified the correctness of the statement. Not only is the danger of driving back into the bladder sharp fragments of stone materially lessened, but the swiftness and effectiveness of the outward current are much increased. I so often see an entirely unnecessary degree of force expended in the working of the bulb during this stage of a litholapaxy, even by expert operators, that it seems worth while to make this note.

49 cases of litholapaxy undertaken by me in male children or boys below the age of puberty. Since then 67 males of fifteen years and under, suffering from stone, have come under treatment, and in 66 of these I have performed litholapaxy—in all with complete success. In only one instance was it necessary to have recourse to lithotomy (suprapubic). The greater my experience of litholapaxy amongst male children becomes, the more I am fascinated by this operation. Though the average number of days such cases were kept in hospital was five and a half as a rule, these little patients may be seen playing about the day after the operation, perfectly happy and untroubled by urinary symptoms of any kind."

Cadge, MacCormac, Jacobson, Kingston, Keyes, Hunt—indeed, most recent writers—press the conviction, though in less sweeping terms, that the field of litholapaxy in children is likely to be considerably enlarged in the near future.

I have once, in a patient of Dr. E. L. Duer's, been compelled to abandon the operation on account of the impossibility of inserting the evacuator, although a lithotrite of equal calibre had gone in easily. Walsham and Marshall have called attention to the necessity of having a number of sizes of lithotrites and evacuating tubes, as they had both found great difficulty toward the end of the operation in children in introducing an instrument which had passed easily at its commencement. This is the only experience of the sort I have had in a child. The patient, *aet.* ten years, passed 40 grains of detritus, and a few weeks later I removed a calculus weighing 240 grains by the lateral operation. Convalescence was then uninterrupted.

Basing my opinion on the facts mentioned in this paper and on my personal experience, I believe the following conclusions to be justifiable:

1. In every case of calculus in male children¹ litholapaxy, on account of ease of performance, low mortality, speedy recovery, and absence of danger of emasculation, should be the operation of predilection, division of the meatus being freely resorted to if that portion of the urethra offers an obstacle to the introduction of instruments.

2. The lithotrite and evacuating-tube should be of a size which can be inserted into the bladder without much effort or over-distention, and great gentleness should be observed in passing these instruments. Keegan says: "When I advocate litholapaxy as being the best operation, in my opinion, for the great majority of stones occurring in male children and boys, I do so with a very important reservation—viz. that no one should attempt to perform it in boys until he has first gained some practical experience of it in adult males. The surgeon who meets with cases of stone only at rare intervals during his career will be acting more wisely if he adheres to lateral lithotomy or suprapubic cystotomy. It is his misfortune, and not his fault, that he has not been afforded many opportunities of gaining a practical familiarity with the use of the lithotrite."

3. The instruments should be withdrawn and reintroduced as seldom as possible, the stone being finely pulverized before the lithotrite is taken out at all. In seeking for or attempting to seize the stone care should be taken to avoid such wide separation of the blades as will bring the male blade in frequent contact with the vesical neck. The crushing should invariably be done only after rotating the blades into the centre of the bladder. Every particle of the calculous dust should be evacuated.

4. Rest in bed, milk diet, and sterilization of the urine by boric acid or

¹ These remarks apply almost as well to adults.

salol given internally, both before and after the operation, are valuable adjuncts. During the operation every antiseptic precaution should be observed.

Southam very properly emphasizes the importance—*a*, of this preliminary sterilization of the urine by the administration of salol and boric acid, and if need be by irrigation of the bladder; and *b*, the avoidance of shock by thorough protection of the patient against surface chilling.

5. The exceptional cases of calculi which are both large and hard may be best treated by suprapubic lithotomy, but neither unusual size nor a moderate degree of density should of itself alone be thought positively to contraindicate litholapaxy.

6. Perineal lithotomy has now a very limited field, and should be employed chiefly in those cases of stone thought to be of small or medium size, in which no lithotrite, however small, can be introduced with safety.¹

Operative Treatment for Stone in Female Children.—Surgical opinion in regard to the choice of operation in female children has not as yet become so definitely established. The possible methods are—

a. Vaginal Lithotomy, which is attended with much disturbance of the parts, requires over-stretching of the vagina, section of the fourchette, destruction of the hymen, etc., and which, even in good hands, has not infrequently been followed by a permanent vesico-vaginal fistula.

b. Dilatation of the Urethra.—This is easy and safe in the case of small stones, but in larger ones, and especially if incision of the urethra is required, is extremely liable to be followed by incontinence.

c. Suprapubic Lithotomy.—This is at present the operation of choice with many surgeons. Jacobson thinks it would be wiser to make use of it in all but the very smallest stones. He adds: "I would refer my readers to a case of suprapubic operation by Mr. Barwell in a child aged nine, from whom a stone weighing two and a half ounces was successfully removed. It is interesting to note that Mr. Barwell was led to adopt the suprapubic operation from his having had within seven months no less than three cases of vesico-vaginal fistulæ originating in the extraction of calculi during infancy and youth by different surgeons."

d. Litholapaxy.—The statistics which are slowly accumulating (chiefly from Indian sources) tend to show that this will be the operation of the future, but cases of stone in female children are so rare comparatively that the figures thus far available cannot be regarded as conclusive. The difficulty of crushing in such small bladders has been alluded to, but it is usually not greater than in the case of males. If a lithotrite and a fair-size evacuating-tube can be inserted without over-distention of the urethra, there would seem to be no *a-priori* reason why the operation should not be as successful in females as in males.

The details of the performance of the various operations in both male and female children belong to the systematic works on general and operative surgery, and need not here be considered.

It may be remarked, finally, however, that an improvement in results scarcely less than that found in other branches of surgery has followed the introduction of antiseptics into genito-urinary work, and that, whichever operation is selected in a given case of vesical calculus in a child, the little patient is on the average safer to-day than he was in the hands of even the most skilful operator twenty-five years ago.²

²I desire to acknowledge my obligation to Dr. Robert G. Le Conte for the collection of much statistical matter upon which some of the above statements are based and for further aid in the preparation of this article.

GONORRHŒA AND VULVO-VAGINITIS.

BY J. WILLIAM WHITE, M. D.,

PHILADELPHIA.

I. GONORRHŒA IN MALE CHILDREN.

IN male children specific urethritis does not differ materially in its course, symptoms, and complications from the same disease in the adult. The cause is often some sexual relation established between the child and an adult female for purposes of sexual gratification of the latter, even though the boy may be so young that intromission is impossible. In other cases mediate contagion has occurred by means of dirty clothing, towels, or cloths used by older persons of the same household, etc. In others, chiefly in boys near the age of puberty, the disease is acquired in the customary manner—*i. e.* during actual or attempted intercourse.

Symptoms.—The usual symptoms, purulent discharge, ardor urinæ, chordee, frequent urination, etc., are present. Of the complications, phimosis and balano-posthitis are more common than in the adult, owing to the relatively excessive length of the prepuce and to the delicate character of the mucous membrane lining it and covering the glans. Cystitis is not uncommon; epididymitis is more so. Prostatitis, as might be expected, is almost unknown, or at least cannot be differentiated from vesical inflammation. The intensity of the urethritis and the severity of the symptoms are both rather greater than in the average case in the adult, and the accompanying constitutional disturbance is much more marked.

Diagnosis.—As such cases are not infrequently the basis of legal proceedings, the physician should be especially guarded in pronouncing upon the character of the disease in any given instance. While specific urethritis can usually be traced to one or the other of the causes above named, there are many cases of simple urethritis which are clinically indistinguishable, and the non-specific nature of which can only be recognized by the absence of a history of infection on the one hand, and by the existence of a sufficient traumatism, such as the passage of instruments, the ejection of a calculus, etc., on the other. I have seen severe urethral inflammation follow retention and decomposition of smegma beneath a long, tight prepuce, the orifice of which was so small that "ballooning" occurred with each act of urination. In such cases a small quantity of urine is always retained beneath the foreskin, and cleanliness is impossible. In comparison, however, with the number of cases in which this condition exists in children the frequency of occurrence of urethritis as a result is extremely small, and caution should be observed in attributing a particular urethritis to this cause.

While bacteriological investigation will throw much light upon the etiology of a case of this kind, our information is not yet definite enough to enable us to predicate absolutely upon the presence of the gonococcus the specific char-

acter of the inflammation. It renders it highly probable that the disease is the result of infection, direct or indirect, from another person having the same disease, but it is not yet safe to say more than that. Competent observers, such as Bumm, assert that in the normal urethra a diplococcus is found having all the peculiarities of the gonococcus. If this be true, even if it occurs with great rarity, it is apparent that it destroys the diagnostic value of the gonococcus in medico-legal cases. A knowledge of its presence is, however, of use clinically, as indicating an inflammation of more severe type than the simple urethritis in which the infection has been exclusively with staphylococci or streptococci.

Treatment.—The child should be kept in bed. If there is marked phimosis, the prepuce should be slit up the dorsum, or, if the œdema and inflammatory exudate are not too extensive, a formal circumcision should be performed. The organ should be wrapped in cloths wet with lead-water and laudanum, and the constitutional disturbance controlled by mild laxatives, small doses of aconite, and full doses of potassium bromide. An excellent formula is the following, the doses of which are proper for a child five years of age:

R. Potassii bromidi ʒj.
 Acid. borici gr. xlviij.
 Tinct. aconiti ℥iij.
 Tinct. belladonnæ ℥xiij.
 Spts. ætheris nitrosi fʒiij.
 Mist. potassii citrat. q. s. ad fʒvj.—M.

Sig. Dessertspoonful in water every two hours.

The diet should consist almost exclusively of milk.

When the inflammatory symptoms have subsided the use of injections may be begun. They should be from one-half to two-thirds of the strength required for the adult, and the excellent rule applicable to the latter should not be deviated from—viz. to avoid the production of pain by the free dilution of the injection to any necessary extent.

It is often well to begin with a lead-and-laudanum injection, substituting the extract of opium for the tincture:

R. Ext. opii aq. gr. vj.
 Liq. plumbi subacetat. dil. fʒvj.—M.

Sig. Use locally.

Later, an antiseptic and astringent injection like the following may be employed with advantage:

R. Hydrarg. chlorid. corros. gr. $\frac{1}{30}$.
 Acid. borici ʒj.
 Zinci sulpho-carbolat. gr. xij.
 Liq. hydrogen peroxid. fʒss.
 Aquæ rosæ fʒvss.—M.

Sig. Use locally.

These injections should be given by a nurse immediately after the child has urinated. From half a drachm to a drachm is a sufficient quantity to throw in at one time.

During the subsiding stage the internal administration of salol will be of use, and if an irregular febrile movement persists, as is sometimes the case, full doses of quinine night and morning will be of great value.

II. VULVO-VAGINITIS.

The vulvo-vaginitis of children may be—*a*, Catarrhal or irritative; *b*, Gonorrhœal.

a. The catarrhal form is caused by any simple irritant, the commonest causes being the prolonged contact of the parts with filthy diapers, the retention of urinous and sometimes of fecal matter between the labia, all forms of dirt, seat-worms, etc. It may be excited by any traumatism or by an attempt at rape. It is an almost pure vulvitis, the vagina being but slightly involved and the urethra very rarely.

It is characterized by the ordinary symptoms of inflammation, heat, swelling, redness, pain or itching, and sometimes by extensive excoriation or actual ulceration.

b. The gonorrhœal form is much more severe. There is free purulent discharge, much swelling of the external genitalia, intense hyperæmia of the mucous surfaces, which bleed readily when touched, ardor urinæ, pelvic and abdominal pain, and often some endometritis, with tenderness and swelling of the uterus.

The constitutional symptoms are quite marked. The fever often has a high range and is very persistent. The local conditions are apt to be rebellious to treatment.

Diagnosis.—The diagnosis between these two conditions is often a matter of the gravest importance, not so much perhaps to the little patient as to others who may be suspected of being the source of infection.

The clinical diagnosis will be based upon the presence or absence of the causes of catarrhal vulvitis enumerated above, and upon the extent and character of the symptoms. The catarrhal variety is not markedly contagious, does not give rise to purulent ophthalmia, and yields readily to treatment. The reverse is true of the gonorrhœal variety. The former occurs most frequently during the first two years of life; the latter, from the third to the seventh year.

The bacteriological diagnosis is open to the same uncertainties as have been mentioned in relation to urethritis in male children.

One of the most carefully observed cases which has been recorded is reported by Dr. Edward Martin,¹ and appears to show that the discharge from a case of vulvo-vaginitis acquired in an entirely non-venereal manner, apparently originating *de novo*, is capable of exciting a severe attack of typical gonorrhœa when inoculated in a healthy urethra. In 5 of 9 cases he made careful microscopic examinations, and found gonococci present in all. In all but one the possibility of contagion was positively denied.

The general evidence shows a remarkable difference between the histories of some of the cases and their bacteriology, as in the above instances, and also between the results arrived at by different observers. Vibert and Bordas in six cases of purely *traumatic* vulvo-vaginitis found diplococci absolutely identical with the gonococci. On the other hand, Martin failed to find gonococci in a single case of irritative vulvo-vaginitis, although he examined a considerable number. It is apparent, therefore, that the mere presence of the

¹ *Jour. of Cut. and Gen. Urin. Dis.*, November, 1892. Dr. Martin's excellent article contains a résumé of the latest observations on this subject, and may be referred to with advantage. I have used it in the preparation of this paper.

gonococcus does not justify the unreserved diagnosis of specific infection, although it may be said strongly to favor that view and practically to establish it when the clinical symptoms coincide.

When the disease appears at a very early age, it is almost always the result of infection from a gonorrhœal inflammation of some portion of the generative tract of the mother. Later, especially if there is an accusation of rape directed against any one, it is well to remember that the same liability exists, and that the disease may have been carried by the fingers or garments of the mother.

Treatment.—In the catarrhal variety absolute cleanliness, obtained by frequent bathing in warm water and soap and favored by first pouring carbolized oil (1 : 60) over the region, dryness of the parts produced by the gentle use of absorbent cotton, separation of the labia by portions of cotton or gauze, and the use of some dusting powder, such as that given below, are the essentials of treatment :

℞. Pulv. zinci oxidi,
 Pulv. acid. boric. *āā*. $\bar{3}$ ss.
 Pulv. amyli $\bar{5}$ j.

In the gonorrhœal form a little more active treatment is required. Vaginal douches of hot soda solution or of soapsuds, followed by antiseptic irrigation, are to be employed two or three times daily ; the soda may be of the strength of 1 per cent ; the antiseptic solution should contain bichloride of mercury (1 : 4000), or carbolic acid (1 : 100), or boric and salicylic acids (10 gr. of the former and 5 gr. of the latter to $\bar{f}\bar{3}$ j), or silver nitrate (1 : 5000). It is important after each irrigation to dry the parts carefully but gently, and then to use a dusting powder, keeping the labia separated.

If the urethra is involved, and especially if there are evidences of cystitis, the internal administration of boric acid and salol, or of some such mixture as that previously given for the same disease in boys, will be found useful.

In all varieties of this disease the general health of the little patient should be scrupulously looked after, as struma, anæmia, and digestive derangements are frequently found associated with local causes in producing the symptoms or favoring their continuance.

PHIMOSIS, ADHERENT PREPUCE, PARAPHIMOSIS.

BY HENRY R. WHARTON, M. D.,
PHILADELPHIA.

I. PHIMOSIS AND ADHERENT PREPUCE.

PHIMOSIS consists in a contraction of the orifice of the prepuce, which is frequently associated with elongation of the prepuce, preventing the exposure of the glans penis. The condition may be either congenital or acquired. In congenital cases the contraction is much more marked in the inner or mucous layer of the prepuce, which adheres closely to the glans penis. Acquired phimosis is usually seen in children who have suffered from balanitis, and is not common in very young children. Adherent prepuce is a very common condition during early infancy, and is often associated with phimosis: this adhesion by pressure tends to dwarf the growth of the glans penis, and causes accumulation of smegma, which may harden and act as a foreign body. I have frequently seen in cases of adherent prepuce a complete cast of hardened smegma filling up the groove behind the corona.

Phimosis with adherent prepuce, as has been stated before, is almost always present in male infants at birth, but as the child develops the condition usually disappears, and in many cases no symptoms are developed referable to it; on the other hand, there are often mechanical irritations and reflex nervous disturbances which can be traced to the presence of phimosis, such as malnutrition, choreic movements, paralysis, convulsions, nocturnal incontinence of urine, dysuria, prolapsus of the rectum, and hernia, the latter conditions being most frequently seen where there is marked contraction of the preputial orifice and severe straining efforts are made during micturition. Adherent prepuce with retained smegma in young infants frequently produces priapism, vesical irritation, defective nutrition, and restlessness at night, which conditions are usually relieved by exposure of the glans. In older children the condition of phimosis with adhesions is apt to give rise to priapism, and is unquestionably the cause of the habit of masturbation in young boys. Bearing in mind these facts, it seems the part of wisdom for the physician to investigate the condition of the genital organs in all male infants, to ascertain the fact that the prepuce and the glans are separable; and it is especially important in any obscure diseases developing in infancy and childhood that this examination should not be neglected.

In cases where the preputial orifice is very small, as in Fig. 2 (Plate XXII.), the adhesion of the mucous layer of the prepuce to the glans penis is usually very firm, and as the glans cannot be exposed, the adhesion becomes firmer as the patient increases in age, so that to expose the glans it is often necessary to dissect the mucous layer of the prepuce from the glans.

It is an unquestionable fact that preputial adhesions are separated spon-

taneously, and that the condition of phimosis is outgrown, and that many cases reach adult life without presenting any symptoms due to the condition described. But when we consider that a very trivial operation in infancy will relieve the condition which may later give rise to serious symptoms, it seems to me to be wise to stretch the prepuce and separate the adhesions in all cases. If phimosis still exists and symptoms are present, it can be relieved later by operative interference.

Treatment of Adherent Prepuce.—This condition is best relieved by stripping the glans, which is accomplished as follows: The foreskin should be drawn slowly backward until the point of adhesion is reached, by grasping the penis between the finger and thumb and making traction upon the margin of the ring in this way: by passing the end of a silver probe around the adhesions between the mucous membrane and the glans, they can usually be separated without difficulty. When all adhesions have been separated and any collections of smegma about the corona have been removed, which is best accomplished with the end of a probe, the foreskin should be movable upon the glans. The exposed surface of the glans should then be anointed with carbolized oil or boracic-acid ointment, and the prepuce again brought forward, care being taken not to keep the foreskin back for any considerable time, as the condition of paraphimosis soon develops, and much difficulty may be experienced in its reduction. This manipulation should be repeated at intervals of a few days, and in ten days or two weeks it will be found that no tendency to readhesion exists. When there is very marked contraction of the preputial orifice, so that the glans cannot be exposed, it is necessary to resort to dilatation or stretching, excision, or circumcision of the prepuce.

DILATATION.—This method of relieving phimosis is accomplished by introducing into the preputial orifice the blades of a pair of dressing or dissecting forceps, or forceps specially devised for the purpose, and separating the blades, thus stretching or rupturing the mucous membrane until the glans can be freely exposed; when this is accomplished, it should be covered with carbolized oil or boracic-acid ointment, and the foreskin should again be brought forward. The manipulation should be repeated at intervals of two or three days for several weeks, until the glans can be exposed without difficulty. The disadvantage of forcible dilatation of the prepuce lies in the fact that there is often a considerable amount of inflammatory induration of the mucous membrane following the procedure, and forcible dilatation has been followed by gangrene of the prepuce. I have knowledge of one case in which this unfortunate complication resulted. Therefore, the procedure is, I think, not to be generally recommended, but, judiciously employed in connection with stripping of the glans, it is often of advantage; but in severe cases it is better to resort to excision or circumcision.

EXCISION.—This procedure for the relief of phimosis consists in first incising the foreskin on the dorsum of the glans from the preputial opening to the corona glandis; the flaps thus made, consisting of skin and mucous membrane, are seized with forceps and trimmed off with scissors, so as to make an oval wound. In performing this operation it is well to introduce the end of a grooved director into the preputial orifice and pass it backward over the dorsum of the glans penis to the corona glandis; the tissues upon the director are next divided with a bistoury or scissors to the corona glandis; the flaps resulting are seized with forceps and trimmed off with a scalpel or scissors, so as to make an oval wound, the frænum being left intact; a few stitches of catgut or fine silk are next introduced to hold the skin and mucous membrane together, and the wound is dressed with boracic-acid ointment spread on lint. The result

PLATE XXII.

PHIMOSIS, SHOWING PIN-POINT ORIFICE.

following this operation is usually very satisfactory, and it will be found most serviceable in cases where the prepuce is indurated or œdematous as a result of balanitis.

CIRCUMCISION.—This operation in most cases of phimosis, and particularly in congenital cases, is the one which is to be selected as securing the most satisfactory removal of the redundant prepuce and the freest exposure of the glans penis. In performing the operation of circumcision the foreskin should be drawn slightly forward and the blades of a pair of forceps, preferably Ricord's fenestrated forceps, or a modification of this instrument, fenestrated spring forceps (Fig. 1), should be placed obliquely upon the foreskin, so that more

FIG. 1.

Fenestrated Spring Forceps.

tissue is included in the region of the corona glandis than in the region of the frænum, care being taken to see that a sufficient quantity of skin is removed, and that no portion of the glans is included in the grasp of the forceps. Neglect of the former precaution often leads to the production of a secondary phimosis after healing has taken place, and a subsequent operation is required to expose the glans. I have been called upon to do a number of secondary circumcisions which were necessitated by the operators having failed to remove a sufficient quantity of the foreskin to expose the glans completely; it is an error which inexperienced operators are apt to commit. The forceps being placed as above described, a narrow bistoury is passed into the fenestra, and the tissues between the blades are divided; or the same purpose may be attained by cutting with scissors close to the forceps. The forceps are then removed and the skin retracts. It will often be found that the mucous membrane has not been divided or has only been slightly removed. If this be the case, it should be divided upon the dorsal surface of the glans and corona by introducing a director and dividing the mucous membrane with bistoury or scissors; any adhesions to the glans should be separated with the end of the director. The triangular flaps of mucous membrane thus resulting should next be seized with forceps, and trimmed off with scissors to correspond to the line of the skin incision. There is usually little hæmorrhage, but occasionally the arteries of the frænum or a dorsal artery or vein bleed freely, in which case they should be secured by means of fine catgut ligatures. To secure prompt healing of the wound the hæmorrhage should be perfectly controlled before the skin and mucous membrane are sutured together. I have seen neglect to control the bleeding at the time of operation give rise to troublesome consecutive hæmorrhage, resulting in great swelling of the penis as the blood escaped into the loose cellular tissue; and I have also seen a child almost exsanguinated by slow consecutive hæmorrhage from the artery of the frænum which had gone on for hours after circumcision. To avoid this complication, I think it is a matter of the first importance to check all bleeding, even if insignificant, at the time of operation, and not to depend upon controlling a hæmorrhage by the final suturing of the wound, as is often recommended. After the mucous membrane has been trimmed, the edges of skin and mucous membrane should next be brought in apposition by introducing fine silk or catgut sutures. I usually employ a fine chromicized catgut suture, as it does not require subsequent removal. The first two sutures are introduced, one at the frænum and the other at the middle line of the dorsum; two more sutures on

each side are usually sufficient. The appearance of the parts immediately after circumcision in the case already depicted, in which there were firm adhesions between the mucous membrane and glans, is seen in the accompanying plate. (Plate XXIII.)

The surface of the glans and the sulcus behind the corona should be dressed with boracic-acid ointment or carbolized zinc ointment, and a dry dressing of sterilized or carbolized gauze may be wrapped around the penis to cover the wound, or a wet dressing, consisting of boracic acid, glycerin, and water, may be employed in the same manner. The dressing may be held in place by the turns of a narrow roller bandage or by the T bandage or by the child's napkin. Subsequent dressings are made daily, and at the end of a week the union is generally complete in the line of incision. Some œdema of the mucous membrane may persist for weeks, but it usually disappears in a short time.

II. PARAPHIMOSIS.

This name is given to the condition in which an abnormally narrow prepuce has been drawn up above the corona glandis and remains irreducible.

FIG. 2.

Paraphimosis.

When this accident happens the glans soon becomes swollen and œdematous from the constriction exercised by the edges of the preputial orifice, and, if the condition is not promptly relieved, ulceration or gangrene may occur. Paraphimosis is usually met with in boys who retract the prepuce and fail to replace it promptly, or may result from the trick of tying strings or bands around the root of the penis. One of the most aggravating cases I have ever seen was caused by an ignorant nurse tying a string around a boy's penis to control nocturnal enuresis. I have also seen the condition resulting in young children from the bites of insects. When paraphimosis has existed for some time, the swelling and œdema of the glans and mucous membrane become so marked that the greatest distortion

of the organ occurs; the appearance is well presented in Fig. 2.

Treatment.—When seen early these cases can be quickly relieved by grasping the lateral folds of skin between the thumb and finger of the left hand, and drawing the foreskin forward at the same time as the thumb and forefinger of the right hand compress the glans and push it backward within the advancing ring (Fig. 3). In cases where this manipulation does not succeed minute punctures of the œdematous mucous membrane with a sharp-pointed bistoury will often cause a decided diminution in its bulk by the escaped serum, so that the above manipulation will then often be followed by success. Should this procedure fail, it is better to anesthetize the patient and resort to operative measures. The operative treatment to effect the reduction of the paraphimosis consists in introducing the end of a blunt-pointed bistoury under the edge of the prepuce and dividing it freely

FIG. 3.

Reduction of Paraphimosis.

PLATE XXIII.

PHIMOSIS, SHOWING APPEARANCE AFTER CIRCUMCISION.

on the dorsum of the glans, or the constricting tissue may be divided at two or three points. After this has been done the glans can usually be reduced without trouble. The after-treatment consists in the application for a few days of a lotion of carbolic acid, chloride of ammonium, glycerin, and water until all swelling has disappeared. When paraphimosis has once occurred, it is better, after the parts have resumed their normal condition, to circumcise the patient and prevent the possibility of a repetition of the accident.

PART XI.

DISEASES OF THE SKIN.

BY W. A. HARDAWAY, A. M., M. D.,

ST. LOUIS.

IN a general way it may be said that the child and the adult are subject to very nearly the same diseases of the skin; nevertheless, a close scrutiny will show that certain differences exist, both of kind and degree, that are worth attentive consideration.¹

In the first place, owing to the greater vulnerability of the skin in children, inflammatory disorders of all sorts take on a more acute aspect than with the grown person, and, for the same reason, mechanical irritants are more apt to be productive of mischief. Then, again, the frequent gastro-intestinal disorders of infancy increase, in an indirect way, the tendency to inflammatory and erythematous cutaneous processes. Although the influence of dentition is much overrated as an etiological factor, it remains true that the nervous erethism set up by the eruption of teeth may be regarded as a complicating agency of importance in certain cases. As regards special diseases, Diday shows that congenital syphilis develops generally in the first three months of life; ichthyosis may be congenital or show itself between the ages of three and six; eczema is more common during the first five years than at any other period; impetigo contagiosa is a disorder of childhood; ringworm of the scalp is essentially a disease of the young, and so is pediculosis capillitii; pemphigus is not infrequently encountered in children; and lupus vulgaris usually begins early in life. On the other hand, by way of contrast, it may be stated that acne is rare before puberty; tinea versicolor is an affection of the adult; epithelioma is uncommon before the fortieth year, and children rarely have essential pruritus. These comparisons might be much extended, but enough has been shown for practical purposes.²

In this article, owing to necessary limitations of space, only those disorders of the skin most common to children will be considered at any length; rare diseases, or those whose nosological positions are still uncertain, will not be noticed at all or only in the briefest manner.

¹ In the preparation of this article the writer is under especial obligations to the papers on dermatology by various authors in Keating's *Cyclopædia of the Diseases of Children*, and to Crocker's *Text-book of Skin Diseases*. Thanks are also due Dr. C. F. Hersman for much valuable assistance.

² See writer's article, "Locality and Age in the Diagnosis of Skin Diseases," *St. Louis Clinical Record*, Nov., 1875.

DISORDERS OF THE GLANDS.

SEBACEOUS GLANDS.

SEBORRHŒA.

SEBORRHŒA is a functional disease of the sebaceous glands, characterized by excessive secretion, which is discharged upon the integument in the form of oily, scaly, or crusted material. There are two varieties—viz. *seborrhœa oleosa* and *seborrhœa sicca*; in the first condition the secretion is fluid or oily, and in the second it is dry and scaly. As the *vernix caseosa* of the new-born it may be regarded as physiological. Both forms of seborrhœa may be present in the same patient, or, on the other hand, the distinction between them may be hard to define. The disease may be present on any part of the body save the palms and soles. A slight amount of seborrhœa of the scalp is often seen during the first month of infancy, and the frantic efforts to get rid of this almost normal secretion frequently leads to an annoying and rebellious eczema. Sometimes the secretion forms a thick crust and extends over the forehead and adjacent parts. Unless the skin has become irritated by the decomposition of the secretion, it will be found cool and even paler than normal. In older children both the dry form, the so-called pityriasis capitis, and the oily variety are not infrequently observed, and, as in the adult, give rise to a dry, lack-lustre state of the hair or comparative baldness.

According to Crocker, the disease is often seen in strumous children in the form of small shining scales situated upon the trunk and limbs, and generally coexisting with lichen scrofulosus. Excessive secretion of sebum at the umbilicus, on the glans penis, the inner surface of the prepuce, and the sulcus in the male, and about the labia and clitoris in the female, is common in ill-cared-for children, and as a consequence of decomposition produces a most sickening odor and sets up an acute dermatitis. Hebra and others regard ichthyosis congenita as a seborrhœa.

Under the term seborrhœal eczema Unna includes not only the dry seborrhœa of the body (*lichen circumscriptus*) common to adults, but those forms of eczema in children situated upon the eyelashes and other regions. This question cannot be discussed here, but it is proper to remark, as long since pointed out by Kaposi, that seborrhœa is a very common provocative of eczema, and that, therefore, the latter disorder is often encountered in regions richly supplied with oil-glands.

Etiology.—Among the common causes of seborrhœa in children may be mentioned various disorders of nutrition arising from struma, anæmia, gastric and intestinal disorders, and, more directly, inattention to personal hygiene. Unna regards seborrhœa as an inflammatory affection of the sweat-glands, and Brooke thinks it is of parasitic origin.

If long continued, the glands are apt to undergo atrophy, but in the beginning the disorder is purely functional. The secretion, examined microscopically, is seen to consist of epithelial scales, amorphous granular material, and free oil-globules and fat.

Diagnosis.—This offers few difficulties. On the scalp the disease is differentiated from eczema by the absence of marked itching and infiltration of the skin and by the greasy character of the scales. The scales in psoriasis are not greasy, but dry, and are arranged in more or less isolated mortar-like heaps scattered over the scalp. Oily seborrhœa of the body is easily recognized: the dry form should be differentiated from eczema, psoriasis, ringworm, and pityriasis rosea. (See articles on these diseases.)

Prognosis.—Infantile seborrhœa is usually very amenable to proper treatment.

Treatment.—The internal treatment is entirely symptomatic, and consists in the removal of any apparent derangement of the health. Minute doses of sulphide of calcium have been recommended, but the writer has seen no benefit from its use. Mothers should be warned against the fine-toothed comb and other harsh measures in their efforts to cleanse the heads of their babies. Instead, the crusts should be soaked off with free applications of olive oil, and then kept clean with Eichhoff's superfatted thymol soap; but if the skin is at all tender, it is better to keep the parts anointed with a little vaseline for a short while. Seborrhœa of the body is managed in the same general way, but if the secretion is persistent—and this holds equally good for the scalp—it is well to apply once or twice daily the following ointment:

℞. Sulphuris præcip. gr. x-xx.
 Acidi salicylici gr. v-x.
 Vaselini ʒj.—M.

Sig. Local use. To be further diluted if too active.

Resorcin, carbolic acid, white precipitate, and tannin are also good remedies.

Seborrhœa of the umbilicus and of the genitals requires absolute cleanliness and the local application of alum or tannin washes. In all cases, if the disease has set up much dermatitis, soothing and antipruritic treatment will be required. (See Eczema.)

COMEDO.

Comedo is a disorder of the sebaceous glands in which their excretory ducts are plugged with inspissated sebum mixed with epithelial cells. These so-called flesh-worms or black-heads are generally slightly elevated, pinpoint to pinhead in size, and can be expressed as a filiform mass when pressure is made at the sides of the lesions. Sometimes the comedo is slightly depressed, and, instead of the usual black color, may have a yellowish or even bluish tint. The usual seats of comedones are the face, neck, chest, and back.

Ordinarily, comedones are not seen before puberty; but some years ago Crocker called attention to cases occurring in the children of the poor in summer. According to this observer, they appear on the upper part of the forehead and corresponding parts of the occiput in boys above three years, on the temples in girls, and on the cheeks in infants. They are densely packed and often grouped, and accompanied by seborrhœa of the scalp. Warmth and moisture seem to be the exciting causes. T. C. Fox has made similar observations.

Treatment.—Cleanliness and the free use of soap and water are all that is required in the way of preventive treatment. To remove the comedones when present, friction with a green-soap lather is usually efficacious:

℞. Saponis olivæ præp., vel saponis viridis . . . ʒj.
 Alcoholis f ʒj.
 Aquæ q. s. ad f ʒiv.—M.

Sig. Apply with flannel rag.

In some cases it may be necessary to express the plugs with a comedo-extractor.

ACNE.

Although Chambord and others have reported a few cases of acne in young children, practically the disorder does not make its appearance until puberty. The acne due to the ingestion of the iodides and bromides and to the use of tar is not a true form of the disease.

MILIUM.

Milia are small white or yellowish papules, varying in size from a pinhead to a split pea, that occur for the most part under the eyes, on the forehead, and over the cheeks. It is a tolerably common affection in infants, and constitutes the *strophulus albidus* of Willan.

Etiology.—The etiology is not always clear when occurring in infancy. Milia are often congenital. They also follow in the wake of other diseases—namely, pemphigus, lupus, erysipelas, etc. They are usually regarded as due to retention in one or several of the acini of an oil-gland, but Robinson thinks that two causes may be operative in their production: in one instance “it is a case of miscarried embryonic epithelium from a hair-follicle or from the rete,” while in milia following pemphigus, lupus, etc., the contents consist of fatty epithelium and cholesterin, the epithelium being often arranged in concentric layers around a central fat-nucleus.

Prognosis.—Favorable.

Treatment.—The electrolytic puncture, as originally suggested by the writer, is not demanded, nor would it be tolerated, in infantile cases. More or less vigorous friction with soap and water is all that is needed.

SWEAT GLANDS.

HYPERIDROSIS.

Hyperidrosis is a functional affection of the sweat-glands, giving rise to hypersecretion of their contents. It may be acute or chronic, general or local, limited or excessive in amount. Universal hyperidrosis is usually symptomatic, occurring in connection with acute febrile states or dependent upon general diseases of a debilitating character, such as phthisis, rickets, etc. In the last-named disease, however, the sweating is most abundant about the head. Generally in babies the profuse local and general sweating is induced by injudicious clothing and excessive heating of living apartments, and when these unhygienic conditions are kept up, intertrigo and eczema are not infrequent sequelæ about the genitals and between the folds of the skin. Generalized eruptions of sudamina from the same causes are also encountered.

Hyperidrosis of the palms and soles and axillæ often develops during childhood, and sometimes is clearly congenital and occasionally hereditary; but it does not follow that all of these localities are involved at the same time, for usually the disorder is limited to one region or the other, the palms and soles being more apt to suffer together. When the palms and soles are affected—that is, if the sweating be at all abundant—the skin becomes sodden and macerated, and from the feet the odor is often disgusting. This condition, known as bromidrosis, is more frequent, however, in the adult.

Etiology.—Aside from the more or less physiological sweating due to high temperature, faulty innervation apparently plays the chief rôle in hyperidrosis. Cutler regards it as a functional affection of the sympathetic system. Fœtid perspiration is due to the presence, according to Thin, of the bacterium fœtidum.

Prognosis.—Sweating of the feet is more controllable than that of other parts. Upon the whole, the prognosis of hyperidrosis should be guarded.

Treatment.—The treatment of general sweating is based upon the causal indications, and need not be dwelt upon here. The debilitating sweating about the head in children may be much mitigated by directing them to lie on hair pillows instead of the usual feathers. Among specific remedies may be mentioned belladonna, atropine, agaricin, and ergot; but their effect at best is only temporary. Crocker highly extols precipitated sulphur, given in milk, twice a day. If it proves too laxative, it may be combined with the compound chalk-and-cinnamon powders.

The local applications are numerous. Among the most satisfactory are a 1 per cent. solution of quinine in alcohol, belladonna salve or liniment, tannin dissolved in bay rum (gr. viij to f̄ḡiv), salicylic acid in alcohol (ʒj-f̄ḡiv), and various dusting powders, composed of zinc, starch, boracic and salicylic acids. For sweating of the hands Pringle recommends pure silicic acid (terra silicea). For foul-smelling perspiration of the feet dusting the stockings with boracic acid is valuable. The following powder, as suggested by Van Harlingen, is to be commended:

R. Pulv. acidi salicylic.	ʒij.
Pulv. zinci carb. præcip.	ʒij.
Pulv. magnesiæ ustæ	ʒij.
Pulv. amyli	ʒviijss.
Pulv. talci	ʒx.—M.

Sig. Dusting powder.

Hebra's plan, although troublesome, is eminently successful. Briefly, it consists in wrapping the feet and toes, the latter separately, in cloths spread with diachylon ointment, which should be changed twice daily, and the parts rubbed dry before each reapplication. This should be kept up for two weeks, water being absolutely interdicted during the treatment. Strapping the parts evenly and firmly with soap or lead plaster often suffices.

MILIARIA.

Miliaria, lichen tropicus, or prickly heat, is an acute inflammatory affection of the sweat-glands, resulting in papular, vesico-papular, vesicular, and even pustular, lesions. It is a very common disorder in young children, and is usually seated upon the trunk, although the face and other parts of the body are also attacked. The subjective symptoms are very annoying, and consist of sensations of intolerable burning and stinging. The rash comes out suddenly, often after profuse sweating, and generally subsides in a few days with slight desquamation; but if the cause is kept up successive crops will appear. According to the lesion present—and this apparently depends upon the intensity of the process—the eruption has been variously designated—viz. *m. vesiculosa* or *rubra* (the "red gum" of the nursery), *m. papulosa* or prickly heat, etc. The non-inflammatory variety is *m. crystallina* or sudamina. Furunculosis and eczema are not infrequent sequelæ of neglected or ill-treated cases.

Etiology.—Intense heat is the common factor, and therefore miliaria is most frequently encountered in summer. Sudamina are noted in connection with states of general debility and in febrile disorders, but also as a consequence of excessive sweating. In sudamina the sweat collects between the deepest laminae of the horny layer; the sweat-duct is obstructed, with consequent

rupture of the wall and formation of a vesicle. In miliaria there is vascular congestion about the ducts, increased secretion, and more or less effusion into and about the sudoriparous organs.

Diagnosis.—Sudamina are non-inflammatory in character; which fact, taken in connection with the history of the case, will be sufficient for their differentiation from varicella. The lesions of eczema papulosum are larger than those of miliaria papulosa, are more persistent, and the pruritus is more intense. The vesicles of vesicular eczema are more closely set than those of vesicular miliaria; they rupture readily (in miliaria the vesicular contents usually dry up without rupture) and give rise to the peculiar sticky discharge.

Treatment.—In relapsing cases tonics are sometimes demanded, and more especially change of climate. Ordinarily, attention to diet, which should be of a plain, non-stimulating sort, with proper clothing and, at the height of the attack, some mild refrigerant mixture, is all that is required in a general way. Children in summer should be kept well powdered with borated talcum or similar preparation as a preventive measure. During the outbreak the speediest relief is secured from the use of the calamine-and-zinc lotion:

℞. Zinci oxidi	℥ss.
Pulv. calaminæ præp.	℥iv.
Glycerini	f℥j.
Liq. calcis	f℥vij.—M.

Sig. Shake and mop on freely.

If the itching be intense, from two to five minims of carbolic acid may be added to each ounce of the mixture.

Anderson's dusting powder is useful:

℞. Pulv. amyli	℥vj.
Zinci oxidi	℥iss.
Pulv. camphoræ	℥ss.—M.

Sig. Dusting powder.

INFLAMMATIONS.

ERYTHEMA SIMPLEX.

In simple erythema the skin presents variously-sized, diffused or circumscribed, hyperæmic lesions that fade temporarily upon pressure, and are usually without sensible elevation above the surrounding surface. Subjective symptoms are trivial, and consist for the most part of slight burning and tingling, or they may be absent entirely. An altogether unnecessary confusion has enveloped this subject, owing largely, perhaps, to errors in diagnosis, but also, to some degree, it has arisen from the cumbersome and pedantic nomenclature which has been applied to comparatively insignificant differences in the appearances of the lesions. Simple erythema may be conveniently divided into two main classes—namely, idiopathic erythema and symptomatic erythema.

IDIOPATHIC ERYTHEMA.

This variety of the disorder is excited by the influence of external irritants acting upon the skin, and passes readily into a true inflammatory state. *Ery-*

thema caloricum is set up by the agency of heat and cold; *erythema traumaticum* arises from pressure, rubbing, etc.; and *erythema venenatum* is produced by the action of animal and vegetable poisons. Two other forms of erythema, both very common in children, are *e. intertrigo* and *e. pernio*, or chilblain.

ERYTHEMA INTERTRIGO.—Intertrigo usually occurs in the groins, in the folds of the neck in fat babies, and wherever, in fact, the skin surfaces come in contact; and it is all the more readily induced by the irritation of the sweat-secretion and by urinary and fecal discharges. Intertrigo is always at first a simple hyperæmia of the skin, but when neglected the skin becomes hot and tender, the epidermis macerated, a profuse, malodorous, muciparous discharge is present, and in bad cases fissuring, and even ulceration, may occur.

The eruption is very common, at times appearing suddenly, and, under simple treatment, disappearing again as rapidly; but if maltreated it may run a long course. In some instances it is symptomatic of grave internal disorders.

Intertrigo naturally occurs most frequently in summer, but this is by no means the rule with children. Relapses are frequent.

Diagnosis.—Intertrigo is easy to recognize. Tilbury Fox says it is to be distinguished from eczema by the nature of the characteristic discharge, which does not stiffen linen. The erythematous syphilide of infancy is apt to attack, like intertrigo, the buttocks and genital regions; but, aside from the color and the general concomitants of syphilis, the diagnosis is facilitated by remembering that intertrigo confines itself to the region of the diaper; the syphilide runs down toward the heels.

Treatment.—The preventive treatment demands absolute cleanliness, the use of a bland soap (Eichoff's superfatted thymol soap, for example) and a simple dusting powder, such as oxide of zinc and lycopodium (ʒ ij—ʒvj). For the curative treatment it is necessary to keep the parts separated by the interposition of thin layers of absorbent cotton, and to apply some remedy that is both astringent and antiseptic. The following is a good example of a powder:

R̄. Thymol gr. j.
Pulv. zinci oleatis ʒj.—M.
Sig. Dusting powder.

A modification of Lassar's paste serves an excellent purpose, besides thoroughly protecting the surfaces from irritating discharges:

R̄. Acidi salicylici gr. x.
Bismuthi subnitrat̄is
Amyli āā ʒij.
Ung. aq. rosæ q. s. ad ʒj.—M.
Sig. Smear gently over the affected parts.

Of late the writer has used Pick's paste with much satisfaction:

R̄. Pulv. tragacanthæ gr. xv.
Glycerini ℥xxiv.
Aquæ f ʒj.—M.

This makes a transparent adhesive dressing, called by its originator linimentum exsicicans. By adding to it 10 per cent. of oxide of zinc and 1 per cent. of carbolic acid there will result a most admirable preparation.

ERYTHEMA PERNIO, OR CHILBLAIN.—Chilblains are prone to occur in chil-

dren with poor circulation, and especially in weakly, anæmic girls. The lesions consist of erythematous patches of various sizes and shapes, and attack by preference the heels, toes, sides of the feet, fingers, knuckles, ears, and tip of the nose. The spots are light red in the beginning, but later on become bluish-red. The burning and itching that accompany their development are much aggravated by warmth. The surface of the patches in bad cases may vesicate and result in the formation of large blebs, possessing serous or sero-sanguinolent contents; or the parts may become denuded and slough.

Treatment.—The internal treatment is symptomatic, but, as most of the cases occur in the weakly, tonics and general hygienic measures are urgently demanded. Woollen stockings and loose shoes, without elastic sides, are to be preferred, and the habit of “toasting” at fires and registers is to be prohibited. Friction with snow or cold water should be tried in threatening cases, and afterward soothing, somewhat astringent, lotions prescribed, such as the lotion of zinc and calamine. Pick’s paste is also useful at this stage. Later, if the erythematous condition has become fully developed, stimulating local treatment becomes necessary.

The unbroken surface may be painted with iodine or with oil of peppermint, pure or diluted. Jackson recommends—

R. Ol. cajuputi
 Liq. ammon. fort. āā f ʒij.
 Lin. saponis comp. f ʒiij.—M.
 Sig. Local use.

In very chronic patches Pringle recommends painting with a solution of nitrate of silver (gr. xvj) in spirits of nitrous ether (f ʒj), or a 5 per cent. solution of salicylic acid in traumaticin. Ulceration and sloughing, when they occur, should be treated on general surgical principles.

SYMPTOMATIC ERYTHEMA.

The symptomatic erythemata are very numerous and are due to a great variety of causes. It is well for the practitioner to remember that many general diseases—*e. g.* variola, diphtheria, measles, scarlatina, and vaccinia—are often preceded, accompanied, or followed by erythematous rashes. The scarlatini-form rash that is not infrequently seen in connection with septicæmia, the puerperal state, etc. is also, according to Crocker, an accompaniment of malarial disorders in children. However, it is necessary to bear in mind that quinine in susceptible subjects induces an erythematous rash. Various other drugs are capable of evoking congestions of the skin.

ERYTHEMA INFANTILE.—This form of erythema, also called roseola infantilis, is comparatively frequent, and possesses an importance out of proportion to its severity on account of the confusion in diagnosis to which it gives rise. Temporary congestions of the skin are quite common in teething children and in those suffering from alimentary derangements. The eruption is usually roseolous; that is to say, made up of variously sized and shaped patches and blotches having a general resemblance to the rash of measles. Much of what is called “scarlatina” is undoubtedly this symptomatic erythema. Accompanying the eruption there is usually some slight elevation of temperature, together with some redness, without swelling, of the palate and fauces.

This infantile erythema is an ephemeral affair, and its only importance is of a negative sort. The diagnosis, however, is at times difficult to the inex-

perienced. It is to be differentiated from scarlet fever by the fact that in the latter affection there is a high temperature, great heat of skin, glandular engorgement, the characteristic state of the tongue and throat, and the location of the eruption—symptoms that are absent in infantile erythema—while the catarrhal prodromal stage, the fever, the maculo-papular rash on the mucous membranes and the skin, are significant of measles, and not of erythema. Røtheln is manifestly the result of contagion, two or more children in the family perhaps being simultaneously attacked: the glands behind the neck are apt to be swollen, the eruption is less evanescent and is more papular than erythematous.

New-born babies are often attacked with an eruption made up of minute red papules seated on a hyperæmic base, which may be made to fade away under pressure. The back and chest are the usual sites of the rash. It lasts but a few days, and disappears with slight desquamation. The mucous membranes are not involved, and there is no fever.

Treatment.—The internal treatment of the various erythemata is purely symptomatic. A little calamine lotion or a dusting powder is all that is required locally.

ERYTHEMA MULTIFORME.

Erythema multiforme is an exudative affection of the skin in which various erythematous, papular, vesicular, bullous, tubercular, and nodose lesions may appear separately or coincidentally. Preceding the outbreak of this eruption, the patient may experience more or less malaise, gastric disturbance, sore throat, rheumatic pains, and fever. Crocker, who has paid much attention to the skin diseases of children, says that the fever and general symptoms are more marked in them than in the adult, the lesions are more severe, and when vesicles form their contents are prone to become purulent and leave cicatrices. However, the lesions are not so apt to be multiform. There are, nevertheless, exceptions to this rule, for often the general symptoms are insignificant, especially when the eruption is limited in extent.

The local subjective symptoms consist mainly of sensations of burning and tingling.

When the disease assumes the erythematous form, the fading of the centre of the patch leaves a ringed appearance that has been called *e. annulare*; or concentric rings, one forming within the other, will leave in their wake, as the effusion becomes absorbed, a variety of different colors, thus justifying the rather fanciful term of *e. iris*; or these advancing rings, meeting others, become broken into various lines, producing *e. gyratum*; or, made up of widely diffused patches with an abrupt and sharply-defined border, it is called *e. marginatum*. As usually seen, however, the disease makes its appearance in the form of discrete or aggregated flat papules, varying in size from a pin-head to a split pea; in color they are bright red or purplish. Often the lesions are considerably larger (*e. tuberculatum*), in which case they have a deeper or violaceous hue that is quite characteristic. Vesicles or bullæ may form in connection with any of the above-mentioned lesions, thus constituting *e. vesiculosum* and *e. bullosum*.

The backs of the hands and feet are common sites of the eruption, particularly for the papular and tubercular types; but the whole surface is often involved. Slight desquamation and pigmentation may occur as sequelæ. The usual duration of the disorder is from two to four weeks; but the general symptoms usually abate at the appearance of the eruption. Relapses are common, especially in the spring, and in a few rare instances, reported by Fox,

Jackson, and the writer, the disease has relapsed at irregular periods for many years.

Many authorities look upon erythema iris and erythema nodosum as independent affections, but the writer regards them as clearly allied to, if not identical with, erythema multiforme.

HERPES IRIS.—It is usually symmetrical, and occurs preferentially on the backs of the hands and feet, but especially the former. There may be one or more patches; sometimes the whole body is affected, even the mucous membranes. The eruption consists of an erythematous base, upon which is seated a conical vesicle: both vesicle and areola increase in diameter, and presently the outer border of the latter is elevated into an annular ring by fresh effusions, while the central vesicle undergoes absorption and leaves in its stead a purplish stain. Here the process may terminate, or else successive rings may form, and the various shades of color thus produced give the rather fanciful rainbow effect. Various other modifications have been noted.

ERYTHEMA NODOSUM.—Before the eruption is developed the patient may complain of the general symptoms observed in connection with other types of *e. multiforme*. The lesions consist of isolated, painful, inflammatory nodes that vary in size from a hickory-nut to an egg or orange. They are usually red at first, but as they decline take on the various shades of a common bruise. They may be well or ill defined, and are at first hard and tense, but later become softer, thus closely simulating abscesses. The favorite site of the eruption is the front of the legs, but it may appear elsewhere. Sensations of burning and tingling are usually present. The disorder may last two to four weeks. Relapses are not infrequent.

Etiology.—The various types of erythema multiforme avoid the extremes of life as a rule; the ages between ten and thirty are most obnoxious to its attacks. It seems to occur as the result of the most diverse causes—*e. g.* changes of temperature, disorders of digestion, as sequelæ of vaccination, in connection with epidemic influenza (*la grippe*); and, as regards *e. nodosum*, it apparently bears some etiological relationship to rheumatism. The explanation would seem to be that these various erythemata are of angeio-neurotic origin, and that under favoring conditions toxic and other agents influencing the central nervous system produce these explosions in the vascular and nervous organs of the skin.

The rash is undoubtedly due to a vaso-motor disturbance, inducing the usual phenomena of inflammation, with a variable amount of exudation. Hæmorrhage into the lesions also occurs.

Diagnosis.—Erythema multiforme is to be distinguished from urticaria by the stability of the eruption, the greater variety of the eruptive elements, and the less degree of itching. The papules of papular eczema are smaller, more pointed, last longer, and are intolerably pruritic. The nodes of syphilis should not be confounded with *e. nodosum*. Attention to the history of the case, the possibility of ulceration, and other concomitants of syphilis should sufficiently emphasize the differences.

Prognosis.—In the majority of cases the prognosis is favorable. Under no circumstances is the disease dangerous to life, but the relapses are not always easy to control.

Treatment.—The prodromic symptoms of erythema multiforme should be treated on general principles. There is no specific remedy for the disease as a whole. Hygienic measures and tonics are demanded in the anæmic and strumous. In rheumatic cases the salicylates are indicated. The calamine-and-zinc lotion, with or without the addition of a little carbolic acid, is a good local

application. In *e. nodosum* the legs should be kept elevated, and the same lotion applied, or a lead-and-opium wash. For *e. tuberculatum* of the hands the unguentum *vaselini plumbicum* (see under *Eczema*), spread on muslin and neatly bound, gives relief.

RELAPSING SCARLATINIFORM ERYTHEMA (FEREOL).

Under the title of "erythème scarlatiniforme desquamatif récidivant" Fereol and Besnier describe a form of disease that occurs in children and young adults, and which really should be discussed along with the other varieties of exfoliative dermatitis. Usually, after a prodromic stage of one or two days, in which the patient feels unwell and has slight fever, a scarlatiniform erythema appears, first on the trunk, and in a few hours, or perhaps not for a couple of days, it spreads over the whole body. In some cases the rash is localized to particular parts of the surface, or it may be widely diffused, but with areas of normal skin between the patches. The oral mucous membranes are also injected. There is some burning and itching present, but the skin remains supple and shows no infiltration. After a few days—one or two—the process comes to an end, and free desquamation occurs. At the end of a week or two the disease has generally run its course; on the other hand, there may be repeated recrudescences and the disorder may be kept up for weeks. Relapses are frequent, especially after vicissitudes of weather or from other general or local exciting causes. It is non-contagious and does not occur epidemically.

Diagnosis.—The distinction between this affection and scarlatina is at times difficult; but in scarlet fever the prodromic symptoms are usually more severe, the eruption comes out first on the neck, chest, and flexures of the joints, the fauces are tumid, the tongue has the strawberry-like appearance, the glands at the angles of the jaw are swollen, and, finally, desquamation does not occur nearly so soon. As additional points it may be remembered that this disorder usually gives the history of relapses, and that it is neither due to nor causes contagion.

Treatment.—This should be directed toward the mitigation of the general and local symptoms—namely, antipyretics and soothing inunctions.

ECZEMA.

Eczema is an inflammatory, non-contagious disease of the skin, characterized by multiformity of lesion and the presence, in varying degrees, of itching, infiltration, and discharge. It may be acute, subacute, or chronic, and undergoes various secondary changes, such as scaling, crusting, fissuring, and dense thickening of the skin. It was formerly held that eczema was invariably a vesicular disease, and that, therefore, the other types which it presents represented other diseases, such as impetigo, lichen, etc. We now fully recognize the fact that it is a truly protean affection in its manifestations, although possessing a pathological unity in its essential features that is unmistakable. This view has been very fruitful from the standpoints of diagnosis and treatment. So far from eczema being a vesicular disease, it may run its course without the appearance of a single vesicle. On the contrary, the disorder is characterized by a polymorphous eruption, consisting of erythema, papules, vesicles, and pustules. All of these lesions are not necessarily present at the same time, although to a limited extent they may be, and one form of elementary eruption may become transformed into another; but, as a rule, one or another of them may so predominate as to establish the anatomical general

type of the eczema; as, for example, *eczema erythematosum*, *e. papulosum*, *e. vesiculosum*, *e. pustulosum*.

In practice, however, the disease is more often encountered in its subacute or chronic phases, and a brief consideration of these secondary changes will be necessary.

Eczema rubrum or *malidans* may develop out of any of the elementary types of the disease, and consists of a raw, red, and weeping surface, the result of exposure of the rete, due to shedding of the upper layers of the epithelium. The itching is very severe. This form of eczema is common on the faces of children. Scaly or squamous eczema may also follow upon any of the elementary forms of the disease. It appears mostly in patches of variable size, which are red, scaly, and infiltrated: and finally, owing largely to situation or duration of the disease, the eczematous surface may become of board-like hardness, or warty, or cracked and fissured.

The chief subjective symptom present in eczema is itching: in fact, it constitutes the disease. The pruritus will vary considerably in degree, sometimes being slight and easily tolerated, or, again, it may be agonizing in its intensity.

Eczema bears a close resemblance to catarrhal states of the mucous membranes, both in its tendency to repeated relapses and, objectively, in its habit of exudation or discharge. This exudation has the property of stiffening and slightly staining linen or cotton fabrics with which it comes in contact. It is not correct to assert that eczema is invariably a "wet disease," for some cases may remain dry throughout: nevertheless, even a papular or erythematous eczema may be made to weep through the influence of scratching or other irritation.

Although eczema in children, especially in those under five years, is a very common disease, the writer fails to see wherein it differs essentially from the same disorder occurring in the adult, although this opinion is one very commonly entertained. Such differences as exist are rather of causation and location than in clinical expression. In a general way, it may be said that eczema occupies certain situations more often in the child than in the adult—the scalp and face, for example—and that the eruption is more acute, of a more inflammatory type. All of the elementary lesions of the disease—*e. g.* erythema, papules, vesicles, and pustules—are seen in children, and often a commingling of them all, although it must be allowed that pustular eczema is of more frequent occurrence in children than in adults. *Eczema rubrum* and *eczema squamosum* are frequent, but leathery-like infiltration is relatively uncommon.

Among other features of importance connected with infantile eczema may be noted secondary glandular swellings, cutaneous abscesses, particularly in the scalps of ill-nourished, strumous children, and post-eczematous furunculosis. The implication of the lymphatics, those in the neck being principally involved, as a result of *eczema capitis*, was formerly regarded as a sure indication of scrofula; and in eczema occurring after vaccination, with coincident glandular swelling, it was held as proof positive of the introduction of struma by the inoculated lymph. As a matter of fact, this adenitis is purely sympathetic, and is more apt to occur from the irritation set up by pediculi. It is exceptional for the glands to suppurate.

A brief summary of some of the more characteristic features of the eczema of children will now be appropriate.

Generalized eczema is uncommon in childhood, although there may be present, scattered over the body and limbs, infiltrated patches of variable size, sometimes scaly or composed of aggregated papules exhibiting moist and exco-

riated surfaces. The disease also attacks the hands, feet, and legs and the flexures of the joints. Eczema intertrigo, or that form of the disease found in the groin and between other opposing surfaces of skin, is frequent, but not attended with much itching. The surfaces are very red and moist, and are apt to emit a most disagreeable odor; moreover, the eruption may spread from these localities to the contiguous portions of the thighs, back, and abdomen. The writer's experience is in agreement with that of Bulkley in regarding the face as the region most frequently first affected. The primary lesions are usually papules, which run together to form exuding, reddened and crusted patches that are intolerably itchy. In this situation the disease is more prone to relapse than elsewhere, as every varying condition of the system is promptly reflected upon a part especially rich in its vascular and nervous supply. A very common starting-point also is the scalp, where it is often evoked by the nurse or mother in the effort to clear away the sebaceous secretion that clings to the new-born infant. From this region it may spread to the forehead, ears, and face, and the well-known picture of the typical *crusta lactea*, or milk crust, is presented. The itching is excessive, and the little sufferers, if old enough, make frantic efforts to get relief by scratching; while infants will rub the face and head against the pillow or the mother's breast. In neglected cases *eczema rubrum* is soon developed.

Etiology.—Eczema is one of the most common of all skin diseases, and it is most frequent during childhood.¹ Even within this period—nay, up to the tenth year—the disease is most frequently developed during the first five years, and, according to Crocker's statistics, one-third of all cases in children begin within the first year of life.

Leaving out of consideration for the present the essential nature of the eczematous process, it may be said that eczema is a catarrhal inflammation of the skin, which may be evoked by a great number of exciting agencies, both internal and external. With children these influences are often sufficiently obvious.

It is not uncommon to find that eczematous parents have eczematous children, but, nevertheless, the disease is not inherited in the sense that syphilis is; it is rather the transmission of a predisposed and vulnerable skin than the inheritance of a diathesis. The ill-nourished and strumous are especially prone to eczema, particularly of the pustular type, with swollen glands, ciliary blepharitis, and otorrhœa as concomitants; and such children, according to Unna, may subsequently develop local or general tuberculosis.² It will be found equally true that depressing influences of all sorts, unhygienic surroundings, insufficient or improper food, both for the child and the nursing mother, may be regarded as causative factors of no slight importance. It is no uncommon thing for eczema to follow in the wake of the eruptive fevers, especially measles, in this latter instance often assuming the form of *eczema tarsi*. Vaccination is often held responsible for inducing eczema, but so also may the operation of piercing the ears for earrings.

As stated above, various dietetic errors induce the disease by provoking gastric and intestinal disorders. The mother's milk may be of an inferior quality from lack of proper nourishment on her part, or it may be at fault from too great indulgence in rich food and stimulating liquids. Over-feeding

¹ In the writer's practice, out of a total of 6724 cases of skin disease of all classes, there were 2148 patients with eczema, or 31.40 per cent. In 3000 cases of eczema analyzed by Bulkley, 907 occurred during the first ten years of life, and 676 of these were observed in children five years old and under; that is, one-quarter of the whole number could be regarded as infantile.

² This latter statement must be taken with many reservations, at least from the standpoint of American experience; for many tubercular children never develop eczema at all, and many children with so-called tuberculous eczema never get tuberculosis.

ECZEMA RUBRUM

is more apt to evoke eczema than under-feeding in children. Very few children are properly fed, and it is no uncommon thing to find very young infants allowed everything that appears on the table. The writer has long maintained that oatmeal is a pernicious food for the eczematously disposed, especially the hastily-cooked article reinforced by rich cream and great quantities of sugar. Jamieson of Edinburgh doubts that oatmeal in itself can initiate an eczema, but he thinks it is quite probable that it can light up an imperfectly cured eczema or perpetuate one already existing, as any other cause of eczema may.

Spoon-fed babies are more apt to develop eczema than those nursed by healthy mothers, but here also it is to be remembered that they are liable to disorders of the alimentary canal.

The local and reflex irritations of the eruption of teeth plays no inconsiderable rôle among the exciting causes of eczema, but to regard teething as the sole cause of the disease is unscientific, and the reassuring advice often given that the disease will recover after teething is frequently not fulfilled.

Any form of external irritant may provoke an eczema—*e. g.*, cold, heat, bad soap, hard water, rough under-garments, etc. Seborrhœa is a prolific source of the disease, and the effort to remove the seborrhœal exudation, especially from the scalp of infants, is perhaps one of the most common causes of the disease in that situation. The agency of micro-organisms is probable, especially in localized forms of the affection where the cutaneous secretions have undergone decomposition.

From the foregoing considerations it will be seen that there is no one cause for eczema. Whatever the essential nature of the disease may be, it is obvious that the eczematous subject has a specially vulnerable and susceptible skin, and that under given conditions the disorder may be evoked by any cause, internal or external, that will arouse this susceptibility.

Diagnosis.—Papular urticaria, the so-called lichen urticatus, bears a general resemblance to papular eczema. In lichen urticatus the papules are larger and more discrete, and the presence of the ordinary urticarial wheal may be detected at some period of the case; moreover, the urticarial papules never run together to form the characteristic scaling, infiltrated, and weeping patch of eczema.

Scabies and eczema are usually confounded by the inexperienced. Both itch severely, and in both multiform lesions may be present; but in scabies contagion can nearly always be made out, the other children in the family or the mother being similarly affected, and the eruption occupies certain preferential localities—namely, between the fingers, the flexor surfaces of the wrists and arms, including the axillæ, the lower part of the trunk, both before and behind, and in older boys the penis. In children of some age the eruption will not be found on the face or feet, but in infants both of those regions may be affected. It is safe to say that a generalized multiform itchy eruption, occupying portions of the body that are normally moist and warm, either from the pressure of garments or from contact of contiguous parts, is almost necessarily scabies. The characteristic burrow, or cuniculus, is more readily demonstrated in the child than in the adult.

Various forms of the syphilide, especially the papular and pustular, are liable to be confounded with eczema. In general it may be said that the specific eruption is most apt to be seen about the mouth, nose, and genitals, and that the individual lesions are larger, less acute in aspect, and of a darker color, besides often presenting a circular arrangement. The weakened appearance of the child, the presence of snuffles, and the discovery of mucous patches are important aids in diagnosis. Moreover, syphilitic eruptions do not itch.

Pediculosis capillitii bears some resemblance to pustular eczema of the scalp, but the dermatitis is usually confined to the occiput, whereas eczema is apt to involve the whole head, and a little search will easily discover the pediculi or their nits.

The possibility of confounding eczema with ringworm and favus should be borne in mind. (See those diseases.)

Treatment.—Before entering upon the subject of treatment it is well to take notice of the opinion still lingering among the laity, and occasionally entertained by physicians, that the cure of the disease may be attended with the most serious consequences. This apprehension—a revival of the old humoralistic theory of peccant humors—both modern science and accumulated experience unite in pronouncing absolutely baseless. Hebra acutely suggested that when the protest against a cure comes from a medical man, it is quite likely that it is due to failure on his part to effect it.

In the matter of internal medication it may be distinctly stated that there are no specifics for the affection. In every instance a searching investigation must be made for possible exciting causes or probable complications. Routine is to be avoided and each case managed on its merits.

It not infrequently happens that the little patient is in apparently perfect general health, the disorder being due to external causes, and no treatment beyond the necessary local applications is demanded. Even in such cases proper attention to diet will prove beneficial, and all the more beneficial if a connection can be established between the eruption and dietetic errors. If the child is being suckled, the mother should abstain from stimulating foods and drinks, but if, on the other hand, she is ill-nourished and anæmic, her condition should receive appropriate attention. As regards the child itself, if old enough to be fed, the strictest attention should be paid to the character of the food and to the time and frequency of meals. The usual stuffing with unwholesome and indigestible food should be strictly forbidden, and the physician will find it wise to write out carefully prepared diet tables. The writer has long been in the habit of using the admirable tables, prepared for different ages, to be found in Dr. Louis Starr's valuable work on the diseases of the digestive organs in children. We would reiterate the statement, already made above, that oatmeal, especially when served with cream and sugar, is harmful to eczematous children. Corn grits with salt and butter are just as nutritious and apparently harmless.

The condition of the alimentary canal must be strictly inquired into, so that constipation, gastric and intestinal catarrhs, or other complicating disorders may receive proper attention. An occasional minute dose of calomel will prove useful in nearly all cases. Anæmic and strumous children, who usually suffer from pustular eczema, are much benefited by the use of iron, particularly the syrup of the iodide, and some form of cod-liver oil. A favorite and agreeable method of administering the oil is as follows:

R̄.	Ol. morrhue	f̄ʒiv.
	Pancreatini saccharati	ʒj.
	Pulv. acaciæ	ʒ. s.
	Glyceriti hypophosphit.	f̄ʒiv.
	Syr. calcis lactophosphatis	
	Aquæ	āā f̄ʒiv.
	Olei gaultheriæ	gtt. xxx.—M.

Sig.—From a teaspoonful to a dessert-spoonful, according to age, three times a day, after meals.

The habit of prescribing arsenic in all cases of eczema is almost a matter of routine with most physicians. Notwithstanding excellent authority to the contrary (Wilson, Bulkley), the writer must insist that this is bad practice. The drug should never be given in acute attacks, and its beneficial effects, even in chronic types of the disease, are by no means constant. Its chief value is in the dry and scaly forms of eczema. Before giving arsenic at all, it is absolutely necessary to see that the digestive functions are unimpaired. Children bear relatively larger doses than adults. Erasmus Wilson, who was a great advocate of the employment of arsenic in infantile eczema after a proper eliminative treatment with mercury, recommends two minims of Fowler's solution for a child from a month to a year old, to be repeated three times a day with, or immediately after, meals:

R. Vini ferri f ʒss.
 Liq. potassii arsenitis ℥ xxxij.
 Syr. tolutani f ʒss.
 Aquæ anethi f ʒj.—M.

Sig. One teaspoonful three times a day.¹

As a general thing, the various local measures should be sufficient to allay itching and procure sleep, but at times it is necessary to resort to internal medicines. Any form of opium is inadmissible, as it increases the pruritus. Small doses of phenacetin are of value in allaying restlessness, and it appears to have no ill effect on the eruption. Quinine is particularly recommended by Dr. Pye-Smith as an antipruritic—a half grain for a child of one year an hour before bedtime, a grain at two years, and five grains at the age of fifteen. Where a rebellious eczema is probably due to reflex irritation, the result of a tight prepuce, circumcision or other methods of uncovering the glans should be recommended.

The local treatment of eczema is of the utmost importance; perhaps, taking all the facts into consideration, of more importance than any direct internal medication; for, as the writer has expressed it elsewhere, in quite a large number of cases internal remedies are not demanded at all, either because the disease is due to entirely local agencies, or because the internal exciting cause has ceased to be operative, and there remains only the effects, which may be got rid of by topical means.

In order to determine the character and stage of the disease, it is a prerequisite that all scales, crusts, and other secondary products be removed. Poultices should be avoided, as a rule, but free inunctions with a bland oil will generally suffice for this purpose. *The rule that an eczema should never be washed is absolute.* The habit of daily washing eczematous surfaces is pernicious in the extreme, and is the principal reason of the apparent rebelliousness of these cases to treatment. Even after recovery is seemingly established the use of an indifferent soap will speedily provoke an exacerbation.² When the eruption is at its height it is better to let the parts go unwashed, or a little warm milk and water will answer the purposes of cleanliness sufficiently.

The principles underlying the local treatment of eczema are in reality very simple. When the disease is acute, soothing remedies should be applied; when subacute, they may be made somewhat astringent; and when the chronic stage

¹ In the writer's judgment such large doses of arsenic as recommended by Wilson should be administered with great caution, if at all.

² The best soaps known to the writer are the superfatted kinds made in Germany. Eichoff's thymol, or Kinderseife, is an excellent toilet article.

is established, a suitable degree of stimulation is demanded. Some few of the many topical applications used in eczema will now be described, together with their special indications, and the subject will be concluded with a brief consideration of the regional forms of the disorder.

Lotions.—Sedative and somewhat astringent lotions are useful in acute eczema. Preparations of lime-water and opium and solutions of soda or borax may be employed for this purpose, but the calamine-and-zinc lotion is the most valuable of all such applications. (See Miliaria.) It should be applied by means of cheesecloth cut into strips and bound on with a neat bandage. If the itching be severe, from two to five minims of carbolic acid may be added to each ounce of this mixture.

Lotions of carbolic acid are often indispensable to allay the tormenting pruritus :

R̄. Acidi carbolici f̄5ss.
Glycerini ℥x.
Alcoholis f̄5j.
Aquæ q. s. ad f̄3iv.—M.

Sig. Local use ; apply several times a day.

This may be used alone or in conjunction with other measures.

Chronic infiltrated patches of limited extent may be made to heal under brisk friction with a tar-and-soap solution :

R̄. Ol. cadini f̄3ij.
Saponis viridis
Alcoholis āā f̄3ij.—M.

This may be quickly rubbed in, then washed off with water, and the parts covered over with unguentum vaselini plumbicum spread on cloth. The necessity for such stimulating treatment does not often arise with children.

Powders.—In general acute erythematous eczema and in the forms of the disease found between folds of the skin, powders are sometimes useful, but as a rule other measures serve a better purpose :

R̄. Pulv. amyli ʒv.
Zinci oxidi ʒjss.
Pulv. camphoræ ʒss.—M.

Sig. Dust on with a puff.

R̄. Thymol gr. j.
Pulv. zinci oleatis ʒj.—M.

This is a good formula in mild cases of eczema intertrigo.

Ointments.—Salves are of especial value where there is crusting and exudation, and since most cases are seen by the physician at this stage, it follows that they are more used than all other preparations together. To secure success it is necessary that the ingredients should be fresh and that the ointment should be thoroughly prepared. Soothing salves should always be spread on suitable strips of muslin and bound on the parts, but when stimulation is desired the remedy may be rubbed in with the finger. When it is desired merely to protect the parts with a bland unguent, the unguentum aquæ rosæ is very beneficial : a little bismuth (ʒij–ʒj) may be added with advantage. To increase its astringency and to allay pruritus the following combination may be advised :

R. Bismuthi subnitrat̄is	ʒiv.
Zinci oxidi	ʒss.
Acidi carbolici	ʒx.
Vaselini	ʒij.—M.

A standard preparation of great value is the unguentum vaselini plumbeum:

R. Emplastri diachyli	ʒss.
Vaselini	ʒss.—M.

These should be melted together by gentle heat and stirred until cold. In subacute and moderately thickened eczema, and in the pustular form of the disease, there are few better preparations.

In the great majority of cases of eczema in children, as ordinarily encountered—that is to say, cases in the subacute stage with slight infiltration and intense itching—there is nothing comparable to the zinc-and-tar salve:

R. Zinci oxidi	ʒj.
Ung. picis liquidæ	ʒij.
Ung. aquæ rosæ	ʒij.
Lanolini	ʒiv.—M.

Sig. Local use.

This should be applied on strips of muslin, but, as children will not usually submit to the face-mask or other bandaging, it does almost as well to smear it on gently with the finger repeatedly during the day and night. To get good results with this ointment it is absolutely essential that the prescription should go to a pharmacist accustomed to the preparation of ointments. Under the use of this ointment, so promptly does it relieve itching, the writer has been enabled in a large measure to abstain from the harsh methods of physical restraint sometimes advocated.¹

It is a safe rule even in seemingly chronic eczema to commence with one of the milder preparations, but if the case prove obstinate, we may then proceed to more stimulating applications, as follows:

R. Hydrarg. ammoniati	gr. x-xv.
Liq. carbonis detergentis	ʒxx-fʒss.
Lanolini	ʒj.—M.

Sig. Apply two or three times daily.

R. Ol. rusci	ʒss-j.
Ung. zinci oxidi	ʒj.—M.

Sig. To be rubbed into the parts.

¹ Bulkley (*Eczema and its Management*) makes the following sensible remarks on the application of ointments: "The first application of any ointment may be resisted by the child, and may seem not to give relief; but if a suitable application has been selected, and if it is renewed as often as it falls off or is brushed off, relief will soon be obtained, and the child who first resisted the application will shortly crave it. This matter of the constant protection day and night of eczematous surfaces from the irritating action of the air and external contact must be insisted upon, and carried out at all hazards with rigid severity. Attendants will often neglect it, and the application will often be intentionally removed in anticipation of the visit of the physician, or when inconvenient on account of ordinary matters of daily life. A single neglect, for even a short period, followed by scratching and irritation of the skin, can result in more damage than can be repaired by long treatment." It may be added that a single washing of an eczematous skin will be equally injurious.

Pastes.—These preparations are very useful when there is neither too much crusting nor too great infiltration; moreover, they are very valuable when an adhesive and protective application is required, as they are not readily scratched off or washed away by secretions. They find their principal utility in irritable papular and erythematous patches and in eczema intertrigo. Lassar's well-known formula is as follows:

R. Acidi salicylici	ʒss.
Zinci oxidi	
Amyli	āā ʒvj.
Vaselini	ʒij.—M.

A small amount of tar may be added to secure greater stimulation.

This paste is also valuable:

R. Resorcini	gr. x-ʒj.
Lanolini	ʒij.
Vaselini	ʒij.
Zinci oxidi	
Pulv. amyli	āā ʒij.—M.

Pick's linimentum exsicicans may also be mentioned under this head:

R. Pulv. tragacanth.	gr. xv.
Glycerini	℥xxiv.
Aquæ	fʒj.—M.

The writer is in the habit of adding to this 10 to 15 per cent. of oxide of zinc and 1 per cent. of carbolic acid or 3 to 5 per cent. of tar. Thus combined, this preparation is of the greatest merit, particularly in cases similar to those mentioned as suitable for pastes in general. The various glycerin jellies have been almost entirely discarded in its favor.

Plasters.—The plaster and salve mulls of Unna, made by Beiersdorf of Hamburg, are very beneficial in suitable cases. The salve mulls are made by incorporating the required remedy, such as lead, mercury, zinc etc., with a base made of benzoated suet and lard, and spread on one or both sides of undressed muslin. The plaster mulls are made of gutta-percha faced with some adhesive substance containing the remedy, and backed with muslin. The salve mulls may be used in subacute cases when a fixed dressing is necessary; the plaster mulls are to be employed only when there is considerable infiltration. In these latter cases the writer's modification of Pick's soap plaster does just as well, and is much less expensive:

R. Empl. plumbi	ʒxxv.
Pulv. saponis	ʒiv.
Aquæ	q. s.
Vaselini	ʒv.
Camphoræ	gr. xx.
Acidi salicylici	gr. x-xx.—M.

Sig. Spread on strips of muslin and change once a day.

This plaster serves an excellent purpose for thickened patches of eczema on the hands and feet.

Paints.—Fixed dressings made with collodion or solution of gutta-percha are of limited range of application, but may occasionally be used to advantage :

R. Ol. rusci ʒss-j.
 Collodii, vel liq. gutta-perchæ fʒj.—M.
 Sig. Apply with camel's-hair pencil.

This may be painted on chronic patches of eczema about the mouth, both to secure the healing effect of the tar and the protective action of collodion or gutta-percha.

Prognosis.—The prognosis of infantile eczema is generally favorable, provided the nature of the disease and the fundamental principles of treatment are thoroughly understood. That it is prone to relapse, like all catarrhal inflammations, when exposed to the manifold exciting causes that are capable of evoking it, must be admitted; but with patience and perseverance, and the hearty co-operation of parents in the general management, the physician is usually rewarded in his efforts. While it is true that the tendency to relapse decreases with age, the assurance often given that the disease will disappear at certain specified periods—for example, at the cessation of dentition—is not borne out by experience. There is a small minority of cases of eczema that almost justifies the term “malignant.” In such cases the disease commences in childhood and recurs with greater or less frequency during life. Fortunately, they are rare.

Treatment of the Regional Forms of Eczema.—*Eczema of the Scalp.*—Remove crusts if present, and clip the hair. If the eruption is acute, apply almond or olive oil with 1 per cent. of carbolic or salicylic acid. A bismuth salve (ʒj-ʒj) is also soothing. After subsidence of the inflammatory symptoms the tar-and-zinc ointment (R. *Zinci oxidi*, ʒj; *Ung. picis liq.*, *Ung. ag. rose.*, *āā* ʒij; *Lanolini*, ʒiv.—M.) makes the best application. In children with little or no pain the ung. vaselini plumbicum, spread on muslin, is efficacious. For scaly eczema salicylic acid and sulphur give speedy result (R. *Acidi salicylici*, gr. x; *Sulphuris præcip.*, ʒss; *Vaselini*, ʒj.—M.). If the eczema is secondary to pediculosis, the pediculi and their nits must be first destroyed.

Eczema of the Ears.—The calamine-and-zinc lotion (R. *Zinci oxidi*, ʒss; *Pulv. calamine præp.*, ʒiv; *Glycerini*, fʒj; *Liq. calcis*, fʒvij.—M.) is the most suitable application for acute eczema of the auricle. Strips of cheese-cloth should be wet with this solution and bound over the parts. The unguentum vaselini plumbicum spread on muslin is well adapted for subacute and chronic cases. The cracked, infiltrated condition found behind the ears is frequently cured after a brisk friction with the tincture of green soap (R. *Saponis viridis*, *Alcoholis*, *āā* ʒiv.—M.), followed by the lead-and-vaseline salve. (The reader is referred to another section of this work for the treatment of eczema of the auditory canal.)

Eczema of the Face.—The calamine-and-zinc lotion affords the best results for very acute erythematous eczema of this region. In children, however, the disease usually begins more insidiously, and when first seen the parts are generally raw and weeping and covered with crusts. These latter may first be removed by oil inunctions or the immediate application of the ung. vaselini plumbicum spread on muslin. This ointment may be continued, or the tar-and-zinc salve above given may be substituted for it, or else used from the beginning. As stated above, this is by far the best application for almost all forms of infantile eczema. Of course the amount of tar may be increased or diminished according to the effect. In slight patches, or toward the end of

a more pronounced case, Pick's paste (see above) with oxide of zinc and tar may be smeared over and allowed to dry on. This makes a valuable protective dressing, which is not readily scratched off. Lassar's paste is also of use under these circumstances. When it is necessary to employ any of the ointments above mentioned, it is best, if the child will allow it, that the muslin strips upon which the salve is spread be kept in place by a light skeleton mask. This is not necessary for the pastes. Chronic infiltrated areas may be treated two or three times a day by working in a little mercurial-and-tar salve (R. *Hydrarg. ammoniati*, gr. x; *Liq. carbonis deterg.*, ℥xv-fʒss; *Lanolini*, ʒj.—M.). Eczema about the mouth is slow to heal, owing to the movements of the parts and the trickling of saliva and food over the inflamed surfaces. Here some form of fixed dressing is indicated (R. *Olei rusci*, ʒss; *Collodii*, fʒj), or one of the adhesive pastes just mentioned.

Eczema of the Lids.—Eczema of the surface of the lids is usually of the erythematous type, and generally demands soothing measures, such as the ointment of cold cream with a little oxide of zinc added to it. Eczema tarsi occurs mostly in strumous children, and is a common sequela to the eruptive fevers. Internally cod-liver oil and iron are invaluable, and locally the yellow-oxide-of-mercury ointment is especially beneficial (R. *Hydrarg. oxidi flav.*, gr. ij-vij; *Vaselini*, ʒj.—M.).

Eczema of the Umbilicus.—The disease in this region is often secondary to seborrhœa, and is very intractable. Ung. vaselini plumbicum makes a good application, but it is usually best to add five or ten grains of salicylic acid to each ounce. Unna's diachylon salve mull is also to be advised. Duhring suggests an ointment of oleate of zinc and calomel. Boracic acid is also useful.

Eczema Intertrigo.—As a prophylactic measure infants should be kept well dusted with some bland borated powder in those parts liable to the disorder; that is, in the genital organs, under the neck, and in the axillæ. When the disease has become established, the affected surfaces should be washed as little as possible, and protected with Lassar's paste (R. *Acidi salicylici*, gr. x; *Zinci oxidi*, *Pulv. amyli*, āā ʒij; *Vaselini*, q. s. ad ʒj.—M.). Pick's linimentum exsicicans, with 10 per cent. oxide of zinc and 1 per cent. carbolic acid, is perhaps even better.

Eczema occurring in other regions of the body requires no special description, and should be treated upon the general principles set forth in the foregoing sections of this article.

LICHEN PLANUS.

As ordinarily encountered, lichen planus consists of an eruption of slightly umbilicated, broad, flat, glazed, purplish-red papules with an angular outline. The papules may remain discrete, or they may be arranged in groups, lines, or bands. By coalescence of the lesions, variously sized, elevated, and sharply defined patches decked with thin scales may be formed. The lesions leave in their wake atrophic spots and distinct pigmentation. Pruritus is sometimes slight or it may be very intense.

The eruption is generally bilateral, and the usual sites of predilection are the flexor surfaces of the wrists, flanks, lower part of the abdomen, around the knees, and on the calves. The face is usually exempt. The mucous membranes may also be implicated.

The disease is rare in children, but Crocker describes an infantile form as follows: "The eruption comes out acutely in groups, each papule of which is

sometimes acuminate at first, but the top seems to die down and a scale comes off, leaving a smooth, shining, angular papule, of a brighter red than usual, though it may get a purplish tint subsequently. It may be on the limbs or trunk, or both, is attended with considerable itching, and gets well in a few weeks with the help of a soothing application." Rickets was present in some cases, conjunctivitis and miliaria in others, while still others were in apparent health.

Etiology.—The causes of lichen planus are obscure. In the acute infantile form Crocker thinks that a sudden chill while in a profuse perspiration is the exciting agency.

Diagnosis.—If the characteristic and typical features of the lichen-planus papule be kept in mind, it is not easy to make a mistake in diagnosis. Even when the lesions have run together into patches, a few outlying angular umbilicated papules may be discovered. When, as sometimes happens, the usual papular eruption is accompanied by an acute erythematous rash, the diagnosis must be held in abeyance for the time being.

Prognosis.—Neglected cases are prone to run an indefinite course, but with proper treatment a favorable issue may be expected.

Treatment.—In acute cases attention to diet and gentle laxatives and diuretics may be beneficially prescribed; and locally, calamine-and-zinc lotion, with a little carbolic acid for the itching, will often speedily remove the eruption. In chronic cases Fowler's solution, with or without iron, is of great value. For external application tar in some form is of most benefit. The following lotion does good:

R. Saponis olivæ præp. ℥iv.
 Olei rusci
 Glycerini āā f℥j.
 Olei rosmarini f℥iss.
 Alcoholis q. s. ad f℥viiij.—M.

Sig. Rub in with a piece of flannel.

A weak tar ointment with mercury is also serviceable:

R. Hydrargyri ammoniati gr. x.
 Liq. carb. detergentis f℥ss.
 Lanolini ℥j.—M.

Sig. Apply twice daily.

Wilson recommended a bichloride-of-mercury lotion, and Unna extols an ointment of carbolic acid and mercury.

PSORIASIS.

Psoriasis is a chronic inflammatory disease of the skin, exhibiting lesions of various sizes having red bases covered with white dry scales. The disorder attacks the extensor surfaces by preference, especially in the neighborhood of the elbows and knees, but it is also found elsewhere on the body, and almost invariably on the hairy scalp. It is almost always symmetrical. The lesions of psoriasis make their first appearance as minute pinhead-sized spots of congestion that are slightly elevated and surrounded by normal integument. The eruption, although discrete, is usually made up of multiple spots, which enlarge peripherally to the size of large or small coins. The papules may then remain

isolated, or they may run together, and in this way form patches of different sizes and shapes, but possessing a general circular arrangement. Various terms are used to designate the manifold shapes and sizes the psoriatic lesion may assume—viz.: *p. punctata*, *p. guttata*, *p. nummularis*, *p. circinata* or *orbicularis*, *p. gyrata*, and *p. diffusa*. Psoriasis nummularis, or the coin-like form, is perhaps the most common variety; but, whatever the shape or the dimension of the lesions, the essential clinical features of the disease remain unaltered. The lesions are infiltrated, and sharply defined against the unaffected skin, and they are covered with shining, mother-of-pearl, imbricated, easily-detached scales, which upon being scraped off show a punctate bleeding surface.

The eruption has no discharge feature, and itching is either entirely absent or very slight. The patches usually disappear by central involution, and in this way rings and segments of circles may form. The eruption upon its disappearance leaves no traces of its previous existence, except that there may be slight pigmentation on the legs. The disorder is rare on the palms and soles, but the nails are usually rough and brittle. The extension of the eruption from the scalp to the forehead in the shape of a band along the border of the hair is quite common. The hair suffers no permanent injury, and even temporary alopecia is unusual. Children rarely suffer from the more pronounced forms of the disease: in them the eruption is mostly discrete, and made up of small lesions rather generally distributed over the body. The elbows, knees, and scalp are the parts commonly first attacked.

Psoriasis is essentially a chronic affection, although at times having an acute aspect. Repeated relapse is the rule; in some cases, indeed, the patient is practically never entirely free of the eruption, but usually longer or shorter periods intervene between the outbreaks. It is, as a rule, worse in winter than in summer. It not infrequently temporarily disappears during the course of acute diseases.

Etiology.—Psoriasis is common to both sexes and to all conditions of life. In this country it represents about 3 per cent. of all cases of skin disease. The disorder makes its first appearance during childhood more frequently than is generally supposed. It is not contagious. In many cases the fact of hereditary transmission is readily established. The disease has been observed in connection with gout and rheumatism, and it may follow in the wake of scarlatina, varicella, and vaccinia. In fact, our knowledge of its essential nature is obscure, and we may assume, as in the case of eczema, that the psoriatic possesses a specially vulnerable skin, and that his disorder may be evoked by a great variety of widely-differing agencies. It may be added that Lang regards psoriasis as due to a special parasite, while Polotebnoff looks upon it as a vaso-motor neurosis. The histological investigations are contradictory.

Diagnosis.—Seborrhœa, eczema, and syphilis are the diseases that bear the closest resemblance to psoriasis. In seborrhœa of the scalp the scales are greasy and yellowish, and not dry and white, as in psoriasis, and the eruption does not take the form of bands and patches, as in the latter disease; moreover, seborrhœa affecting the scalp may be limited to that region, whereas psoriasis of the scalp will occur in connection with the same eruption on the elbows and knees and other parts of the body. Seborrhœa of the body is not necessarily symmetrical, and is found particularly about the sternal and interscapular region, while psoriasis is nearly always symmetrically disposed, and affects the elbows and knees in addition to other parts of the body. The character of the scales is the same as in seborrhœa of the scalp, and they differ altogether from those found in psoriasis.

Scaly or squamous eczema in patches sometimes strongly simulates psoriasis.

PSORIASIS.

(From the Collection of Geo. H. Fox, M. D.)

but the patches of eczema are not symmetrically arranged, occur on the flexor rather than the extensor surfaces, and the scales are light, tenacious, and do not show a punctate bleeding surface when removed; besides, eczema itches markedly, and there is usually a history of discharge.

The scaling syphilides are not unlike psoriasis in a superficial way. The history of the case must always be taken into consideration, and the presence of concomitant symptoms noted. The scales of the squamous syphilide are dirtier-looking and more adherent than in psoriasis, and the patch is usually more infiltrated. Again, the fact that psoriasis is almost always found on the elbows and knees on both sides of the body, and that the syphilide observes no such localization, is to be kept in mind.

Prognosis.—The prognosis as to permanent cure is unfavorable, but it is usually easy to remove the eruption temporarily.

Treatment.—Beyond remedying obvious defects of health and instituting a rational system of diet, the internal treatment of psoriasis in children is mainly restricted to the use of arsenic, which in this disease is of undeniable value. As young children tolerate relatively larger amounts than adults, it may be given in considerable doses without inconvenience. If the patient is anæmic, it may advantageously be combined with iron. (See formula under head of Eczema.) If, however, the eruption is acute, the use of arsenic should be deferred until the disease has assumed a less inflammatory aspect.

Before undertaking the local treatment it is necessary to remove the scales thoroughly from the patches. In recent outbreaks this is best accomplished by means of warm soda baths, followed by inunctions with vaseline. These measures will sometimes alone be sufficient for the removal of the eruption. If the disease has existed for some time, the scales may be taken off by scrubbing with soap and water or by means of friction with salicylic acid and alcohol (ʒj to fʒiv).

Chrysarobin is by far the most efficacious remedy in psoriasis, but it must be used very cautiously with children, as it sets up so much irritation. When the eruption is sparse the following pigment may be tentatively employed:

R. Chrysarobini gr. xx.
 Acidi salicylici gr. xx.
 Liq. gutta-perchæ fʒj.—M.
 Sig. Apply with camel's-hair pencil.

This may be painted on every fourth day, a bath being taken at the end of this period and before each reapplication. If this causes too much dermatitis, its use should be intermitted for a season. The chrysarobin is, however, too severe for some skins, and other remedies should be tried. Bulkley recommends the following application:

R. Acidi carbolicæ gr. v.
 (vel Resorcini, gr. x).
 Bismuthi subnit. ʒss.
 Ung. hydrarg. ammon. ʒj-ij.
 Ung. aq. rosæ q. s. ad ʒj.—M.
 Sig. To be rubbed into affected parts.

For delicate skins it may need to be made weaker.

Greenough suggests the employment of a tar lotion consisting of equal parts of alcohol, glycerin, and oil of cade. This prescription may also be considerably diluted.

Among other remedies may be mentioned thymol, naphthol, salicylic acid, sulphur, and the mercurials.

Psoriasis of the scalp is best treated with an ointment of tar and mercury :

R̄. Hydrarg. ammoniati gr. x.
 Liq. carbonis detergentis ℥xx.

PEMPHIGUS.

Pemphigus is a very rare disorder. It is characterized by the appearance of successive crops of variously-sized blebs. It may be acute or chronic, but as ordinarily encountered it runs a chronic course. It is customary to speak of two principal forms of the disease—viz. *p. vulgaris* and *p. foliaceus*—but the nomenclature is encumbered with an infinite number of sub-varieties, partly dependent upon the clinical appearances of the lesions, and largely also on the imagination of the observers.

Pemphigus Vulgaris.—Constitutional symptoms are rare, but when the eruption is widespread each outbreak may be preceded by a chill. The blebs usually appear first as minute vesicles, but soon reach the maximum dimensions. They are oval or hemispherical, tense, and vary in size from a pea to an orange, but more generally are the diameter of a hazelnut or walnut. They may arise on normal skin, or they are preceded at the point of eruption by a degree of erythema. The contents of the lesions are at first clear, but gradually become turbid, and sometimes even purulent. The life of a bleb is from two to ten days; it rarely ruptures spontaneously, but desiccates with a thin dry crust. After the fall of the crust the site of the bulla shows slight excoriation, and lastly more or less pigmentation.

Pemphigus may occur on any part of the body, but is more frequent on the face, limbs, and trunk. The mucous membranes, including the alimentary and respiratory tracts, may also be attacked. In the mild forms of the disease the eruption may be kept up by successive crops, more or less continuous or markedly intermittent, for weeks or months; but in malignant pemphigus death may ensue in a few weeks.

As to the existence of an acute pemphigus there has been considerable difference of opinion. Undoubtedly there has been much confusion of diagnosis in this regard, and instances of bullous erythema, urticaria, varicella, etc. have been so classified; but the writer has convinced himself, from obser-

vations made in infants' asylums and elsewhere, that an eruption bearing the clinical features of pemphigus and running an acute course really occurs among children. So good an observer as Crocker agrees in this opinion, and says that there are grades of severity in the acute pemphigus of infants, from the mild, usual type to cases in which those attacked die in a few days. On the other hand, many of the so-called cases of pemphigus contagiosa undoubtedly represent varicella bullosa and impetigo contagiosa (Crocker).

Pemphigus foliaceus is rare even in adults, but Jamieson reports a case in a child which followed the ordinary form. In this type of the disease the bullæ are flaccid, with cloudy contents, and display a sticky secretion when their covers are removed. The whole body eventually becomes involved, and after a time, when the bullous stage has passed away, the surface has the appearance of an exfoliative dermatitis.

Etiology.—The disease is equally common in both sexes, and is met with far more frequently in children than in grown persons. Pemphigus has been observed in connection with a variety of different conditions, such as diseases of the nervous system, disorders of nutrition, after local injury, etc. It also occurs in the apparently healthy. An hereditary tendency to the malady has been noted, and septic influences recognized. Morbid changes in the cord and the peripheral nerves have been discovered in some cases.

Diagnosis.—The mere occurrence of blebs does not constitute pemphigus, for lesions of this character are encountered in erythema, erysipelas, scabies, syphilis, urticaria, and as the result of traumatism; but in all these instances the history of the case and the concomitant symptoms will usually establish the points of difference.

Prognosis.—The prognosis must be guarded, as it is difficult to forecast the ultimate outcome of any case; still, in children at least and in the more acute forms, a favorable termination may be expected.

Treatment.—In acute pemphigus an endeavor should be made to discover the exciting cause or causes of the disease, and to meet such complications as may arise in its course. In the chronic form of the disorder the strength should be maintained by suitable nourishment. So far as direct medication is concerned, arsenic is the chief reliance. It should be given in full doses, freely diluted and frequently administered. According to Bulkley, the quantity of the drug should be fearlessly increased until the disease yields or until it causes diarrhœa or other evidences of disagreement. Opium, an excellent remedy in itself for pemphigus, according to Hutchinson, may be combined with the arsenic, or, if the latter is not tolerated, it may be given alone. Fowler's solution and the deodorized tincture of opium are the best preparations of the respective remedies.

Locally, the tense blebs may be punctured at their bases, so as to allow their roofs to form a protective covering over the excoriated surfaces beneath. Cloths dipped in lime-water and linseed oil, to which may be added 1 per cent. of carbolic acid, make a good application.

The calamine-and-zinc lotion is sometimes grateful, or a powder of oxide of zinc and lycopodium may be dusted on and covered with cotton wool. Raw surfaces may be dressed with the following salve:

R. Zinci oxidi ℥j.
 Ung. aq. rosæ ℥ij.
 Lanolini ℥vj.—M.

Two or three drops of carbolic acid may be added to each ounce of this ointment.

HERPES SIMPLEX.

This affection, variously known by the names of herpes facialis, herpes febrilis, fever blisters, and cold-sore, is an acute inflammatory disorder characterized by the eruption of one or more groups of vesicles seated upon reddened bases. The vesicles come out abruptly, usually being preceded by sensations of burning and tingling. Their contents are at first clear, but presently—that is, in a day or two—become puriform, and the lesions dry up into light-brown crusts which show no loss of substance upon being detached. The whole process occupies eight or ten days.

The favorite sites of the eruption are the lips, the angles of the mouth, and anywhere on the face below the forehead. The mucous membranes may also be attacked. Herpes simplex is usually symptomatic of febrile disorders, and is often preceded by chilly sensations; in other cases it is due to gastric disturbances or is produced by local irritation. Repeated recurrence is not an uncommon feature.

Diagnosis.—This offers no difficulties.

Treatment.—Regulation of the diet and appropriate remedies for gastrointestinal disturbances are demanded in recurrent cases, but if there are no obvious causal indications, small doses of Fowler's solution will probably do good. Herpes symptomatic of general febrile states requires no treatment other than that for the exciting cause. Locally, the vesicles should be protected from rupture, and this is best accomplished by painting them over with flexible collodion or mopping on the calamine-and-zinc lotion.

HERPES ZOSTER.

Herpes zoster, zona, or shingles, is an inflammatory disease of the skin which is characterized by grouped vesicles seated on reddened bases and following the distribution of cutaneous nerves. Although the eruption most frequently occurs around the trunk in the course of the intercostal nerves, it is well to remember that it may develop anywhere else, so that, for example, according to the anatomical seat of the disorder, it will be designated as *z. capillitii*, *z. frontalis*, *z. ophthalmicus*, *z. nuchæ*, *z. facialis*, etc.

Before the eruption of the vesicles the patient may complain of considerable pain in the part to be attacked, or there may be slight febrile reaction. The lesions vary in size from a pinhead to a split pea, and by the coalescence of one or more vesicles a quite considerable bulla may be formed. Their contents are at first serous, in rare cases hæmorrhagic, but presently become puriform. It is characteristic of herpetic vesicles that they do not rupture spontaneously, but in the course of some ten days to three weeks they desiccate into brown crusts, which, falling off, exhibit a reddened surface and not infrequently slight loss of substance. In children the neuralgic pain may entirely cease when the eruption appears, or in severe attacks it may persist throughout.

In nearly every instance the eruption is unilateral, and but rarely recurs. Zoster is usually a descending interstitial neuritis of the spinal ganglion, but Kaposi points out that it may be of cerebral, spinal, ganglionic, or peripheral origin.

Etiology.—Zoster is very common in young people, and is perhaps most prevalent in the spring and autumn of the year. It is contended by some authorities that this affection should be classed with the acute infectious diseases. Hutchinson thinks that zoster is prone to develop during an arsenical treatment.

HERPES ZOSTER

Diagnosis.—The recognition of an ordinary case of shingles presents no difficulties: the grouped vesicles following the distribution of cutaneous nerves, the neuralgic pain, etc. are sufficiently patent symptoms. There are two points, however, worth remembering—viz. first, that zoster occurs elsewhere than around the trunk; and, secondly, that sometimes there are abortive forms—that is, merely reddened patches or clustered papules that do not become vesicular; but in both instances the grouping and distribution of the eruption are the same, as is also the pain.

Prognosis.—In children the prognosis of zoster is always favorable.

Treatment.—Zoster is an acute self-limited disease, which, however, runs a very variable course, and conclusions as to the value of internal medication in its treatment are, therefore, usually fallacious. It is idle to attempt to abort an attack by remedies in our possession, and such treatment is restricted to the relief of pain. As a rule, children suffer but little inconvenience in this latter regard, and a few appropriate doses of phenacetin at night are all that is required.

Some writers believe that it is possible to limit the amount and duration of the eruption by local measures. Duhring advises a weak galvanic current, and Leloir praises pure alcohol or alcoholic solutions of certain drugs for this purpose:

R. Alcoholis (90 per cent.) f̄ʒj.
Resorcini ʒj.—M.

R. Alcoholis (90 per cent.) f̄ʒj.
Menthol gr. xv.
Ext. cannabis Indicæ gr. xxv.—M.

Pads made of wadding are to be wet with these solutions and frequently applied.

The essential point of treatment is to prevent the vesicles from rupture. Flexible collodion, with or without a little morphia, makes an excellent protective dressing and gives marked relief. Pick's paste, the linimentum exsiccans, is also excellent when made as follows:

R. Zinci oxidi gr. xlviii.
Acidi carbolicæ ℥x.
Tragacanthæ gr. xxiv.
Glycerini ℥x.
Aquæ f̄ʒi.—M.

Sig. Smear gently over the parts, and allow to dry on.

Various bland dusting powders, such as oxide of zinc, corn starch, and rice powder, are also useful. It is well to protect the parts with absorbent cotton and a bandage to prevent friction. Ointments should never be prescribed, as they are prone to macerate the vesicles and thus produce ulceration. Should ulceration occur, it may be treated on general surgical principles. Persistent neuralgia following zoster is very unusual with children, but, should it supervene iron and arsenic may be given internally and galvanism applied locally.

IMPETIGO CONTAGIOSA.

Impetigo contagiosa is an acute contagious disease of the skin characterized by the appearance of vesico-pustules or bullæ. In some cases the eruption is

preceded by slight fever, but more often this symptom is absent. Crocker is authority for the statement that in the febrile cases the eruption appears in successive groups for about a week, but that when unattended by elevation of

FIG. 1.

Impetigo Contagiosa (after Lesser).

temperature the cutaneous manifestations are more limited, and the course of the affection is less definite.

The lesions begin as small, isolated, acuminate vesicles that slowly increase to the size of a split pea or silver quarter-dollar, that are surrounded for a short time by a slight erythematous halo. The contents, at first serous, soon become sero-purulent, and the fully-formed flat or slightly umbilicated vesico-pustule dries to a thin, straw-colored granular crust. As by this time the erythematous ring around the lesions has faded away, the crusts have the appearance of being "stuck on" (T. Fox). When the crusts drop off the underlying surface is red and has the appearance of a burn, but there is no loss of substance.

Jackson calls attention to another variety of the disease, in which the lesions consist of large blebs of an irregular oval shape and several inches long, but usually other typical forms are found elsewhere.

Impetigo contagiosa is generally seen on the face and hands. The lesions may be discrete or else coalesce into patches. Itching is not marked. The disorder runs no special course; it may last two or three weeks, or by repeated auto-inoculations a considerably longer time.

Etiology.—Children are the usual subjects. It is contagious, and often many children in the same house or neighborhood, especially among the indigent, are simultaneously attacked. The writer has known of dozens of cases in a single poor settlement. It is apt to appear in summer. A number of different fungous elements have been described as occurring in the crusts, but definite results are lacking. By some authorities the affection has been ascribed to pus-inoculation from any source, but the clinical facts do not bear out this con-

tention. Its connection with vaccinia has been remarked, but this is perhaps accidental.

Diagnosis.—The presence of large, generally discrete, slightly umbilicated, non-pruritic vesico-pustules, occurring on the lower part of the face or on the hands, is generally sufficiently distinctive for purposes of diagnosis. Bearing these symptoms in mind, it is usually easy to exclude pustular eczema, chicken-pox, and pemphigus. Even when the lesions have run together into patches, or the large bullous form predominates, a few at least of the more usual vesico-pustules may be found.

Prognosis.—Favorable under proper treatment.

Treatment.—The removal of the eruption is comparatively easy. A weak preparation of mercury generally suffices :

R. Hydrarg. ammoniati gr. x-xv.
 Ung. zinci oxidi ʒj.—M.
 Sig. Apply to lesions after removal of the crusts.

To prevent auto-inoculation it is a good plan to smear boric-acid paste over the intervening skin :

R. Acidi boraci ʒss.
 Pulv. amyli ʒij.
 Zinci oxidi ʒij.
 Vaselini q. s. ad ʒj.—M.

DERMATITIS EXFOLIATIVA NEONATORUM.

Ritter has called attention to a severe form of exfoliative dermatitis that occurs between the second and fifth weeks of life. It is apparently non-contagious and unaccompanied by fever. The affection begins around the mouth as an erythema, and extends to the rest of the body. The surface has the appearance of an extensive burn, and the epidermis exfoliates after some amount of fluid has accumulated beneath it. In some cases the eruption resembles an eczema, in others a pemphigus ; or, again, when it is limited, it is dry throughout, and the skin becomes infiltrated and fissured. The whole process lasts about a week. Often it is followed by eczema, furunculosis, and gangrenous processes. Death results in one-half the cases. Ritter regards the disorder as of septic character, while Behrend thinks it is merely a foliaceous pemphigus. The treatment is symptomatic.

Other forms of exfoliative dermatitis may occur in children either as primary or secondary processes, but they are unusual. Relapsing scarlatiniform erythema, which is in reality an acute exfoliative dermatitis, has been already described.

DERMATITIS GANGRENOSA INFANTUM.

Gangrene of the skin is not uncommon in strumous and syphilitic children, especially following in the wake of chicken-pox and vaccination, and also developing from simple pustular affections. The disorder varies in intensity: in some instances the gangrenous patches are widespread and numerous, with high temperature and a rapid lethal ending, or, on the other hand, there may be present a series of small pustules, each of which sloughs and leaves a small scar, and the disease may be prolonged indefinitely by successive crops (Pringle). As stated elsewhere, T. C. Fox regards the vari-

cella-prurigo of Hutchinson as in reality a form of urticaria. Secondary gangrene of the skin is comparatively rare in this country, even in the infant asylums, and the writer has never met with a case in private practice.

Treatment.—The general treatment consists in the administration of tonics, such as iron, quinine, and the hypophosphites, with cod-liver oil. Good food and proper hygienic surroundings are essential adjuncts. Locally, it is necessary to employ the usual antiseptic dressings.

URTICARIA.

Urticaria, nettlerash, or hives, is characterized by evanescent efflorescences called wheals or pomphi, which come out suddenly, retain their forms for a few minutes or several hours, and as suddenly disappear, leaving no trace behind. The lesions usually vary in size from a pea to the diameter of the finger-nail, or they may be much larger. Wheals are generally oval or circular in shape, but also occur in bands or streaks, and observe no special grouping. They are somewhat elevated above the general surface, are flat, and present a sense of resistance to the touch. They are usually white in the centre and bright-red or pink at the periphery. The mucous membranes may also be attacked. The eruption is accompanied by intense burning, itching, and tingling. There may be considerable febrile disturbance accompanying the outbreak in the skin in acute cases, or there may be a day or two of malaise, with coated tongue and other evidences of indigestion, before the rash appears. Sometimes no deviation from the normal condition can be detected.

The type of the disease most commonly seen in young children is the papular—*urticaria papulosa* or *lichen urticatus*. In these instances, as a result of the inflammatory effusion, a small solid papule remains after the disappearance of the more evanescent wheal. In many cases the urticarial element is not manifest to a casual inspection, and the only visible lesions are white or pale-red miliary, scratched papules, more or less discretely scattered over the surface. The eruption is accompanied by intense itching, usually worse at night. Interspersed among the papules, various crusted and excoriated lesions, the result of scratching, may be detected.

T. C. Fox says that while the usual lesion is papular, it may be vesicular, pustular, or bullous as a result of the evolution of the lesion itself, and not as a secondary result of irritation. He claims, moreover, that Bateman's lichen urticatus, Hutchinson's varicella-prurigo, the infantile prurigo of the English, and many of the papular, vesicular, and pustular rashes following vaccination, should be included as phases of infantile eczema.

In addition to the usual form of the disease just described, several other varieties are observed. The titles are sufficiently descriptive—viz. *urticaria papulosa*, *u. tuberosa*, *u. vesiculosa* or *bullosa*, *u. hæmorrhagica*, and, in cases artificially produced by scratching or other irritation, *u. factitia*.

Etiology.—The exciting causes are very numerous, and may be of central, peripheral, or reflex character, acting upon the vaso-motor system. The wheal is probably brought about by a spasmodic contraction of the capillaries, which in return is followed by relaxation and consequent serous effusion. Among the local causes may be mentioned bites of insects, coarse under-clothing, and, in fact, irritants of any sort.

Gastro-intestinal derangement occupies the first place among the indirect causes of urticaria. Many foods have a bad reputation in this regard, such as oatmeal, buckwheat cakes, pork, pastry, and especially strawberries. Intestinal worms often excite the disease in children. Malaria is known to set up

an intermittent type of the disorder. Many medicines also induce it, especially the preparations of cinchona. While it is true that in dispensary practice the papular urticaria of infancy is often caused by bites of insects and other irritating local influences, the writer believes that the majority of cases are due to gastro-intestinal disturbances the result of injudicious diet.

Diagnosis.—The ordinary type of urticaria is readily recognized. Occasionally, when the eruption occupies the greater part of the body in continuous sheets and with accompanying fever, scarlatina may be suggested; but the history of the case, the absence of the scarlatinal throat implication, and the discovery of isolated urticarial wheals somewhere on the body will usually clear up the diagnosis.

Papular urticaria, especially if commingled with eethymatous lesions, bears a close likeness to scabies; but the localization of the eruption in the latter disease, the absence of burrows, and the freedom of other members of the same family from a similar eruption furnish sufficient grounds for the distinction.

Prognosis.—The prognosis of the acute cases is favorable if properly managed. Papular urticaria is exceedingly obstinate often lasting for months, but even these cases eventually get well.

Treatment.—In all cases the cause must be assiduously sought out, and, if possible, removed. Acute attacks are generally due to gastric disturbance from injudicious diet, and a brisk emetic, followed by a laxative, will be apt to bring about a speedy recovery. The more persistent attacks, kept up by repeated exacerbations, are rare in children. Above all, the diet must be carefully regulated. Quinine is of much value when malaria is suspected. Phenacetin will often cut short an attack. The usual empirical remedies, such as atropine, ergot, pilocarpine, and salicylate of sodium, are scarcely demanded.

In the chronic papular form it is first necessary to remove all sources of external irritation, and, secondly, to clearly indicate the proper method of diet to be pursued. Constipation should be relieved, and appropriate remedies prescribed for any gastric irregularity that may be present.

There is a great variety of measures recommended for the local treatment. Among the household remedies may be mentioned lotions of soda, vinegar (pure or diluted), and the application of cologne-water or other spirits. The calamine-and-zinc lotion, as previously given, with carbolic acid (gr. ij to f̄ʒi) is especially valuable. Menthol in solution (ʒss-f̄ʒiv) is also a good antipruritic.

In lichen urticatus the same preparations may be employed. Fox recommends the following:

R. Liq. plumbi subacetatis f̄ʒss.
 Liq. carbonis detergentis f̄ʒijss.—M.
 Sig. Add a teaspoonful to a pint of water.

The same authority advises a dilute white-precipitate ointment or paste for the pustular form.

URTICARIA PIGMENTOSA.

This is a rare form of disease, only a few cases having been observed in this country. It begins within the first six months of life in the form of wheals that come out suddenly, singly or in numbers. The lesions are brownish-red, split-pea sized tubercles, and in the beginning are surrounded by a delicate pink areola; subsequently, however, they increase in size and assume a buff color.

The course of the disease is chronic, and while the first lesions are undergoing involution new ones are constantly forming, so that all the varied stages

can be seen at the same time. Urticaria pigmentosa affects principally the trunk and neck, then the head, face, and limbs. It may or may not itch. In the pruritic variety factitious urticaria is common. The disease is usually arrested at puberty.

The cause of the affection is unknown, and the treatment purely symptomatic.

PITYRIASIS ROSEA.

Pityriasis rosea is a trivial disorder, its only special importance arising from the liability to confound it with grave affections. It is claimed by some writers that the cutaneous eruption is preceded by some elevation of temperature, but this symptom is by no means constant. Brocq states that he has observed that the more general eruption is preceded by a single patch that makes its appearance about the waist, neck, or arm. The lesions in the beginning are minute pinkish papules, which soon enlarge into circular or oval macules having slightly depressed centres and a defined raised border. They are covered with somewhat greasy yellowish or yellowish-white scales. When the patches, by peripheral extension, have reached a diameter of one-half to three-quarters of an inch, the centre assumes a yellow-parchment hue, while the extending scaly margins are distinctly reddish. The patches may remain discrete, or they may run together and produce irregular gyrate areas: these bizarre outlines are also formed by the central recovery and peripheral extension of the single lesions. The skin is but little thickened, and pruritus is, as a rule, insignificant. The eruption is usually found on the trunk, but it may migrate over the body generally with the exception of exposed parts. Papules, ringed patches, and patches that are undergoing involution may be present at one and the same time. The disorder is self-limited, and tends to spontaneous recovery in from two weeks to two months.

Etiology.—English and continental writers state that this affection principally attacks young children, but this is not true in the writer's experience, although he has been brought much in contact with the skin diseases of infants and young persons. It occurs in quasi-epidemics, especially in the spring and fall, but considerable differences of opinion exist as to its contagiousness, and neither has its parasitic nature been satisfactorily demonstrated.

Diagnosis.—Pityriasis rosea is distinguished from the scaling circinate syphilide by its more inflammatory color and the absence of pigmentation; besides, along with the syphilide would be found other evidences of syphilis. Its resemblance to seborrhœa of the body is superficially close, but in seborrhœa the eruption is usually found only over the sternum and between the shoulders, while in pityriasis rosea it is not so limited; moreover, the scales of seborrhœa are thicker and greasier, and there is often a history of considerable chronicity. Pityriasis rosea differs from ringworm in its wider distribution, the absence of papules, vesicles, or pustules from the borders of the patches, and the absence of the tricophyton fungus in the scales.

Prognosis.—The disease undergoes spontaneous arrest within from a fortnight to two or three months.

Treatment.—Internal treatment is useless; indeed, treatment of any sort is unpromising. The calamine-and-zinc lotion is agreeable when itching is a symptom, and ointments of sulphur and boracic acid may be prescribed. A pigment of salicylic acid has seemed to be serviceable:

R̄. Acid. salicylici gr. x-xv.
Liq. gutta-perchæ f̄ $\frac{3}{j}$.—M.

PRURIGO.

Prurigo is a chronic inflammatory disease of the skin characterized by an eruption of pale papules accompanied by severe itching. This disease begins in infancy, the lesions first consisting of urticarial wheals, to which the papules succeed. The papules are quite small, and, as it were, buried in the skin, so that they are more easily felt than seen; their color is in the beginning that of the surrounding skin, but in time, as the result of scratching, they become of a darker hue. The most noticeable feature of prurigo is the intense itching, which at times becomes unbearable. The disease is most marked upon the extensor aspects of the limbs, while the flexor surfaces, the genitals, the scalp, and the face are rarely attacked.

Various secondary changes in the skin are to be noted, such as infiltration, pigmentation, desquamation, etc. A severe form of the malady (*prurigo ferox*) is marked by intercurrent attacks of wheals, severe dermatitis, pustulation, scabbing and deep pigmentation, and enlargement of the lymphatic ganglia, especially those of the groin.

In a few cases prurigo directly causes death by the constant worry and loss of sleep, setting up a condition of marasmus; but usually it is not fatal.

Etiology.—By some writers prurigo is regarded as a neurosis of the skin. Others do not admit it is an entity, but think it only a group of symptoms caused by the action of various irritants upon a sensitive skin. Prurigo is mainly found among the poor, who cannot have its earlier manifestations treated. The disease is not so rare in this country as it was at one time supposed, a number of cases having been recently reported by Zeissler.

Diagnosis.—Unless the whole course of the disease be taken into consideration, together with the lesions actually present at any one time, there is danger of confounding prurigo with eczema, scabies, and pediculosis. Careful attention to the history and to the situation of the lesions will usually enable a diagnosis to be made.

Prognosis.—The earlier in a case treatment is begun, the better the chance of cure. In cases of very long standing, though a cure may not be effected, the condition may be much benefited.

Treatment.—The diet should be carefully regulated, all those articles which are calculated to provoke a nettle-rash being eliminated.

The general health will often demand tonics and cod-liver oil. Some cases seem to have improved under arsenic. Bromide of potassium, carbolic acid, cannabis Indica, and the salicylates have been used for their effect upon the itching. Pilocarpine and atropine are both well recommended, but since they act best when given hypodermatically, they are rarely ever used in children.

Locally, bathing in quite warm baths, followed by the inunction of an ointment, will probably yield the best results. The ointment may contain tar, sulphur, naphthol, or salicylic acid in quantities varying with the condition of the patient.

FURUNCULUS.

A furuncle is a circumscribed phlegmonous inflammation occurring about a hair-follicle or a gland of the skin. The appearance of a boil may be preceded by a slight tingling or itching of the skin. In a short time a small red papule will be noticed, which is very sensitive to pressure and is accompanied by a burning sensation. The skin immediately around the papule becomes hard and swollen, and thus a hemispherical nodule is formed, varying in size from a pea to a walnut. The color of the boil itself is a

dull red or purplish, while the skin in the immediate neighborhood is of a brighter red. The furuncle at this stage is firm and hard to the touch, very tender, and accompanied by a dull throbbing pain. Within a week or ten days pus accumulates in the boil, and if it is not opened the skin ruptures, giving exit to a more or less free discharge. Lying in the centre of the furuncle is now exposed the core, a whitish necrotic mass, which if left alone comes away of itself in a few days. As soon as the pus is evacuated the pain in a boil ceases, and when the core has separated the hardness in the surrounding skin gradually disappears, while the small cavity remaining fills by granulation. A scar results, which is at first of a violaceous hue, but in time becomes white. Occasionally a boil stops short of suppuration and resolves: this is known, in popular parlance, as a blind boil.

Furuncles may occur singly, or numbers may be on the body at the same time. In some cases the affection is indefinitely prolonged by the appearance of one crop after another, constituting the condition known as furunculosis. Boils may occur on any part of the body except on the palms and soles. In children they are common on the back, the head, the eyelids, and in the axilla. When a boil occurs in a ceruminous gland in the auditory canal, there is great pain on account of the denseness of the tissues in that region.

When boils are single or in small numbers, there is, as a rule, no constitutional disturbance, but in furunculosis appetite and flesh may be lost, while sleep is disturbed by the pain.

A furuncle always commences about a hair-follicle, a sebaceous gland, or a sweat-gland. The severe inflammation causes the death of the follicle or gland, which then constitutes the core.

Etiology.—Boils may be the result of local injury, such as bruising or pressure, as on the buttocks from prolonged sitting. They often occur in depraved conditions of health, as after scarlatina or measles. In summer they often accompany prickly heat. Boils are contagious under certain conditions, such as sleeping in the same bed with a person affected. They may arise during the course of any pruritic disease, probably from inoculation of the skin by scratching. The pus from a boil will produce other boils if inoculated upon another part of the body or upon another person. The virus may be carried from one person to another by flies. These facts, together with the observation that pus-cocci are always found in boils, seem to warrant the conclusion that the disease is due to the presence of a micro-organism.

Diagnosis.—The only disease of infancy with which furuncle is apt to be confounded is that rare syphiloderm described by Barlow, in which several circumscribed abscesses in the skin occur; but here the inflammatory symptoms will be less severe, other symptoms of syphilis will be present, while the abscesses possess no core. In children carbuncle is a rare affection, and can be differentiated from furuncle by the fact that it has several centres of suppuration, which in turn become so many openings.

Prognosis.—The prognosis of furunculus is, as a rule, favorable. Whenever suppuration occurs permanent scarring is the result. In furunculosis the prognosis must be guarded, as in some cases successive crops of boils occur in spite of the best-directed therapeutic efforts.

Treatment.—In the treatment of furuncle the first step is to look for and to correct any condition of general health which might act as a predisposing cause. All local conditions which may be presumed to favor the development of boils should be removed.

Various remedies, such as yeast, sulphide of calcium, hypophosphite of sodium, have been advised for internal administration in the treatment of

furuncle, but their effect upon the local condition is, to say the least, problematical. A great many different drugs have been recommended as possessing the power to abort boils: the apex may be cauterized with a solid stick of nitrate of silver; Guigeot advises painting with tincture of iodine till quite a thick layer covers the boil; boric acid in saturated solution may be frequently sprayed upon the affected surface, and by this means some authorities claim excellent results; the following formula is given by Jamieson:

R̄. Tr. iodi fʒj.
 Acidi tannici ʒss.
 Pulv. acaciæ ʒss.—M.

This mixture is to be painted upon the boil and the surrounding skin in successive layers, each one being allowed to dry before the next is put on, till a thick coating is obtained. Unna's carbolic-acid-and-mercury plaster will sometimes cause a boil to disappear: a piece of the mull a little larger than the boil, with its centre cut out to avoid pressure on the sensitive apex, should be applied, and renewed every twenty-four hours. Hypodermatic injections into and around the boil, as well as electrolytic puncture, may succeed in arresting the process, but these methods are too painful to be of use in children.

One of the best methods of treating a boil consists in applying a pledget of absorbent cotton saturated with $2\frac{1}{2}$ per cent. carbolic-acid solution, over which is placed a piece of rubber tissue large enough to cover the cotton and a small area of the surrounding skin; even if this does not prevent suppuration, it will be found to give relief.

Poultices in their ordinary forms are to be entirely discarded, as they favor the development of other boils around the ones to which they are applied.

The skin for some distance around a furuncle should be frequently anointed with an antiseptic ointment, to prevent the inoculation of the neighboring hair-follicles. The following is an appropriate formula:

R̄. Acidi boraci gr. xx.
 Zinci oxidi ʒij.
 Lanolini ʒj.—M.

As soon as pus is collected in a boil a free opening should be made, the cavity washed out with some antiseptic solution, then dusted with iodoform, and an antiseptic dressing applied.

In the treatment of furuncles in the auditory canal, Cholewa recommends inserting into the ear a plug of absorbent cotton which has been moistened with a 20 per cent. solution of menthol in olive oil. Spencer inserts a cotton plug, having first applied to the boil an ointment of extract of arnica, extract of belladonna, and morphine.

HÆMORRHAGES.

PURPURA.

The term "purpura" is applied to certain conditions in which hæmorrhages occur in the skin or mucous membranes. The lesions of purpura may be of a bright red or of a livid bluish hue. They do not disappear upon pressure. The individual hæmorrhages vary much in size, and from this fact various names have been applied to them, as petechiæ, where the extravasations occur

in the form of minute points; vibices, where they occur as streaks; ecchymoses, where they occur as larger spots or blotches. At times hæmorrhages are combined with other lesions of the skin; thus we may find blood effused into a papule or a bulla. Occasionally blood finds its way into the sweat-glands, whence it is extruded along with the perspiration, giving to it a hæmorrhagic appearance—hæmatidrosis.

Hæmorrhages occur in the skin under such manifold conditions that any classification upon an etiological basis is impossible. Clinically, three forms are found with sufficient frequency to warrant a description as special diseases. The mildest form in which the affection occurs is known as purpura simplex. The person affected is usually in good health when the disease manifests itself: the lesions appear suddenly upon any part of the body—in children especially about the neck, upper portion of the trunk, and arms. The eruption is commonly made up of petechiæ, though streaks and larger spots may also occur. The hæmorrhages usually remain discrete, and when sufficiently copious may cause a slight elevation of the skin. The duration of the disease is prolonged by the repeated appearance of fresh crops of the lesions. Each crop, as resorption occurs, passes through the different changes in color that we remark in a bruise. There are no subjective symptoms. The condition is most likely to be confounded with flea-bites.

In purpura rheumatica the extravasation of blood into the skin constitutes the most remarkable feature of the disease, and for this reason it is classed among hæmorrhages. The appearance of the skin affection is preceded by malaise: pain in the joints is complained of, and frequently swelling may be detected. After a day or two a petechial eruption shows itself upon the surface. In its general characters this eruption does not differ from the lesions found in purpura simplex, except that there is a tendency to localization about the affected joints. The disorder may be indefinitely prolonged by relapses, and sometimes passes into a condition simulating purpura hæmorrhagica. The heart may become implicated during the course of the malady, with a resulting lesion of the valves. Hænoch and Couty have described a form of purpura which occurs most frequently in children, and is characterized by pains in the joints, vomiting and intestinal pain, and a localized œdema of the skin. (See Purpura Hæmorrhagica.) While purpura rheumatica is at its height there is often a moderate rise in temperature.

The most severe form in which purpura occurs is as purpura hæmorrhagica (morbus Werlhofii). In this affection we find, in addition to the phenomena of purpura simplex, bleeding from various mucous membranes and hæmorrhages into various internal organs. The disease may develop suddenly or be preceded by symptoms of an indefinite kind, such as headache, loss of appetite, lassitude, etc. The hæmorrhages into the skin are frequently larger than those found in purpura simplex, and effusion of blood occurs also in the mucous membranes, as indicated by its escape from the mouth, nose, anus, vagina, and urethra. Bleeding occurs also in the parenchyma of the organs, and when the brain is thus affected speedy death may result. The serous cavities often contain blood.

The disease is usually accompanied by a moderate fever. When the amount of blood lost is not large, recovery may follow, but relapses are not uncommon.

For purpura hæmorrhagica as it occurs in the new-born the designation purpura neonatorum has been given. The disease hardly warrants a special description, since it presents symptoms similar to those found in purpura hæmorrhagica, its only point of distinction being that it occurs within the first few days of life.

Etiology.—In those cases in which hæmorrhage into the skin is merely a secondary or symptomatic phenomenon a cause for the affection can often be ascribed. Illustrations of such cases would be the purpura that often occurs with the specific fevers, as measles, scarlatina, and malaria; or where certain drugs, such as quinine or iodide of potassium, have been ingested; or in cases where we may be able to determine some decided obstruction to the blood-current, as some valvular heart trouble; or where a congenital or acquired weakness of the vessel-walls may be supposed to exist, as in hæmophilia, rickets, or syphilis. In those cases in which the effusion of the blood seems to constitute the chief feature of the disease the etiology is far from being definitely determined. In that form which manifests itself in the new-born babe it has been supposed that the violent changes which then occur in the circulation may account for the phenomenon. Of late years the presence of various forms of micro-organisms has been invoked to explain the occurrence of purpura. Petrone injected blood from patients with purpura into rabbits, and produced a general hæmorrhagic state. Letzerich found a bacillus which, injected in pure culture into rabbits, occasioned hæmorrhages. Several other investigators have made somewhat similar observations. Hanot and Luzet found in the body of a fetus, the mother of which was dead of purpura, streptococci of identical characteristics with those found in the mother. These observations, though as yet too recent to be wholly relied upon, serve to show that there may be certain cases of purpura which are acute, infectious diseases; and this assumption is corroborated by the clinical history in some instances.

Diagnosis.—The diagnosis of purpura rarely presents any difficulty, as the lesions differ from those caused by inflammatory conditions in not disappearing under pressure. A fleabite differs from a petechia in having a central point, indicating its traumatic origin. Scurvy may be distinguished from purpura hæmorrhagica by the fact that it is caused by a diet deficient in vegetables, that it attacks more than one of those so situated, and that in it we find a spongy condition of the gums, loosening of the teeth, and brawny swelling of the limbs.

Prognosis.—Care must be exercised in giving an opinion as to the course and ultimate result even in simple cases of purpura, as the complications which may arise are manifold. As a rule, the simple forms recover, though the attack may be prolonged by relapses. The prognosis in purpura hæmorrhagica is always grave.

Treatment.—Mild cases of purpura will require no special treatment. In all cases rest in bed is of prime importance, as in this way further hæmorrhage is best guarded against. When the hæmorrhages from the mucous cavities threaten danger, an effort should be made to arrest them by means of tampons, hot and cold water, or a spray of perchloride of iron or other astringent. In the way of drugs to be administered internally, turpentine, acetate of lead, dilute sulphuric acid, ergot, and iron have the best reputation. A combination that has proved of service to the writer is the following:

R. Ext. ergotæ fld.
 Tr. ferri chloridi. *āā* f̄ss.—M.
 Sig. Three to ten drops in water, *t. d.*

In purpura rheumatica the salicylates may benefit the affection of the joints.

HYPERTROPHIES.

LENTIGO.

The affection known as lentigo, or freckles, consists in the appearance, mostly upon exposed surfaces, of variously-shaped, usually small, yellow, brownish, or black spots. Freckles are most common on the hands and face, but may occur on covered parts. As a rule, the affection appears in the second decade of life, though Wilson mentions congenital cases. The spots are prone to become darker and more numerous in the summer, while in the winter they may almost disappear. In its pathology a freckle is a circumscribed hyperpigmentation situated in the rete.

Etiology.—Lentigo is rarely seen before the sixth or seventh year. It affects especially those of a light complexion. Exposure to the effects of sunlight is, by universal consent, the most common cause, though, that it is not the only one is shown by the occurrence of freckles on parts not exposed.

Treatment.—Freckles may be temporarily removed by many stimulating ointments and lotions. One of the best of the former is—

R \acute{y} . Hydrarg. ammoniati ʒj.
 Bismuthi subnit. ʒj.
 Ung. aq. rosæ ʒj.—M.

Sig. Apply at night.

In cases where the pigment is very black, pricking each freckle, very superficially, with a needle attached to the negative pole of the galvanic battery often hastens its disappearance.

Freckles, though they have disappeared, are prone to return under exposure to exciting causes.

ICHTHYOSIS.

Ichthyosis is a congenital disease characterized by dryness and scaliness of the skin, and at times by the development of thickened warty patches. Two principal varieties are described, though their difference is of degree and not of kind. *Ichthyosis simplex* affects the general surface, but is often most marked on the extensor sides of the limbs. Often there is only to be noticed a dryness and scaliness of the skin, with small papules due to an accumulation of horny cells in the hair-follicles. In more severe cases a thickening of the skin exists and painful fissures may occur. Large scales form on the surface, which get to be of a dark color from accumulations of dirt; and from their being somewhat of a diamond shape may give the skin a resemblance to the hide of an alligator. The face, scalp, palms, and flexor surfaces are apt to be but little involved, the disease in these parts manifesting itself as a branny desquamation. The hair is often harsh and without lustre, and the nails rough and brittle. Both sweat and sebaceous matter are deficient in quantity. The condition grows better in summer and worse in winter.

In *ichthyosis hystrix* there is present in localized areas an exaggeration of the condition just described: the skin is rough and bark-like, or may be covered by actual spines, due to a papillary hypertrophy in addition to the thickening of the epidermis. The usual sites for ichthyosis hystrix are the back, the neck, and the extremities. The lesions may be distributed along the course of a nerve. Occasionally ichthyosis is present at birth, but, as a rule, it first manifests itself after some months or even a couple of years.¹

¹ Sometimes ichthyosis exists at birth, or in the premature; the "harlequin fetus" of

Though the disease remains through life, the general health is entirely unaffected. The most striking microscopical changes are thickening of the epidermis, with more or less hypertrophy of the papillary layer of the cutis.

Etiology.—The only recognized factor in the etiology of ichthyosis is heredity. It is apt to recur in successive generations of the same family, though this is not always the case.

Diagnosis.—The diagnosis will be easy if the history be considered along with the characteristic appearance of the disease.

Prognosis.—The disease persists through life, but does not show any detrimental effect on the health.

Treatment.—Arsenic and pilocarpine have been recommended, though in the experience of the writer they exert no permanent influence on the malady. The local treatment is of importance, since by it much relief may be given. In mild cases frequent warm baths, followed by inunctions with glycerin or lanoline, suffice. In cases of greater severity it is advisable to use alkaline baths. Duhring recommends that some simple ointment be rubbed on; after this has remained a few hours a hot bath with green soap is given, and then rinsing in simple water, after which ointment is again applied. The following ointment is recommended:

R̄. Adipis benzoati ʒj.
 Glycerini ℥xl.
 Vaselini ʒss.—M.

Sig. Apply after bathing.

Various authors recommend the following ointment for constant use:

R̄. Potassii iodidi ʒj.
 Glycerini ʒj.
 Adipis benzoati āā
 Ol. bubuli āā ʒss.—M.

Sig. Rub in once a day.

Naphthol in 5 per cent. ointment, with the use of naphthol soap, is advised by Kaposi. Sulphur or ichthylol (one drachm to an ounce of vaseline) may be used as a daily inunction. In ichthyosis hystrix large horny growths must be removed by the knife or other surgical means. Smaller patches may be treated by the application of salicylic-acid plaster mulls, as devised by Unna, or a solution of the same drug in collodion or traumaticin:

R̄. Acidi salicylici ʒj-ʒiss.
 Traumaticini ʒj.—M.

Sig. Apply every two or three days after removing the application previously made.

MOLLUSCUM EPITHELIALE.

Molluscum epitheliale is a comparatively rare affection. The lesions are from a pinpoint to a pea in size, according to the duration of the disease. They form little tumors, usually sessile, varying in color from white to a decided pink, often semitransparent, resembling wax, and presenting at one point on

English writers. The body is covered with plates of fatty epidermis separated by furrows. If these children are born alive, they succumb in a few days.

the surface a pit or umbilication indicating the situation of a follicle. Through this orifice on firm pressure a milky fluid may be sometimes squeezed. The lesions are generally few in number, and most frequently occur on the face, on the eyelids, cheeks, and chin. They may be found in other regions, as the neck, breast, or genitals. After the tumors have attained their full size they may remain stationary for an indefinite time, or become inflamed and undergo spontaneous cure by suppuration. Subjective symptoms are absent in molluscum epitheliale. As to the anatomical changes present there are various opinions. Virchow considers that the process begins as a hyperplasia of the hair-follicles, while Leloir and Vidal support the older view, that the tumor is the result of changes occurring in sebaceous glands.

Etiology.—The affection is commoner among children than adults. It is without doubt contagious. As to the cause of the malady there is much difference of opinion. Neisser and others believing it to be the result of some form of coccidia; Wickham contending that molluscum epitheliale is a cutaneous psorospermosis; while Piffard is among those who hold that the pathological process at the basis of the disease is a corneous degeneration of the epithelium.

Diagnosis.—No other affection of childhood is apt to be confounded with molluscum epitheliale.

Treatment.—The little tumors may be successfully treated by laying them open with a knife and pressing out the contents; the base should then be touched with nitrate of silver. Electrolysis also may be used in the treatment of molluscum epitheliale, each lesion being transfixed several times by a slender steel needle attached to the negative pole of a galvanic battery. In a few days, if the operation has been successful, the tumors shrivel up, and eventually disappear: if this result is not attained by the first sitting, the operation must be repeated. Jamieson's method of touching each tumor with pure carbolic acid, and then painting over it with flexible collodion, is said to be effective.

VERRUCA.

Warts represent papillary hypertrophies, and present great variations in appearance: they may be congenital or acquired. They may occur upon any portion of the body in numbers or singly, though exposed surfaces, such as the hands and face, seem their favorite sites. Various names have been applied to the different clinical manifestations of verruca. *Verruca vulgaris* occurs most often on the hands of children as one or more elevations from a pinhead to a large pea in size, of the natural color of the skin or of a dark hue, with a smooth or rough, shagreen-like surface; *verruca digita* is usually found on the scalp, and, as the name implies, presents one or more finger-like projections from the skin, caused by an unusual outgrowth of individual papillæ; *verruca acuminata* is found in such parts as are kept damp and warm and are subject to the irritating influences of discharges, as about the genitals or anus: this wart occurs as a vascular growth, sessile or pedunculated, of a reddish or purplish color, and is frequently accompanied by an offensive purulent discharge. Various other more or less fanciful names have been applied to different forms of warts, but their importance is not sufficient to warrant description here.

No matter how different the outward form of verrucæ may be, microscopically they consist of exaggerated papillary growths covered by epidermis more or less thickened.

Etiology.—The etiology of warts is enveloped in obscurity: some forms

MOLLUSCUM EPITHELIALE

seem to be contagious; and an explanation for this clinical fact is offered by various observers, who have found micro-organisms—sometimes micrococci, sometimes bacilli, sometimes psorosperms—in the affected tissues.

Diagnosis.—The only other disease of childhood with which verruca may be confounded is that rare form of lymphangioma circumscriptum in which the dilated lymph-spaces are covered and concealed by warty growths. Here careful examination will demonstrate that the seeming warts contain lymph-like fluid.

Treatment.—Recently Epsom salts in sufficient doses to cause two or three evacuations a day has been said to bring about rapidly a cure of warts: this is endorsed by good authority, but the writer has had no experience of it.

Where children can be induced to endure the pain, the wart may be caused to disappear by transfixing it one or more times with the needle attached to the negative pole of a galvanic battery.

One of the best topical remedies is a saturated solution of salicylic acid in alcohol painted on once or twice a day; or this formula may be used:

R. Acidi salicylici ʒss.
Collodii fʒj.—M.

Sig. Paint on the wart every other day.

Sometimes powders kept dusted over the affected area will bring about a cure; this powder is as good as any:

R. Pulv. zinci oleatis ʒss.
Bismuthi subnit. ʒss.—M.

Sig. Dust on the part.

Nearly all of the various caustics have been used to remove warts, but the methods mentioned are equally effective and much safer.

NÆVUS PIGMENTOSUS.

By the term "*nævus pigmentosus*," or mole, is meant a circumscribed deposit of pigment in the skin, which may be congenital or may develop at a later period. The size of moles varies from a pinhead to a bean, and in some instances a large part of the body is involved. The most frequent sites of *nævus pigmentosus* are the neck, face, and back. The color of moles varies from a light brownish-yellow to black. Hyperpigmentation may be the only pathological condition present, or this may be accompanied by other anatomical changes: these differences in structure have given rise to special names, such as *nævus spilus*, where a simple smooth deposit of pigment exists: *nævus verrucosus*, where the surface is warty and uneven; *nævus pilosus*, where the mole is covered with hairs.

Moles are of importance from a cosmetic point of view, and because, in later years, they may undergo a malignant change. Anatomically, a mole is a collection of pigment in the rete, often accompanied by an increase in the connective tissue of the skin.

Etiology.—No cause for the appearance of *nævus pigmentosus* has yet been certainly ascertained. The fact that moles sometimes occur scattered along the course of a nerve seems to point to a neurotic origin in some cases.

Prognosis.—Pigmentary *nævi* persist through life, only rarely disappearing spontaneously. Where practicable, it is best to remove them, because

of the possibility of a cancerous or sarcomatous growth originating from the moles as life advances.

Treatment.—Electrolysis offers the best method of removing moles of ordinary size. A needle attached to the negative pole of a galvanic battery is introduced into the mole at several points till, in the judgment of the operator, a sufficient amount of destruction is accomplished. To avoid scarring it is best not to attempt to complete the removal at one sitting. For the minutiae of the operation the reader must be referred to works in which the subject is treated more fully, as space is not here afforded. Electrolysis presents advantages in the removal of large *nævi*, as there is no hæmorrhage, and scarring is less than by most other methods. The operation is, however, tedious, as a number of sittings are required for the larger growths. When time is an element in treatment, excision with the knife gives the most satisfactory results. It is not good practice to attack moles with caustics, as the results are less favorable than by the methods mentioned, while a malignant change may possibly be provoked.

SCLEREMA NEONATORUM.

Sclerema neonatorum manifests itself as an induration and stiffening of the skin in new-born children. The disease may be congenital, but when this is the case the children are usually still-born. More frequently the trouble develops within the first few days of life. The skin of the legs is usually first attacked, and successive portions of the integument are affected till the whole surface has become involved. Occasionally the disease begins in the cheeks and spreads downward. At first the skin is of a whitish, waxy appearance, and feels thick when pinched between the fingers; but as the malady advances a livid hue is developed, and the skin becomes adherent, so that it can no longer be picked up. When the process is fully developed the child lies rigid, with no perceptible motion save that due to its feeble respirations. The joints are not readily flexed, and the child may be picked up by the legs and held out horizontally; the jaws are so stiff that nursing is impossible. The pulse decreases to 60 per minute; the respirations are slow and shallow; and the temperature is below the normal by two or three degrees: under such conditions life cannot long persist, and is generally extinguished in five or six days.

Sclerema neonatorum was until the time of Parrot confused with œdema, which may occur in the new-born from various causes. Parrot makes the essence of the disease a drying up or desiccation of the skin; he denies that there is a true sclerosis. Langer attributes the stiffness of the integument to solidification of the subcutaneous fat; in infants the fat becomes solid at 89.6° F., while in adults this occurs at a temperature lower than 32°F. If by any depressing cause the infant's temperature is sufficiently reduced, the fat solidifies, and sclerema neonatorum is the result.

Etiology.—The disease is most common in those born prematurely. Any conditions which depress the general health, such as congenital heart affections, bronchitis, diarrhœa, exposure to cold, etc., seem to act as predisposing causes.

Diagnosis.—Sclerema neonatorum is distinguished from œdema by the fact that the skin is stiff and unyielding, and that there is no pitting on pressure. (For the differential diagnosis between sclerema neonatorum and scleroderma the reader is referred to the article on the latter subject.)

Prognosis.—The disease is nearly always fatal. Encouragement is, however, offered by the few cases that have recovered.

Treatment.—An effort should be made to bring the temperature of the child to the normal by enveloping it in cotton wool, or, better, by placing it in

an incubator. As nursing is impossible, nourishment must be maintained by other methods. Milk with brandy may be administered per rectum or by means of a catheter passed into the stomach through the nose. Money reports success in two cases by inunctions of mercury.

SCLERODERMA.

Clinically, scleroderma presents itself as a thickening and induration of the skin. A limited area or the whole surface may be involved.

The disease may occur on any part of the body, but shows a preference for the upper portions—the head, the thorax, or the upper extremities. The malady may come on acutely, and in a few days involve the entire surface; but more commonly the progress is so slow that the person affected does not notice the presence of the disease till the skin is already hard and stiff. Sometimes the real infiltration is preceded by œdema. When fully developed the affected area is to the touch dense, hard, and will not pit on pressure. The skin cannot be picked up from the underlying structures, nor slid about, as in the normal state. The diseased area is usually on the same level with the healthy integument, and passes so gradually into it that no line of demarcation can be seen. Generally, the surface is somewhat paler than normal, though it may be a uniform or mottled brown from increased pigmentation: it is most often smooth and shining, with the markings of the natural skin obliterated, but in some instances it is scaly. Around the border of the area there is sometimes a zone of hyperæmia. The movement of all the parts affected is limited by the rigid skin, so that the face is expressionless, the neck cannot be easily turned, respiration is hindered, and the joints are not readily flexed. Sensation may be increased or diminished, but pressure on the diseased skin is acutely painful. The mucous membranes may become involved, as may also the muscles. Having persisted in this stage for an indefinite time, the affected skin may become normal, or it may pass into the second or atrophic stage. It then becomes thin, parchment-like, of a dull-white color, with telangiectic vessels showing here and there, and is stretched tensely over the underlying structures. The pressure thus caused brings about atrophy of the tissues beneath, so that the face may resemble a skull with only the skin stretched over it, and the limbs seem made up of only skin and bones. Various distortions of the hands and extremities occur, and ulceration over bony prominences is common.

During the course of scleroderma, endocarditis and pericarditis may develop. There is frequently no disturbance in health till the disease has persisted for a long time, when a state of marasmus may appear and death result. In children the disease is prone to run an acute course, and does not so often terminate in atrophy. The denseness of the skin in scleroderma is due to an increase in the connective-tissue elements. The changes are found chiefly in the corium and subcutaneous tissue. There is at times an increase of pigment in the rete. Around the vessels are found masses of cells the exact origin of which is unknown. In a case examined by Méry there was a development of connective tissue in the muscles of the limbs and in the heart.

Etiology.—The cause of scleroderma is not known. Obstruction of the lymph-channels has been suggested, but this remains an hypothesis. Various observers have detected lesions of the central or peripheral nervous system in connection with scleroderma. The disease seems to have followed exposure to cold, and it has been remarked after erysipelas.

Diagnosis.—The only disease of childhood with which the first stage of scleroderma can be confounded is sclerema neonatorum: here the time of

development will suffice to distinguish, as the youngest child in whom scleroderma has been reported was thirteen months old.

In the atrophic stage scleroderma most resembles Kaposi's disease, but the history of scleroderma, which begins as a thickening of the skin, will, in most cases, differentiate it from this affection, which begins with pigmentation and atrophy. (For other points of difference see Kaposi's Disease.)

Prognosis.—It is impossible to give an opinion as to the result when the case is seen in the first stage. When atrophy has occurred it is permanent.

Treatment.—The body should be clothed with flannel, and exposure to cold, which always seems to aggravate, guarded against. The general nutrition should be cared for by a generous diet and the exhibition of cod-liver oil and tonics. Hot baths often give comfort to the patient. The suppleness of the skin may be increased by vigorous inunctions of oil. Massage has seemed of service in some cases. The constant current has been recommended by some authors, and in a circumscribed patch of scleroderma in an adult Brocq used electrolysis with apparent improvement.

MORPHŒA.

The affection of the skin known by the name "morphœa" is thought by some dermatologists to be only a circumscribed scleroderma. However this may be, the disease presents enough clinical peculiarities to entitle it to a separate description.

The lesions of morphœa consist of variously sized spots, streaks, or bands with sharply-defined borders surrounded by a zone of dilated capillaries, which zone is often of a violet hue. The affected area is frequently of a waxy-white color, so that it has been likened to a piece of old ivory let into the skin, but at times the color may be pinkish, yellow, brown, purple, or even black. The patches are, as a rule, not raised above the level of the surrounding skin. Generally, the surface is smooth and the skin is not adherent to the underlying tissues, so that it may readily be picked up, when it is found to be slightly thickened; sometimes in one part of a patch there exists thickening, while in another the skin is thinner than normal. The disease occurs frequently upon the breast, and may affect any part of the body. Sometimes several patches are grouped along the course of a nerve. At times the disease presents itself as a number of small atrophic pits in the skin.

The subjective symptoms are insignificant, being limited to slight itching. Occasionally, the centre of a patch will be insensitive.

The disease persists for months or years, and then may disappear, leaving the skin normal; or the final result may be an atrophy of the skin, and even deeper structures. Crocker found in the earlier stages of morphœa a considerable infiltration, in the corium, of cells which later become connective tissue, and by their contraction cause atrophy of the blood-vessels and glands.

Etiology.—The disease may occur at any age beyond two years. It is thought by many to be a neurotic affection, and certain facts lend countenance to this belief, as its occurrence with other disturbances of the nervous system, such as hemiatrophia facialis, canities, alopecia areata, etc., and its being often distributed along a nerve-trunk.

Diagnosis.—Leucoderma differs from morphœa in not presenting any alteration in the texture of the skin, there being simply an absence of pigment. The atrophic spots of leprosy show marked anæsthesia, and the concomitant symptoms will aid in the diagnosis. Keloid is more vascular and

denser than morphœa, is redder, and its lesions present the well-known claw-like processes.

Prognosis.—Although morphœa has a tendency toward recovery in the course of time, with no permanent damage to the skin, yet in view of the cases followed by atrophy the prognosis must be somewhat guarded.

Treatment.—No internal medication has any effect on the lesions of morphœa, and thus far local remedies may be said to be equally futile.

ATROPHIES.

ALBINISM.

ALBINISM is a congenital absence of pigment: it may be total or partial. When general, not only the skin, but also the hair, the iris, and the choroid lack their normal coloring matters. Persons thus affected are termed albinos, and present the well-known characteristics of a pink skin, white hair, and pink irides. Frequently nystagmus may be observed in albinos, from the irritating effect of the light upon the unsheltered retina. These persons are often poorly developed, both physically and mentally. Albinos are quite frequently the offspring of negro parents.

Partial albinism is most common among negroes, and occurs as limited areas in which the pigment of the skin is absent. Should these areas be found in hairy regions, the hair also lacks its coloring matter. In rare cases partial albinism spontaneously recovers by a new deposit of pigment in the affected part.

LEUCODERMA.

Leucoderma is an acquired diminution of the pigment of the skin. It usually occurs as one or more round or irregular-shaped areas, in which the skin is of a much whiter color than the surrounding integument. Such patches of skin vary in size from a quarter of an inch in diameter up to several inches, and their borders are strongly defined from the healthy skin by a line of abnormally deep pigmentation which surrounds the leucodermic plaque. Hairs growing on the affected areas may be white or may retain their natural color. Save for the absent pigment the diseased skin is quite normal.

Leucoderma is generally symmetrical, and occurs most frequently on the neck, face, backs of the hands, and about the hips. The disease tends to slowly progress, till in the course of time the whole body may become involved. When leucoderma has thus extended over a whole member, it is often thought to have recovered, as the contrast with the healthy skin can no longer be remarked. As a matter of fact, the pigment is rarely if ever restored. The disease appears to grow worse in summer, because at this season the pigment of the normal skin becomes darker.

Etiology.—Leucoderma usually develops between the ages of ten and thirty, though the writer has seen it in a child four years old. Beyond the fact that the malady seems to be due to some disturbance in innervation, nothing is known as to its etiology. It is sometimes secondary to other diseases, such as morphœa, alopecia areata, and eczema.

Diagnosis.—From the congenital absence of pigment known as partial albinism leucoderma is distinguished by its history, its symmetry, and its pro-

gressive tendency. From morphea it will be differentiated by the fact that in the former disease there is a change in the structure of the skin. From the white spots which occur in nerve-leprosy, leucoderma can be told by the fact that the macules of leprosy are anaesthetic and often scaly.

Prognosis.—There is little hope of recovery, though in time, by the spread of the disease, the effect is rendered less startling.

Treatment.—No drug, either internally or locally, has any effect upon the disease. The most that can be done is to remove the hyperpigmented border and thus relieve the contrast. (For the various means of accomplishing this see Treatment of Lentigo.) Tattooing or staining the patches with walnut-juice may be tried where the cosmetic effect must be cared for.

ALOPECIA AREATA.

Sometimes, after certain premonitory symptoms, such as headache or burning or itching, the hair is lost from the scalp in one or more circumscribed spots; more frequently, however, these sensations are absent, and the patient's attention is first attracted by the peculiar and striking areas of baldness. The patches are usually quite white and perfectly smooth, and give the appearance of slight depression. There may be one or many bald spots, and they may vary in size from a dime-piece to that of the palm, the larger areas usually resulting from coalescence of the smaller ones. Sometimes the loss of hair is general, but this must be rare in children. The disorder runs a chronic course. It may persist from a few months to several years. When recovery sets in, the returning hairs are white and downy, but gradually attain their normal size and color.

Etiology.—The disease is comparatively frequent in children. It is sometimes noted to occur after various illnesses, but more often there is no such history.

FIG. 2.

Alopecia Areata.

A blow on the head, or, in the adult, persistent neuralgia, is occasionally apparently responsible for limited areas of the disease. By some authorities it has been regarded as contagious (Hillier and others), but certainly in the majority of instances this is not so, and it is likely that the recorded cases of such character are susceptible of some other explanation. Neither has the parasitic theory been maintained. The writer is in agreement with most dermatologists in looking upon alopecia areata as a trophoneurosis.

Diagnosis.—The disease is so striking that its recognition is a matter of little difficulty. Ringworm of the scalp bears the closest resemblance, but in this latter affection the patches are not smooth and glistening, but are covered with grayish scales, and scattered over

the surface are to be seen the stumps of broken-off hairs; besides, if any doubt arise, the microscope will soon settle the question. Favus, syphilis, and certain forms of folliculitis would also be differentiated.

Prognosis.—The alopecia areata of young people generally tends to spon-

taneous recovery, although undoubtedly much hastened by appropriate treatment.

Treatment.—There is no special internal treatment beyond attention to any obvious defects of the general health. In rebellious cases small doses of arsenic might be tried. Locally, the demand is for thorough and persistent stimulation. The following, briskly rubbed in twice a day, is useful:

R. Acidi salicylic.	ʒj.
Sulphuris præcipitati	ʒj.
Vaselini	ʒj.
Olei rosæ	q. s.—M.

Equal parts of tincture of cantharides and glycerin serve an equally good purpose. Pilocarpine in ointment or the fluid extract of jaborandi in lotion may be advised. Galvanic stimulation with a metallic brush (negative pole) is also to be recommended. In obstinate cases blistering limited regions at a time with cantharidal collodion gives excellent results.

NEW GROWTHS.

KAPOSI'S DISEASE.

This disease, which is also known as xeroderma pigmentosum and angioma pigmentosum et atrophicum, develops in the first year of life, frequently as an erythema, upon the disappearance of which small, variously colored pigment-spots, resembling freckles, are noted. Sometimes the pigmentation is the first morbid change observed. In a short time small atrophic spots begin to appear, and as the atrophy advances vascular telangiectases of various sizes develop, which may, in severe instances, form small elevated blood-tumors. Often warty growths are seen arising from the pigmented spots. As the malady progresses the atrophic skin, by contraction, may cause marked deformities. Ulcers are prone to form, and these or the warty growths referred to may be the starting-point for malignant tumors which often terminate the patient's life. The most frequent sites of the malady are those parts which are habitually exposed—the face, neck, hands, and feet.

Kaposi's disease is essentially an atrophy of the skin beginning in the papillary body and epidermis. The tumors which are associated with this process are usually described as epitheliomata, though some observers found papillomata and sarcomata.

Diagnosis.—The atrophic stage of some cases of scleroderma most resembles the disease under consideration, but the history of the two affections is entirely different.

Prognosis.—The prognosis is in all cases bad, for after the malignant growths have once developed the patient has only a few years, at the most, to live.

Treatment.—No internal medication has any effect upon this disease. The ulcers should be treated on general surgical principles, and the tumors removed at as early a date as possible.

NÆVUS VASCULARIS.

The affection known as nævus vascularis consists in a congenital new-growth of blood-vessels, which may be manifest at birth or may show itself

at a later period. The clinical picture will vary much according to the size of the vessels involved and the presence or absence of implication of other structures, such as the connective tissue, hair-follicles, or fatty tissue.

As usually seen, *nævus vascularis* consists of spots of various sizes, in color from a pale red to a bluish hue, not raised above the skin, disappearing largely on pressure, and due to a new formation of capillary vessels. Sometimes there will be only a small pinhead-sized point, radiating from which are numerous red lines (*nævus araneus*): at other times areas as large as the palm may be involved (port-wine mark). This capillary form of *nævus* may spontaneously disappear, may remain stationary, or may increase rapidly in size till large areas become involved. According to Depaul, one-third of the children born at the Clinique de la Faculté de Médecine in Paris have this form of birth-mark, but in most cases the mark disappears within a month.

Often over the surface of a capillary *nævus* warty growths occur, and at times small erectile vascular tumors may be seen. The most common sites for this form of *nævus* are the face, scalp, neck, arms, and genitals.

When the vascular channels constituting the *nævus* are of a larger size, we find elevated areas, usually of a bluish color, often lobulated, soft and frequently fluctuating, compressible, but rapidly filling again when pressure is removed. In such tumors pulsation may at times be observed. *Nævi* of this form seem sometimes to develop from the capillary variety. They vary in size from a pea to an orange, and occasionally attain enormous proportions. In some instances these growths lie entirely in the subcutaneous tissue, the skin being simply stretched over them, but not altered otherwise. *Nævi* of this kind most often occur on the neck about the lower jaw, on the buttocks, and on the lower limbs.

As a rule, vascular *nævi* are not accompanied by any subjective symptoms, but in some of the pulsating tumors there are neuralgic pains.

Nævus, especially *nævus vascularis*, consists of new-formed vessels which are variously distorted, being convoluted or varicose. Sometimes, from pressure, parts of the intervening vascular walls are broken through, and irregular intercommunicating chambers are formed (cavernous tumors of some authors). In connection with the growth of the vessels there may be an increased development of other elements of the skin—connective and fatty tissue, glands, hairs, etc.

Etiology.—Maternal impressions are thought by some to determine the location of *nævi*, and such views have been supported by many instances. When we consider how common *nævus vascularis* is, it does not seem strange that there should often be an accidental coincidence of birth-mark in the child and "maternal impression" in the parent.

Diagnosis.—*Nævus vascularis* cannot readily be confounded with any other affection of the skin, and the diagnosis is easy.

Prognosis.—The prognosis must be guarded. Though small *nævi* may remain stationary, or may even disappear as the child grows older, on the other hand they often increase rapidly in size, and this may occur after the growth has remained stationary for years: this is especially true of the prominent and pulsating *nævi*.

Treatment.—For the cure of the elevated or pulsating *nævi*, when the area involved is of limited extent and a reasonable hope of cure in a few sittings may be entertained, the most satisfactory means is the coagulating effect of electricity. The child must be anæsthetized, as the operation occasions a good deal of pain. A slender steel needle attached to the negative pole of a galvanic battery is thrust into the tumor; the positive sponge electrode is then placed upon some convenient portion of the child's body. The length of time the current should be passed must be determined by the thickness

of the skin and the size of the vessels of the tumor. As coagulation occurs, a paling of the tumor usually follows. The needle must be passed through different parts of the *nævus*; the number of times will depend upon the size of the growth. A current from twenty to thirty cells of a galvanic battery will suffice. To secure the complete cure a number of sittings will generally be required, and this fact constitutes the principal objection to the method. Some operators plunge needles attached to both the positive and negative poles into the tumor, but the writer prefers the method above described.

When *nævi* of this class are very large, their treatment must be undertaken by surgical means, a discussion of which is not within the scope of this article.

In the treatment of the superficial *nævi*, where the affected vessels are capillaries, electrolysis is not so satisfactory, for if the area involved be of any extent, an indefinite number of repetitions of the operation will be required, and, moreover, as the vessels to be destroyed are so small and so numerous, each sitting must be of considerable length; as the operation requires anæsthesia in young children, the number of the sittings and the length of time employed in each become serious objections to its performance.

Unless the birth-mark is very small, other methods will be found more applicable. Ethylate of soda may be painted over the *nævus*, and when the eschar thus formed has separated the remedy may be reapplied till a cure is effected.

A 4 per cent. solution of corrosive sublimate in collodion is recommended, and it is stated that the resulting cicatrix is thin and smooth.

Pure carbolic acid may be brushed over the *nævus*; by several applications a cure will usually be effected. A host of other escharotics has been recommended, but those mentioned are among the most reliable.

Multiple puncture and incision, though strongly advocated by some, have failed in the hands of many careful operators.

LUPUS VULGARIS.

Lupus vulgaris is a chronic granuloma of the skin, depending upon the presence of the tubercle bacillus. It usually manifests itself in early childhood as small brownish-red spots, which may be a trifle depressed below the skin, on a level with the surface, or even slightly raised. Several such spots are generally noticed in the same neighborhood: as they grow older they increase in size, while at the same time an infiltration of the skin occurs: they are then of a brownish color, semi-transparent, softer than the surrounding tissues, so as to be more readily broken down under pressure, and constitute what is known as *lupus tubercles*. These tubercles gradually coalesce by peripheral extension to form patches of a brownish-red color, raised at the borders, often depressed in the centre, accompanied by deep and firm infiltration of the skin. The typical *lupus tubercles*, which have been likened to masses of apple-jelly, though they may not be discoverable in such a patch, may generally be detected about its edges. After remaining in this condition for an indefinite time, one of two processes occurs in the *lupus patch*: interstitial absorption may take place, producing eventually a shining depressed cicatrix; or the *lupus tissue* may break down, leaving ulcers of various shapes and depths, often covered with crusts and having raised infiltrated borders. When healing takes place after ulceration the scars are thick and rough.

Various accidental features may present themselves during the course of *lupus*, which have given rise to a number of special names; thus, if warty

growths are present on the patch, the disease is known as *lupus verrucosus*, if granulations are exuberant, it is *lupus hypertrophicus*; if the borders advance in a sinuous manner, the title *lupus serpiginosus* is given.

Lupus usually occurs on the face about the nose and cheeks, but it may attack any part of the body except the forehead, chin, palms, soles, and penis, which portions of the body seem to be exempt. The mucous membranes may be involved, but this is most often by extension from the adjacent skin. Whole organs or entire regions may ultimately be destroyed by the disease, but the onward progress of lupus is so slow that such ravages are usually not witnessed till the patient is of some age.

The course of the malady is not uniform; at one period it advances with great rapidity, and then for long intervals it may remain quiescent.

Various complications may arise during the course of lupus: when the disease occurs upon the limbs and extremities, the bones may be destroyed by caries; erysipelas sometimes develops in the lupus patch, but often exercises a favorable influence upon the malady; the inflammatory processes accompanying lupus may involve the lymph-vessels, which, becoming obstructed, give rise to a condition resembling elephantiasis.

Microscopically, lupus tissue is made up of a reticulum of fibrous tissue, the meshes of which are filled with round cells and a varying number of giant-cells. Some observers have been able to demonstrate the presence of tubercle bacilli, but they usually occur in such small numbers that their discovery is difficult.

Etiology.—Lupus generally begins in childhood, and is more common in females than in males. It is stated by excellent observers that a tubercular family history may be obtained in a majority of the cases, though comparatively few of those suffering from lupus have consumption. The observations of Koch, Piek, Doutrelepont, and others make it very certain that lupus vulgaris is a tuberculosis of the skin.

Diagnosis.—The history of the case and the presence of the lupus tubercles generally make the diagnosis easy. In children the only disease with which it might be confounded would be a gummatous syphilide, and this is very rare in childhood; when a gumma appears, it goes through its evolutions much more rapidly than lupus, frequently breaking down into a punched-out ulcer with sharp-cut, thin borders, which readily heals under appropriate treatment.

Prognosis.—The progress of lupus is so slow that, save in those rare instances where the disease involves a vital organ, death results more often from some intercurrent trouble than from the disease itself. If neglected, horrible deformities occur, and even in those cases where a cure results from treatment, permanent and disfiguring scarring is left.

The disease justly has the reputation of being very rebellious to treatment. Perhaps one of the chief reasons for this is that treatment to be successful must be so long protracted that the patient becomes discouraged ere it is completed.

Treatment.—Lupus demands both constitutional and local treatment. The child should be given the most nutritious diet; plenty of fresh air and sunshine should be recommended; the sleeping apartment should be well ventilated, and habits of cleanliness insisted upon. The two remedies for internal administration are cod-liver oil and the preparations of iodine. As large doses of the oil should be given as can be borne by the stomach. The iodide of potassium or the syrup of the iodide of iron will be found the most eligible forms for the administration of iodine.

Hypodermatic injections of tuberculin, as proposed by Koch, have not yielded the brilliant results at first expected of the remedy, and the most enthusiastic can now only claim for this method of treatment a very limited field.

The local remedies that have been used in lupus are so many that merely to enumerate them would require more space than can here be given. When a case of lupus is first seen it is often of benefit to apply for a time soothing remedies, as in this way external irritation is removed and it is possible to see what part of the trouble is due to the lupus and what part to accidental inflammatory complications: for this purpose nothing is better than unguentum vaselini plumbicum spread on linen and changed twice a day. With the idea of destroying the tubercle bacilli, any ulcers present may be dusted with iodoform before the ointment is applied.

One of the oldest methods, and still regarded by some as the best, for destroying the lupus growth is by the application of the stick of nitrate of silver: this is of special use in small patches. To be effectual the sharpened point should be bored deeply into the affected tissues.

Pyrogallic acid is one of the remedies most frequently used, and is an efficient caustic: it may be applied in the form of a plaster, for which Dühring's formula is—

R. Acidi pyrogallic. ʒij.
Emp. plumbi ʒj.
Cerati resinæ comp. ʒv.—M.

Sig. Apply on cloth.

This plaster should be renewed every twenty-four hours for three days, and then the surface dressed with a simple oil dressing till the eschar is separated. A mild mercurial ointment then forms a most excellent dressing. The procedure may have to be repeated several times before cicatrization is secured.

Hebra's modification of Cosme's paste often produces excellent results. The formula is—

R. Acidi arseniosi gr. xx.
Hydr. sulphuret. rubri ʒj.
Ung. aq. rosæ ʒj.—M.

Sig. Apply on muslin.

This should be renewed once a day for two or three days: it should never be used on a large surface at a time, for fear of arsenical poisoning.

Unna's salicylic-creasote plaster-mull is highly recommended by some writers: this mull is prepared in strengths varying from 5 to 20 per cent. of salicylic acid, with twice as much creasote; the strength used will depend upon the age of the patient and the amount of infiltration in the lupus patch. A piece of the mull sufficiently large to cover the area which it is desired to attack should be applied each day until enough destruction has been produced; a mild mercurial ointment should be applied on cloth until the healing occurs.

Various surgical procedures have been used in the treatment of lupus. Multiple linear scarification has been much employed in the early stage of the disease, the tissue being minced as finely as possible by numerous cuts made at right angles to each other; but this method of treatment has been largely

superseded by other more successful procedures. It is probable that when a surgical operation is found necessary, scraping with Volkmann's spoon will be most satisfactory: the lupus tissue is softer than the healthy structures, and is more readily broken down by the curetting. After it is judged that all the diseased tissue is removed, the area operated upon should be cauterized with an 8 per cent. solution of chloride of zinc or with the galvano-cautery; the wound should then be dressed in an antiseptic manner. No matter how thoroughly curetting may be done at each sitting, it will usually have to be repeated several times before a cure is effected.

The galvano-cautery or Paquelin cautery may be used to destroy the lupus growth: after the tissue has been thoroughly burned away, the wound should be dressed with a moist antiseptic dressing till the slough has separated, and then dusted with iodoform and a dry dressing applied.

When very small nodules only are present, electrolysis may be used for their destruction: the needle is to be thrust into the lupus nodule and the skin immediately surrounding it until it is judged that sufficient destruction has been produced. After two or three weeks, if the lupus process still seems active, the operation must be repeated. The tediousness of its use forms the principal objection to electrolysis.

Whatever method may be employed, the treatment must be actively followed, and the operations repeated again and again as long as any of the lupus tissue remains.

SCROFULODERMA.

As to which diseases shall be grouped under the term "scrofuloderma" there is great difference of opinion among authors. Three different forms of skin trouble occur with considerable frequency in those who are affected with the tuberculous diathesis; these diseases will here be considered as the scrofulodermata proper.

The most frequent form of scrofuloderma is the ulcerous lesion which is often found over tubercular lymphatic ganglia, especially in the neck. When such an enlarged ganglion begins to soften and break down, the skin over it becomes thinned and of a violaceous hue. Finally, the pus and necrotic remnants of the ganglia break through the skin, and an ulcer results. Such ulcers are round or oval, their edges purplish and frequently undermined, their floors covered with pale, unhealthy granulations. A thin more or less purulent fluid is constantly secreted, which dries into thin, light-colored crusts. The progress of these ulcers toward recovery is very slow, and when healing does occur thick, ridged scars result.

Duhring describes a scrofuloderm which consists of one or more large flat pustules seated upon an inflamed base. A crust, which is thin and brown, forms slowly; underneath is an ulcer which has the "peculiar scrofulous character:" the scars are flat and superficial. The same author describes an eruption of small pustules which occurs on the face and extremities in scrofulous subjects, and leaves variola-like scars.

Another eruption which occurs usually in the scrofulous is the lichen scrofulosorum. The disease consists of numerous pinhead-sized papules of a red or yellowish color, situated usually on the trunk, sometimes on the limbs, and not accompanied by itching or other subjective symptoms. The papules often have a grouped arrangement. Each papule is crowned by a few thin scales. This affection is very rare in this country.

Etiology.—The scrofulodermata occur most often in children. That form

which is found with tuberculous lymph-ganglia is due to the presence of the tubercle bacillus.

Lichen scrofulosorum is an inflammation which commences about a hair-follicle or sebaceous gland, but whether this inflammation is of microbic origin is not yet determined.

Diagnosis.—Scrofulous ulcers are to be distinguished from those of syphilis by the history, the concomitant symptoms, and the differences in appearance of the ulcers themselves. Lichen scrofulosorum differs from the other papular rashes in that it occurs in subjects presenting evidences of scrofula, and further that it is not accompanied by itching.

Treatment.—The therapeutic efforts must be directed especially toward bringing the general health up to the highest point. The best of food and out-door life and sufficient exercise will be indicated. Cod-liver oil, iron, and some form of iodine are the drugs most to be recommended. The local treatment of the diseased glands and the consequent ulcers of the skin belong more to the realm of surgery than to dermatology, and the reader is referred to works on this branch of medicine for full details of the various operative procedures. When the ganglia have not yet broken down an ointment of iodoform, rubbed in several times a day, is said sometimes to cause their resolution. This ointment may be made thus:

R. Iodoformi ʒj.
Vaselini ʒj.—M.

In lichen scrofulosorum the remedy most in favor is cod-liver oil, given in full doses and also rubbed into the affected skin.

SYPHILODERMA.

Under the term syphiloderma are included all those manifestations of syphilis which occur upon the cutaneous surface. In children syphilis is almost exclusively a congenital disease. In those exceedingly rare cases where it is acquired it runs the same course and presents the same lesions as the acquired disease in adult life. In congenital syphilis, however, the skin manifestations present certain peculiarities which place the syphilodermata of childhood, as it were, in a special class.

A foetus affected with syphilis may die *in utero*, and thus occasion an abortion; the pregnancy may progress to term and the child be born with the signs of the disease upon its body; or it may be born apparently healthy, and the skin lesions of syphilis develop only after several weeks. At times infants will be seen presenting evidences of hereditary syphilis in whom no actual eruption may be found upon the skin, but in whom the nutrition of the skin is evidently affected, as it is thin and dry, wrinkled, and parchment-like.

The syphilodermata are accompanied by the general manifestations of the disease, such as inflammations of the nose and larynx, giving rise to "snuffles" and hoarseness; periostitis and epiphysitis of the bones; loss of the hair and eyelashes; iritis, etc.

Congenital syphilis of the skin presents itself as erythematous, papular, vesicular, pustular, bullous, and tubercular eruptions; but it must be remembered that these various elementary lesions may coexist in the same subject or be evolved from one another, just as happens in the acquired forms of the disease. Upon the bodies of infants the *erythematous syphiloderm* may present an appearance and grouping similar to the erythematous syphilide as it

occurs in acquired syphilis: this, however, is not the most common appearance of this form of eruption. The erythematous rash usually begins about the buttocks and perineum, or at times about the neck, as reddish macules, which soon coalesce to form sheets of yellowish-red, shining, often slightly moist skin, which resembles an intertrigo. The eruption differs from intertrigo in that it is not confined to those parts kept warm and damp, as by the diaper, but extends both above and below, being found especially along the back of the thighs and legs, and even on the soles. In regions where warmth and moisture are not present the rash is usually accompanied by a slight branny desquamation. While the eruption is upon the body the palms and soles may be found red and scaling.

The *papular syphiloderm* is the next most common rash of congenital syphilis. The papules are generally discreet, sometimes grouped, flat, more rarely acuminate, and may exist alone or be combined with erythematous eruptions; the papules occasionally scale slightly, are of the brownish-red tint of syphilis, and when of an irregular angular outline may somewhat resemble the lesions of lichen planus; when they occur around the mouth or anus or in other regions where they are exposed to irritation, they may become transformed into mucous patches exactly like those which are found with acquired syphilis. Around parts which are much in motion the presence of the papules causes cracks and fissures, which result in scars, such as are commonly seen in the angles of the mouth and nose in syphilitic children.

The *vesicular lesion*, as the primary form of congenital syphilis, is rarely seen; vesicles are more commonly found developing after some other lesion, as upon papules.

The *pustular syphiloderm* occurring early indicates a severe affection; it may be present on any part of the body, but is usually most abundant on the face, buttocks, and thighs; about the mouth crusts are apt to form, covering superficial ulcers; pustules sometimes form around the borders of the nails. Secondary suppuration may supervene upon any syphilitic rash, and is to be distinguished from the real pustular syphilide. Barlow has described a syphilitic eruption which occurs as small cutaneous abscesses, resembling boils, but having no cores.

The *bullous syphiloderm* occurs quite frequently in the first two weeks of life, and indicates a severe phase of the disease. The bullæ nearly always affect the palms and soles; they may occur on other portions of the limbs and about the lower part of the face, but often spare the trunk entirely. The bullous lesions develop upon dusky-red areas as small vesicles or pustules, which rapidly grow to the size of a pigeon's egg or larger; they may be tense or flaccid, round or irregular in outline, and are usually filled with a cloudy, purulent fluid which sometimes is bloody. When the bullæ rupture a dark brownish-red, somewhat thickened base remains covered with the remnants of the roof of the bulla; at times greenish crusts form, covering an unhealthy ulcerating surface. Death frequently follows this form of syphilis, though by prompt and efficient treatment life may be saved.

The *tubercular syphilide* is not frequent in hereditary syphilis, and then it occurs late, so that it will rarely be found in children. When seen, this eruption is similar to that found in the adult, and most frequently occurs on the face and anterior surface of the legs.

The gumma is a lesion not uncommon in hereditary syphilis, though it is usually a late lesion. Gummata when present exhibit the ordinary signs of these lesions as seen in acquired syphilis, which are so well known as not to

require special description here. They may occur upon any part of the body, singly or in groups.

Etiology.—Syphilis occurring in children is usually the result of a previously existing syphilis in one or both parents. The disease may be transmitted by either mother or father. If the mother be syphilitic, abortion is more likely to occur than where the disease is transmitted by the father, since not only is the ovum directly syphilized by her, but the nutrition of the embryo is interfered with by the impaired state of the parent's blood. In regard to the question whether a woman who is free from syphilis at the time of her impregnation by a healthy man, but who contracts the disease at a later period of her pregnancy, can then infect her fœtus, there is great difference of opinion. The experiments of Pellizzari go to show that the vehicles of syphilitic virus are cells, or, at all events, formed albuminous bodies. Under ordinary circumstances only the serum of the blood of the mother passes into the circulation of the fœtus, and we should not expect it to become thus infected; but the writer can see no reason why, if some syphilitic inflammation occur in the placenta, the cellular elements bearing the poison might not pass directly into the fœtus.

It seems to be a fact founded on careful observation that mothers of syphilitic children who are themselves apparently healthy do not acquire the disease from nursing and handling the children, while healthy nurses often do: the facts disclosed by modern research concerning the immunity against infections conferred by the so-called antitoxins of the blood-serum of an animal suffering from the disease, when introduced into the blood of another animal, are of interest in this connection.

Diagnosis.—In making the diagnosis of hereditary syphilis a thorough knowledge of the personal history of both parents is of importance; but in the absence of such knowledge the diagnosis can usually be made by attention to the characteristics of the lesions as they present themselves upon the child's body.

The erythematous syphilide is most apt to be mistaken for an intertrigo on account of its situation, but it differs in the fact that it extends beyond the regions which alone would be involved in intertrigo.

The bullous syphilide may be mistaken for acute pemphigus neonatorum, but it can be distinguished by the facts that the bullæ are in the palms of the hands and upon the lower part of the face, while the trunk is left almost free, and that they are often seated on an infiltrated brownish-red base and contain cloudy serum or pus.

Prognosis.—In a general way it may be said that the greater the length of time between the acquiring of syphilis by the parent and the procreation of the child, the better will be its chances for life. The date of appearance of the rash on the infant and its severity will largely determine the prognosis; thus a child born with a bullous eruption will very likely die in a few days, while one developing a roseola in the second month will probably survive.

Treatment.—The treatment of hereditary syphilis is conducted in accordance with those principles which govern the therapy of acquired syphilis in the adult, with such modifications as are demanded by the age of the patient. For a very long time efforts have been made to introduce medicaments into the nursing infant along with the mother's milk: for this purpose mercury has been administered to the mother even when she gave no evidence of the disease. Only the most minute quantity of mercury has ever been discovered in the milk under such circumstances, so that, save as an accessory form of treatment, it is not to be recommended.

The best method of administering mercury to infants is unquestionably by a modified form of inunction. The preparation best adapted for this purpose is an ointment of equal parts of unguentum hydrargyri and vaseline. A piece of this as large as a hazelnut is rubbed into the abdomen of the child night and morning, and the entire abdomen is closely covered with a white flannel binder. Once a day the abdomen should be washed with warm water and white castile soap before new ointment is applied. The same binder should be used continuously, as it becomes gradually charged with the ointment, so that it produces a constant inunction with every motion of the infant. In case the skin becomes irritated, the application may be temporarily suspended, or inunctions given in the usual way may be substituted till the binder can again be applied.

If there be lesions upon the belly which will prevent the use of the method just described, mercury should be administered by the mouth. Calomel and mercury with chalk are the preparations most used; from one-eighth to one-half grain of either preparation, made into a powder with sugar of milk, should be placed upon the infant's tongue just before it is to be nursed, three times a day. Tannate of mercury, in doses of one-twentieth to one-eighth of a grain, is prompt in its action, and is said not to be likely to cause intestinal disturbance. The bichloride of mercury has many enthusiastic advocates. One of the best methods of giving it is in the form of Van Swieten's liquid, the formula of which is—

R̄. Hydrg. bichloridi 1 part.
 Spts. rectificat. 100 parts.
 Aquæ 900 parts.—M.
 Five to ten drops of this should be given three times a day.

The administration of mercury by hypodermatic injection has been in use for many years: it gives prompt results, and the intestinal tract is not irritated as when the remedies are given *per os*. As the method partakes somewhat of the nature of a surgical operation, the parents nearly always raise objections to its employment; its use will therefore usually be confined to those cases in which the symptoms are very urgent. In the hypodermatic administration of mercury the bichloride is the most satisfactory salt, and should be given in doses of one one-hundredth to one twentieth of a grain.

The use of bichloride-of-mercury baths is of value, principally as an aid to other methods of giving the drug. Seven to thirty grains, with an equal quantity of ammonium chloride, are dissolved in some hot water, which is added to a bath consisting of eight gallons of warm water; the child should remain in the bath from five to ten minutes, and should then be warmly wrapped up; the bath may be repeated every second or third day. If no signs of weakness or loss of appetite result and the patient improves, the use of the baths may be continued.

The use of iodide of potassium is restricted to the later manifestations of hereditary syphilis, such as gummata, bony lesions, cerebral affections, eye and ear troubles, etc. When thought necessary, it may be given by itself in doses of one to five grains three times a day, freely diluted, or it may be prescribed with more benefit in combination with mercury:

R̄. Hydrg. bichloridi gr. j.
 Potass. iodidi ʒss.
 Syr. aurantii cort.
 Aquæ āā fʒij.—M.
 Sig. Five to ten drops, with plenty of water, three times a day.

Aside from the specific treatment of syphilis itself as detailed above, the general health of the child should be cared for. It should have mother's milk if possible: when this cannot be given, a young syphilitic wet-nurse should be obtained, for a healthy woman by suckling a syphilitic child exposes herself to great risks. In the absence of either one of these means of supplying nourishment, cow's milk, properly diluted to render it as nearly as possible like human milk, should be given. It will often be of the utmost importance to endeavor to assist the general nutrition by the administration of cod-liver oil, malt, and hypophosphites. If the child be anæmic, some preparation of iron will be beneficial; it may be given in the form of the saccharated carbonate, or, if mercury be administered by the mouth, the lactate of iron may be combined with it:

R. Hydrarg. chlor. mit. gr. iss.
 Ferri lactatis gr. v.
 Sacchari albi q. s.—M.
 Ft. pulv. No. x.
 Sig. One to four a day.

In whatever form mercury is given, its effect must be closely watched; upon the appearance of anæmia or intestinal trouble or general weakness it should be temporarily suspended. Even if the child be doing well it is always best to stop the drug, during the whole course of treatment, at the end of every month; after a week or so it may be again resumed. The treatment should be continued for some time after all signs of syphilis have disappeared, and the patient should then be constantly under the notice of the physician, so that at the first sign of any relapse treatment may be resumed.

In the presence of ulcerative lesions local applications should be made; after the ulcer is thoroughly cleansed with some antiseptic solution, it should be dusted with the following powder:

R. Zinci oxidi ʒij.
 Iodoformi ʒss.
 Hydrg. chlor. mit. ʒss.—M.

The ulcer, if discharging, should then be dressed with bichloride gauze, but if fairly dry unguentum vaselini plumbicum may be spread on cloth and placed over it. Condylomata and mucous patches should be frequently washed with a 2 per cent. carbolic-acid solution, thoroughly dried, and then dusted with the same powder. In some cases the use of iodoform excites a dermatitis of the surrounding skin; it should then be left out of the formula.

Affections of the mucous membranes, such as "snuffles," should be treated by douches of a 2 per cent. boric-acid solution, and any localized lesions touched with nitrate of silver in strengths appropriate to the condition.

PARASITIC AFFECTIONS.

TINEA FAVOSA.

Favus is a vegetable parasitic disease affecting the skin and its appendages. It is most common on the hairy scalp, though it occurs on the general surface, and at times attacks the nails. On the scalp the favus fungus grows in the hair-follicle, in which it gives rise to an inflammation which often spreads to the adjacent tissues. If seen in the beginning, erythematous, scaly, itching patches will be noticed; after a time the scutula develop, and these are the characteristic clinical signs of the disease. At its full development the scutulum is a sulphur-colored, cup-like mass, slightly

FIG. 3.

Achorion Schenleinii in hair-shaft and follicle (after Kaposi).

elevated above the surface of the scalp, surrounding a hair and dipping into the follicle; these cups are about an eighth of an inch in diameter. In the course of time the scutula touch each other and become fused into a grayish crust, which, firmly adhering to the base of the hairs, may cover a large portion of the scalp. The hairs in the affected area become dry and

TINEA FAVOSA

lustreless, and, as their nutrition is destroyed by the fungus, gradually fall, thus leaving irregular more or less bald areas. A peculiar odor is to be detected in those suffering from favus, which has been likened to the odor of a mouse's nest. When favus attacks the general surface, it usually commences as vesicles surrounded with inflammatory areolæ; after a time the characteristic scutula develop upon the skin. When the nails are involved a yellow spot, in reality a scutulum, may occasionally be seen at one point: more often, however, the nails become rough, dry, brittle, pitted, and gradually crumble away. When the disease has existed upon the scalp for any length of time, permanent atrophy and loss of hair result. The affection generally begins in childhood, and, untreated, may persist for years or throughout life. The subjective symptoms are limited to a slight itching.

Under the microscope the scutula are seen to be formed almost entirely of fungus.

Etiology.—All those conditions which depress the general nutrition, such as bad food, foul air, and filthy surroundings, predispose to favus. The disease exists in many of the lower animals—cats, mice, etc.—and it is likely that it is often conveyed from these to man. The cause of tinea favosa is the achorion Schœnleinii (Fig. 3), which invades the horny layers of the epidermis, the root-sheaths of the hair especially, and often the hair itself. Recently, Quincke, Unna, and others have separated the achorion Schœnleinii into several varieties: certain trifling clinical differences in favus may be accounted for by the presence of one or the other of these forms.

FIG. 4.

Achorion Schœnleinii (after Kaposi).

Microscopically, the fungus of favus is distinguished by the short and jointed appearance of the mycelia, by the rarity of the smooth-bordered mycelia, and by the great number of conidia (Fig. 4). Unna states also that the mycelia of favus grow at right angles to the strata of the horny layer of the epidermis, while in other fungi the direction is more nearly parallel.

Diagnosis.—Only in the beginning, or after the scutula have united into a large mass will the diagnosis be difficult: here it is necessary to distinguish favus from eczema, ringworm, psoriasis, seborrhœa, and lupus erythematosus. The simplest way of arriving at a definite diagnosis is by an appeal to the microscope.

Prognosis.—The prognosis must be given with care. When upon the

scalp, if the disease has been of long standing, there will be permanent loss of hair. When apparently cured it is prone to relapse.

Treatment.—Whatever method of treatment may be pursued, it must be supplemented by patience and perseverance. In recent cases the disease may yield promptly, but in those of longer duration treatment must be continued for months. If any depraved state of the general health be noted, it must receive attention. The treatment of the disease itself is purely local. First, the crust must be removed; this is best done by cutting the hair short and then saturating the scalp for a night or two with sweet oil, when the crusts may be readily scraped away with a spatula. Perhaps the most important part of treatment is epilation, as by this procedure not only are masses of the fungus actually removed with the diseased hair, but the follicle is thus opened up and more readily permits the entrance of medicaments. Epilation, if practised over a small area at a time, is not a severe operation, especially as the hairs are loosened by the disease. As soon as the hairs have been removed the following solution should be applied :

R_y. Hyd_g. bichloridi gr. ij-iv.
 Alcoholis fʒj.—M.

This solution should be mopped on the affected area once a day, and especially applied to those parts that have just been epilated.

An ointment of chrysarobin and ammoniated mercury has been useful in the hands of the writer :

R_y. Chrysarobini ʒss.
 Hydrarg. ammoniati gr. xx.
 Vaselini ʒj.—M.

Sig. Rub in well at night.

Chrysarobin is prone to excite in many persons an erysipelatous inflammation of the scalp, and its use therefore demands caution: it is best to begin with a weak ointment and gradually to increase the strength.

A great number of parasiticides have been recommended by authors, among them sulphur, tar, carbolic acid, salicylic acid, sulphurous acid, oleate of copper, various preparations of mercury, etc. It will often be found necessary to vary the use of these drugs, as they seem to lose their effect after a time.

While the diseased area is being treated with these remedies the whole scalp should be washed daily with a saturated watery solution of boric acid, the intent of this procedure being to prevent the inoculation of the fungus upon new areas. Every two or three days it will be necessary to remove the old ointment by shampooing with a liquid soap made thus :

R_y. Saponis olivæ præp., ʒij.
 Alcoholis fʒij.—M.

Sig. A tablespoonful for each shampoo.

After the treatment has been continued till all signs of the disease have disappeared, the patient should be kept under observation for several months, and at the first sign of relapse treatment should again be actively instituted.

TINEA TRICHOPHYTINA.

The trichophyton fungus grows in the skin, hair, or nails; in each situation it gives rise to such peculiar clinical phenomena as to merit a special name. As seen on the skin the disease is known as *tinea circinata*, or ring-worm of the body. The most common sites of the eruption are the exposed surfaces—the face, the neck, the hands. The first evidence of the disease is usually a small, faint red, slightly raised, scaling spot; this soon begins to spread peripherally, while at the same time healing occurs in the centre; thus there is produced a ring of small scaling papules enclosing a healthy area of skin. The border goes on enlarging till it reaches the size of a dollar, when the disease may spontaneously disappear, or remain stationary for an indefinite time. Often there are several such rings close together; as they enlarge their borders touch, and, disappearing where contact occurs, leave gyrate figures. Occasionally several rings may be found, one within the other. If the inflammation excited be severe, we may see the border composed

FIG. 5.

Trichophyton tonsurans in hair-shaft and follicle (after Kaposi).

of vesicles or pustules instead of papules. Occasionally the centre fails to clear up as the border grows, and thus plaques of reddened, somewhat thickened, scaling skin occur. Rarely the disease involves the nails, when they become rough, lustreless, and brittle.

Tinea tonsurans, or ringworm of the scalp, is almost never found in the adult, being essentially a disease of childhood. It occurs as one or more circular scaly patches, in which the stumps of broken hairs may be seen, not lying in one way, as is natural to the hair of the scalp, but pointing in all directions. The color of the affected scalp varies, in dark complexions being a dirty gray, while in blonds it is a faint red. When the hair becomes diseased, it loses its lustre and is very brittle, so that it readily breaks off. The loss of hair in

the patches is occasionally complete, and the scalp is left smooth and shining, so that the disease is indistinguishable from an alopecia areata. In a rare form of the disease, known as *tinea tonsurans disseminata*, there occur scattered over the scalp small clumps of diseased hairs. Sometimes small pustules may be seen around some of the hairs in an affected area; this resembles what occurs in a more severe form in kerion, which is an acute folliculitis, giving rise to a circumscribed, doughy swelling, studded over which may be seen the widely-gaping diseased follicles. When pressure is made upon such a swelling, a thick muco-purulent material exudes from the follicles, which have usually lost their hairs.

Ringworm of the scalp is not accompanied by subjective symptoms. Untreated it may continue indefinitely.

Etiology.—The cause of ringworm is the trichophyton fungus.¹ It is an odd fact that it attacks the scalp almost always only in children, while the general surface may be affected at any age. The fungus exists in the lower animals, and may be transferred from them to man; it grows only in the epidermic structures, and is not found in living tissues.

Diagnosis.—*Tinea circinata* must be distinguished clinically from syphilis, eczema, psoriasis, and seborrhœa. In syphilis the concomitant symptoms will generally suffice for differentiation; the border of the circinate syphilide is more sharply defined and of a darker red color than the border of ringworm; the erythematous syphilide is widely diffused and scaling is absent. In eczema the itching forms a marked feature, and the disease, as a rule, does not present the sharply-defined border of *tinea circinata*, while exudation and crusting are more marked; furthermore, when *tinea* occurs in solid plaques, so as to resemble eczema, it is often present simultaneously on the scalp. The lesions of the circinate form of psoriasis present a heavier scaling, and the disease may often be found occupying its characteristic sites on the knees and elbows. In seborrhœa the scales are thick and greasy, and on their removal patulous sebaceous ducts may be seen.

Tinea tonsurans may be confounded with alopecia areata and eczema, psoriasis, and seborrhœa affecting the scalp. In eczema the patches are not sharply limited, crusting and itching are present, and the hairs are only matted together, not broken, as in *tinea*. In psoriasis the scales are thick and abundant; the hairs are not affected; and the disease may be found elsewhere, occupying its favorite sites. Seborrhœa usually affects the whole scalp; the scales are greasy; and, though the hair is thin, no broken or twisted stumps are seen. Ordinarily *tinea* presents a very different appearance from alopecia areata with its smooth shining patches of perfectly bare scalp; in those cases of *tinea* mentioned above, which very closely resemble alopecia areata, often some affected hairs may be discovered at the border of the patches, and a microscopical examination may reveal the true nature of the disease.

In every case of *tinea* the surest way of avoiding mistakes is by a microscopical examination. Scales should be removed or hairs drawn and placed in a few drops of liquor potassæ upon a slide and covered with a cover-glass; after a few hours the scales or hairs will be rendered transparent enough to permit the fungus to be seen. The trichophyton fungus occurs as smooth-bordered branching mycelia, and as conidia, single or in chains (Fig. 5); in the hair both forms may be found in the inner root-sheath and in the substance of the hair itself.

Prognosis.—Ringworm of the body is readily curable. On the scalp it may last indefinitely unless the treatment be kept up with untiring patience and vigor.

¹ Recently Sabouraud and others have described four varieties of the trichophyton fungus.

Treatment.—The treatment of tinea circinata is purely local; it is usually readily cured. Often a few applications of tincture of iodine will suffice, or one of the following ointments may be used:

R. Acidi salicylici gr. xxx.
Sulphuris præcip. ʒj.
Vaselini ʒj.—M.

Sig. Rub into affected area once or twice daily.

R. Hydrarg. ammoniati gr. xx.
Lanolini ʒj.
Olei olivæ ℥ʒij.—M.

Sig. Apply twice a day.

R. Cupri oleatis ʒss-j.
Vaselini ʒj.—M.

Sig. Apply twice a day.

In the treatment of tinea tonsurans the entire armamentarium of the physician will sometimes be required to bring about a cure. As a preliminary step the hair should be cut short and all scales removed. Epilation, though not absolutely necessary, is no doubt of assistance, and should be practised in all inveterate cases; many advise removing the hairs from the area immediately surrounding the patch of tinea, thus hindering its spread. During the whole course of treatment the head should be washed daily with soap and water, and then sponged with a saturated solution of boric acid. In young children, the disease in the beginning will often yield to a simple ointment like the following:

R. Sulph. præcip. ʒj.
Ung. aq. rosæ ʒij.
Lanolini ʒvj.—M.

Sig. Apply twice a day.

Coster's paint may be applied to the patch with a stiff brush every four or five days, the formula of this is:

R. Iodine ʒij.
Colorless oil of wood-tar ʒv.—M.

In an epidemic recently treated, the application of a 1 per cent. aqueous solution of rosanilin hydrochlorate, rubbed in well once a day, served to check promptly the disease in its early development.

Of the mercurial preparations, the oleate and white precipitate are the most efficacious. They may be prescribed in the form of ointments varying from 2 to 5 per cent.

In the experience of the writer the most valuable drug in the treatment of chronic cases is chrysarobin. It may be used in the form of an ointment slightly modified from that recommended by Hutchinson:

R. Chrysarobini ʒss-j.
Hydrarg. ammoniati gr. xx.
Liq. carbonis detergentis ℥xx.
Lanolini ʒj.
Olei olivæ ℥ʒj.—M.

Sig. Rub in at night.

Chrysarobin must always be used with caution on account of its tendency to excite severe inflammation.

Crocker thinks highly of the use of croton oil in cases of limited extent in children over six years old; it may be used in a liniment with olive oil, 1:10, rubbed into the patch until inflammation is excited; or it may be pricked into the diseased follicle with a needle; the suppuration which the croton oil excites destroys the fungus.

Of late much has been said in favor of the employment of electric cataphoresis in the treatment of tinea tonsurans. The positive sponge electrode is saturated with a 1 per cent. solution of corrosive sublimate and applied to the patch, while the negative electrode is placed upon some other part of the body.

When the fungus has invaded only a few follicles or remains in a limited number in spite of treatment, the electric needle may be introduced and the follicle destroyed.

In kerion the hairs should be pulled and some soothing antiseptic ointment applied.

In any case of tinea tonsurans treatment is to be actively continued as long as any hair-stumps can be detected.

SCABIES.

This disease is not so common in this country as on the Continent. The lesions seen in scabies are due to the ravages of the itch mite (*acarus scabiei*). It is only the female which attacks the skin, the male merely

remaining upon the surface. The female burrows under the epithelium for the purpose of laying her eggs. She lives about two months, and lays in this time about fifty eggs, which hatch in two weeks. The itch-mite selects those parts of the skin in which to make her burrow where the epithelium is not very dense, as between the fingers, flexures of the joints, axillæ, about the genitals, etc.

The lesions found in scabies are those directly due to the presence of the mite and secondary ones due to scratching. The burrow is the most characteristic lesion. This consists of a small, fine, black, zigzag line, from one-eighth to one-half an inch long, lying just beneath the upper layers of the epidermis. It is often difficult to find the burrows, as scratching

and bathing destroy them. Sometimes the acarus may be seen lying at one end of the burrow as a small white speck.

The presence of the itch-mite excites various grades of inflammation: papules, vesicles, and pustules will be found intermingled on those parts of the body where the skin is thin and where warmth and moisture exist. In

FIG. 6.

Female *Acarus* (after Anderson).

infants in arms the face is often involved, as it is kept warm by pressure against the mother when the child nurses; the feet and buttocks may present the lesions of scabies, as they are protected by the warm clothing. Itching is severe, and we usually find various lesions as the result of scratching—scratch-marks, crusts, furuncles, and pigmentations. None of the lesions of scabies show any tendency toward grouping, but are scattered irregularly over the surface.

In severe cases nearly the whole body may be involved, while in very mild ones only a few scattered papules or vesicles may exist. If not treated, the disease may persist for years.

Etiology.—Though markedly contagious, the disease does not seem to be communicated by ordinary contact, but only by prolonged exposure, such as wearing infected garments or sleeping in infected beds. No age, sex, or social condition is exempt, but filth and infrequent bathing give the acarus a better chance by leaving its burrow undisturbed.

Diagnosis.—Scabies might be mistaken for an eczema, but eczema does

FIG. 8.

Male Acarus (after Anderson).

FIG. 7.

Larva (after Anderson).

not present such multiformity of lesions, is not apt to be so widely disseminated, and the individual elements are aggregated or grouped. The finding of the burrow, and more especially of the acarus itself, is proof positive of scabies (Figs. 6, 7, 8).

Prognosis.—The prognosis of scabies is always favorable.

Treatment.—The disease is readily cured if the treatment be properly carried out. Before any local application is given the patient should receive a hot bath, with thorough rubbing, using green soap. Probably the most generally successful remedy in the treatment of scabies is sulphur. The following ointment should be well rubbed in over all the affected parts of the body morning and evening for three days:

R_y. Sulphuris præcip. ʒiij-vj.
 Vaselini ʒvj.
 Ol. rosæ q. s.—M.

The same under-clothing and sheets should be used until the treatment is completed; then the patient takes a hot bath with soap, puts on fresh under-clothes, and sleeps between clean sheets, all that he has previously used being boiled; his outer garments should be ironed with a very hot iron.

Many other remedies have been recommended, and a few of the most useful formulæ are added :

- R_y. Styrcis liquidi f̄ʒj.
 Adipis ʒj.—M.
 Sig. Rub in twice a day.
- R_y. Sulphuris præcip. ʒj.
 Balsami Peruv. ʒss.
 Vaselini ʒj.—M.
 Sig. Rub in twice a day.

Kaposi advises the use of naphthol.

It is of the utmost importance, no matter what method of treatment may be used, to prevent reinfection by attention to the rules in regard to clothing and bedding above laid down. If, when specific treatment is completed, the skin remains inflamed and irritable, some soothing ointment should be used ; the following answers very well :

- R_y. Zinci oxidi ʒj.
 Ung. aq. rosæ ʒj.
 Lanolini ʒvj.
 Sig. Apply as often as necessary.

PEDICULOSIS.

In the children of the poor the head-louse is very common, and occasionally the pubic-louse may be found on the hairs of the eyebrow or on the

FIG. 9.
 Male *Pediculus Capitis*
 (after Kuchenmeister).

lashes. On the head the louse (Fig. 9) is most apt to confine itself to the occipital region ; here the irritation it causes, together with scratching, soon sets up a dermatitis, which may range from a few scattered pustules to a condition in which the whole region is covered by crusts and exudes a thick, sticky liquid, which mats the hair and by its decomposition gives rise to a disagreeable odor : this purulent matter may be conveyed to other parts of the body upon the fingers, and thus set up a pustular eruption. The lymph-ganglia of the neck, which communicate with the lymphatic channels of the scalp, are apt to become enlarged, tender, and in poorly-nourished children may suppurate. If the hair be long, so that it hangs upon the neck, a similar dermatitis may be caused in that region.

Whenever we find a pustular eczema confined to the occipital region of a child, we should at once look for pediculi. If these are present only in small numbers, it is often easier to discover the eggs or nits than the louse. Usually one or two nits will be attached to a single hair, though sometimes many are found upon one shaft ; they appear as small white specks firmly attached to the side of a hair. They may be mistaken for crusts, but a hair passes through the centre of a crust, and a crust may be easily brushed away, while a nit is firmly

FIG. 10.
 Nits of *Pediculus Capitis*
 (after Kaposi).

glued to the shaft. In the rare cases where the pubic louse has infested the eyebrows or lashes of a child, the most noticeable signs of its presence are the punctate hæmorrhages in the surrounding skin, caused by the bite of the insect. In these regions the pediculi and their knits may be found upon the hairs close to the skin.

Etiology.—Pediculosis is contracted by contact with a lousy person or some object containing pediculi, such as hats, caps, and other articles of clothing.

Treatment.—In children the hair should be cut short and the crusts softened with olive oil and removed. The head should then be thoroughly anointed with petroleum, the parents being warned not to allow the child to approach a lamp or fire while the coal-oil is on the hair. The petroleum, having remained on all night, should be washed off the following morning with soap and water. Two such applications, made on successive nights, will kill the pediculi, but the nits are more difficult to destroy. To remove them, in cases where the hair cannot be cut off, it should be taken up in small bunches and carefully sponged with vinegar; this softens the glue which attaches the nits to the hair-shafts, so that they may be readily removed with a fine-toothed comb.

The treatment as above detailed, if carefully carried out, will be found entirely satisfactory. If for any reason petroleum cannot be used, the following ointment may be applied for several days:

R. Hydrarg. ammoniati gr. xx.
Vasellini ℥j.—M.

Whatever method of treatment may be used, a dermatitis will still remain, which should be treated by soothing ointments.

PART XII.

DISEASES OF THE EAR.

BY B. ALEXANDER RANDALL, A. M., M. D.,

PHILADELPHIA.

THE organ of hearing is, in its normal function, one of the most important of the body, especially in the child, since it is the seat of the sense which is second to the sight only, if at all, as the link between the individual and his fellows, and through the help of which a very large part of his education is acquired and his value as a worker made available. Loss of hearing reacts sadly upon most adults in cutting them off from easy intercourse, and is very apt to engender a suspicious and discontented frame of mind; while in the child it is still more serious, since it bars, to a greater or less degree, so many channels of learning, sympathy, and practical usefulness before they have even begun to convey their wealth to the forming mind.

The diseases of the ear are of great importance, also, because of their frequency and seriousness—facts which are all too little understood or accepted—for they endanger life, as well as function, much oftener than do the more noticed lesions of the eye, which are probably little more numerous. They are far more insidious and readily overlooked in children than in adults, since complaint is rarely made of any subjective symptom except pain; and only slowly will parents generally appreciate that the alleged “slowness” or “stupidity” of children, and their habit of “asking over again,” are due to a real physical infirmity. Add to this the weighty fact that in childhood are quietly laid the foundations for most disqualifying and steadily progressive forms of deafness, which are little amenable to later treatment, and the importance becomes manifest of their recognition at the earlier period, when they can be successfully combated.

Embryologically, the organ of hearing arises in three distinct portions, the first being the otic vesicle, which forms as a pouch from the epiblastic surface, develops to form the labyrinth, and becomes distinctly nerve-tissue in part and intimately connected, by the auditory nerve, with the brain; the second is the mucous cavity, extending out and back from the pharynx in the line of the closed second branchial cleft to form the Eustachian tube and tympanic cavity, including the so-called mastoid antrum and the communicating cells; while the third portion is a cutaneous projection and pouch growing outward and in, respectively, to form the auricle and the external auditory meatus. Mesoblastic tissues remain as barriers between these parts, yet serve to link them together—the tympanum having the drumhead with the malleus separating it from the external ear, and the bony labyrinth-capsule with the membranes of the fenestra constituting the division between it and the internal ear.

Physiologically and pathologically, this distinction is maintained; the

internal ear remaining as the sound-receiving apparatus, in contrast to the conducting apparatus external to it: and disease shows that the labyrinth inclines to share in brain disorders; the tympanum remains part of the upper air-passages, involved in most of the lesions of that tract; while the external ear suffers little except from the disorders of the cutaneous surface. Clinical work, likewise, maintains the divisions thus defined, and our methods of study fall largely into the three forms of topical, pneumatic, and acoustic measures according as the external, middle, or internal ear is aimed at. Treatment of the aural disorders is principally on the same lines; and, in spite of the incompleteness of the demarcation in some instances, this forms the most natural and advantageous division of our subject.

In the study and treatment of the ear in children some care is generally requisite as to the holding of the patient. If small, he is usually best held in the lap of an adult, as the mother, with head resting upon her breast and the ear to be examined turned toward the physician. One arm passes around the child's waist from behind and holds the hands, while the other is ready to steady the head or meet any other requirement. Some throwing back and twisting of the head may be expected; but the physician's hand in drawing and holding the auricle outward, backward, and down or up, as the configuration of the parts may demand, can take points of counter-pressure for his hand upon the child's head and do much to steady it. In mopping and other manipulations the movements of the child should be followed as closely as possible, especially if the ear is painful, for much roughness and restraint may be thus avoided. The active struggles and screaming of a child cease most acceptably in many instances as the applicator actually enters the ear, and perfect quiet is maintained until it is withdrawn, as though the child, in anticipation of something awful, were reserving its powers to do justice to the occasion. With older children quiet can often be obtained by allowing them to *stand* or sit free, while the examination is directed first to the unaffected ear, the nose, and the throat, and they are plied with questions, jesting as well as serious. Moderate stillness yielded spontaneously is generally better than that which can be enforced by the efforts of three or four strong adults, and considerable patience in winning confidence and obedience will usually prove good policy; but if restraint has to be enforced, it should be as overwhelming as possible, so as to demonstrate the futility of resistance and the real gentleness of the treatment, for it is generally fright or wilfulness, rather than pain, that is the disturbing element. Facility in the measures of examination and treatment, especially without instrumental aids, counts for a great deal, since every speculum, tongue-depressor, or other instrument may be an object of terror as well as a probable source of discomfort. The unaided view into a canal may be restricted and incomplete, yet if the light spot can be seen and no redness is visible along the handle of the malleus, tympanic inflammation may be excluded: and flakes of epidermis, etc. along the walls may then be let alone, which would be pushed up before a speculum and require removal before any view could be obtained.

AFFECTIONS OF THE EXTERNAL EAR.

The external ear, although tangible and prominent, is far less important for our consideration than the middle, and furnishes hardly 25 per cent. of aural work; and the labyrinth suffers so rarely that less than 10 per cent. of ear diseases affect it, leaving the mucous membrane of the tympanum to bear the responsibility of quite two-thirds of all aural disorders. Yet access to the

deeper structures is partly through the auditory canal, and the disorders and study of this portion may best be first considered.

The auricle, as a skin-covered projection of fibro-cartilage, is open to ready inspection and palpation for its study, and its position exposes it to trauma as well as to various cutaneous affections. Its *congenital malformations* of distortion, reduplication, or defect are of interest rather as curiosities than as pathological conditions, and, except for appearance' sake, rarely concern the aural surgeon. Supernumerary auricles or auricular appendages may be removed if conspicuous; the persistence of the branchial cleft, as the so-called "aural fistula," may call for a tiny plastic operation to close it; huge auricles may be brought to more reasonable dimensions by the excision of a wedge-shaped segment, or very prominent auricles may be fastened more closely in by excising a crescentic flap behind them. These are mere matters of surgical common sense. Minuteness of the auricle or absence, congenital or traumatic, may tempt the surgeon to plastic efforts; but it must be remembered that without cartilaginous framework any semblance of an auricle is quite hopeless, and that transplanting of cartilage, except from the adjacent meatus, has always proven a failure. Upon the hearing, these conditions are practically without influence, and any rash experimentation is unjustifiable.

The habit of piercing the ears for ear-rings is responsible for some of the lesions of the auricle, aside from the tearing of the lobules from traction upon them; for the services of an itinerant vender of ear-rings are sometimes followed by a surprising group of cases of abscess of the lobule, apparently affecting in a neighborhood every little girl who had not previously been subjected to the rather barbarous custom. Although usually limited and without diffused infection, these abscesses deserve some surgical care, for their healing may be slow and disfiguring. The infiltration may be of less passing nature, and there may result a fibroid or so-called keloid tumor, which tends to grow rather persistently and to recur after removal. These are rather uncommon, except in the negro. The malignant tumors are too rare, even in adult life, to demand notice. Dermoid cysts, probably congenital, may occur in the sulcus behind the auricle, and cyst-like perichondritic effusions or hæmatomata may fill the concavities of its anterior aspect as the result of trauma.

The *inflammatory lesions* of the auricle are almost always of an eczematous character. *Herpes* is rarely met and hardly distinguished with certainty, except by the occurrence of severe pain for hours or days before the visible lesions. True *erysipelas* is very rare, though not infrequently simulated by a severe eczema. *Specific lesions* may take almost any form, though generally pustular or rupial.

ECZEMATOUS INFLAMMATIONS.—These are usually secondary to some irritant, such as an excoriating purulent discharge from the tympanum; and the main measure of treatment is protection from the cause, which should be removed if possible. The eczema is generally marked in the furrow back of the auricle, where fissuring may be deep and inveterate, and cicatrization may bind the auricle tightly down upon the mastoid; but fissures of the lobule and intertragus notch may be deep and disfiguring. The dyscrasia, conveniently though vaguely termed "strumous," is apt to underlie and strongly influence the condition; and similar lesions of eyelids, nares, and lip are apt to be present, with swelling or suppuration of the adjacent glands. For its cure eczema often demands long, varied, and laborious treatment. Internally such tonics as cod-liver oil, hypophosphites, and iodide of iron are called for, with close attention to the hygienic surroundings. The diet must be regulated, the perversions of appetite, which have often been encouraged by giving cakes

and candy to still the fretful child, must be corrected, tea, coffee, and other inappropriate food forbidden, and simple but generous nourishment given. Locally, cleansing to the verge of meddling is called for as often as the lesions become crusted, since healing is generally tardy or absent beneath the inspissated discharge. Alkaline solutions or peroxide of hydrogen will soften the crusts and permit their removal with little violence, and while all rude handling is detrimental, it is generally less so than permitting the pathological tissue to remain bathed in pus and protected from medication beneath its incrustation. Any of the many lauded measures may prove promptly successful or largely futile, but a routine treatment, with a bland calomel ointment (gr.xx-xl, ad vaseline ʒj), has usually served me excellently. In the very moist forms free painting with silver nitrate may make a better beginning, and drying powders, such as boric acid, may be used on the eczema, as well as in the suppurating tympanum from which the irritation has often proceeded. The ichthyol ointment has decided value in reducing the swollen lymph-glands, and may be well used upon the infiltrated aural surfaces, especially after visible lesions are about gone, yet there remains a rigidity, which is often a useful diagnostic sign.

FURUNCLE.—Circumscribed inflammation of the external canal is less common in children than in adults, who are more inclined to scratch the irritated and itching surfaces caused by eczema. Yet it is met at times, as is a similar lesion of the auricle. Its painfulness raises its importance beyond anything due to its influence upon the function, although it may close the canal by swelling in a way to muffle hearing and to conceal and possibly seriously obstruct a deeper suppuration. Diagnosis may remain uncertain, and call for treatment as though a tympanic lesion were certainly present. Cleansing with hydrogen peroxide, rubbing in of a salve of the yellow oxide of mercury, and firm pressure by a conical cotton pledget, will generally secure prompt resolution; but sometimes this cannot be borne, and must be substituted by the rather agreeable and pain-relieving hot douche. The poultice or moist warmth in any form is to be deprecated, and the warmth or actual heat furnished by a salt-bag or hot-water bottle must be relieved of any macerating effect by the thorough drying of the ear after douching. No single measure is as valuable in aural treatment as this hot douche, serving as it does to clean away secretion, to reduce swelling by relieving stasis, and to soothe the pain; and it is as applicable to the acute tympanic inflammation as it is to the external suppuration of the canal, and is especially appropriate in the mixed cases. Any sort of syringe, gently used, will serve, the bulb and nozzle of soft rubber being often best; but a medicine-dropper or a teapot will do nearly as well, and the temperature should be as high as the patient can be induced to bear. Careful use of the cotton-carrier, under illumination by the forehead mirror, should follow, if possible, in order to remove the moisture, to press out secretion from any open furuncle, to disclose and possibly dislodge any cerumen mass or unsuspected foreign body (recent or long present) which may be hidden beyond the swelling, and, as a probe, to demonstrate the most swollen and tender point as a preliminary to incision. It can also seek for uncovered bone beneath a discharging opening; for it must not be forgotten that the furuncle may lead to caries of the wall of the canal; and, still more important, that burrowing of pus from deeper localities, in antrum or attic, may appear externally as furuncle-like lesions. The knife may shorten treatment and is indicated to release pus, but, without prejudice to the result, it can often be dispensed with, to the patient's great mental relief. When used, the smaller and sharper the blade the better, a cataract knife-needle being admirably suited to this and similar incisions, which may be almost painless when pointing is well marked. A

series of furuncles is to be expected, and prognosis and treatment given accordingly. Whether to be ascribed to dyscrasia and demanding tonics, or regarded as a matter of microbic auto-inoculation to be combated by rigid antisepsis, both local and general measures are indicated to forestall or control this tendency.

CERUMEN IMPACTION.—This is also much less common in the child than in later life, associated as it so often is with a chronic tympanic catarrh. It is almost invariably a sign of lessened, not increased, secretion of wax, with change in its consistency, so that it tends to mass in dark scales or lumps instead of passing constantly out in tiny, light, unnoticed flakes. Those who suffer are often victims of misplaced efforts at cleanliness, for Nature is given no chance to displace the material as it forms, but meddling attempts to hasten the process push back and pack inward the emerging masses. The epithelium seems to grow most rapidly at the centre of the drumhead, and to tend to push outward from this point to the margins and then along the meatus walls; so an outward march of the lining skin and all that rests upon it is generally discernible, the slow progress of which is aided, as the exit is approached, by the movements of the jaw. Many have probably felt at times a little tickling in the ear, and found that a wax-flake had been ejected by the spring of hairs upon which it had been pressed. The movements of the auricle, also, whether accidental or by its own muscles, serve to dislodge any clinging masses. Formed, as the cerumen is, only in the outer two-thirds of the canal, it can only by interference be pressed into the deeper parts, although the epidermal débris which serves to increase the collection can arise in the neighborhood of the tympanic membrane. So long as the mass does not absolutely occlude the canal, sound-waves may pass through an invisible crevice and the hearing remain perfect; but the hygroscopic mass can easily swell, if only through atmospheric moisture, and thus give rise to sudden deafness. If there has been displacement of the mass, as in the movements of the head upon the pillow, pressure upon the drumhead or other sensitive point may also be suddenly caused, with most varied and possibly severe, reflex attacks of vertigo, coughing, or symptoms of more remote and inexplicable character. The unsuspected presence of these masses should never be forgotten, and both ears looked into, not only in aural patients, but in all nasal and many other obscure cases.

Treatment.—This consists in syringing away the collection with hot water. Previous instillations of oil or glycerin are to be deprecated as rarely useful and not always harmless; and medicinal additions to the syringing fluid do little, if anything, to increase its efficiency. Plain water is about as good a solvent of cerumen as can be found, and its value increases with its temperature. At the same time, the dizziness or faintness which syringing oftener than other aural manipulations is apt to cause is less probable or severe if the fluid be warm. The water must be thrown with well-controlled and well-directed force; so the canal must be straightened by traction, illuminated with the forehead mirror, and the stream directed along one wall, especially up and back, in the attempt to insinuate it beside the mass. The syringe is to be emptied with gently increasing force, and after the first ounce or so, the fluid ought to be stained with dissolved cerumen, the softened lumps should follow, and soon the residual mass, softened and reduced in size, appears in the exit, and may be hastened out, if it clings there, by a touch of the probe. If fair employment of the syringe has not been thus successful, with good illumination and a steady hand the mass may be touched with a probe, such as the cotton-carrier, and gently loosened, when the syringing will probably succeed. When the epidermal element is large and the solubility correspondingly small, considerable instru-

mentation may be needful; but it takes a skilful hand to employ forceps or curette safely or effectively. A small sharp spoon is a most useful instrument, for with it a channel can be excavated in the centre or side of the mass, portions displaced so as to be easily grasped and withdrawn by the forceps, or the whole engaged and adroitly extracted. Yet it is decidedly dangerous, and the

FIG. 1.

The Aural Syringe in Use.

blunt ear-spoons more so than the sharp ones, since the operator is apt to presume upon the supposed innocuous character of the former. First and last, and often between-times, the syringing is to be relied upon as the really appropriate measure; and, well used, it will rarely need much help in securing complete removal of impacted cerumen at the first sitting. On clearing the canal some congestion of the walls and drumhead is usually seen, with excoriation, perhaps, if the pressure of the mass has been ill borne or the manipulation rough in removal. The canal should be gently dried with absorbent cotton on the cotton-carrier, any excoriated surfaces lightly dusted with boric acid, and the exit filled with a flake of cotton in order to exclude the dust and too rapid movement of the air. A repeated visit should be called for, to make sure of prompt restoration to normal; while any tympanic catarrh should be appropriately treated at the first as well as later visits.

FOREIGN BODIES in the auditory canal owe their importance almost solely to the utter misapprehension with which they are regarded and the maltreatment to which the ear is often subjected on their account. They are rare, and generally of no importance if let alone; but the panic with which they are frequently regarded by patient and parent is too often fostered by the almost breathless haste with which the physician undertakes heroically to remove them.

Placed in the canal with little pressure, kept in place often only by the force of gravity, the foreign body may be ready to fall out spontaneously as soon as the ear is directed downward so as to permit it. Shaking or jarring of the head may greatly aid this, and rotary rubbing in front of the tragus will often serve to coax an intruder out. The jaw condyle presses upon the canal and narrows it, so the mouth should hang open, and the meatus should be drawn outward and back to straighten it. The syringe, with warm water, is the proper instrument for the removal of the great majority of foreign bodies, not excepting seeds and such bodies as will swell if long soaked. Swelling of the canal-walls through irritation or injury in rash attempts at removal may preclude prompt success by this means: if so, the hot irrigation will be of value to reduce it. The canal may be dried with absorbent cotton and the body dehydrated with alcohol or glycerin if maceration or germination is feared, a drying powder, such as boric acid, dusted in, and, unless urgent symptoms should arise, further intervention delayed until a more favorable occasion. It is important, however, to preface any attempt with an explanation of the intention to do only a limited amount of intervention because of the danger of overdoing; for this will come with better grace and find readier acceptance *before* a non-success. The temperature and general condition must be closely watched if expectancy is attempted and brain-symptoms looked for; but if great violence has been done, delay is both safe and advisable. Nearly half of the foreign bodies noted as found in our clinics have been present longer or shorter times without the knowledge of patient or friends.

Accurate diagnosis is of course a prerequisite to any intervention, and this will, as usual, be much aided by inspection of the fellow-ear. Thus we can learn the probable size and form of the canal, the pre-existence of eczema or other irritation which may have led to the introduction of the foreign body, and other valuable points. Not very infrequently a foreign body is really present in the fellow-ear, either because one has been placed in each ear, or because, in the panic over the case, its true location has been forgotten. The cases are far too numerous where harsh or destructive efforts at extraction have been blindly made in the wrong ear or in one from which the intruder had already fallen out. The presence and the nature of a mass to be removed must, therefore, be decided, although in some instances blood or swelling in a maltreated ear may preclude certainty of diagnosis. The hearing should be tested by speaking or whispering questions or commands into each ear, better with the other one closed with a finger-tip; since retention of good hearing is of good omen as to the incompleteness of impaction and the uninjured condition of the tym-

Fig. 2.

panum—points of great prognostic importance. The syringe should be used gently at first, and so directed as to seek a passage past the body if visible and localized, the upper back wall of the canal being generally the best along which to throw the stream. Much ingenuity has been wasted in trying to float up with mercury a foreign body too heavy to be readily lifted by the stream of water, when the mere inclining the ear downward while syringing would have far more effectually enlisted the aid of gravity. This position is awkward and need not be attempted at first, until syringing has been vainly tried in the ordinary fashion. Here, as in all syringing, work under good illumination with the forehead mirror is strongly advisable; for syringing may wholly fail when blindly used, though perfectly

competent if intelligently employed, and the well-straightened canal is as necessary for success as in inspection. When well seen, yet immovable by a strong and well-directed stream of water, a gentle touch of the probe may do good service, if the patient is quiet and tractable; for much may thus be learned as to the impaction, and perhaps the body rotated into better position or disengaged.

If space beside the body can be seen and vigorous syringing has failed to move it, a delicate wire-loop may be passed beyond it and serve as an efficient yet gentle tractor. But all use of instruments is dangerous, even in hands well accustomed to precisely these manœuvres, and should rarely be attempted except under ether, and then with great caution. Almost no form of forceps is to be commended, since they are apt to injure the walls and push the body deeper in the attempt to grasp it; and slipping, as they so often will, even when fairly and firmly placed, they are almost sure to drive the intruder deeper. Yet some wholly unsuitable pair of forceps, thrust into the canal of an unanæsthetized and struggling child, on the mere suspicion of a foreign body, without aid of illumination, is rather generally the first resort of the practitioner who has little experience in aural work, and scarcely enough knowledge of the anatomy not to share the "lay" fear that the body, unless removed at any cost, may work its own way into the brain. The risk of brain lesion is indeed great when the ear is subjected to such an attack, for there may be no foreign body there to be encountered, and the ossicles or any other normal structures may fall victims to the heroic resolve not to retire empty-handed. If present, the body will probably be driven through the drum-head into the tympanum, with more or less destruction of the ossicles; and the numerous fatal results on record give ghastly but incomplete evidence of the seriousness of the situation. If such an impaction in the tympanum has occurred, and the air-douches through the Eustachian tube and syringing through the meatus both fail, little place remains for expectancy or gentle measures. Only in cases with no fever or disquieting symptoms can the brush of glue be allowed to attach itself to the mass, or delicate skilful traction by instruments be tried in the effort to dislodge the body. It is actually safer and simpler to dissect the auricle and cartilaginous canal forward, and work with free view in the short, broad bony canal, chiselling away the upper back wall if greater space is needed, than to do unknown and more serious damage to the deeper structures in the effort to work through the natural passage. The fact that this operation has not been more often done since it was proposed argues little for the manual skill of aural and other surgeons, and much against their wisdom and judgment.

CARIES OF THE WALL OF THE AUDITORY CANAL may occur apparently idiosyncratically, and cause much enlargement through loss of tissue. The granulation tissue formed is sometimes redundant, and the healing process may cause fibrous stenosis or division of the canal by a membranous septum across it. Bony outgrowths may also arise, congenital, perhaps, in origin, yet increasing later, and may narrow and close the canal.

CONGENITAL ATRESIA, or defect of the meatus, may be met, with or without malformation of the auricle. Operation may, with difficulty, secure patency in cases where the closure is by soft tissues; but the formation or freeing of a canal closed by bone is a serious and often unsuccessful measure. Good bone-conduction must be present as evidence of a useful labyrinth; and the hearing by way of the Eustachian tubes may be as good as the case admits of; so these passages are to be kept in as open a condition as possible. The proper location of the auditory canal is to be determined by the mastoid process,

for the auricle may be widely displaced; and as absence of the tympanum may render nugatory all efforts, drilling or such procedures can be attempted only with great caution.

AFFECTIONS OF THE MIDDLE EAR.

Inflammation of the Middle Ear, arising, as it generally does, from a nasal origin by way of the Eustachian tube, may involve any or all portions of the tract, from the pharyngeal mouth of the tube to the remotest cells of the mastoid. It is readily distinguished into acute and chronic, with a few intermediate forms, and the types of catarrhal and suppurative, which are distinct and strongly contrasting in the chronic inflammations, are with less certainty distinguishable in the acute. Localized subdivisions can be made, *a fortiori*, as the brunt of the attack falls on the tube, drumhead, or mastoid, or the disease tends to cling there, as salpingitis, myringitis, or mastoid periostitis, etc.; yet such nomenclature can be strictly applied in few cases, and rarely with profit, especially if taken to mean that adjacent parts are free from implication. The gravity of all the severer middle-ear inflammations lies in the facts of the proximity of very important structures like the labyrinth, the meninges, and the great blood-vessels, and that to a large extent the lining mucous membrane is practically the periosteum, and readily causes the dependent bone to share its inflammation or its destruction. What would elsewhere in the air-passages be a mere superficial mucous ulcer may here lay bare the bone to carious or necrotic process. The intricacy of the tract also hampers the escape of the secretions and degenerated products; and retention of these maintains and increases the disease at the focus, often gives rise to most excruciating suffering, and may lead to penetration of septic material in most dangerous directions.

ACUTE SIMPLE INFLAMMATION OF THE MIDDLE EAR.—This usually originates in a coryza by an extension of the process up the Eustachian tube; for as this entire tract is essentially a part of the upper-air passages, its involvement is as natural as that of the pharynx. Bathing, especially in the surf, with penetration of the water into the naso-pharynx and tubes, is responsible for many cases, some of which are ascribed to the action of the cold water in the external canal; and the improper use of the nasal douche or syringe is fairly blamed for a further series of cases, sometimes disastrous. Intranasal surgery has not infrequently such a sequence, and all too often the aural inflammation takes on the suppurative character. All of the exanthemata, including typhoid, are very apt to give rise to it, and its symptoms are likely to be ascribed to the general condition or be masked by it; so routine investigation of the ears is called for in such cases. The prime symptom is usually earache; and the prevalent error of regarding this as an entity instead of a symptom, and combating it by narcotics instilled into the ear, instead of striking at the underlying inflammation, is responsible for many unhappy results. Neuralgias of the ear are rare, and while points of reflex irritation may be suspected and sought in teeth, tonsils, and other neighboring structures, it is only after careful investigation, proving the uninfamed condition of the aural tract, that a painful condition should be set down as otalgia. Usually in children some fever is present, there is tenderness elicited by pressure on the tragus or traction on the auricle, and inspection will show a congested and perhaps distended condition of the drumhead.

It is important here to correct misapprehensions as to the drum-membrane in childhood, which have been fostered by some of the authorities.

The tympanic membrane and the annulus in which it is set are upon the sur-

face of the skull in infancy, open to view when the soft structures have been removed, and revealing the nearly horizontal inclination of the drumhead: hence the impressions that the tympanic membrane is more superficial and more horizontal in infancy. Neither is true; for the canal is about thirty millimetres long, as in the adult, with a membranous portion where the tympanic scroll later forms the bony canal; and removal of the bony canal in adults shows that

FIG. 3.

Schematic Vertical Section of Adult Ear, showing direction of the auditory canal and the length of the bony portion.

the two drumheads maintain identically the same inclination to each other as in infants. Much as is the growth of the temporal bones and their separation by the occipital, the plane of the tympanic membrane, like its size, is unaltered after birth. An anatomical point which lends color to the error has much practical importance. The direction of the adult canal is upward as it passes inward, while the auricle falls downward and forward, and must be drawn up and back to straighten the cartilaginous portion (Fig. 3). In infancy the auricle is above the tympanum, and the flaccid canal is pressed against the upward-curving surface of the squama, and can be straightened only by drawing it down and out (Fig. 4). Long, narrow, and readily collapsing, the infant meatus gives but a poor view of the drumhead, even when correctly straightened; and the distinction between back wall and drum-membrane is unrecognized, unless shown by the normal coloration. In an inflamed ear the practised eye is often puzzled to find landmarks or make a certain diagnosis, and one less expert is apt to make insufficient attempt to discern details—too soon discouraged because the picture is not unmistakable. Yet the triangular light spot on the lower anterior portion of the drumhead ought to be visible in every healthy ear, and from its absence or alteration valuable data can be easily obtained as to the position and surface. The malleus handle ought to be distinguishable, and any congestion will show first and last in the plexus along its posterior margin. Distention of the tympanic membrane generally shows up and back, and the color indicates the character of the collection, being generally greenish if filled with serum or mucus—yellowish, if purulent; while the thinness of the sac usually reveals whether only a bleb or the whole thickness is protruded. Inflation of the tympanum, if successfully accomplished, generally alters the appearances; thus giving evidence of the patency of the Eustachian tube and a new view of the

the two drumheads maintain identically the same inclination to each other as in infants. Much as is the growth of the temporal bones and their separation by the occipital, the plane of the tympanic membrane, like its size, is unaltered after birth. tympanic condition, with a clear surface line to the contained fluid, perhaps, or bubbles moving in it. The pneumatic speculum may do similar service in clearing obscure details, whether inflation succeeds or fails.

Congestion, serous exudation, and hypersecretion of mucus are the usual stages of the affection; and imperfect drainage by the Eustachian tube constitutes a cause for retention and pressure. In the absence of septic infection and consequent suppuration, there is little danger, except to the hearing, in adults; but with children the barriers are too thin and imperfect to protect the meninges and other important structures from involvement, and most severe brain-symptoms, which are not always merely reflex, may arise in cases where the collection is simply mucus. Stupor, hemiplegia, convulsions, opisthotonos, and other indications of meningeal or cerebral inflammation may occur, with little to direct attention to the ear; and marvellous improvement may be gained, as though by magic, from relief of the pressure, either by freeing the Eustachian tube or by incising the tense drumhead. For diagnosis, as well as treatment, therefore, the nares should be sprayed free of any mucus, the pharynx vault and tube-mouths mopped with the curved cotton-carrier passed above the velum, and the inflation tried with the Politzer bag. If no voluntary aid be given by the child in puffing out the cheeks, saying "Huck," or swallowing, a cry will often be as helpful; and often the short, wide, flaccid tube opens readily without special assistance. A quick, spontaneous movement of the hand to the ear will often tell of the passage of air to the tympanum; and as this may be painful, its first employment should be gentle, with force increased when needed. No harm is likely to result, even should the increased pressure cause rupture of the tympanic membrane, for this can happen only when it is about to occur spontaneously.

Exit of the secretion by its normal drainage-channel may be impossible because of tubal swelling or from the tenacious character of the mucus, and incision of the drumhead may be demanded in order to give relief. This should be a simple and harmless measure, yet its pain is often severe enough to forbid its needless performance. It may cause injury to the stapes or the inner tympanic wall if done with a stab, and has been known to open the head of the jugular; and it may convert a non-suppurating into a septic inflammation if all the requirements of asepsis are not secured and maintained. It must be done, of course, under good illumination, and should generally be preceded by delicate use of the probe in order to let touch assist sight in getting the true relations. The most protruded portion of the membrane should usually be chosen, and the needle-point inserted for a distinct cutting motion, avoiding any contact with the ossicles or inner wall. The oblique position of the drumhead must be clearly borne in mind, and a hand skilled in aural procedures is generally requisite. Inflation of the tympanum should follow, if possible; and hot syringing of the canal will remove the blood and evacuated secretion, allay the pain, and serve to favorably stimulate the inflamed tissues and inaugurate resolution. The canal should then be gently dried and protected by a flake of cotton or wool, and a pad of the same laid on outside in unfavorable weather. The same result can commonly be gained without incision, and, unless the symptoms are urgent, the little operation had better be delayed. The hot syringing can impress the tympanum, controlling the pain and other symptoms, about as fully and favorably with the drumhead intact. Nasal treatment, aided by the shrinking effect of cocaine, can generally free the Eustachian tube and fairly maintain its patency; and dry heat, as by a hot-water bottle, can increase the comfort and further the cure. The hot douching should be frequently employed, and if drying be done with reasonable care, no undue mace-

ration need be feared. Greatly distended drumheads can thus be brought back to normal condition with perhaps greater safety and promptness than by more radical intervention.

The habit of treating "earache" by instilling sedatives is not to be commended. Any fluid introduced should be warm, and is efficient in proportion to its heat rather than to its ingredients. A tincture, such as laudanum, is apt to be irritating; oils and glycerin are more apt to harm than help; and cocaine, except in strong solution, has less value than atropine or morphine. More than would be a full dose by the mouth had better not be instilled, lest it find penetration and cause poisoning. Poultices are apt to macerate, and are generally inferior, in convenience and directness of application, to hot douching or fomentations. They should be used very hot, if at all, and removed before they have cooled to the body temperature. They are so liable to improper use that their employment is not to be commended. Leeching is advisable only during the rise or acme of the inflammation, and is rarely well borne by children. As it is generally impossible to determine at first whether the acute tympanic inflammation will prove suppurative and serious, the prognosis should be guarded and the treatment include rest in bed, with regulated diet and anti-febrile medication—matters easier to regulate in children than in adults. After improvement has begun, protection against renewed or increased cold-taking is still very important, and covering of the ear-region is advisable in inclement weather. Tonics and alteratives may be necessary as well as advisable—cod-liver oil probably serving better than almost any other. Chloride of ammonium and syrup of iodide of iron are each very useful in its place. Quinine, which is often taken to "break up a cold," has been vigorously condemned by some aurists because it stimulates the circulation in the ears as well as elsewhere. Yet stasis is worse than active congestion, and the facts by no means fully support the contention as to its counter-indication.

One form or phase of acute tympanic inflammation deserves a word in passing. The most inflamed and distended portion of the drumhead is sometimes its upper flaccid portion, especially the part above the short process of the malleus. This indicates collection in the upper tympanic cavity, or attic, and the rather isolated pouches of this region, largely independent of the condition elsewhere. Rupture may give exit to a single drop of fluid with relief and prompt resolution; but the perforation may remain as a pinhole opening—the so-called "foramen of Rivinus"—claimed to be a congenital defect of development, although less often seen in children than in adults.

ACUTE SUPPURATIVE INFLAMMATION OF THE MIDDLE EAR differs little from the catarrhal form in its onset, although apt to be more severe in its febrile and painful symptoms. It is specially characterized by the rupture of the drumhead and more persistent flow of secretion, which generally contains pus and the pyogenic bacteria. The perforation is less often the mere pushing apart of the tissues, although frequently assuming a pouting, nipple-like form, for there is generally some loss of substance; and in the cases due to scarlatina and diphtheria the destruction of the membrane may rapidly be extensive or total. Ulceration of the inner surface of the drumhead is only one indication of the destructive influence of the inflammation or its products; and as the attic and antrum are generally involved, as well as the tympanum proper, the dangers to meninges, blood-vessels, and mastoid are real and great. Paracentesis may be promptly called for, either to make or enlarge an opening, if the symptoms point to retention of secretion; and the temperature should be carefully watched for evidence of extension or exacerbation of inflammation. Tenderness of the mastoid and other neighboring parts is to be frequently sought;

and it, with or without swelling, redness, or oedema, calls for redoubled precautions. The position of the auricle should be critically compared with that

FIG. 5.

Swelling of the Mastoid Region, pushing the auricle out and forward.

of the other side, especially by study from directly behind the head (Fig. 5), for displacement is almost invariably present if there be any surface involvement of the temporal. The size and form of the auditory canal should be noted, so as to detect any bagging, especially of the upper back wall, by retained secretion. The position of the perforation is probably of small importance, unless it be in the flaccid membrane, as an indication of suppuration partly or wholly isolated in the cavities of the attic; and its form depends principally on its size. The opening at the apex of a pouting, nipple-like protrusion has importance, however, since it is in itself an evidence of incomplete relief of pressure, is rather prone to clogging, and serves as a valve to exclude all medicinal applications. It may readily be mistaken for a polyp, and attacked with the snare; and while this, used only to cut, is not

very bad as a method of enlarging the pin-hole opening, any traction may be very injurious.

Incision should be free, and maintained, if made at all; for it has a tendency to heal quickly, and even close what little exit was present. Dilatation with a conical pledget is generally better, if practicable. The distinctly unfavorable meaning which the pouting perforation has in adults does not obtain in children; although the muco-purulent secretion, which is its usual concomitant, is in youth almost as dangerous as the more destructive pus. It is most often in such cases that the use of dry boric powder has been charged with dangerous sequences, and caution is necessary, although its contra-indication is not proven. A standing rule may be made for all insufflations, that free use of insoluble powder always brings danger of clogging the outflow; and boric acid is but slightly soluble in mucus. Hot douches are more valuable in these than most cases, since the heat can penetrate to the inflamed tissues when drugs cannot, and the effect upon actual or imminent involvement of the mastoid cells may be most valuable and grateful. In other respects the treatment is much the same as that in catarrhal inflammation—the naso-pharyngeal spraying and mopping, Politzer inflation after such cleansing, and the syringing through the canal for the maintenance of the utmost possible cleanliness of the tympanum. A course of several weeks is usual, and early cessation of the discharge is to be looked upon with suspicion, and evidences of retention carefully sought. The hearing may be much impaired, to improve but slowly; and the termination of the discharge may leave the auditory apparatus unduly dry and stiff, with a temporary decline of the hearing in consequence. It is best to prognosticate this, for patients often retain the old idea that it is dangerous to check all such flows, and may be alarmed or discouraged.

CHRONIC SUPPURATION OF THE MIDDLE EAR.—This condition is almost always the result of a neglected acute attack, although debility may invalidate

the very best treatment and cause the maintenance or recurrence of the condition. Its symptoms are often inconspicuous, and neglect is quite frequent, especially under the impression that "it will get well of itself." Histories in such matters are apt to be wholly untrustworthy, and perforations, cicatrices, losses of the bony parts, massive chalk deposits, or collections of exfoliated epithelium or inspissated discharge may be present in one or both ears which are declared to have been always sound. A tuberculous affection is occasionally insidious and painless in its onset, and may be characterized by multiple perforations, which probably represent broken-down tubercles of the drum-membrane. The exanthemata are responsible for a large number of cases, sometimes following doubtful or unrecognized attacks; while more often the illness of the patient masks the ear disease or overshadows it in apparent importance. The spontaneous cure for which many physicians look, as well as the laity, is often obtained, but may prove temporary and incomplete; and treatment is called for in all cases as lessening the danger to hearing and life, mitigating the annoyance to patient and companions due to the discharge, and tending to hasten and complete the cure.

The character of the discharge deserves attention. If fetid, it tells of retention and neglect; if bloody, polypoid growths are probably present; if ichorous, search should be scrupulously made for dead bone; if stringy from mucous admixture, subacute involvement of the antrum and mastoid cells is probable, and a slow, obstinate case may be anticipated. As cleanliness is the prime factor in restraining evil tendencies and securing resolution, the character and source are noteworthy as bearing on the means required to remove secretion. The syringe remains the best cleanser here, and the heat which its fluid can so well convey can have efficacy little short of that in the acute conditions. Frequently, isolated cavities, into which ordinary syringing hardly penetrates, need cleansing, and intratympanic injections are needed. A steady hand can make these in a quiet patient with almost any long, fine canula introduced, under good light, to the precise point requiring it; but where these requisites are lacking, the auditory canal should be filled with fluid—best the peroxide of hydrogen—and pressure exercised by finger-tip or Politzer bag to force it into every opening; and it can often be thus carried down into the pharynx. In some obstinate cases syringing through the Eustachian catheter proves very efficient, though this cannot so often be used in children. Drying should follow cleansing, and all epidermal flakes or similar material removed as perfectly as possible, even to the verge of meddling. It is never safe to form a diagnosis of the precise condition until the whole accessible tract has been studied by the eye, and perhaps with the probe. Polyp masses or other protrusions often show most characteristically when standing out as reddish islands, surrounded by whitish pus; so study before cleansing is important: and many conditions need probing for their comprehension, for which the cotton-carrier, guarded with a tip of cotton of appropriate size, is best adapted. In seeking for bare bone and roughnesses, the fibres catch upon these, and may not only reveal but remove them. The mopping is an excellent means of cleansing, independent of syringing, and should always follow it to remove the remaining fluid. It also affords valuable instruction and practice in aural, and especially intratympanic, manipulation, preparing the physician for the more delicate measures, such as paracentesis. Often a flake of cerumen-like material clings closely to some part of the wall or fundus, and its removal is requisite in order to learn whether or not a sinus or other lesion lurks beneath. These leathery crusts are common near the short process, and frequently indicate an attic inflammation, with a perforation in the flaccid membrane, and all too often carries of ossicles or adja-

cent walls. Backward, too, there may be an opening into the antrum or its communicating cells sometimes with polypoid granulations surrounding it.

“Polyp of the ear” is no sufficient diagnosis. Although usually a symptom of chronic suppuration of the tympanum, its real cause should be determined as soon and accurately as possible, and its removal regarded as essential to a fair beginning of treatment. In rare cases polyps arise in furuncles, generally after poulticing; but most of them come from the tympanum. When seated upon the canal-wall they generally indicate a carious condition, and call for scrupulous study and care. Their removal is rarely worth considering an operation, since it can often be done without the knowledge of the patient and the probable consequent increase of difficulty. Mere rotation with the probe will often “wring the neck” of a polyp, or it can be bitten off with forceps or snare. The new tissue is generally insensitive, and it is the traction on its base or adjacent parts which is felt more or less painfully. Complete removal is desirable, and chromic-acid or other cauterization of the stump; but the mere drying effect of boric or alum powder often suffices for those not arising from inflamed bone. General anæsthesia may be required for proper exploration and removal, and the arrangements should be made beforehand to carry through at once any requisite operation on the bone. Caries of small extent can often be sufficiently treated by rubbing vigorously with the cotton-carrier, or may be curetted with the small sharp spoon. The ossicles can be excised if considerably involved, since their usefulness is generally gone, and they remain as obstacle to treatment and often to hearing. Yet such intervention is far from sure to give either prompt or lasting relief if confined to cases really demanding it; for it may fairly be claimed in the majority of cases of limited caries of the ossicles that healing can be secured as quickly and surely without excision, and that with it prompt cure can be expected in only some 60 per cent. of the apparently appropriate cases. The operation of Stacke, in which the tympanic attic, and often the antrum, is at the same time laid freely open by removal of all wall intervening between it and the canal, is called for in many of these cases; and the turning forward of the auricle and cartilaginous canal, by incision behind it, greatly favors thoroughness and safety, while not increasing the risk of operation.

Chronic suppurations commonly resist any treatment which parents or nurses can give, and the physician who treats them with no more insight rarely succeeds better. Yet a single thorough cleansing, with insufflation of boric powder, will often cut short a case that has been trifled with for years. Such prompt drying had better be distrusted, for recurrence is probable. Foci of trouble often are unreached, and the exciting causes in nares and tubes generally remain. Hearing may be temporarily lessened by reason of the stiffness of the parts, no longer even duly moist; and perforations in the drum-membrane may be retained by repression of the reparatory inflammation. Yet these charges against the dry treatment are rarely justly condemnatory, and proper maintenance of naso-pharyngeal treatment, with inflation of the tympanum, will generally secure all that any other measures can do, and with real gain in time and safety. Serious secondary conditions, like mastoid empyema or caries may thus be averted; but there is no evidence that they are not rather lessened, and they are not so apt to be masked by the tympanic condition.

Aside from the dangers to hearing, a number of perils surround both the acute and chronic forms of tympanic suppuration. The bony walls are everywhere more or less dependent for their nutrition upon the mucous membrane, and caries of ossicles and other parts can readily take place, with occasionally extensive necrosis. Yet without this, extension of inflammation, even when

not septic, may involve the meninges, the great blood-vessels or the labyrinth; and from any of these serious or fatal cerebral lesions may arise. Brain-abscess depends, in most cases, upon aural suppuration, and subdural abscess and septic thrombosis are still more frequent in children (Fig. 7). Suppuration in the labyrinth gains ready access to the intracranial cavity through the internal auditory canal, and the basilar meningitis resulting is usually fatal. This is noteworthy, for the leptomeningitis due to caries or necrosis of the temporal bone is often salutary, and builds a defence against serious invasion for the more important structures. (See Figs. 8 and 9).

Necrosis may lead to exfoliation of large portions of the temporal bone, including the labyrinth and facial canal; yet the cranial contents may escape unharmed, in spite of loss of much of the meningeal surface of the bone, and the facial nerve may reorganize. Facial paralysis is not rarely met, for the facial canal is frequently incompletely bony, and is always vulnerable as it passes above the oval window. Bell's palsy in children is usually a part

FIG. 7.

Portion of Base of Skull of Child of Three Years, showing carious defect in the roof of left tympanum and the overlying dura. Death resulted from a large brain-abscess communicating with the suppurating tympanum.

FIG. 8.

Inner Aspect of the Temporal Bone of a Boy of 2½ years, showing caries of roof of attic and antrum. Dural thickening effectually protected the brain at this point, but pus penetrated with fatal result through the internal auditory meatus.

FIG. 9.

Outer Aspect of the same Bone, showing destruction of mastoid cortex and meatus wall, throwing into one open cavity the canal and tympanic chambers. The oval window is seen, as in life, to be empty; the facial canal above it is open and vacant, and a third opening is into the horizontal semicircular canal.

of an otitis media, although the aural symptoms may be slight and fleeting. When the nerve is actually destroyed, restoration is not likely, and the canal may prove a path for infection. (See Fig. 10).

Burrowing of pus may so easily take place out along the bone, instead of through it, that its presence upon the surface should never be accepted as proof of a bone-lesion, but the region must be carefully searched for sagging

FIG. 10.

Large Sequestrum, showing much of the outer surface of mastoid. It comprises also much of the facial and semicircular canals, the antrum, and its removal uncovered extensively the dura and lateral sinus, but was followed by recovery, with deafness and facial palsy of this side. The whole temporal bone is sketched in to show the relations of the exfoliated portions.

of the condition is obtained. Incision freely down upon the bone is called for, in order to lay open the tract throughout as soon as it is detected, and stimulating measures, especially the hot syringing, should be vigorously employed. Weak acid solutions, best in 75 per cent. glycerin, have been warmly advocated as capable of decalcifying and aiding to remove any dead portions of bone, while energetically stimulating the growth of healthy granulations.

CHRONIC CATARRHAL INFLAMMATION OF THE MIDDLE EAR may remain as the result of one or more acute attacks, but more frequently is an insidious and progressive disease due to continuous nasal trouble, directly or indirectly acting through the Eustachian tube. These slit-like canals are normally closed, yet open readily in yawning, swallowing, or forced respiration, and serve to ventilate the tympanum and maintain equality of pressure upon the inner and outer surfaces of the drumhead. Nasal catarrh may lead to violent nose-blowing, with undue distention of the tympanum; but much oftener the swelling of the mouth or lumen of the Eustachian tube both guards the ear against this and also precludes the normal transmission of air. The unrenewed air in the drum-cavity is absorbed, the tympanic membrane pressed in by the preponderating external pressure, and swelling or hypersecretion of the lining mucous membrane, or transudation through it, results from the partial vacuum. In still other cases the tube is duly patulous, and nasal obstruction gives rise to suction at every act of swallowing, just as in the "Toynbee experiment" with the nose held closed. Whether thus medially, or through direct extension of inflammation by continuity, the tympanum becomes involved in a low grade of inflam-

of the walls of the canal, especially above, or other indications of subperiosteal burrowing. Up and back, near the drumhead, where but a thin lamella separates the antrum from the meatus, a rounded protrusion, more generally of reddish color, may be found as the result of purulent collection, which has come around or through the bony plate; and the relations of the Shrapnell membrane are such that suppuration in the attic may pass out along the wall, instead of perforating the membrane. Bone-lesion may, therefore, be absent; but as the periosteum is generally detached, superficial caries is almost certain to follow unless prompt relief

mation tending toward sclerosis. So marked is this tendency that some cases may well, from their start, be designated as sclerotic; yet such are rarely recognizable in early childhood, and the hypertrophic form is here the most important. Slight congestion of the whole tract is usually present, as indicated by the distended vessels visible along the malleus handle; infiltrations take place in limited or diffused areas of the drumhead or other parts of the tracts, leading to fibrous or chalky deposits; and, more important still, the ligaments of the ossicles and the less constant reduplications of mucous membrane about them undergo stiffening and contraction. The pull of the tensor tympani upon the malleus handle may thus be exaggerated through the affection of its tendon sheath, increasing the depressed or retracted condition of the drumhead; and the stapes, which is often surrounded by bands of tissue, becomes anchored firmly in its niche or undergoes true ankylosis of its foot-plate in the oval window. The effect of this in hindering the due transmission of aerial sound-waves is evident, for the drum-membrane is stretched too tightly to respond properly to the lower tones, the conduction through the chain of ossicles is hindered, and the cardinal factor—the slight piston-like movement of the stapes—is reduced or prevented. Pain of a neuralgic character is sometimes present, possibly through the sharp pressing inward of the drumheads, and subjective noise or vertigo is apt to be added to the deafness.

Even in childhood chronic tympanic catarrh may be very obstinate and require long and persistent treatment. The naso-pharynx is to be put in the best practicable condition, with reduction of turbinal hypertrophies, shrinkage or destruction of "adenoid vegetations" of the vault of the pharynx, and reduction of the tonsils by astringents, cauterization, or excision. My routine nasal treatment is to spray clean the nares with a detergent alkaline solution, such as Dobell's, mop the pharynx-vault with glycerole of iodine on the bent cotton-carrier, give a protective spray with a 10 per cent. menthol-camphor solution in alboline, and dust lightly with calomel. Inflation of the tympanum can usually be satisfactorily done with the Politzer method, the patient aiding by puffing out the cheeks or saying "Huck" at command. If water is given to aid the swallowing effort, the sip should be small, the inflation made as the larynx is seen to rise, and the physician will be wise to stand out of range of the probable spluttering. If the collapse of the drum-membrane be considerable, its distention may be painful, even by gentle inflation; and it is well to have the fingers thrust into the ears to compress the air in the canals and mitigate the pressure. The air blown in may be advantageously medicated by filling the bag from a bottle containing a little iodine or other stimulant. The pneumatic speculum is of decided value, not only in studying the condition of the drumhead, but also as an excellent means of using massage. Any fulness, pain, or discomfort caused by inflation may be thus promptly relieved, tinnitus and deafness much lessened, and a rational method of relieving the worst features of the trouble readily inaugurated. Its effect can be continued and increased by "tragus-pressure," or pneumatic massage, done with the fingertip moving in and out while hermetically closing the canal. Valsalva inflation had better not be taught, as it is very liable to be abused, but this other measure is generally as useful and probably wholly harmless.

AFFECTIONS OF THE INTERNAL EAR.

Lesions of the internal ear are fortunately rather rare in children. Congenital defects are hard to prove during life, but may be assumed when other malformations are present, with no evidence of disease and where no hearing

has ever been detected. When deafness is total, labyrinthine lesion is almost certain, since disease of the conducting apparatus can hardly abolish the function of the organ.

ACQUIRED LABYRINTHINE DEAFNESS is usually syphilitic, except in the cases of necrotic destruction or exfoliation as the result of tympanic suppuration; and evidence of the inherited taint should be sought in the eyes and teeth. Even when no sign of interstitial keratitis or other ocular syphilis is found, and the teeth are well formed and spaced, the facies may have a pinched expression, with precocious marking of the naso-labial lines, which is quite characteristic. The loss of hearing is generally sudden, and, although considerable tympanic trouble may be present to confuse the diagnosis, the routine treatment of the middle-ear lesion will prove it to be too slight to be a probable cause of the profound deafness, and alteratives will have distinct influence in improving the hearing. Tuning-fork tests are not very reliable with young patients, even when intelligent enough to understand what we wish to learn, and the objective methods are of uncertain value. It is claimed that through long stethoscopic tubes connecting the ears of patient and observer the tuning-fork on the vertex can be better heard from the less-affected or normal ear if the lesion is labyrinthine, but on the more affected side if tympanic. The contrary is sometimes, if not generally, true. The Galton whistle is of value in testing if any hearing be present, as it can be concealed in the hand and sounded at various pitches in proximity to the ear without attracting any notice unless its sound be heard. Yet the question of total deafness may remain undecided, and the history throw little light upon diagnosis, especially in children who do not talk. Sounds accompanied by concussion, even of the air, are apt to be noticed, and calls and phrases may be comprehended in spite of abolition of hearing; but any words spoken beyond accidental semblances of "ma-ma," etc. may be taken as proof that some hearing is or has been present. Cases of labyrinthine deafness due to extravasation or sudden exudation, and accompanied by the Menière symptoms of vertigo, etc., are very rare in children, and usually unilateral. It is still a question how far acute bilateral otitis interna is mistaken for cerebro-spinal meningitis, the intracranial symptoms of which are merely reflex, and recovery takes place with surprising promptness except for the persistence of total deafness. Such cases do occur, but more often the lesion is doubtless in the floor of the fourth ventricle, with destruction of the auditory tracts; and any labyrinth lesions later found are due to atrophic degeneration.

Whether syphilitic or not, the treatment of these disorders is about the same. A full mercurial impression should be obtained with all possible promptness, and the alterative effect of this drug and iodine well maintained. Mercurial inunction is generally safest and most convenient in children, the ointment being given in drachm or half-drachm pellets, of which one is to be rubbed once or twice daily upon the belly and covered with a flannel band, a new surface being taken each time till the waist is encircled. Pilocarpine has some curative value, but is probably much less safe or certain than mercury.

When hearing is lost in early life, from whatever cause, speech is either not learned or is very apt to be lost, and the child becomes a deaf-mute. Yet some trace of hearing is present in the majority of those in the mute institutions, since the deafness is usually tympanic; and acquired, as it often is, after some language has been learned, this only needs preservation and cultivation. A considerable proportion can be taught to speak intelligibly and read the lips of others with facility. The process is slow and difficult; so it should be begun early and with rigorous exclusion of the easier but far less useful sign-

language. Any remnant of hearing may be of immense aid, and it should be made as good as possible by treatment; and the vocal apparatus should in like manner be put in the best practicable condition, that it may add no needless impediment to the acquisition of useful speech.

Mechanical aids to the hearing may be of value to the mute as well as to other deaf persons, both for hearing the sounds of the words spoken to them and their own voices in speaking. The appliances are of two principal forms—either a trumpet to receive in the expanded mouth a larger number of sound-waves than the ear itself could catch, and transmit them by air-conduction to the auditory apparatus, or else of the “dentaphone” type—an elastic surface to respond to the vibrations and convey them by bone-conduction. Each has its limited value and its applicability to individual cases; and it is claimed that they sometimes greatly facilitate that exercise of the auditory apparatus which can occasionally work a slow but immense improvement in apparently hopeless cases. A similar therapeutic idea has led to use of the phonograph as a means of exercise or massage, especially by the believers in infinitesimals—perhaps “proved” by the fact that the attenuated sounds of telephone and phonograph can work harm to diseased ears. Numerous improved forms have been devised, all promising wonders as soon as, like perpetual-motion machines, a missing cog shall be adjusted.

PART XIII.

DISEASES OF THE EYE.

BY G. E. DE SCHWEINITZ, M. D.,

PHILADELPHIA.

IN the following pages only those diseases of the eye are recorded which the general practitioner of medicine and surgery is likely to encounter, and which do not demand the use of instruments of precision for their detection and study.

DISEASES OF THE LIDS.

ABSCESS AND FURUNCLE OF THE LID.—An abscess of the lid, sometimes called *phlegmon*, appears as a localized red elevation, which may arise in debilitated children without ascertainable cause, and also results from exposure, injury, or diseases of the orbit. The affection may terminate in the formation of a slough or “core,” and then receives the name “*furuncle*,” and in subjects of poor nutrition may be complicated with gangrene of the surrounding integument.

Treatment.—Pointing should be favored by the application of moist heat with compresses of lint steeped in hot, slightly carbolized solutions. As soon as fluctuation is detected, or even earlier, the abscess should be incised with a knife thrust through it parallel to the muscle-fibres, and the cavity kept clean with a solution of bichloride of mercury or with peroxide of hydrogen. Nourishing food and tonics, as quinine and iron, are indicated.

HORDEOLUM, OR STYE, is a small furuncle on the margin of the lid caused by a circumscribed inflammation of the connective tissue, or of one of the glands of this region.

Ordinarily, the affection, though annoying, is trifling in character; the swelling becomes invested with a yellow cap, indicating suppuration, and the purulent contents are evacuated by spontaneous rupture or by incision. Sometimes, however, the appearances are similar to those of purulent ophthalmia, from which it may be differentiated by observing the indurated portion of the lid, the point of suppuration, and the absence of profuse purulent discharge.

Styes tend to recur or to come in “crops.” They are excited by exposure to dust and cold and the strain of uncorrected ametropia, especially hypermetropic astigmatism. The repeated occurrence of styes always indicates some general derangement—dyspepsia, constipation, and, in girls at the age of puberty, menstrual disorders.

Treatment.—An attempt to abort a styne may be made by the repeated application of compresses steeped in hot boric-acid solution, by rubbing the

inflamed area with an ointment of yellow or red oxide of mercury, or by painting the surface with collodion. When suppuration occurs the swelling should be incised by cutting through its base parallel to the lid. Constipation, dyspepsia, and menstrual disorders should be corrected, and in children of suitable age refractive anomalies should be neutralized with appropriate glasses. Sulphide of calcium has some influence in preventing the recurrence of styes.

EXANTHEMATOUS ERUPTIONS are found upon the eyelids during the various eruptive fevers, and in small-pox a pustule may form, by preference at the commissure, leaving a disfiguring scar, or it may terminate in an ulcer of stubborn character which is denominated *post-variolous ulcer*. Vaccine vesicles on the free border of the lids have been reported by Hirschberg, Berry, and others, after contact with vaccine. The affection receives the name *vaccine blepharitis*.

BLEPHARITIS.—This term describes the various subacute and chronic inflammations of the border of the lids, and the affection usually appears in a *non-ulcerated* and an *ulcerated* form.

The non-ulcerated varieties manifest themselves as a simple hyperæmia of the lid margins, the “red eyes” of common parlance, characterized by swelling, redness, and passive congestion of the superficial blood-vessels; or in an abnormal secretion of the sebaceous glands, characterized by the formation of crusts and scales of hardened sebum (a similar process often affecting the eyebrows at the same time) at the roots of the cilia, and lying upon a slightly inflamed and occasionally abraded surface. Distinct ulcers usually are not present. This form is always bilateral, and is known as *seborrhœa of the lid border*, *blepharitis ciliaris*, or *squamous blepharitis*.

The ulcerated varieties manifest themselves as a *marginal eczema*, which resembles an aggravated form of the simple hyperæmia; or as a *blepharo-adenitis*, characterized by the matting of a tuft of cilia in a crust which covers a distinct ulcer, and which often affects a single lid; or as a *pustular* inflammation, characterized by the development of thick yellow crusts covering deep ulcers that destroy the nutrition of the eyelashes, which are misshapen and readily fall from their follicles. This type, called *blepharitis ulcerosa*,¹ often affects all of the lid margins, and may lead to deformities, owing to the loss of the cilia and the change in the shape of the ciliary border, which becomes thickened, everted, and rounded (“*lippitudo*,” or *blear-eye*).

Etiology.—Blepharitis in many of its forms is distinctly a disease of childhood, and is apt to attack children of blonde complexion and strumous habit. It frequently follows in the wake of the exanthemata, but may arise in other subjects in seemingly perfect condition. Not infrequently, affections of the nares and naso-pharynx are present (various types of rhinitis, catarrh, and adenoid vegetation), which probably act as causative factors. Eczema around the nares and auricle is often present. Ametropia, especially hypermetropia and astigmatism, as originally pointed out by Roosa, probably causes many cases, and is responsible for the continuance of others. Abnormal shortness of the palpebral fissure may originate blepharitis (Fuchs).

Treatment.—This depends upon the type of the disease, but in children of suitable age refractive anomalies should always be corrected. The forms described as hyperæmias will often disappear by this means alone; if not, the lids may be washed frequently with warm water and castile soap, and an eye-

¹ Eczema of the border of the lids, according to its manifestations, was formerly described under several names—blepharitis ciliaris, blepharitis ulcerosa, psorophthalmia, lippitudo ulcerosa, tinea tarsi, sycosis tarsi, ophthalmia tarsi, etc.

douche may be employed, the water of which, at a temperature of about 60° F., is conducted from a can held above the head through a tube to the end of which a small rose is fitted, which distributes the fluid in fine, shower-like jets upon the closed lids. Stimulating salves are not indicated in this variety.

In the seborrhœas the crusts should be removed with an alkaline solution, bicarbonate of sodium (gr. viij-f̄3j), or bionate of sodium (gr. iv-f̄3j), and then an ointment of milk of sulphur or of resorcin (2 or 3 per cent.) applied to the lid margins. In the eczemas, after removal of all crusts, the yellow oxide of mercury (gr. j-f̄3j) is the most useful application. In any type associated with much ulceration all loose cilia should be removed with epilating forceps and the ulcers touched with a solution of nitrate of silver. In place of the salves which have been mentioned, boracic-acid ointment (10 per cent.), zinc ointment, or aristol ointment (2 per cent.) may be used. The puncta and lachrymo-nasal duct should be patulous, and any diseased condition of the nares and naso-pharynx should be corrected. As constitutional remedies, cod-liver oil, lacto-phosphate of lime, iodide of iron, and syrup of hydriodic acid will usually find suitable indications.

PHTHEIRIASIS OF THE LIDS.—The pediculus pubis (crab louse) occasionally infests the eyebrows and eyelashes. The parasites cause much irritation, and the affection may be mistaken for ordinary blepharitis.

Treatment.—The margins of the lids should be rubbed with balsam of Peru, mercurial ointment, or a solution of corrosive sublimate.

SYPHILIS OF THE EYELIDS.—A hard chancre may develop on any portion of an area included by the lid borders and inner canthus, the tarsal conjunctiva and the cul-de-sacs (De Beck), the inoculation usually taking place by contact with the secretion from a syphilitic mouth. The affection begins as a pimple which develops into a characteristic ulcer with indurated base.

A small papular syphilide has been noted upon the eyelids of infants the subjects of hereditary syphilis a few weeks after birth, and madarosis (falling of the lashes), as well as a form of ulcerated blepharitis, has been ascribed to the same cause.¹

TUMORS AND HYPERTROPHIES.—Clear, small cysts, warts, and little masses of granulations may occur on the margin of the eyelid, the last arising from the mouth of a Meibomian duct. In addition to these attention is directed to the following growths:

Nœvi (angiomas).—These are congenital growths, either small red spots or cavernous structures analogous to those which occur elsewhere in the body. They should be removed as soon as practicable. If small, excision may be practised: if large, they may be destroyed by galvano-cautery puncture.

Chalazion.—This is a small tumor arising in the tarsus, due to inflammation of a Meibomian gland and its surrounding tissue; hence it is an adenitis or a periadenitis, and not a true cyst. It occurs in children, but is much more common in adolescence. The exact cause is not known, although it is connected with stoppage of the duct of a Meibomian gland, which in its turn may be caused by inflammatory affections of the lid border. Chalazia are apt to occur in the lids of those suffering with hypermetropia and astigmatism.

Treatment.—The lid should be everted and the discolored spot on the tarsal conjunctiva, which marks the position of the chalazion, exposed. This

¹ Those interested in this subject should consult De Beck, *Hard Chancre of the Eyelids and Conjunctiva*, Cincinnati, 1886; and Alexander, *Syphilis und Auge*, Wiesbaden, 1889.

is incised and the contents scraped out with a small curette. Large chalazia should be removed by cutaneous incision, the area of operation being enclosed in a suitable clamp forceps (Snellen or Knapp). Resolvent ointments (yellow oxide of mercury gr. j-5j) have some reputation, but usually their employment is a waste of time.

Sarcoma of any of the types occurs in the eyelids of children, both upper and lower, as a primary growth. At first the growth is movable under the skin and slightly elastic to the touch, but rapidly develops, and may be complicated with ulceration of the overlying tissue. Thorough removal should be practised as soon as the diagnosis is established, but return and metastasis are likely to take place.

TARSITIS.—This is a chronic (very rarely acute) inflammation of the tarsus, often syphilitic in origin, and then consisting of a gummatous infiltration. An idiopathic tarsitis also exists which resembles a chronic blepharitis, from which it must be differentiated by observing the induration of the tarsal portion of the lid. If it be syphilitic, the usual constitutional remedies are indicated; if idiopathic, the treatment of chronic blepharitis is suitable.

BLEPHAROSPASM.—This term comprises several varieties of involuntary contraction of the whole of the orbicularis palpebrarum or of a few of the fibres. It is either clonic or tonic in character.

Clonic Blepharospasm.—The most trifling type of the clonic variety consists in the twitching of a few fibres of the muscle, sometimes spoken of as "life in the eyelid," being significant of eye-strain or some loss of tone in the nervous system, and correctible by removing the evident cause. Occasionally, however, it becomes stubborn, and requires, in addition to suitable glasses, the administration of antispasmodic remedies—gelsemium or conium.

That form of nervous disorder which Weir Mitchell has called "*habit chorea*" manifests itself in undue winking of the eyelids and jerky movements of the facial muscles, partaking of the nature of a grimace. It is very common in nervous school-children, and almost always refractive error, usually hypermetropic astigmatism, follicular conjunctivitis, and blepharitis will be found. Suitable glasses and the exhibition of iron and arsenic usually suffice to cure the disease.

Tonic Blepharospasm appears as a more or less persistent cramp of the orbicularis, and may be caused by foreign bodies in the conjunctival cul-de-sac or in the cornea, by conjunctivitis, and by various types of keratitis.

In rare instances a persistent cramp of the lid occurs in children, generally in those of poor nutrition, which continues for weeks and even months, and for which there is no obvious cause. When the lids are finally opened, there may be blindness, temporary in character and without changes in the fundus oculi, or associated with definite lesions in the choroid and retina. In the one instance the blindness is probably due to the long-continued exclusion of the rays of light, and in the other to alteration in the coats of the eye from pressure.

Treatment.—As the affection in the large majority of cases partakes of the nature of a reflex originating from an irritation of the peripheral trigeminal fibres, the source of irritation—foreign body, phlyctenule, or fissure at the commissure—must be removed. If the cramp continues, morphine, conium, or gelsemium may be tried. In bad cases section of the supraorbital nerve has been performed.

PTOSIS.—In this affection the upper lid droops over the eyeball, and more or less perfectly covers it. It may be congenital or acquired, unilateral or bilateral, and is usually divided into that form of ptosis which is caused by an hypertrophy of the connective tissue or an excessive accumulation of fat, and that variety which depends upon imperfect development of the levator palpebrarum or paralysis of this muscle. Ptosis may also be the result of paralysis of the oculo-motor nerve, and can be caused by injury to the levator of the upper lid.

Cases of constitutional origin—for example, from syphilis or rheumatism—require the usual remedies. The treatment of congenital ptosis, either of the hypertrophic variety or that due to imperfect muscular development, requires an operation.

LAGOPHTHALMOS, or an inability to close the eyelids, may result from paralysis of the facial nerve, and also when the globe is pushed forward by a tumor of the orbit, or is prominent as the result of exophthalmic goitre, or protuberant on account of a staphyloma. The affection is referred to because, under certain circumstances, the exposure which the cornea suffers may lead to ulceration, especially if with the facial palsy there exists an involvement of the trigeminal fibres. Under these circumstances the operation of tarsorrhaphy, which consists in uniting the margins of the upper and lower lids in the neighborhood of the external commissure, is indicated.

SYMBLEPHARON is really an affection of the conjunctiva, and consists of a cohesion between the eyelids and the ball which may be partial or complete. It generally follows an injury, particularly a burn of the conjunctiva with acid or lime, and may also result from violent inflammations of the conjunctiva. It occasionally occurs as a congenital defect.

Treatment.—If adhesions form, they should be broken down with a probe, and their reattachment prevented by introducing between the lid and the ball a piece of gold-beater's skin or by keeping the cul-de-sac packed with a pledget of lint smeared with boric-acid ointment. If these simple measures fail, then one of the many operations for the relief of symblepharon must be performed.

TRICHIASIS; DISTICHIASIS.—*Trichiasis* is that affection in which the cilia are turned inward and rub against the ball. It is most commonly caused by chronic inflammation of the border of the lid—for example, blepharitis—and by granular conjunctivitis. The cilia produce much irritation, and may cause an ulceration of the cornea.

When incurved rows of supplementary eyelashes are developed from the intermarginal part of the lid, the affection receives the name *distichiasis*. Sometimes this is congenital, but it also arises under the same circumstances which produce trichiasis.

Treatment.—If the misplaced lashes are not too numerous, they may be removed with cillum forceps, and the procedure repeated when they grow again; but if the affection is extensive, some operation which consists in strangulating or destroying the roots of the incurved lashes, or in which a single or double transplantation of the entire margin of the lid is effected, must be performed.

ENTROPION.—With or without trichiasis there may be an inversion of the lid. The organic variety follows long-continued granular conjunctivitis, atrophy of the conjunctiva, and diphtheritic ophthalmia. A spasmodic entropion is common as the result of inflammation of the cornea or conjunctiva, or from the

presence of foreign bodies, and is sometimes a marked symptom shortly after birth, owing to an undue activity of the orbicularis muscle.

Treatment.—Spasmodic varieties usually subside by removing the cause. In the event of failure the inverted lid may be drawn outward and held in place by a piece of adhesive plaster attached near the margin of the lid and passing downward on the cheek, or by a piece of gauze fastened with collodion. When there is organic entropion a formal operation must be undertaken for its cure.¹

ECTROPION.—This consists in an eversion of the lid, partially or completely exposing the conjunctival surface. It may occur as an acute affection, especially in children with inflammatory affections of the conjunctiva and cornea. In its organic form, however, the eversion is generally caused by an injury—for example, the laceration of the lid with a sharp instrument—by cicatricial contraction as the result of burns, by chronic disease of the margin of the lid, and by caries of the orbital border or malar bone. A slight eversion of the lid is practically always present in children with facial palsy.

Treatment depends entirely upon the type of the affection. The spasmodic varieties get well with removal of the cause, associated with replacement of the everted lids; mild types are sometimes curable by dilating the punctum lachrymale, but in the organic forms there is no remedy except a formal operation.

MILIUM.—Milia are common on the eyelids about the age of puberty, and consist of small, yellowish elevations which are due to a distention of the sebaceous glands. They result from improper care of the skin, but often indicate disturbances in the alimentary canal, particularly dyspepsia and constipation. They may be removed by pricking each elevation with a needle and evacuating the contents.

MOLLUSCUM CONTAGIOSUM, a disease of the sebaceous glands, perhaps of the rete mucosum, and probably of parasitic origin, may develop upon the eyelids. It is generally seen in ill-nourished children, and in asylums sometimes constitutes an epidemic. Each molluscum is a rounded papule about the size of a pea, of a somewhat waxy color, and with a slight depression near its centre.

The treatment consists in incising it and forcing out the contents.

SEBACEOUS CYSTS, as well as **DERMOID CYSTS**, may occur in the eyelids, but are more commonly seen in the upper portion of the eyebrows. Sometimes in the latter situation they adhere to the periosteum and may pass deeply into the orbit. They should be removed by an ordinary dissection.

INJURIES OF THE EYELIDS.—The eyelids may receive an incised, lacerated, or contused wound, depending upon the character of the implement which has caused the injury. The treatment does not differ from that of similar injuries elsewhere located, but it is of the utmost importance that scrupulous asepsis should be followed, and accurate adjustment of the lips of the wound effected with fine silk sutures.

Blows upon the lid may cause a *simple œdema* on account of the distention of the cellular tissue with serum.

¹For the description of operations the reader is referred to systematic works on ophthalmic surgery.

Edema does not alone result from an injury, but independently of its common association with severe inflammations of the cornea and conjunctiva, appears in renal and cardiac diseases; and one variety, which has received the name *fugitive œdema*, may occur in connection with migraine, and sometimes arises in association with the establishment of the menstrual function, and, again, spontaneously and apparently without cause. In one case which the author has seen with Dr. Louis Starr, in a very young child, it depended upon the circulatory disturbances associated with slight goitre.

In the non-constitutional varieties evaporating lotions—for example, lead-water and laudanum—and removal of the cause, if possible, are the proper remedies.

A *burn of the eyelid*, either by hot water, acid, or caustic, should be treated upon general principles, care being taken to prevent adhesions between the eyeball and lid. One of the very best preparations for soothing the pain of burns is a lotion of carbonate of sodium.

Powder-burns.—The bluish-black specks caused by the implantation of the grains of powder in the skin should be picked out with a fine needle as soon as possible after the injury, and recently Dr. Jackson, of this city, has suggested that each grain may be removed by touching it with a finely-pointed galvano-cautery needle. Afterward the ordinary applications for burns may be applied.

EMPHYSEMA OF THE LIDS generally indicates a fracture of the orbit, permitting the escape of air into the cellular tissue through a communication with the ethmoidal or frontal sinus.

If blood collects in the same situation, *ecchymosis of the lid* results. This condition, commonly called “black eye,” most frequently follows a blow. It may also occur with fracture of the base of the skull, and occasionally appears in an alarming fashion by the rupture of a small blood-vessel after a violent paroxysm of whooping-cough.

Treatment.—Frequent applications of very hot water, tincture of arnica, lead-water and laudanum, or diluted fluid extract of hamamelis, have some effect in producing absorption of the effused blood. It is useless to attempt to cause absorption of the blood by the application of leeches.

AFFECTIONS OF THE CONJUNCTIVA.

Inflammatory diseases of the conjunctiva are exceedingly common in children, constituting about 40 per cent. of the eye cases in hospital practice. The most important group is that described under the general term *conjunctivitis*, which for purposes of description may be conveniently divided into six varieties:

I. **SIMPLE CONJUNCTIVITIS**, generally called *catarrhal* or *muco-purulent conjunctivitis*, is characterized by hyperæmia of the conjunctiva, loss of its transparency, some dread of light, with a feeling of grittiness under the eyelids and a muco-purulent discharge, which may be slight or profuse.

Etiology.—The disease readily passes from one eye to its fellow, and from one subject to another, and in this sense is distinctly contagious. Bacteria are probably the active agents of this contagion. The affection is common in changeable weather, and is often seen in the spring and fall. It may attack perfectly healthy children, but is more common in scrofulous subjects, and is more likely to be implanted in a conjunctiva already hyperæmic or studded with swollen follicles. It may be associated with eczema, erysipelas, impetigo

contagiosa, naso-pharyngeal affections, bronchitis, and rheumatism, and commonly follows or attends the exanthemata. It may further arise from exposure to dust or irritating substances, and is sometimes the result of eye-strain. One form, common in the spring and fall, has received the singularly inappropriate name "pink eye," being really an epidemic catarrhal inflammation probably due to a special micro-organism (Weeks).

Symptoms.—These are—swelling of the lids and slight œdema of their margins; mucous or muco-purulent discharge, which may excoriate the surrounding skin; hyperæmia of the conjunctiva and congestion of the posterior conjunctival vessels, in bad cases associated with œdema of this membrane and small hæmorrhages; and some photophobia, especially if small corneal ulcers are present. The character of the discharge and appearance of the conjunctiva, the free mobility of the iris and lack of change in its color, distinguish it from iritis.

Prognosis is good, cure usually resulting in one or two weeks, but when neglected or when occurring in homes or asylums conjunctivitis of this character may spread with great rapidity and become a stubborn epidemic.

Treatment.—This should be as follows: Removal of the cause in so far as this is practicable; protection of the inflamed eyes with a pair of dark glasses or a shade, but *under no circumstances the application of a bandage or of a poultice in the form of flaxseed, tea-leaves, bread and milk, or scraped potatoes*; prevention of contamination with the discharge through any medium (in homes, etc. the affected inmates should be isolated); scrupulous removal of the secretion, which may be effected by washing the eyes frequently with tepid water and castile soap and irrigating the conjunctival cul-de-sac with the following collyrium:

R̄.	Boric acid	gr. xv.
	Table salt	gr. ij.
	Distilled water	fʒj.—M.

When the discharge becomes profuse, the lids should be everted and carefully painted with a small cotton mop or camel's-hair brush dipped in a solution of nitrate of silver (gr. v-fʒj).

The following collyria have also found favor with many surgeons:

Bichloride of mercury (1 : 10,000); alum (gr. iv-fʒj); sulphate of zinc (gr. ij-fʒj); peroxide of hydrogen (diluted one-half or three-quarters); and creolin (1 per cent.). Atropine is generally unnecessary. A saline laxative and tonic doses of quinine are suitable remedial agents in cases which do not present special therapeutic indications.

II. PURULENT CONJUNCTIVITIS.—This affection, in so far as infants are concerned, is generally described under the name "Ophthalmia Neonatorum."

Etiology.—The infecting material enters the eye from some portion of the genito-urinary tract during the passage of the head of the infant through the birth-canal, or inoculation may be effected shortly after birth; in rare instances it takes place *in utero* when there has been a rupture of the membranes.

The gonococci of Neisser are demonstrable in most of the cases and in all severe forms, and bear the same relation to this disease that they do to gonorrhœa. There is, however, one non-specific variety in which this micro-organism is not present. Therefore a virulent vaginal discharge (gonorrhœal) is not a *sine qua non* of this affection, but it may arise from the introduction of any muco-purulent discharge during birth, while careless bathing and the use of soiled towels or sponges after birth are evident sources of infection.

It is probable that injudicious intravaginal antiseptics with strong solutions

of bichloride of mercury may originate a vaginitis itself capable of inducing one form of ophthalmia neonatorum, and the best obstetricians confine the application of germicidal solutions in uncomplicated labors to the external genitalia. The author is confirmed in this belief by a consultation with Prof. B. C. Hirst.

Boys are more apt to be affected than girls, and inoculation is more likely to occur during retarded labors and with face presentations.

Symptoms.—Ophthalmia neonatorum usually begins on the third day after birth, but may set in sooner, and when it results from secondary infection—for example, from soiled clothes—it begins at a later date. Almost invariably both eyes are affected.

At first there is a slight discharge, which gathers at the corners of the eye, rapidly succeeded by intense injection and chemosis of the conjunctiva, great swelling of the lids, and the free secretion of contagious pus. The swollen lids are at first tense, and the serous infiltration of the bulbar conjunctiva almost hides the cornea, sometimes forming a hard rim around it; the discharge increases and flows out underneath the lids, often being mixed with blood and serum. During the earlier stages the conjunctiva is red and velvety and often covered with flakes of lymph; later it becomes dark red, rough, and easily bleeds. In from six to eight weeks, if unattended, the disease gradually declines and the relaxed conjunctiva is thick and granular-looking, and slowly regains its normal appearance.

The intense chemosis of the conjunctiva strangulates the vessels which supply nutrition to the cornea; hence the vitality of this membrane is threatened, constituting the chief danger of the disease. Ulcers are likely to form, either at the margin or centre, and their tendency is to spread and perforate; or the entire corneal tissue becomes hazy.

The results of perforation are the formation of a *partial* or *complete staphyloma* and *adherent leucoma*, or a *pyramidal cataract*. Even without perforation the ulcers leave scars which, according to their density, are nebulous or leucomatous. In extensive perforation there may be an inflammatory involvement of all the coats of the eye, constituting panophthalmitis, which is followed by shrinking and atrophy of the globe.

Some non-specific cases of ophthalmia neonatorum do not have so violent a course, and present the appearance of an ordinary muco-purulent conjunctivitis. Again, others are analogous to diphtheritic conjunctivitis, and the danger of corneal destruction is even greater than is ordinarily the case.

Prognosis.—This is always grave, but under the guidance of competent medical advice, *if the eye be seen while the cornea is still clear*, except in those examples which assume the diphtheritic type, the case should be brought to a successful termination. The chief fault lies in the indifference of attendants to what seems to them at first a trivial inflammation.

Treatment.—The treatment should meet four indications:

(a) During the earlier stages, when the inflammatory swelling of the lids is great, in addition to proper cleanliness the local application of cold is the most useful agent. This should be applied as follows: Upon a block of ice, square compresses of patent lint are laid, which, in turn, are placed upon the swollen lids, and are as frequently changed as may be needful to keep up a uniform cold impression. The length of time occupied with these cold applications must vary according to the severity of the case. Sometimes they may be almost continuously used, and sometimes frequently for periods of half an hour.

(b) The discharge should be constantly removed, and, if possible, by a

trained hand. In order to accomplish this, proceed as follows: Gently separate the lids, wipe away the tenacious secretion with bits of moistened lint or absorbent cotton, and irrigate the conjunctival sac freely with an antiseptic solution, care being taken that the point of the pipette does not come in contact with the cornea. For this purpose a saturated solution of boracic acid—which, while it is not germicidal, is still feebly antiseptic and slightly astringent—is the most useful. Bichloride of mercury, one grain to the pint, may also be employed.

(c) As soon as the discharge becomes free and creamy, which is very early in the disease, nitrate of silver should be employed; and this drug is *facile princeps* of the local remedial agents. It must be applied as follows: Carefully evert the lids and secure complete exposure of the inflamed tarsal conjunctiva; remove all discharge and flakes of lymph by irrigating the surfaces with the cleansing lotion, wiping away the adherent particles with moistened cotton; carefully touch the area thus prepared with a cotton mop or camel's-hair brush which has been dipped in a solution of nitrate of silver, ten, or at most twenty grains, to the ounce; neutralize the excess with a solution of common salt—a pinch of salt in a cup of water will suffice—and keep applying the saline solution until a clean, red surface is secured; finally, return the lids to their proper position and carefully inspect the cornea before leaving the case, and see that this inspection is made at each dressing of the eye; finally, grease the margins of the lids with pure vaseline, some of which should be introduced within the conjunctival cul-de-sac.

(d) Should the cornea become hazy or should a small ulcer form, eserine may be employed in a strength varying from a sixth to a half grain to the ounce, but cautiously, lest it produce iritis. Under the latter circumstance, or if the ulcer be central, atropine is the better drug, and may be used in a strength of from two to four grains to the ounce. Very good results usually follow the use of eserine two, three, or four times during the day, according to the severity of the corneal ulceration, and a drop or two of the atropine solution toward night, with due caution lest the constitutional disturbance from these drugs arise in young infants. If there is corneal haze, indicating low vitality of the membrane, the cold compresses may be replaced by *hot* applications, which should consist of squares of lint wrung out in a slightly carbolized solution of a temperature of 120° F.

The author has thus described the treatment which he has employed many times with success. Among the other solutions which have found favor with surgeons are the following: Alum (eight grains to the fluid ounce);¹ carbolic acid ($\frac{1}{2}$ to 5 per cent. solution); weak solutions of nitrate of silver; alcohol and bichloride-of-mercury solutions; creolin in 1 per cent. solution; peroxide-of-hydrogen solution; permanganate of potassium (1:1000), employed in copious irrigations; cyanuret of mercury (1:1500), and aqua chlorinata. Many others might be mentioned, but the evidence is not sufficient to warrant their recommendation or even their trial.

While the author does not wish to condemn the use of a *proper strength* (1:8000) of bichloride of mercury in the treatment of this disease, because it has often served him to good purpose, he is convinced that in many instances a sense of false security has arisen simply because the drug has been employed and because of its vaunted germicidal properties. Strong solutions of sublimate may occasion cloudiness and even ulceration of the cornea. The success of treatment depends largely upon seeing the case *early* while the cornea

¹ This has recently received fresh endorsement from Mr. Brudenell Carter (London *Lancet*, December 10, 1892).

is still bright, upon the faithfulness of the attendants, and upon assiduous attention to the details of the treatment.

Prophylaxis.—Inasmuch as ophthalmia neonatorum is one of the most fruitful causes of blindness, prophylactic measures are of the utmost importance. All things considered, Cr  d  's method of treating the eyes of the new-born child is the one which is followed by the best results. This consists in the instillation of two drops of a 2 per cent. solution of nitrate of silver in the eyes of the new-born child, which, as soon as it is expelled from the maternal passages and before the cord is cut, is placed upon its back in the bed, the eyelids carefully cleansed, then parted, and the drug introduced. This instillation, when there is reason to suspect gonorrh  al contagion, should be repeated on the second day. In the mean time, small compresses soaked in a solution of salicylic acid are laid upon the closed lids. Sometimes the instillation of the silver solution causes hyper  mia, which disappears in a few days. In a few instances smart conjunctival h  morrhage has followed this treatment. The enormous value, however, of this prophylaxis far outweighs the few accidents which have occurred after its use.

Numerous other methods have been employed in the prophylaxis of ophthalmia neonatorum, and most of the antiseptic fluids have had their advocates, particularly carbolic acid, 1 per cent., bichloride of mercury, 1:5000, Van Swieten's solution (corrosive sublimate 1 part, alcohol 100 parts, water 900 parts), and aqua chlorinata, the last drug being especially recommended by Schmidt-Rimpler. On the other hand, many obstetricians are content with painstaking cleanliness during birth and also during childbed, believing that this will reduce the possibility of the disease to a minimum. While this may be true in private practice and in the absence of any suspicious secretion in the maternal passages, Cr  d  's method or an analogous one ought certainly to be used in hospital practice always and whenever there is the least suspicion of contagion. There is reason to hope that stringent legislative regulations will be formulated to lessen this appalling cause of blindness, but in their absence it is the evident duty of physicians, nurses, and directors of public charities to disseminate among the poorer classes a knowledge of the dangers of this disease and the necessity for prompt treatment. When the disease has developed and is monolateral, the unaffected eye may be protected with a bandage. Attendants should be warned of the danger of contamination.

III. DIPHTHERITIC CONJUNCTIVITIS.—This is an exceedingly contagious conjunctivitis, which may arise from a similar case or during the course of a purulent ophthalmia. It may appear in connection with eczema of the face or accompany an acute illness, as scarlet fever or measles. The disease is also seen during epidemics of diphtheria, when it is occasioned by direct inoculation. A comparatively rare affection in America and England, it is common in certain parts of France and in the north of Germany. It is most frequent in children between the ages of two and eight.

Symptoms.—The chief symptoms are swelling of the lids, which become exceedingly hard and board-like; a dull, grayish, false membrane, either discrete or confluent, covers the conjunctival surface. The membrane is often deeply incorporated with the subjacent tissue. The cornea rarely escapes, and destruction of this membrane may take place in twenty-four hours. Even in the mild cases severe ulceration is common.

Treatment.—During the earlier stages cold compresses are proper, to be substituted by hot affusions later on, especially if there be corneal ulceration. The eyes should be frequently cleansed with boric acid or weak solutions of bichloride of mercury, and atropine drops should be instilled if the ulceration

of the cornea is peripheral; but in most instances eserine is the better drug. French physicians warmly recommend the application of lemon-juice and citric-acid ointment, and, on the recommendation of Tweedy, solutions of quinine have been much employed. The internal treatment is that suited to a case of diphtheria, and in the experience of the author, with the few cases which he has seen in the Children's Hospital of this city, the best results were obtained by the administration of bichloride of mercury or calomel, associated with quinine suppositories.¹

IV. SPRING CONJUNCTIVITIS (*Fruehjahr's Catarrh*).—This curious form of conjunctival disease is generally seen in children between the ages of five and fourteen years. Its exact cause is unknown. *One of the characteristics of the disease is its return about April*, and its subsidence in the fall and winter, although sporadic cases are seen in almost every month of the year. Sometimes it accompanies the disease known as hay fever.

Symptoms.—The chief symptoms are photophobia, mucous secretion, hypertrophy of the tissues surrounding the limbus of the cornea in the form of grayish nodules, and a pale, dull color of the palpebral conjunctiva, which has been compared to the appearance of a thin layer of milk, together with the formation of large flattened granulations covering the tarsal folds and causing the eyes to droop and give the patient a peculiar, sleepy expression. It must not be confounded with granular lids, from which it is distinguishable by the flat appearance of the granulations and the absence of corneal complications. So far as vision is concerned, the prognosis is good, but the prominent tendency of the disease to return with the early spring and warm weather makes it a difficult disorder to manage.

Treatment.—The eyes should be protected with dark glasses, the conjunctival cul-de-sac freed from the accumulated secretion, which is sometimes quite free, with a lotion of boric acid and salt. When the granulations are prominent the lids may be everted and their surfaces touched with a 20 per cent. solution of boroglyceride or with a strong solution of bichloride of mercury (1:500), this application to be made once a day. In bad cases the actual cautery may be employed to destroy the granulations, or these may be crushed with roller forceps, as in the treatment of granular lids. Internally, some form of arsenic is advisable, preferably Fowler's solution.

V. FOLLICULAR CONJUNCTIVITIS.—This, as its name implies, is an inflammation in which numerous pinkish, round elevations appear in the conjunctiva, chiefly in the retrotarsal folds, sometimes associated with the symptoms of an ordinary catarrhal conjunctivitis of mild degree. These bodies are tumefied lymphatic follicles, and disappear under treatment without leaving cicatricial changes in the conjunctiva, and the cornea is not involved—points which distinguish the affection from true granular lids. Some authors regard it as an early stage of granular conjunctivitis. The evidence is in favor of a separate classification.

It occurs usually in children and young people, and in its aggravated forms arises under the influence of bad hygienic surroundings in overcrowded schools and asylums. A mild form is common in school-children under good conditions. When neglected, it may become a serious and epidemic disorder.

Treatment.—This consists of improvement of the surroundings, building up of the general health if this is below par, and, locally, boric-acid solution

¹ There is also a true *croupous conjunctivitis* which occasionally attacks children between the first half year of life and the fourth year. It is not contagious, and the cornea generally escapes, and although membrane forms upon the conjunctiva, the lids remain pliant. It is a rare disease, and the distinction between it and true diphtheria of the conjunctiva is not always maintained by authors.

or sublimate collyrium, a salve of sulphate of copper ($\frac{1}{2}$ gr. to ʒj), or dusting upon the retrotarsal folds iodoform, aristol, or equal parts of subnitrate of bismuth and calomel. Refractive errors should be corrected. If the disease is at all stubborn, the swollen follicles should be destroyed, preferably with Knapp's roller forceps.

VI. GRANULAR CONJUNCTIVITIS (*Trachoma*).—This is a serious form of inflammation in which rounded granulations¹ (trachoma-bodies) form in the conjunctiva, resulting in cicatricial changes in the lids and vascularization and ulceration of the cornea. The disease may be *acute* or *chronic*. It is distinctly contagious.

Although not nearly so common in childhood as in adult life, many cases occur among children, especially of the poorer classes. It is most frequent among the Jews, Irish, Italians, Indians, and inhabitants of the East, but, except in rare instances, is unknown among the pure negroes. Inhabitants of low and damp regions are more liable than those who live on high ground, an altitude of one thousand feet conferring comparative immunity. This predisposition to granular lids is also encouraged by residence in badly-ventilated homes and asylums, where the disease may become epidemic, and by imperfect nutrition, but there is no known constitutional disorder at the bottom of the disease. The essential characteristics of the affection are the "granulations" (trachoma-bodies), sometimes called "follicles," which differ from those seen in follicular conjunctivitis because they may be regarded as pathological new formations. It is probable that the active agent in the production of trachoma and its dissemination is a special micro-organism, the *trachoma-coccus*, but its identity is not clearly established.

Symptoms.—In *acute* granular conjunctivitis, in addition to the phenomena of a violent conjunctivitis, associated with great dread of light, free lachrymation, and later a muco-purulent discharge, the conjunctival papillæ become hypertrophied and there is a liberal growth of roundish granulations in this membrane. This acute type must be distinguished from the exacerbations which are common in the chronic variety of the disease.

In *chronic* granular conjunctivitis there may be a stage of acute inflammation, such as has just been described, but most frequently it appears without such preceding condition. The grayish-white, semi-transparent granulations, often in rows and sometimes resembling the spawn of frogs, develop chiefly in the retrotarsal folds. The most important types are (*a*) papillary trachoma, (*b*) follicular trachoma, and (*c*) mixed or diffuse trachoma. In the papillary and mixed varieties, in addition to the granulations, there is much hypertrophy of the conjunctival papillæ. At first there is little discharge, but as the development of the follicles increases a softening process takes place and the secretion becomes abundant and is extremely contagious. Gradually the stage of cicatrization is reached, which results in the formation of scar-tissue, the cicatrices often lying in characteristic parallel lines, while the lids become indurated and their borders inverted, resulting in conditions which have already been described. In bad cases there is a practical drying up, or *xerosis*, of the conjunctiva, with obliteration of the sulcus.

Sequelæ.—The most important sequels of granular lids have been referred to, with the exception of the vascularization of the cornea, or *pannus*, which is really a form of *vascular keratitis*. It always begins under the upper lid by the development of blood-vessels in the superficial layers of the cornea, often associated with ulceration and opacification of that membrane. This pannus is

¹ These should not be confounded with the granulations of wounds.

partly due to the mechanical effect of the granulations, and partly to a special implantation of the disease in the cornea.

Treatment.—Acute granular conjunctivitis must be managed on the principles already laid down in connection with an acute inflammation of the conjunctiva.

In chronic granulations the object is to promote absorption of these with the least cicatricial change, and consequently the application should never be so caustic as to create scars, which would be worse than those resulting from the natural subsidence of the disease. It would be impossible in this brief description even to refer to the numerous applications which have been made, and the author will hence recommend those which in his own practice he has found most efficacious—namely, (*a*) nitrate of silver, 10 grains to the ounce, during any stage of granular lids when there is much discharge, to be applied in the manner already described; (*b*) strong solutions of bichloride of mercury (1 : 300 or 1 : 500), applied to the everted lids with a cotton mop, associated with frequent irrigation of the conjunctival cul-de-sac with a tepid solution of the same drug, 1 grain to the pint; suitable in practically any stage of granular lids, but especially when there is decided development of the follicles; (*c*) sulphate of copper in the form of a smooth crystal, which is rubbed over the everted lids and well across the retrotarsal folds, useful in any stage except that in which there is much discharge, and particularly valuable in the later periods of the disease; (*d*) boro-glyceride, 20 or 50 per cent., applied in the usual manner to the affected conjunctiva, most valuable after cicatrization has begun. In mild cases an excellent remedy is a solution of tannin and glycerin, 20 or 30 grains of tannic acid to the ounce of glycerin.

Generally, pannus will disappear with the subsidence of the granulations. If it does not or if exacerbations are present, it must be treated after the manner suited to keratitis. (See page 1141.)

Operative interference, except in the acute cases, yields the most satisfactory results in the treatment of granular lids. The best method is expression of the granulations by means of forceps, and of those thus far devised, the one advocated by Knapp, which works on the principle of a roller, is the most valuable. After the lids have been thoroughly rolled the local treatment must be continued, and generally the sulphate-of-copper crystal will then be found useful. The roller forceps, however, are not sufficient in cases of diffuse trachoma. Then the operation called "*grattage*" is much practised. This consists essentially in deep scarifications and rubbing out the trachoma-bodies with a stiff brush which has been dipped in a solution of bichloride of mercury. This last-named method is a vigorous means which should be utilized in selected cases, and for a description of which, and of the many other methods, the reader is referred to systematic treatises on diseases of the eye.

ECCHYMOSIS OF THE CONJUNCTIVA, which consists of an escape of blood into the meshes of the connective tissue, is particularly interesting in children as the common result of a violent paroxysm of whooping cough, although it may arise under any straining effort. It is also seen with girls at the beginning of the menstrual epoch. The entire conjunctiva may become blood-red. The blood disappears without treatment, although hot compresses seem to hasten its subsidence.

CHEMOSIS OF THE CONJUNCTIVA is common in various types of conjunctivitis, but it is also a symptom of deeper diseases of the eye; for example, inflammatory affections of the uveal tract. Sometimes it occurs without appa-

rent cause. The œdema may be very great, and the conjunctiva appear like a huge bleb and protrude between the lids. Usually the œdema subsides under the influence of hot compresses and an astringent lotion; for example, a weak solution of alum. If it be very severe, the swollen tissues may be incised.

TUMORS AND CYSTS OF THE CONJUNCTIVA.—Several varieties of benign tumors and cysts (dermoids) have been described, and among the malignant tumors in children should be mentioned sarcoma, which develops usually at the limbus, and is generally pigmented. The benign growths and cysts can easily be removed. If a sarcoma appears, it may be necessary to extirpate the entire eyeball.

TUBERCLE OF THE CONJUNCTIVA, under rare circumstances, occurs as a primary affection in the form of uneven ulcers beset with grayish-red nodules, in which a decisive diagnosis could be made by bacteriological examination.

PEMPHIGUS may attack this membrane. There is a curious form of *atrophy of the conjunctiva* in which the membrane dries up entirely and the borders of the lid become fixed to the ball. This is probably a form of pemphigus, but it has also been described as *essential shrinking of the conjunctiva*. Ordinary atrophy of the conjunctiva following granular lids and diphtheritic conjunctivitis has been referred to.

INJURIES OF THE CONJUNCTIVA.—Burns, especially with lime and acid, are to be feared mostly on account of the symblepharon which they are likely to produce. After a lime-burn the alkali may be neutralized with a weak acid, but usually it is best to speedily flood the eye with a rapid stream of water—for example, from a spigot—and pick off any pieces which the water fails to wash away. Iced compresses may then be applied. Atropine drops should be instilled if there is corneal involvement, and the conjunctival cul-de-sac should be frequently cleansed with a solution containing boric acid and common salt. An acid burn is treated on the same principles, an alkaline wash composed of carbonate of sodium being at first employed. It is usually recommended to drop olive oil on the conjunctiva after a burn, and certainly it can do no harm. A good plan is to incorporate with liquid vaseline some atropine (gr. iv- $\bar{3}$ j) and freely introduce this substance.

PHLYCTENULAR KERATO-CONJUNCTIVITIS (*Phlyctenular Ophthalmia, Strumous, Pustular, and Vesicular Keratitis and Conjunctivitis*).—It is customary to describe phlyctenular conjunctivitis and phlyctenular keratitis as two distinct affections, but as both cornea and conjunctiva are associated in the inflammation, and as the lesion is the same in both cases, it is better to include them under one name.

The disease is characterized by the formation on the bulbar conjunctiva, at the corneal margin, or on the cornea, of small, grayish-white elevations, often called *vesicles* or *pimples*, and usually classified under the generic term *phlyctenules*, associated with injection, lachrymation, and dread of light.

Etiology.—It usually occurs in children before their tenth year, and most frequently in those of strumous constitution. Eczema of the face is frequently present. The use of unwholesome food (sweetmeats, pastry, tea, and coffee), and consequent derangements of the alimentary canal, are predisposing causes: the conjunctival form follows in the wake of scarlet fever and measles. All varieties are more common and more aggravated in warm and moist weather.

There is a direct relation between this disease and various lesions in the nasal fossæ and naso-pharynx (rhinitis, congested turbinals, and adenoid vegetations). It is probable that astigmatic eyes are more liable than those with refractive conditions approaching emmetropia. Several varieties of micrococci have been described, but no definite causal relation has been established.

Symptoms.—In the conjunctival variety the phlyctenules form on the bulbar conjunctiva and especially affect the margin of the cornea. There may be only one or two of them (*single form*), or they may be numerous and scattered everywhere over the membrane (*multiple form*). At first translucent, they soon become turbid and break down. The conjunctival vessels are freely injected.

In the corneal types the phlyctenules, about the size of a millet-seed, appear near the corneo-scleral junction or encircle the margin (*marginal keratitis*), or a single one develops near the border and creeps across the face of the cornea, followed by a leash of blood-vessels (*fascicular keratitis*). There are, in addition, conjunctival hyperæmia, free lachrymation, and intense photophobia. Soon the phlyctenules grow yellow, break down, and ulcers (*phlyctenular ulcers*) are formed, which at first are superficial and may remain so; or, in the more aggravated varieties, they will grow deeper, the surrounding cornea become infiltrated, and perforation may ensue. This is especially apt to occur if a large yellow phlyctenule (*pustular form*) develops just at the margin of the cornea. Relapses are frequent; new phlyctenules form, fresh ulcers result, and, unless the process is checked, the epithelium of the cornea becomes roughened, opaque, and vascular, and *phlyctenular pannus* arises. Almost invariably there is an irritating rhinitis, causing an acrid secretion to flow from the nose and excoriate the lip, while frequently patches of eczema appear around the nares, on the face, or at the auricle.

Treatment.—The extreme photophobia makes it difficult to properly apply local remedies. For this reason the child's head should be taken between the surgeon's knees, while an assistant holds the hands and body. The lids are then separated and the cornea can be gradually coaxed into view. A lid-elevator may be employed, and in very bad cases it is sometimes needful to use ether or chloroform before the necessary inspection of the eye is possible. Cocaine will temporarily relieve the photophobia, but it should never be employed as a constant application where corneal ulceration exists. If the child is of sufficient age, the eyes may be protected with goggles, and under all circumstances the little patient should be encouraged not to bury its head in the bed-clothes or hide in dark corners of the room. Photophobia may be allayed by douching the eyes with cold water, and search should always be made for a fissure at the external commissure, which is apt to keep up the dread of light; if this be present it may be touched with a crystal of blue-stone or the fibres of the orbicularis divided at this point with a sharp knife.

The best possible hygienic surroundings, with strict regulation of the diet, out-door exercise in good weather, and frequent sponge baths with salt water are advisable. Atropine drops, 4 grains to the ounce, should be used until complete mydriasis is obtained, and this dilatation of the pupil should be kept up as long as there is irritation. If there is much discharge, boric-acid drops, with or without the addition of common salt, may be used. In severe ulceration of the peripheral type, eserine (gr. $\frac{1}{2}$ or $\frac{1}{6}$ to the fluidounce) is useful, and may be employed during the day, a drop or two of the atropine solution being instilled at night. After the irritation has subsided yellow oxide of mercury, 1 grain to the drachm, should be employed as a local application, or in its place finely-powdered calomel may be dusted into the eye, provided the patient

is not taking iodide of potash or any preparation of iodine, under which circumstances such practice will result in a violent inflammation of the conjunctiva.

Internally, after the alimentary canal has been prepared by a course of calomel, the most useful drugs are cod-liver oil, iron, quinine, and arsenic.

It is essential in all these cases to treat the nasal conditions which have been described, an excellent routine practice being to spray the parts with Dobell's solution or listerine, and insufflate powdered iodoform, or a mixture composed of camphor, boric acid, and subnitrate of bismuth, or finely-pulverized chlorate of potassium. If, however, adenoid vegetations or hypertrophied turbinated bodies are present, these must be treated on the principles known to nasal surgery. In stubborn cases and with ulcers tending to perforate the measures to be described for treating corneal ulcers will be required. After the subsidence of the disease suitable glasses should be ordered, if the corneal astigmatism is of such character that it can be corrected.

DISEASES OF THE CORNEA.

ULCERS OF THE CORNEA.—When the stage of infiltration which accompanies an inflammation of the cornea, or a *keratitis*, fails to end in absorption, and the corneal tissue disintegrates, an open lesion or an *ulcer* results. In children the majority of corneal ulcers which are of primary origin result from the disease which has just been described, and are hence known as *phlyctenular ulcers*. Systematic writers have described a number of other types of ulcer, among which the following varieties may be mentioned:

(a) SIMPLE ULCER.—This, sometimes called “pimple ulcer” when it arises from a phlyctenule, is a small gray infiltration, and may develop from an injury. Frequently it appears right in the centre of the cornea, and as a slightly cone-shaped, gray-white opacity, without much irritation, and is then known as the *small central ulcer of childhood*. It heals, leaving a small scar directly in the axis of vision. It is seen in poorly-nourished children of the strumous habit, and probably represents one of the results of imperfect nutrition. It may heal quickly or develop into a deep ulcer.

(b) DEEP OR PURULENT ULCER.—This is practically described in its title, and is a more aggravated form of the type just described, of yellowish appearance with infiltrated margins, and a tendency to penetrate the layers of the cornea. It may be the result of injury, or may follow certain conjunctival inflammations, or arise because a simple ulceration has been neglected. It heals with a dense white scar.

(c) INDOLENT ULCERS.—Several varieties of these have been described. One is apt to occur in the centre of the cornea—a small shallow lesion with a slightly turbid base and not much injection of the surrounding tissues (*shallow central ulcer*). It is often seen accompanying granular lids. Another variety is called *gouged-out ulcer*, almost without any injection accompanying it, its most common situation being near the corneal margin. These ulcers heal with less dense scars, sometimes only a faint opaque facet remaining (*faceted ulcer*). They are common in anæmic and scrofulous patients, and evidently depend upon failure in the nutrition of the cornea.

(d) SLOUGHING ULCER.—A sloughing or infecting ulcer is the representative of *purulent keratitis*, and is a more serious grade than the deep or purulent ulcer already noted. This is not so common in children as in elderly people; but at the same time very violent and serious ulcers, which are *serpiginous* or *creeping* in type, arise in children as the result of injury, because the abrasion

thus produced has been infected, probably, with a special form of micro-organism. Not only is there extensive purulent infiltration of the cornea, but also the iris is involved and pus forms in the anterior chamber, and hence the disease is called *hypopyon keratitis*. In like manner, instead of an open ulcer of this character, the pus may be confined within the layers of the cornea, and an *abscess* results, or its superficial layers may burst and there is an open lesion. This also is due to the fact that the area has been inoculated with pathogenic micro-organisms. Some of the most typical examples of abscess of the cornea and hypopyon keratitis occur not only from injuries and neglected ulcers, but with small-pox, scarlet fever, measles, typhus, and typhoid fever.

Treatment.—Everything which tends to improve the surroundings of the patient and to build up his nutrition is indicated. Proper protection of the eyes with goggles is important; whenever possible, out-door exercise is advisable. The remedies already suggested with phlyctenular keratitis are usually needed, care being taken to inquire into possible etiological conditions, which should be met with suitable measures.

Search should always be made for the presence of a foreign body and for irritating, misplaced cilia. The lachrymal passages should be explored to see if they are patent, and the teeth should be examined, and if they are carious the services of a dentist should be secured. The nasal passages and the nasopharynx should be carefully examined and treated.

In mild cases of simple ulcer atropine drops for a few days, to be followed later by a salve of yellow oxide of mercury (gr. j-5j), usually suffice. In severe cases atropine drops may be employed, provided the ulcer is central and if there is any hyperæmia of the iris; if not, eserine in the strength already mentioned may be dropped into the eye three or four times a day, with one or two drops of the atropine lotion at night. The conjunctival cul-de-sac should be frequently irrigated with a mild antiseptic lotion, a saturated solution of boric acid, a weak solution of bichloride of mercury (1:10,000), or aqua chlorinata. These drugs are particularly indicated if there is an associated conjunctivitis with muco-purulent discharge, which should then be treated also on the principles already laid down.

If the ulcer is sluggish, it may be stimulated to heal by the introduction of the yellow-oxide salve. In sloughing ulcers, in addition to the measures already indicated it may be necessary to curette the surface, touch it gently with a solution of nitrate of silver, 10 grains to the fluidounce, or dust upon it finely-powdered iodoform. In many cases the most effectual treatment is the cautery, the point of a galvano- or a thermo-cautery being applied gently but thoroughly to the involved area. In hypopyon keratitis or in abscess of the cornea, paracentesis of the cornea or the section of Sæmisch is sometimes necessary. In any case in which rupture is impending, and there is no contraindication—as, for example, associated catarrhal conjunctivitis—much good may be done by a carefully applied compressing bandage. In any type of corneal ulceration hot compresses are often invaluable, as they aid in healing and preserve the nutrition of the cornea.

The Results of Corneal Ulceration.—Every ulcer is followed by a scar, which may be a mere haze, or *nebula*, a more pronounced spot, or *macula*, or a dense white scar, or *leucoma*. If the cornea has ruptured, the anterior chamber is evacuated, and the iris falls forward and is entangled in the opening. This, then, is an *anterior synechia*, and the scar on the cornea is an *adherent leucoma*. Sometimes an eye of this character becomes quiet; sometimes, however, it cannot resist the intraocular tension and the area bulges forward, forming a *staphyloma*. If there has been an extensive rupture of the cornea and

complete matting of the prolapsed iris with the inflamed and broken-down corneal tissue, the whole cornea protrudes as an opaque elevation, forming a *complete staphyloma*.

TREATMENT OF SEQUELS.—Slight corneal scars and nebulas may be influenced beneficially by massage of the cornea, aided by the previous introduction of a small particle of Pagenstecher's ointment (yellow oxide of mercury, 1 gr. to the drachm). The dense white leucomas, however, are not thus influenced. If they are central and clear cornea remains at the side, an optical iridectomy may be performed and the scar tattooed with India ink to improve its appearance. After the perforation of an ulcer and prolapse of the iris it is sometimes possible, when recent, to disentangle this with the aid of an instrument and the vigorous use of eserine or atropine, according to the situation of the ulcer. If this fails, staphyloma should be prevented by the vigorous use of a compressing bandage. If, in spite of this, staphyloma, either partial or complete, forms, various surgical measures are indicated, according to the extent of the damage—namely, iridectomy, the operation for partial staphyloma, or, in hopeless cases, evisceration or enucleation.

INFANTILE ULCERATION OF THE CORNEA, WITH XEROSIS OF THE CONJUNCTIVA (*Kerato-malacia*).—In certain anæmic and badly-nourished children, sometimes after measles, scarlet fever, violent diarrhœa, and other illnesses with great depression of nutrition, the cornea undergoes a rapid destructive ulceration, while the conjunctiva becomes greasy and dry, little flakes of cheesy appearance forming upon its surface. Not only is the destruction of the sight almost inevitable, but most of the infants—for it usually occurs during the first year of life—die, generally of intercurrent pneumonia.

The usual treatment of corneal ulceration is indicated, with an attempt to improve the general condition.

This disease should not be confounded with a type of conjunctival disease known as *xerophthalmos*, in which the same cheesy flakes form and the membrane becomes greasy and dry, and which sometimes occurs as an epidemic with the curious symptom of *night-blindness*, especially in people who have long fasted.

INTERSTITIAL KERATITIS (*Syphilitic, Parenchymatous Keratitis*).—In this disease, which is an inflammation of the chronic type, a diffuse keratitis, practically always without ulceration, arises, and the cornea gradually becomes thick with haziness until it resembles ground glass, while superficial and deep vascularization accompanies the condition.

It is most often seen between the ages of five and fifteen, and is more frequent in females than in males. A very large percentage of cases is due to inherited syphilis, but it has also been attributed to rachitis, scrofula, malaria, rheumatism, and depressed nutrition. In the syphilitic cases generally some other mark of syphilis is present, particularly Hutchinson's teeth, or evidence of this taint can be acquired from the family history.

Symptoms.—The disease begins with slight ciliary congestion, a few spots of infiltration in the cornea, which speedily develop into the general haze already described, the infiltration being in the interstitial tissue; blood-vessels become thickly set in the layers of the cornea, which in its upper part assumes a dull reddish color. In some types this is so pronounced that a special variety of it is denominated *vascular keratitis*. There are considerable pain and photophobia. Quite commonly iritis develops, and in many instances inflammation of the deeper coats of the eye occurs. It requires from six months to a year and a half before the disease passes through its various stages. Under proper

treatment clearing of the cornea usually takes place, but years afterward careful examination will show traces of the disease, especially in the presence of minute channels through the corneal tissue, indicating the course of the former vessels.

Treatment.—Any irritating application is distinctly contraindicated. Hence it is proper to employ atropine to maintain dilatation of the pupil and prevent iritis; this, if the photophobia be severe, may be combined with cocaine. Hot compresses are agreeable and soothe the inflammation. The eyes should be protected with goggles, and the child encouraged to have outdoor exercise in proper weather. The best general medication is mercury, and, in the opinion of the author, inunction is the preferable method of administration, pushed to the point of tolerance, but never to that of salivation. Subconjunctival injections of bichloride of mercury—two drops of a 1:1000 solution—have recently acquired a favorable reputation. After the mercurial course iodide of potassium may be given. Later, bichloride of mercury combined with the tincture of the chloride of iron is suitable, and, if the indications are present, the administration of cod-liver oil, arsenic, and quinine. When all irritation has subsided the remaining opacity may be treated by massage with the yellow-oxide-of-mercury ointment. Iridectomy is sometimes necessary to check the disease or to make a new pupil if a central opacity remains. The disease is stubborn, subject to relapses, and nearly always bilateral, although both eyes are not attacked at the same time, and a long period may elapse between the two attacks.

INJURIES OF THE CORNEA.—The most important of these are the ordinary wounds, burns, and scalds; and practically the directions which have already been given in diseases of the conjunctiva are applicable, although, naturally, a wound of the cornea is likely to result in much more serious disaster than one confined to the conjunctiva, because the lens, iris, and even deeper structures, are liable to injury.

After a wound of the cornea the most thorough antiseptics is required. If the iris is prolapsed, it may be seized and cut off and an antiseptic compressing bandage applied. Traumatic iritis is best combated by the frequent use of iced compresses. In severe cases the question of enucleation to prevent sympathetic irritation must be considered.

FOREIGN BODIES IMBEDDED IN THE CORNEA must be removed with a spud after the eye has been rendered insensitive with cocaine. Avoidance of much digging at the corneal tissue is desirable. It is necessary to locate small bodies by means of oblique illumination, and much aid is often given by dropping a fluorescein solution into the eye, which colors green the abraded cornea and brings out in contrast the foreign body as a black spot. After the removal of the foreign body it is desirable to thoroughly cleanse the conjunctival cul-de-sac, lest the abrasion be infected and a serious corneal ulcer result. It is equally necessary that the instruments used should be clean in the surgical sense of the word.

DISEASE OF THE IRIS AND CILIARY BODY; SYMPATHETIC INFLAMMATION OF THE EYE.

Diseases of the iris and, indeed, of the entire uveal tract, are comparatively rare in childhood.

IRITIS.—This may arise *in utero*, and is then called *congenital iritis*. The child is born with occlusion of the pupil, and actual shrinking of the eyeball may ensue.

It also develops, but infrequently, during the first few months of life (from two to nine months), and in practically all instances is due to inherited syphilis. The ordinary symptoms of iritis are present, but not usually in so severe a type as in adults: fine pericorneal injection, discoloration of the iris, sluggish or immobile pupil, abnormal reaction of the iris to a mydriatic, and the formation of attachments between the pupillary margin of the iris and the capsule of the lens, or *posterior synechiæ*,—symptoms which are absent in conjunctivitis, and hence should always serve as distinguishing features.

Iritis associated with inflammation of the ciliary body, opacity in the vitreous and changes in the choroid, and the deposition of a triangular patch of punctate exudations upon the posterior layer of the cornea (*keratitis punctata*, *serous iritis*, *serous irido-cyclitis*) is also seen in young subjects, and, like the preceding affection, may be due to inherited syphilis. Sometimes the iritis which frequently accompanies interstitial keratitis is the most prominent feature of the disease.

Gumma of the Iris and so-called *gummatous iritis* have occasionally been seen in children of syphilitic parents (Alexander, Watson, Mules).

As the age of puberty is approached diseases of the uveal tract become more frequent, and iritis, both plastic and serous, may be seen, the latter especially in girls with disturbances attending the development of the menstrual functions. In one form of iritis lardaceous deposits or nodules appear in the iris, somewhat resembling the small yellowish bodies seen in so-called gummatous (really papular) iritis, constituting the disease called *scrofulous iritis*, which is seen in strumous and anæmic subjects. An insidious form of iritis, associated with vitreous opacities, occurs in the children of gouty parents. The author has seen several examples, and this taint should be suspected in the iritis of boys near the age of puberty.

Tubercles may also appear in the iris (*tubercular iritis*) and constitute a primary tuberculosis.

Finally, an iritis may arise from injury (*traumatic iritis*), and under the influence of infection become purulent (*purulent iritis*)—a type of the disease which has also been described in connection with several infectious diseases (recurrent fever, pneumonia, typhus and typhoid fever, and pyæmia).

Treatment.—This consists in ascertaining the cause and exhibiting suitable remedies, the most important of which are mercury and iodide of potassium. Locally, atropine drops, sufficient to maintain mydriasis, are indicated in practically all cases.¹ In children of a proper age, if there be much pain and inflammatory reaction, leeches may be applied to the temple. Hot compresses are soothing. In traumatic iritis it is proper to employ iced applications, but not in the other varieties of the disease. The ordinary astringent applications are never needed unless there should be associated conjunctivitis. The speedy detection of iritis and prompt use of atropine are important, lest the posterior synechiæ become too strong to be influenced by the drug.

INJURIES TO THE IRIS AND CILIARY REGION; SYMPATHETIC IRRITATION AND SYMPATHETIC INFLAMMATION.—Surrounding the cornea there is a zone about one-quarter of an inch wide, which Mr. Nettleship has very properly called “the dangerous area,” and which indicates the ciliary region. Wounds of this portion of the eye, when followed by plastic or purulent inflammation

¹There are a few exceptions to the rule in serous iritis if the intraocular tension rises.

of the ciliary body (*cyclitis*), are liable to cause functional disturbance of the other eye (*sympathetic irritation*), or serious organic change, which manifests itself as an iritis, irido-cyclitis, or choroido-retinitis, to which the general term sympathetic inflammation or *sympathetic ophthalmitis* is applicable. The eye primarily injured or diseased is usually spoken of as the *excitor*, and the one which becomes involved in the manner just described as the *sympathizer*. Sympathetic inflammation may also be produced by a foreign body which is retained within the eye, and less commonly by corneal ulcers which have ruptured and in which the iris has become entangled, and by shrunken eyeballs—for example, after a panophthalmitis.

Sympathetic irritation is probably a neurosis, and manifests itself in the form of blurred vision, photophobia, tenderness in the ciliary region, and conjunctival hyperæmia. It may be the prodrome of sympathetic inflammation, but this is not necessarily the case, as the latter may arise quite independently, and sometimes insidiously, in one of the forms already noted. If sympathetic irritation is pronounced, the exciting eye should be enucleated, or one of the substitutes for this operation should be performed. This usually suffices to cure the case.

If an eye is so injured that it is sightless and the dangerous region is affected, and especially if a foreign body has entered, enucleation should be performed in order to prevent sympathetic inflammation, because when this has once begun enucleation is often without avail and both eyes may be lost; or indeed, the exciting eye may sometimes be the better one in the end, provided the original injury was not so great as to destroy its sight.

It is impossible in the space here allowed to do more than refer to this most important subject, and for the rules governing the treatment of injuries of the ciliary region and sympathetic inflammation, the reader is referred to systematic treatises on diseases of the eye. Sympathetic inflammation is more apt to occur in children and young people than in adults, and may arise as early as two weeks after the injury or be postponed for years.

DISEASES OF THE LACHRYMAL APPARATUS AND ORBIT.

INFLAMMATION OF THE LACHRYMAL GLAND (*Dacryoadenitis*) is an uncommon affection, and may be either acute or chronic, a lobulated swelling appearing at the upper and outer part of the eyelid, associated with chemosis of the conjunctiva. Sometimes suppuration occurs, and an abscess points upon the skin or in the conjunctiva. The chronic form has been seen among scrofulous children, and may follow an injury or diseases of the conjunctiva. In acute cases warm applications should be applied to encourage suppuration, and the pus evacuated by an incision through the conjunctiva. In chronic cases appropriate internal remedies are the various preparations of iodine, and locally iodide-of-cadmium ointment may be applied over the swollen gland.

DISEASES OF THE LACHRYMAL SAC AND NASAL DUCT.—The universal symptom of almost every form of disease of this region is an excessive secretion of tears, or *epiphora*. Acute inflammation of the sac, which is not uncommon in children, is known as *dacryocystitis*. The sac becomes distended with secretion, which may be catarrhal or purulent, forming a little swelling in the region of the lachrymal sac, pressure upon which causes the contained fluid to exude from the puncta lachrymalia. Occasionally this inflammation is very acute and assumes a phlegmonous type, the surrounding connective tissue becoming infiltrated with purulent material, while a brawny swelling spreads

over the face. Usually the *lachrymal abscess* under these circumstances points below the *tendo oculi*, where it may rupture and the opening become surrounded by pouting granulations. Stricture of the nasal duct generally precedes these inflammations of the sac, but in many instances there is no true stricture, but simply a swelling of the lining membrane.

A *fistula of the lachrymal sac* may be congenital or may result from the failure of a rupture of the lachrymal sac to heal. The little opening which generally leads into the sac appears about half an inch below the punctum or further outward along the lower orbital border, and can generally be detected by the presence of a drop of fluid at its mouth.

The causes of diseases of the lachrymal sac and duct are various. Dacryocystitis has been noted a great many times in infants, sometimes shortly after birth and apparently without cause. A great many cases are due to an inflammation which starts in the nose or naso-pharynx, and hence it is not uncommonly seen after measles, scarlet fever, and small-pox. Other cases are due to inherited syphilis and disease of the bones (periostitis and caries) and to traumatism.

Treatment.—A lachrymal abscess, if it is pointing in the manner already described, should be opened with a sharp scalpel, and the sac and abscess-cavity frequently syringed with bichloride of mercury, peroxide of hydrogen, or blue pyoktanin (1:1000). The cavity may be packed with iodoform gauze and allowed to heal by granulation. Sometimes it is possible to effect a cure by dilating the punctum and irrigating the sac through the natural passages. If there is a stricture, positive and cicatricial, the canaliculus should be split, the stricture divided, and probes passed; but it is extremely desirable to avoid mutilating the punctum and the canaliculus if it is possible to effect a cure without it. Naturally, all cases require intranasal treatment on account of the common association of disease in this region, particularly rhinitis, hypertrophied turbinals, and deflections of the septum. A fistulous communication into the sac may be cured by freshening the edges and closing it or by the use of the galvano-cautery. Generally, however, capillary fistulas may be allowed to remain undisturbed. A judiciously applied pressure bandage will sometimes permanently close up one of these openings. Internally, iron, cod-liver oil, and mercury are indicated, according to the general conditions which may be present.

DISEASES OF THE ORBIT.

PERIOSTITIS.—Either acute or chronic periostitis, which may be due to syphilis, scrofula, tuberculosis, or injuries, sometimes attacks the margin of the orbit, causing localized pain, injection and chemosis of the conjunctiva, swelling of the lids, and protrusion of the eyeball. *Caries of the orbit* occurs quite frequently in children, and is situated nearly always at the margin of the orbit. It may be due to syphilis, scrofula, tuberculosis, or to an injury, and presents practically the same symptoms as those which occur with periostitis. A probe will detect the carious condition of the bone. Great deformity of the lid (ectropion) is not uncommon as the result of this disease.

Treatment.—The treatment consists in the use of the proper constitutional remedies and the surgical measures which are suited to the treatment of periostitis and caries.

CELLULITIS OF THE ORBIT (*Phlegmon of the Orbit*).—Phlegmonous inflammation of the cellular tissue of the orbit, producing in its acute variety

exophthalmos, limitation of the movements of the eye, swelling and œdema of the lids, and considerable hyperæmia and chemosis of the conjunctiva, together with decided constitutional disturbances—chills and fever—may occur in children from a variety of causes. The most common are caries of the orbit, septic phlebitis, injuries, and inflammations of the eye which result in panophthalmitis. Sometimes the disease occurs in infants a very short time after birth.

Treatment.—In addition to proper supporting measures and frequently changed hot compresses, an incision should be made, preferably from the conjunctiva, which secures the evacuation of the pus at as early a moment as possible. Proper drainage must afterward be secured, and the case treated upon the general principles which govern the management of purulent inflammations.

Morbid growths are not uncommon in the orbit, either because an intra-ocular tumor (sarcoma or glioma) has ruptured and invaded the orbit, or as primary growths—namely, the various forms of sarcoma.

Simple and compound cysts are also seen, and, under rare circumstances, a pulsating exophthalmos due to arterio-venous aneurism.

Bleeding in the orbit has sometimes been observed in new-born children, and also occurs in hæmophilia, scurvy, and occasionally in violent attacks of whooping-cough.

CONGENITAL CATARACT.

A certain number of infants are born with *complete cataract*, which is usually white or bluish-white in color, and may readily be detected even without instruments of precision. The eye may be otherwise healthy, or there may be associated with it other congenital anomalies and diseases of the choroid, retina, or optic nerve.

Treatment.—The treatment of complete congenital cataract consists in discission, and the patient is ready for operation after the completion of the first dentition; indeed, it is advisable to operate as early as possible, so that the retina may receive the stimulus afforded by the rays of light, and that the sense of sight may thus be educated.

In addition to the complete congenital cataracts, there are numerous varieties of partial cataract which occur in infants and children, of which the most important are: (a) *Zonular or Lamellar Cataract*; (b) *Central Cataract*; and (c) *Pyramidal or Polar Cataract*. The acquired anterior polar cataracts which develop in infancy are due, as has already been explained, to perforating corneal ulcers, especially during ophthalmia neonatorum.

Treatment.—In some of these cases the treatment is practically without avail; in others, particularly in zonular cataract, either iridectomy, discission, or sometimes extraction, may be practised.¹

THE REFRACTION OF THE EYE IN CHILDHOOD.

The most important study of the refraction of the human eye, made from a careful study of the recorded examinations of the eyes of school-children,

¹ Those interested in congenital cataract and its numerous varieties should consult Professor Michel's article in Gerhardt's *Handbuch der Kinderkrankheiten*, Fünfter Band, Zweite Abtheilung. Tübingen, 1889; and Picqué, *Anomalies de Développement et Maladies congénitales du Globe de l'Œil*, Paris, 1886.

was published by Dr. B. Alexander Randall in the *American Journal of the Medical Sciences*, in 1884. From this author's investigations we know that myopia scarcely ever occurs in infancy and is very infrequent before the beginning of school-life; that hypermetropia, or far-sightedness, is the preponderating condition of refraction in infancy and early childhood, and that there is but little reduction in this proportion even during the first years of school-life; that astigmatism is common, and that a measurable degree of it is found in the majority of ametropic eyes; and that the approximately emmetropic or normal eye is infrequent at all ages, and probably at no time exceeds more than 10 per cent.

The great frequency of hypermetropia and hypermetropic astigmatism in children is responsible for a number of the inflammatory conditions which have already been described, particularly blepharitis, and slight conjunctivitis, as well as hyperæmia of the external and internal coats of the eye. Moreover, it is well established that fully 50 per cent., if not more, of the headaches of functional origin which occur in school-children are due to eye-strain, which in its turn is the result of the refractive anomalies which have been mentioned. Not only is headache commonly caused by hypermetropia and astigmatism, but they also contribute to the existence of a variety of so-called reflex neuroses—habit chorea, chorea itself, night-terrors, irritability of disposition, and general nervousness. While the influence of eye-strain in these respects has sometimes been grossly exaggerated, in the sensitive organism of a growing child it is very frequently one of many factors which foster and aggravate these affections, and the evident indication in the investigation of all functional headaches and nervous diseases is the proper examination of the eyes, and in children of suitable age the prescription of glasses to neutralize the refractive anomalies.

It is not always necessary to condemn a child to glasses for the remainder of his life because he happens to be somewhat hypermetropic, and very often a temporary use of spectacles will bridge him over until he has gained sufficient strength to control the symptoms induced by slight accommodative strain. Glasses should not be ordered unless proper examination has demonstrated their real necessity. Judicious hygiene, quitting school, and perhaps the use of tonics, will often relieve symptoms which are inaccurately ascribed to eye-strain simply because emmetropia is not present.

STRABISMUS, OR SQUINT.

In general terms, strabismus includes those conditions in which the visual axis of one eye is directed away from the point of fixation.

Squint may be *convergent*—that is, the visual line of one eye deviates inward and crosses that of the sound eye at some point nearer than the object fixed; or *divergent*—that is, the visual line of one eye fixes the object, while the visual line of the other eye fails to intersect that of its fellow at the point of fixation. More rarely there is an *upward* or a *downward* squint. So far as children are concerned and for the purpose of the present paragraph, convergent strabismus is the most important. This may be either *concomitant*—that is, the squinting eye is able to follow the movements of the other eye in all directions, or *paralytic*—that is, there is limitation of movement in the direction of the action of the affected muscle.

Concomitant Convergent Squint.—This is the ordinary "crossed eye" of children, and usually begins between the third and fourth years of life. It may be either *permanent* or *periodic*, and the last-named variety may

affect one eye alone or each eye in turn; that is, it is either *monolateral* or *alternating*.

There are numerous causes of concomitant squint, to which only a brief reference can be made. The most important of these is a disturbance of the relation which exists between the power of accommodation of the eyes and their power of convergence, which is caused by errors of refraction—in convergent squint, usually by hypermetropia, in divergent squint, generally by myopia. Squint may also be caused by a disparity in the length or thickness of opposing muscles; for example, the internal rectus muscle may be strong and well developed, while the external rectus is flat and poorly developed. Quite commonly the squinting eye is very amblyopic, and this has been regarded as a cause of convergent squint. This amblyopia, according to one theory, is due to lack of use on the part of the squinting eye, and, according to the other, depends upon imperfect development of the visual centres; that is to say, the amblyopia in the squinting eye is congenital. There is a widespread popular belief that convergent squint may be brought about by fright or by imitation or by looking at some object hung in an oblique direction. These causes, of course, never obtain. Squint, however, is quite commonly first noticed in children after an acute illness—for example, scarlet fever, measles, diphtheria (which may cause one form of paralytic squint), or very depressing illnesses—cholera infantum and similar conditions. These, by weakening the system, determine a strabismus, the conditions for the production of which are already present in the eyes of the child.

Concomitant strabismus must be distinguished from a paralytic strabismus, which may be caused by syphilis, rheumatism, diphtheria, poisons, and, especially in children, by diseases of the base of the brain—for example, tubercular meningitis—by observing that in concomitant strabismus the squinting eye follows the movements of the other eye in all directions; that the secondary and primary deviations of the eye are equal; that double vision is extremely uncommon; and that there are usually considerable degrees of refractive error. In paralysis of an ocular muscle there is limitation of movement of the affected eye in the direction of the paralyzed muscle; the secondary deviation (*i. e.* the deviation of the sound eye, while the affected eye “fixes” an object held about one foot from it) is greater than the primary deviation; double vision is the rule; and there is no special relation to refractive errors. Many of the differential points are difficult to determine in young children, although usually it is possible to elicit that which compares the movements of the eyes.

Treatment of Concomitant Convergent Strabismus.—This may be divided into the mydriatic treatment, the spectacle treatment, and the operative treatment. In very young children who begin to squint good results will sometimes follow the use of a weak solution of atropine—for example, a half or one grain to the fluidounce—continued for long periods of time, just sufficient being introduced into the conjunctival sac to maintain mydriasis and keep the ciliary muscle paralyzed. As soon as the child is of sufficient age the refractive error should be carefully neutralized by means of spectacles. In many instances of periodic squint properly adjusted spectacles will produce a cure, and the effect of the treatment is in direct ratio to the youth of the patient. In the event of failure the eyes may be straightened, either by tenotomy of one or both internal recti, or tenotomy combined with advancement of the external rectus. It is not advisable to operate upon a case of convergent strabismus before the sixth year; in fact, many of the cases do better if the time of operation is postponed to a later period than the one

just mentioned. It is also never proper to operate upon children, even if there is very considerable amblyopia of one eye, until the spectacle treatment has been given a faithful trial. For the method of performing tenotomy and the rules which govern the expediency and character of the operation the reader is referred to systematic treatises on diseases of the eye.

STANDARD *and* Surgical Medical Works

PUBLISHED BY

W. B. Saunders, 925 Walnut Street,
Philadelphia.

MR. SAUNDERS, in presenting to the profession the following list of publications, begs to state that the aim has been to make them worthy of the confidence of medical book-buyers by the high standard of authorship and by the excellence of typography, paper, printing, and binding.

The works indicated in the Index (see next page) with an asterisk (*) are sold by **subscription** (*not by booksellers*), usually through travelling solicitors, but they can be obtained *direct* from the office of publication (charges of shipment prepaid) by remitting the quoted prices. Full *descriptive circulars* of such works will be sent to any address upon application.

All the other **books** advertised in this catalogue are commonly for sale by *booksellers* in all parts of the United States; but any book will be sent by the publisher to any address (post-paid) on receipt of the price herein given.

(For Announcement of Forthcoming Publications see back cover.)

AN AMERICAN TEXT-BOOK OF SURGERY. Edited by WILLIAM W. KEEN, M. D., LL.D., and J. WILLIAM WHITE, M. D., PH. D. Forming one handsome royal-octavo volume of over 1200 pages (10 × 7 inches), with nearly 500 wood-cuts in text, and 37 colored and half-tone plates, many of them engraved from original photographs and drawings furnished by the authors. Prices: Cloth, \$7.00 net; Sheep, \$8.00 net; Half Russia, \$9.00 net.

The want of a text-book which could be used by the practitioner and at the same time be recommended to the medical student has been deeply felt, especially by teachers of surgery; hence, when it was suggested to a number of these that it would be well to unite in preparing a text-book of this description, great unanimity of opinion was found to exist, and the gentlemen below named gladly consented to join in its production.

Especial prominence has been given to Surgical Bacteriology, a feature which is believed to be unique in a surgical text-book in the English language. Asepsis and Antisepsis have received particular attention. The text is brought well up to date in such important branches as cerebral, spinal, intestinal, and pelvic surgery, the most important and newest operations in these departments being described and illustrated.

The text of the entire book has been submitted to all the authors for their mutual criticism and revision—an idea in book-making that is entirely new and original. The book as a whole, therefore, expresses on all the important surgical topics of the day the consensus of opinion of the eminent surgeons who have joined in its preparation.

One of the most attractive features of the book is its illustrations. Very many of them are original and faithful reproductions of photographs taken directly from patients or from specimens, and the modern improvements in the art of engraving have enabled the publisher to produce illustrations which it is believed are superior to those in any similar work.

Specimen Illustration (largely reduced).

“If this text-book is a fair reflex of the present position of American surgery, we must admit it is of a very high order of merit, and that English surgeons will have to look very carefully to their laurels if they are to preserve a position in the van of surgical practice.”—*London Lancet*.

“The soundness of the teachings contained in this work needs no stronger guarantee than is afforded by the names of its authors.”—*Medical News*, Philadelphia.

AN AMERICAN TEXT-BOOK ON THE THEORY AND PRACTICE OF MEDICINE. By American Teachers. Edited

by WILLIAM PEPPER, M. D., LL.D., Provost and Professor of the Theory and Practice of Medicine and of Clinical Medicine in the University of Pennsylvania. Complete in two handsome royal-octavo volumes of about 1000 pages each, with illustrations to elucidate the text wherever necessary. Price per Volume: Cloth, \$5.00 net; Sheep, \$6.00 net; Half Russia, \$7.00 net.

VOLUME I. CONTAINS:

Hygiene.—Fever (Ephemeral, Simple Continued, Typhus, Typhoid, Epidemic Cerebro-spinal Meningitis, and Relapsing).—Scarlatina, Measles, Rôtheln, Variola, Varioloid, Vaccinia, Varicella, Mumps, Whooping-cough, Anthrax,

Hydrophobia, Trichinosis, Actinomycosis, Glan-
ders, and Tetanus.—Tuberculosis, Scrofula,
Syphilis, Diphtheria, Erysipelas, Malaria, Chol-
era, and Yellow Fever.—Nervous, Muscular, and
Mental Diseases.

VOLUME II. CONTAINS:

Urine (Chemistry and Microscopy).—Kidney
and Lungs.—Air-passages (Larynx and Bronchi)
and Pleura.—Pharynx, Oesophagus, Stomach
and Intestines (including Intestinal Parasites),
Heart, Aorta, Arteries and Veins.—Peritoneum,

Liver, and Pancreas.—Diathetic Diseases (Rheu-
matism, Rheumatoid Arthritis, Gout, Lithæmia,
and Diabetes).—Blood and Spleen.—Inflamma-
tion, Embolism, Thrombosis, Fever, and Bacte-
riology.

The articles are not written as though addressed to students in lectures, but are exhaustive descriptions of diseases, with the newest facts as regards Causation, Symptomatology, Diagnosis, Prognosis, and Treatment, including a large number of approved formulæ. The recent advances made in the study of the bacterial origin of various diseases are fully described, as well as the bearing of the knowl-
edge so gained upon prevention and cure. The subjects of Bacteriology as a whole and of Immunity are fully considered in a separate section.

Methods of diagnosis are given the most minute and careful attention, thus enabling the reader to learn the very latest methods of investigation without consulting works specially devoted to the subject.

Horatio C. Wood, Philadelphia.

"We reviewed the first volume of this work, and said: 'It is undoubtedly one of the best text-books on the practice of medicine which we possess.' A consideration of the second and last volume leads us to modify that verdict and to say that the completed work is, in our opinion, the BEST of its kind it has ever been our fortune to see. It is complete, thorough, accurate, and clear. It is well written, well arranged, well printed, well illustrated, and well bound. It is a model of what the modern text-book should be."—*New York Medical Journal*.

"A library upon modern medical art. The work must promote the wider diffusion of sound knowledge."—*American Lancet*.

"A trusty counsellor for the practitioner or senior student, on which he may implicitly rely."—*Edinburgh Medical Journal*.

For Sale by Subscription.

AN AMERICAN TEXT-BOOK OF THE DISEASES OF CHILDREN. By American Teachers. Edited by LOUIS STARR, M. D., assisted by THOMPSON S. WESTCOTT, M. D. In one handsome royal-8vo volume of 1190 pages, profusely illustrated with wood-cuts, half-tone and colored plates. Prices: Cloth, \$7.00 net; Sheep, \$8.00 net; Half Russia, \$9.00 net.

The plan of this work embraces a series of original articles written by some sixty well-known pædiatrists, representing collectively the teachings of the most prominent medical schools and colleges of America. The work is intended to be a PRACTICAL book, suitable for constant and handy reference by the practitioner and the advanced student.

One decided innovation is the large number of authors, nearly every article being contributed by a specialist in the line on which he writes. This, while entailing considerable labor upon the editors, has resulted in the publication of a work THOROUGHLY NEW AND AHEAD OF THE TIMES.

Especial attention has been given to the consideration of the latest accepted teaching upon the etiology, symptoms, pathology, diagnosis, and treatment of the disorders of children, with the introduction of many special formulæ and therapeutic procedures.

Special chapters embrace at unusual length the Diseases of the Eye, Ear, Nose and Throat, and the Skin; while the introductory chapters cover fully the important subjects of Diet, Hygiene, Exercise, Bathing, and the Chemistry of Food. Tracheotomy, Intubation, Circumcision, and such minor surgical procedures coming within the province of the medical practitioner, are carefully considered.

AN AMERICAN TEXT-BOOK OF GYNECOLOGY, MEDICAL AND SURGICAL, for the use of Students and Practitioners.

Edited by J. M. BALDY, M. D. Forming a handsome royal-octavo volume, with 360 illustrations in text and 37 colored and half-tone plates. Prices: Cloth, \$6.00 net; Sheep, \$7.00 net; Half Russia, \$8.00 net.

In this volume all anatomical descriptions, excepting those essential to a clear understanding of the text, have been omitted, the illustrations being largely depended upon to elucidate the anatomy of the parts. This work, which is thoroughly practical in its teachings, is intended, as its title implies, to be a working text-book for physicians and students. A clear line of treatment has been laid down in every case, and although no attempt has been made to discuss mooted points, still the most important of these have been noted and explained. The operations recommended are fully illustrated, so that the reader, having a picture of the procedure described in the text under his eye, cannot fail to grasp the idea. All extraneous matter and discussions have been carefully excluded, the attempt being made to allow no

Specimen Illustration.

unnecessary details to cumber the text. The subject-matter is brought up to date at every point, and the work is as nearly as possible the combined opinions of the ten specialists who figure as the authors.

The work is well illustrated throughout with wood-cuts, half-tone and colored plates, mostly selected from the authors' private collections.

"The most notable contribution to gynecological literature since 1887, . . . and the most complete exponent of gynecology which we have. No subject seems to have been neglected, . . . and the gynecologist and surgeon and the general practitioner, who has any desire to practise diseases of women, will find it of practical value. In the matter of illustrations and plates the book surpasses anything we have seen."—*Boston Medical and Surgical Journal*.

DISEASES OF THE EYE. A Hand-book of Ophthalmic Practice. By G. E. DESCHWEINITZ, M. D., Professor of Diseases of the Eye, Philadelphia Polyclinic; Professor of Clinical Ophthalmology, Jefferson Medical College, Philadelphia, etc. Forming a handsome royal-octavo volume of more than 600 pages, with over 200 fine wood-cuts, many of which are original, and 2 chromo-lithographic plates. Prices: Cloth, \$4.00 net; Sheep, \$5.00 net; Half Russia, \$5.50 net.

The object of this work is to present to the student, and to the practitioner who is beginning work in the fields of ophthalmology, a plain description of the optical defects and diseases of the eye. To this end special attention has been paid to the clinical side of the question; and the method of examination, the symptomatology leading to a diagnosis, and the treatment of the various ocular defects have been brought into special prominence. The general plan of the book is eminently practical. Attention is called to the large number of illustrations (nearly one-third of which are new), which will materially facilitate the thorough understanding of the subject.

Specimen Illustration.

“For the student and practitioner it is the best single volume at present published.”—*Medical News*, Philadelphia.

“A most complete and sterling presentation of the present status of modern knowledge concerning diseases of the eye.”—*Medical Age*, Detroit, Mich.

PROFESSIONAL OPINIONS.

“A work that will meet the requirements not only of the specialist, but of the general practitioner in a rare degree. I am satisfied that unusual success awaits it.”

WILLIAM PEPPER, M. D.,

Provost and Professor of Theory and Practice of Medicine and Clinical Medicine in the University of Pennsylvania.

“Contains in concise and reliable form the accepted views of Ophthalmic Science.”

WILLIAM THOMSON, M. D.,

Professor of Ophthalmology, Jefferson Medical College, Philadelphia, Pa.

“Contains in the most attractive and easily understood form just the sort of knowledge which is necessary to the intelligent practice of general medicine and surgery.”

J. WILLIAM WHITE, M. D.,

Professor of Clinical Surgery in the University of Pennsylvania.

“A very reliable guide to the study of eye diseases, presenting the latest facts and newest ideas.”

SWAN M. BURNETT, M. D.,

Professor of Ophthalmology and Otology, Medical Department Univ. of Georgetown, Washington, D. C.

MEDICAL DIAGNOSIS. By Dr. OSWALD VIERORDT, Professor of Medicine at the University of Heidelberg. Translated, with additions, from the Second Enlarged German Edition, with the author's permission, by FRANCIS H. STUART, A. M., M. D. Third and Revised Edition. In one handsome royal-octavo volume of 700 pages, 178 fine wood-cuts in text, many of which are in colors. Prices: Cloth, \$4.00 net; Sheep, \$5.00 net; Half Russia, \$5.50 net.

Specimen Illustration.

In this work, as in no other hitherto published, are given full and accurate explanations of the phenomena observed at the bedside. It is distinctly a clinical work by a master teacher, characterized by thoroughness, fulness, and accuracy. It is a mine of information upon the points that are so often passed over without explanation. Especial attention has been given to the germ-theory as a factor in the origin of disease.

This valuable work is now published in German, English, Russian, and Italian. The issue of a third American edition within two years indicates the favor with which it has been received by the profession.

"Rarely is a book published with which a reviewer can find so little fault as with the volume before us. All the chapters are full, and leave little to be desired by the reader. Each particular item in the consideration of an organ or apparatus, which is necessary to determine a diagnosis of any disease of that organ, is mentioned; nothing seems forgotten. The chapters on diseases of the circulatory and digestive apparatus and nervous system are especially full and valuable. Notwithstanding a few minor errors in translating, which are of small importance to the accuracy of the rest of the volume, the reviewer would repeat that the book is one of the best—probably, *the best*—which has fallen into his hands. An excellent and comprehensive index of nearly one hundred pages closes the volume."—*University Medical Magazine*, Philadelphia.

PROFESSIONAL OPINIONS.

"One of the most valuable and useful works in medical literature."

ALEXANDER J. C. SKENE, M. D.,
Dean of the Long Island College Hospital, and Professor of the Medical and Surgical Diseases of Women.

"Indispensable to both 'students and practitioners.'"

F. MINOT, M. D.,
Hersey Professor of Theory and Practice of Medicine, Harvard University.

"It is very well arranged and very complete, and contains valuable features not usually found in the ordinary books."

J. H. MUSSER, M. D.,
Assistant Professor Clinical Medicine, University of Pennsylvania.

A NEW PRONOUNCING DICTIONARY OF MEDICINE, with Phonetic Pronunciation, Accentuation, Etymology, etc. By JOHN M. KEATING, M. D., LL.D., Fellow of the College of Physicians of Philadelphia; Vice-President of the American Pædiatric Society; Ex-President of the Association of Life Insurance Medical Directors; Editor "Cyclopædia of the Diseases of Children," etc.; and HENRY HAMILTON, Author of a "A New Translation of Virgil's *Æneid* into English Rhyme;" Co-Author of "Saunders' Medical Lexicon," etc.; with the Collaboration of J. CHALMERS DACOSTA, M. D., and FREDERICK A. PACKARD, M. D. With an Appendix, containing Important Tables of Bacilli, Micrococci, Leucomaines, Ptomaines; Drugs and Materials used in Antiseptic Surgery; Poisons and their Antidotes; Weights and Measures; Thermometric Scales; New Official and Unofficial Drugs, etc. Forming one very attractive volume of over 800 pages. Second Revised Edition. Prices: Cloth, \$5.00 net; Sheep, \$6.00 net; Half Russia, \$6.50 net. With Denison's Patent Index for Ready Reference.

PROFESSIONAL OPINIONS.

"I am much pleased with Keating's Dictionary, and shall take pleasure in recommending it to my classes."

HENRY M. LYMAN, M. D.,
Professor of Principles and Practice of Medicine, Rush Medical College, Chicago, Ill.

"I am convinced that it will be a very valuable adjunct to my study-table, convenient in size and sufficiently full for ordinary use."

C. A. LINDSLEY, M. D.,
*Professor of Theory and Practice of Medicine, Medical Dept. Yale University;
Secretary Connecticut State Board of Health, New Haven, Conn.*

"I will point out to my classes the many good features of this book as compared with others, which will, I am sure, make it very popular with students."

JOHN CRONYN, M. D., LL.D.,
*Professor of Principles and Practice of Medicine and Clinical Medicine;
President of the Faculty, Medical Dept. Niagara University, Buffalo, N. Y.*

AUTOBIOGRAPHY OF SAMUEL D. GROSS, M. D., Emeritus Professor of Surgery in the Jefferson Medical College of Philadelphia, with Reminiscences of His Times and Contemporaries. Edited by his Sons, SAMUEL W. GROSS, M. D., LL.D., late Professor of Principles of Surgery and of Clinical Surgery in the Jefferson Medical College, and A. HALLER GROSS, A. M., of the Philadelphia Bar. Preceded by a Memoir of Dr. Gross, by the late Austin Flint, M. D., LL.D. In two handsome volumes, each containing over 400 pages, demy 8vo, extra cloth, gilt tops, with fine Frontispiece engraved on steel. Price, \$5.00 net.

This autobiography, which was continued by the late eminent surgeon until within three months before his death, contains a full and accurate history of his early struggles, trials, and subsequent successes, told in a singularly interesting and charming manner, and embraces short and graphic pen-portraits of many of the most distinguished men—surgeons, physicians, divines, lawyers, statesmen, scientists, etc.—with whom he was brought in contact in America and in Europe; the whole forming a retrospect of more than three-quarters of a century.

SURGICAL PATHOLOGY AND THERAPEUTICS. By J. COLLINS WARREN, M. D., Professor of Surgery, Harvard Medical School, etc. In one very handsome octavo volume of over 800 pages, with 135 illustrations, 33 of which are chromo-lithographs, and all of which are drawn from original specimens. (Passing through the press.)

Infiltration of Columna Adiposa and Subcutaneous Tissue with Pus in Carbuncle.

Condition of the Nerve-centres in Shock: *a*, Stimulated cell; *b*, Resting cell.

Specimen Illustrations.

Covering as it does the entire field of Surgical Pathology and Surgical Therapeutics by an acknowledged authority, the publisher is confident that the work will rank as a standard authority on the subject of which it treats. Particular attention has been paid to Bacteriology and Surgical Bacteria from the standpoint of recent investigations, and the chromo-lithographic plates in their fidelity to nature and in scientific accuracy have hitherto been unapproached.

Practical, Exhaustive, Authoritative.

SAUNDERS'

NEW AID SERIES OF MANUALS.

FOR

STUDENTS AND PRACTITIONERS.

MR. SAUNDERS is pleased to announce as in *active preparation* his **NEW AID SERIES OF MANUALS** for **Students and Practitioners**. As publisher of the **STANDARD SERIES OF QUESTION COMPENDS**, and through intimate relations with leading members of the medical profession, Mr. Saunders has been enabled to study progressively the essential *desiderata* in practical "self-helps" for students and physicians.

This study has manifested that, while the published "Question Compends" earn the highest appreciation of students, whom they serve in reviewing their studies preparatory to examination, there is special need of thoroughly reliable handbooks on the leading branches of Medicine and Surgery, each subject being compactly and authoritatively written, and exhaustive in detail, without the introduction of *cases* and foreign subject-matter which so largely expand ordinary textbooks.

The Saunders Aid Series will not merely be condensations from present literature, but will be ably written by well-known authors and practitioners, most of them being teachers in representative **American Colleges**. This *new series*, therefore, will form an admirable collection of advanced lectures, which will be invaluable aids to students in reading and in comprehending the contents of "recommended" works.

Each Manual will further be distinguished by the beauty of the *new* type; by the quality of the paper and printing; by the copious use of illustrations; by the attractive binding in cloth; and by the **extremely low price, which will uniformly be \$1.25 per volume.**

SAUNDERS' NEW AID SERIES OF MANUALS.

VOLUMES NOW READY.

- PHYSIOLOGY.** By JOSEPH HOWARD RAYMOND, A. M., M. D., Professor of Physiology and Hygiene, and Lecturer on Gynecology in the Long Island College Hospital, etc. Price, \$1.25 net.
- SURGERY, General and Operative.** By JOHN CHALMERS DACOSTA, M. D., Demonstrator of Surgery, Jefferson Medical College, Philadelphia, etc. Double number. Price, \$2.50 net.
- DOSE-BOOK AND MANUAL OF PRESCRIPTION-WRITING.** By E. Q. THORNTON, M. D., Demonstrator of Therapeutics, Jefferson Medical College, Philadelphia. Price, \$1.25 net.
- MEDICAL JURISPRUDENCE.** By HENRY C. CHAPMAN, M. D., Professor of Institutes of Medicine and Medical Jurisprudence in the Jefferson Medical College of Philadelphia, etc. Price, \$1.25 net.
- SURGICAL ASEPSIS.** By CARL BECK, M. D., Surgeon to St. Mark's Hospital and to the German Poliklinik; Instructor in Surgery, New York Post-Graduate Medical School, etc. Price, \$1.25 net.

VOLUMES IN PREPARATION FOR EARLY PUBLICATION.

- OBSTETRICS.** By W. A. NEWMAN DORLAND, M. D., Demonstrator of Obstetrics, University of Pennsylvania; Chief of Gynecological Dispensary, Pennsylvania Hospital; Member of Philadelphia Obstetrical Society, etc. Price, \$1.25 net.
- MATERIA MEDICA AND THERAPEUTICS.** By HENRY A. GRIFFIN, A. B., M. D., Assistant Physician to the Roosevelt Hospital, Out-patient Department, New York City. Price, \$1.25 net.
- SYPHILIS AND THE VENEREAL DISEASES.** By JAMES NEVINS HYDE, M. D., Professor of Skin and Venereal Diseases in Rush Medical College, Chicago. Double number. Price, \$2.50 net.
- NERVOUS DISEASES.** By CHARLES W. BURR, M. D., Clinical Professor of Nervous Diseases, Medico-Chirurgical College, Philadelphia, etc. Price, \$1.25 net.
- PRACTICE OF MEDICINE.** By GEORGE ROE LOCKWOOD, M. D., Professor of Practice in the Woman's Medical College and in the New York Infirmary, etc. Double number. Price, \$2.50 net.
- NOSE AND THROAT.** By D. BRADEN KYLE, M. D., Chief Laryngologist to St. Agnes' Hospital, Philadelphia; Instructor in Clinical Microscopy, and Assistant Demonstrator of Pathology in the Jefferson Medical College, etc. Price, \$1.25 net.

* * * There will be published in the same series, at close intervals, carefully-prepared works on the subjects of Anatomy, Gynecology, Pathology, Hygiene, etc., by prominent specialists.

A MANUAL OF PHYSIOLOGY. By JOSEPH H. RAYMOND, A. M., M. D., Professor of Physiology and Hygiene, and Lecturer on Gynecology in the Long Island College Hospital; Director of Physiology in the Hoagland Laboratory; formerly Lecturer on Physiology and Hygiene in the Brooklyn Normal School for Physical Education; Ex-Vice-President of the American Public Health Association; Ex-Health Commissioner City of Brooklyn, etc. Illustrated. Price, Cloth, \$1.25 net.

A work for the student and practitioner, representing in a concise form the existing state of Physiology and its methods of investigation, based upon Comparative and Pathological Anatomy, Clinical Medicine, Physics, and Chemistry, as well as upon experimental research.

Specimen Illustration.

A MANUAL OF SURGERY, General and Operative. By JOHN CHALMERS DACOSTA, M. D., Demonstrator of Surgery, Jefferson Medical College, Philadelphia; Chief Assistant Surgeon, Jefferson Medical College Hospital; Surgical Registrar, Philadelphia Hospital, etc. One very handsome volume of over 700 pages, with a large number of illustrations. (Double number.) Price, Cloth, \$2.50 net.

A new manual of the Principles and Practice of Surgery, intended to meet the demands of students and working practitioners for a medium-sized work which will embody all the newer methods of procedure detailed in the larger text-books. The work has been written in a concise, practical manner, and especial attention has been given to the most recent methods of treatment. Illustrations are freely used to elucidate the text.

Specimen Illustration.

A MANUAL OF OBSTETRICS. By W. A. NEWMAN DORLAND, M. D., Demonstrator of Obstetrics, University of Pennsylvania; Chief of Gynecological Dispensary, Pennsylvania Hospital; Member of Philadelphia Obstetrical Society, etc. Profusely illustrated. Price, Cloth, \$1.25 net.

This work, which is thoroughly practical in its teachings, is intended, as its title implies, to be a working text-book for the student and of value to the practitioner as a convenient handbook of reference. Although concisely written, nothing of importance is omitted that will give a clear and succinct knowledge of the subject as it stands to-day. Illustrations are freely used throughout the text.

DOSE-BOOK AND MANUAL OF PRESCRIPTION-WRITING.

By E. Q. THORNTON, M. D., Demonstrator of Therapeutics, Jefferson Medical College, Philadelphia. Price, Cloth, \$1.25 net.

But little attention is generally given, in works on *Materia Medica* and Therapeutics, to the methods of combining remedies in the form of prescriptions, and this manual has been written especially for students in the hope that it may serve to give a thorough and comprehensive knowledge of the subject.

The work, which is based upon the last (1890) edition of the *Pharmacopœia*, fully covers the subjects of Weights and Measures, Prescriptions (form of writing, general directions to pharmacist, grammatical construction, etc.), Dosage, Incompatibles, Poisons, etc.

MEDICAL JURISPRUDENCE AND TOXICOLOGY.

By HENRY C. CHAPMAN, M. D., Professor of Institutes of Medicine and Medical Jurisprudence in the Jefferson Medical College of Philadelphia; Member of the College of Physicians of Philadelphia, of the Academy of Natural Sciences of Philadelphia, of the American Philosophical Society, and of the Zoological Society of Philadelphia. 232 pages, with 36 illustrations, some of which are in colors. Price, \$1.25 net.

Specimen Illustration.

For many years there has been a demand from members of the medical and legal professions for a medium-sized work on this most important branch of medicine. The necessarily proscribed limits of the work permit only the consideration of those parts of this extensive subject which the experience of the author as coroner's physician of the city of Philadelphia for a period of six years leads him to regard as the most material for practical purposes.

Particular attention is drawn to the illustrations, many being produced in colors, thus conveying to the layman a far clearer idea of the more intricate cases.

"The salient points are clearly defined, and ascertained facts are laid down with a clearness that is unequivocal."—*St. Louis Medical and Surgical Journal.*

"One that is not overloaded with an unnecessary detail of a large amount of literature on the subject, requiring hours of research for the essential points in the decision of a question; that contains the most lucid symptomatology of questionable conditions, tests of poisons, and the readiest means of making them—such is the new book before us."—*The Sanitarian.*

A GUIDE TO THE BACTERIOLOGICAL LABORATORY. By LANGDON FROTHINGHAM, M. D. Illustrated. (In preparation.)

The technical methods involved in bacteria-culture, methods of staining, and microscopical study are fully described and arranged as simply and concisely as possible. The book is especially intended for use in laboratory work.

NURSING: ITS PRINCIPLES AND PRACTICE. By ISABEL ADAMS

HAMPTON, Graduate of the New York Training School for Nurses attached to Bellevue Hospital; Superintendent of Nurses, and Principal of the Training School for Nurses, Johns Hopkins Hospital, Baltimore, Md.; late Superintendent of Nurses, Illinois Training School for Nurses, Chicago, Ill. In one very handsome 12mo volume of 484 pages, profusely illustrated. Price, Cloth, \$2.00 net.

This entirely new work on the important subject of nursing is at once comprehensive and systematic. It is written in a clear, accurate, and readable style, suitable alike to the student and the lay reader. Such a work has long been a desideratum with those intrusted with the management of hospitals and the instruction of nurses in training schools. It is also of especial value to the graduated nurse who desires to acquire a practical working knowledge of the care of the sick and the hygiene of the sick-room.

METHODS OF PREVENTING AND CORRECTING DEFORMITIES OF THE BONES AND JOINTS: A Handbook of Practical Orthopedic Surgery.

By H. AUGUSTUS WILSON, M. D., Professor of General and Orthopedic Surgery, Philadelphia Polyclinic; Clinical Professor of Orthopedic Surgery, Jefferson Medical College, Philadelphia, etc. (In preparation.)

The aim of the author is to provide a book of moderate size, containing comprehensive details that will enable general practitioners to understand thoroughly the mechanical features of the many forms of congenital and acquired deformities of the bones and joints.

The mechanical functions that are impaired will be considered first as to prevention as of primary importance, and following this will be described the methods of correction that have been proved practical by the author. Operative procedures will be considered from a mechanical as well as a surgical standpoint. Prominence will be given to the mechanical requirements for braces and artificial limbs, etc., with description of the methods for constructing the simplest forms, whether made of plaster of Paris, felt, leather, paper, steel, or other materials, together with the methods of readjustment to suit the changes occurring during the progress of the case. A very large number of original illustrations will be used.

AN OPERATION BLANK, with Lists of Instruments, etc. required in Various Operations.

Prepared by W. W. KEEN, M. D., LL.D., Professor of Principles of Surgery in the Jefferson Medical College, Philadelphia. Price per Pad, containing Blanks for fifty operations, 50 cents net.

A convenient blank (suitable for all operations), giving complete instructions regarding necessary preparation of patient, etc., with a full list of dressings and medicines to be employed.

At the back of pad is a list of instruments used—viz. general instruments, etc., required for all operations; and special instruments for surgery of the brain and spine, mouth and throat, abdomen, rectum, male and female genito-urinary organs, the bones, etc.

The whole forming a neat pad, arranged for hanging on the wall of a surgeon's office or in the hospital operating-room.

DISEASES OF WOMEN. By HENRY J. GARRIGUES, A. M., M. D., Professor of Obstetrics in the New York Post-Graduate Medical School and Hospital; Gynæcologist to St. Mark's Hospital, and to the German Dispensary, etc., New York City. In one very handsome octavo volume of about 700 pages, illustrated by numerous wood-cuts and colored plates. Prices: Cloth, \$4.00 net; Sheep, \$5.00 net.

Specimen Illustration.

A PRACTICAL work on gynæcology for the use of students and practitioners, written in a terse and concise manner. The importance of a thorough knowledge of the anatomy of the female pelvic organs has been fully recognized by the author, and considerable space has been devoted to the subject. The chapters on Operations and on Treatment are thoroughly modern, and are based upon the large hospital and private practice of the author. The text is elucidated by a large number of illustrations and colored plates, many of them being original, and forming a complete atlas for studying *embryology* and the *anatomy* of the *female genitalia*, besides exemplifying, whenever needed, morbid conditions, instruments, apparatus, and operations.

EXCERPT OF CONTENTS.

Development of the Female Genitals.—Anatomy of the Female Pelvic Organs.—Physiology.—Puberty.—Menstruation and Ovulation.—Copulation.—Fecundation.—The Climacteric.—Etiology in General.—Examinations in General.—Treatment in General.—Abnormal Menstruation and Metrorrhagia.—Leucorrhœa.—Diseases of the Vulva.—Diseases of the Perineum.—Diseases of the Vagina.—Diseases of the Uterus.—Diseases of the Fallopian Tubes.—Diseases of the Ovaries.—Diseases of the Pelvis.—Sterility.

The reception accorded to this work has been most flattering. In the short period which has elapsed since its issue, it has been adopted and recommended as a text-book by more than 60 of the Medical Schools and Universities of the United States and Canada.

“One of the best text-books for students and practitioners which has been published in the English language; it is condensed, clear, and comprehensive. The profound learning and great clinical experience of the distinguished author find expression in this book in a most attractive and instructive form. Young practitioners, to whom experienced consultants may not be available, will find in this book invaluable counsel and help.”

THAD. A. REAMY, M. D., LL.D.,
Professor of Clinical Gynecology, Medical College of Ohio; Gynecologist to the Good Samaritan and to the Cincinnati Hospitals.

ESSENTIALS OF ANATOMY AND MANUAL OF PRACTICAL DISSECTION, containing "Hints on Dissection." By CHARLES B. NANCREDE, M. D., Professor of Surgery and Clinical Surgery in the University of Michigan, Ann Arbor; Corresponding Member of the Royal Academy of Medicine, Rome, Italy; late Surgeon Jefferson Medical College, etc. Fourth and revised edition. Post 8vo, over 500 pages, with handsome full-page lithographic plates in colors, and over 200 illustrations. Price: Extra Cloth or Oilcloth for the dissection-room, \$2.00 net.

No pains nor expense have been spared to make this work the most exhaustive yet concise Student's Manual of Anatomy and Dissection ever published, either in America or in Europe.

The colored plates are designed to aid the student in dissecting the muscles, arteries, veins, and nerves. The wood-cuts have all been specially drawn and engraved, and an Appendix added containing 60 illustrations representing the structure of the entire human skeleton, the whole being based on the eleventh edition of Gray's *Anatomy*, and forming a handsome 8vo volume of over 500 pages.

A MANUAL OF PRACTICE OF MEDICINE. By A. A. STEVENS, A. M., M. D., Instructor of Physical Diagnosis in the University of Pennsylvania, and Demonstrator of Pathology in the Woman's Medical College of Philadelphia. Specially intended for students preparing for graduation and hospital examinations, and includes the following sections: General Diseases, Diseases of the Digestive Organs, Diseases of the Respiratory System, Diseases of the Circulatory System, Diseases of the Nervous System, Diseases of the Blood, Diseases of the Kidneys, and Diseases of the Skin. Each section is prefaced by a chapter on General Symptomatology. Third edition. Post 8vo, 502 pages. Numerous illustrations and selected formulae. Price, \$2.50.

Contributions to the science of medicine have poured in so rapidly during the last quarter of a century that it is well-nigh impossible for the student, with the limited time at his disposal, to master elaborate treatises or to cull from them that knowledge which is absolutely essential. From an extended experience in teaching, the author has been enabled, by classification, to group allied symptoms, and by the judicious elimination of theories and redundant explanations to bring within a comparatively small compass a complete outline of the practice of medicine.

A SYLLABUS OF LECTURES ON THE PRACTICE OF SURGERY, arranged in conformity with *The American Text-book of Surgery*. By NICHOLAS SENN, M. D., PH. D., Professor of Surgery in Rush Medical College, Chicago, and in the Chicago Polyclinic. Price, \$2.00.

This, the latest work of its eminent author, himself one of the contributors to the "American Text-book of Surgery," will prove of exceptional value to the advanced student who has adopted that work as his text-book. It is not only the syllabus of an unrivalled course of surgical practice, but it is also an epitome or supplement to the larger work.

SYLLABUS OF OBSTETRICAL LECTURES in the Medical Department, University of Pennsylvania. By RICHARD C. NORRIS, A. M., M. D., Demonstrator of Obstetrics in the University of Pennsylvania. Third edition, thoroughly revised and enlarged. Crown 8vo. Price, Cloth, interleaved for notes, \$2.00 net.

"This work is so far superior to others on the same subject that we take pleasure in calling attention briefly to its excellent features. It covers the subject thoroughly, and will prove invaluable both to the student and the practitioner. The author has introduced a number of valuable hints which would only occur to one who was himself an experienced teacher of obstetrics. The subject-matter is clear, forcible, and modern. We are especially pleased with the portion devoted to the practical duties of the accoucheur, care of the child, etc. The paragraphs on antiseptics are admirable; there is no doubtful tone in the directions given. No details are regarded as unimportant; no minor matters omitted. We venture to say that even the old practitioner will find useful hints in this direction which he cannot afford to despise."—*Medical Record*.

OUTLINES OF OBSTETRICS: A Syllabus of Lectures Delivered at Long Island College Hospital. By CHARLES JEWETT, A. M., M. D., Professor of Obstetrics and Pediatrics in the College, and Obstetrician to the Hospital. Edited by HAROLD F. JEWETT, M. D. Post 8vo, 264 pages. Price, \$2.00.

This book treats only of the general facts and principles of obstetrics: these are stated in concise terms and in a systematic and natural order of sequence, theoretical discussion being as far as possible avoided; the subject is thus presented in a form most easily grasped and remembered by the student. Special attention has been devoted to practical questions of diagnosis and treatment, and in general particular prominence is given to facts which the student most needs to know. The condensed form of statement and the orderly arrangement of topics adapt it to the wants of the busy practitioner as a means of refreshing his knowledge of the subject and as a handy manual for daily reference.

NOTES ON THE NEWER REMEDIES: their Therapeutic Applications and Modes of Administration. By DAVID CERNA, M.D., PH.D., Demonstrator of and Lecturer on Experimental Therapeutics in the University of Pennsylvania. Post-octavo, 175 pages. Price, \$1.25.

The work takes up in alphabetical order all the newer remedies, giving their physical properties, solubility, therapeutic applications, administration, and chemical formula.

It thus forms a very valuable addition to the various works on therapeutics now in existence.

Chemists are so multiplying compounds, that, if each compound is to be thoroughly studied, investigations must be carried far enough to determine the practical importance of the new agents.

"Especially valuable because of its completeness, its accuracy, its systematic consideration of the properties and therapy of many remedies of which doctors generally know but little, expressed in a brief yet terse manner."—*Chicago Clinical Review*.

"A timely and needful book . . . which physicians who avail themselves of the use of the newer remedies cannot afford to do without."—*The Sanitarian*.

LABORATORY EXERCISES IN BOTANY. By EDSON S. BASTIN, M. A., Professor of Materia Medica and Botany in the Philadelphia College of Pharmacy. With over 75 plates. (In preparation.)

This work is intended for the beginner and the advanced student, and it fully covers the structure of flowering plants, roots, ordinary stems, rhizomes, tubers, bulbs, leaves, flowers, fruits, and seeds. Particular attention is given to the gross and microscopical structure of plants, and to those used in medicine. Illustrations have freely been used to elucidate the text, and a complete index to facilitate reference has been added.

The folding charts which supplement the subjects will be found useful in connection with the study of the text.

Trailing Arbutus (*Epigaea repens*).

Specimen Illustration.

SAUNDERS' POCKET MEDICAL LEXICON; or, Dictionary of Terms and Words used in Medicine and Surgery. By JOHN M. KEATING, M. D., Editor of "Cyclopædia of Diseases of Children," etc.; Author of the "New Pronouncing Dictionary of Medicine," and HENRY HAMILTON, Author of "A New Translation of Virgil's *Æneid* into English Verse;" Co-Author of a "New Pronouncing Dictionary of Medicine." A new and revised edition. 32mo, 282 pages. Prices: Cloth, 75 cents; Leather Tucks, \$1.00.

This new and comprehensive work of reference is the outcome of a demand for a more modern hand-book of its class than those at present on the market, which, dating as they do from 1855 to 1884, are of but trifling use to the student by their not containing the hundreds of new words now used in current literature, especially those relating to Electricity and Bacteriology.

"Remarkably accurate in terminology, accentuation, and definition."—*Journal of American Medical Association.*

"Brief, yet complete . . . it contains the very latest nomenclature in even the newest departments of medicine."—*Medical Record.*

SAUNDERS' POCKET MEDICAL FORMULARY. BY WILLIAM M. POWELL, M. D., Attending Physician to the Mercer House for Invalid Women at Atlantic City. Containing 1750 Formulæ, selected from several hundred of the best-known authorities. Forming a handsome and convenient pocket companion of nearly 300 printed pages, with blank leaves for additions; with an Appendix containing Posological Table, Formulæ and Doses for Hypodermic Medication, Poisons and their Antidotes, Diameters of the Female Pelvis and Foetal Head, Obstetrical Table, Diet List for Various Diseases, Materials and Drugs used in Antiseptic Surgery, Treatment of Asphyxia from Drowning, Surgical Remembrancer, Tables of Incompatibles, Eruptive Fevers, Weights and Measures, etc. Third edition, revised and greatly enlarged. Handsomely bound in morocco, with side index, wallet, and flap. Price, \$1.75 net.

"This little book, that can be conveniently carried in the pocket, contains an immense amount of material. It is very useful, and as the name of the author of each prescription is given is unusually reliable."—*New York Medical Record*.

HOW TO EXAMINE FOR LIFE INSURANCE. BY JOHN M. KEATING, M. D., Fellow of the College of Physicians and Surgeons of Philadelphia; Vice-President of the American Pædiatric Society; Ex-President of the Association of Life Insurance Medical Directors. Royal 8vo, 211 pages, with two large phototype illustrations, and a plate prepared by Dr. McClellan from special dissections; also, numerous cuts to elucidate the text. Price, in Cloth, \$2.00 net.

PART I., which has been carefully prepared from the best works on Physical Diagnosis, is a short and succinct account of the methods used to make examinations; a description of the normal condition and of the earliest evidences of disease.

PART II. contains the Instructions of twenty-four Life Insurance Companies to their medical examiners.

"This is by far the most useful book which has yet appeared on insurance examination, a subject of growing interest and importance. Not the least valuable portion of the volume is Part II., which consists of instructions issued to their examining physicians by twenty-four representative companies of this country. As the proofs of these instructions were corrected by the directors of the companies, they form the latest instructions obtainable. If for these alone the book should be at the right hand of every physician interested in this special branch of medical science."—*The Medical News*, Philadelphia.

MANUAL OF MATERIA MEDICA AND THERAPEUTICS. BY A. A. STEVENS, A. M., M. D., Instructor of Physical Diagnosis in the University of Pennsylvania, and Demonstrator of Pathology in the Woman's Medical College of Philadelphia. 435 pages. Price, Cloth, \$2.25.

This wholly new volume, which is based on the 1890 edition of the *Pharmacopœia*, comprehends the following sections: Physiological Action of Drugs; Drugs; Remedial Measures other than Drugs; Applied Therapeutics; Incompatibility in Prescriptions; Table of Doses; Index of Drugs; and Index of Diseases; the treatment being elucidated by more than two hundred formulæ.

SAUNDERS' QUESTION COMPENDS.

Arranged in Question and Answer Form.

THE LATEST, CHEAPEST, AND BEST ILLUSTRATED SERIES
OF COMPENDS EVER ISSUED.

Now the Standard Authorities in Medical Literature

WITH

Students and Practitioners in every City of the United States
and Canada.

THE REASON WHY

They are the advance guard of "Student's Helps"—that DO HELP; they are the leaders in their special line, *well and authoritatively written by able men, who, as teachers in the large colleges, know exactly what is wanted by a student preparing for his examinations.* The judgment exercised in the selection of authors is fully demonstrated by their professional elevation. Chosen from the ranks of Demonstrators, Quiz-masters, and Assistants, most of them have become Professors and Lecturers in their respective colleges.

Each book is of convenient size (5 × 7 inches), containing on an average 250 pages, profusely illustrated, and elegantly printed in clear, readable type, on fine paper.

The entire series, numbering twenty-three subjects, has been kept thoroughly revised and enlarged when necessary, many of them being in their fourth and fifth editions.

TO SUM UP.

Although there are numerous other Quizzes, Manuals, Aids, etc. in the market, none of them approach the "Blue Series of Question Compends;" and the claim is made for the following points of excellence:

1. Professional distinction and reputation of authors.
2. Conciseness, clearness, and soundness of treatment.
3. Size of type and quality of paper and binding.

**** Any of these Compends will be mailed on receipt of price.**

- 1. ESSENTIALS OF PHYSIOLOGY.** By H. A. HARE, M. D., Professor of Therapeutics and Materia Medica in the Jefferson Medical College of Philadelphia; Physician to St. Agnes' Hospital and to the Medical Dispensary of the Children's Hospital; Laureate of the Royal Academy of Medicine in Belgium, of the Medical Society of London, etc. Third edition, revised and enlarged by the addition of a series of handsome plate illustrations taken from the celebrated "Icones Nervorum Capitis" of Arnold. Crown 8vo, 230 pages, numerous illustrations. Price, Cloth, \$1.00 net; interleaved for notes, \$1.25 net.

Specimen Illustration.

"An exceedingly useful little compend. The author has done his work thoroughly and well. The plates of the cranial nerves from Arnold are superb."—*Journal of American Medical Association.*

- 2. ESSENTIALS OF SURGERY,** containing also, Venereal Diseases, Surgical Landmarks, Minor and Operative Surgery, and a Complete Description, together with full Illustrations, of the Handkerchief and Roller Bandage. By EDWARD MARTIN, A. M., M. D., Clinical Professor of Genito-Urinary Diseases, Instructor in Operative Surgery, and Lecturer on Minor Surgery, University of Pennsylvania; Surgeon to the Howard Hospital; Assistant Surgeon to the University Hospital, etc. Fifth edition, Crown 8vo, 334 pages, profusely illustrated. Considerably enlarged by an Appendix containing full directions and prescriptions for the preparation of the various materials used in Antiseptic Surgery; also, several hundred recipes covering the medical treatment of surgical affections. Price, Cloth, \$1.00; interleaved for notes, \$1.25.

Specimen Illustration.

"Written to assist the student, it will be of undoubted value to the practitioner, containing as it does the essence of surgical work."—*Boston Medical and Surgical Journal.*

- 3. ESSENTIALS OF ANATOMY,** including the Anatomy of the Viscera. By CHARLES B. NANCREDE, M. D., Professor of Surgery and of Clinical Surgery in the University of Michigan, Ann Arbor; Corresponding Member of the Royal Academy of Medicine, Rome, Italy; late Surgeon to the Jefferson Medical College, etc. Fifth edition, Crown 8vo, 380 pages, 180 illustrations. Enlarged by an Appendix, containing over sixty illustrations of the Osteology of the Human Body. The whole based upon the last (eleventh) edition of Gray's *Anatomy*. Price, Cloth, \$1.00; interleaved for notes, \$1.25.

"Truly such a book as no student can afford to be without."—*American Practitioner and News.*

"The questions have been wisely selected, and the answers accurately and concisely given."—*University Medical Magazine.*

4. **ESSENTIALS OF MEDICAL CHEMISTRY, ORGANIC AND INORGANIC**, containing also, Questions on Medical Physics, Chemical Physiology, Analytical Processes, Urinalysis, and Toxicology. By LAWRENCE WOLFF, M. D., Demonstrator of Chemistry, Jefferson Medical College; Visiting Physician to the German Hospital of Philadelphia; Member of Philadelphia College of Pharmacy, etc. Fourth and revised edition, with an Appendix, Crown 8vo, 212 pages. Price, Cloth, \$1.00; interleaved for notes, \$1.25.

"The scope of this work is certainly equal to that of the best course of lectures on Medical Chemistry."—*Pharmaceutical Era*.

5. **ESSENTIALS OF OBSTETRICS**. By W. EASTERLY ASHTON, M. D., Professor of Gynæcology in the Medico-Chirurgical College of Philadelphia; Obstetrician to the Philadelphia Hospital. Third edition, thoroughly revised and enlarged, Crown 8vo, 244 pages, 75 illustrations. Price, Cloth, \$1.00; interleaved for notes, \$1.25.

"An excellent little volume containing correct and practical knowledge. An admirable compend, and the best condensation we have seen."—*Southern Practitioner*.

"Of extreme value to students, and an excellent little book to freshen up the memory of the practitioner."—*Chicago Medical Times*.

Specimen Illustration.

6. **ESSENTIALS OF PATHOLOGY AND MORBID ANATOMY**. By C. E. ARMAND SEMPLE, B. A., M. B. Cantab. L. S. A., M. R. C. P. Lond., Physician to the Northeastern Hospital for Children, Hackney; Professor of Vocal and Aural Physiology, and Examiner in Acoustics at Trinity College, London, etc. Crown 8vo, 174 pages, illustrated, (sixth thousand). Price, Cloth, \$1.00; interleaved for notes, \$1.25.

Specimen Illustration.

"A valuable little volume—truly a *multum in parvo*."—*Cincinnati Medical News*.

7. **ESSENTIALS OF MATERIA MEDICA, THERAPEUTICS, AND PRESCRIPTION-WRITING**. By HENRY MORRIS, M. D., Late Demonstrator, Jefferson Medical College; Fellow College of Physicians, Philadelphia; Co-Editor Biddle's *Materia Medica*; Visiting Physician to St. Joseph's Hospital, etc. Fourth edition, Crown 8vo, 250 pages. Price, Cloth, \$1.00; interleaved for notes, \$1.25.

"One of the best compends in this series. Concise, pithy, and clear, well suited to the purpose for which it is prepared."—*Medical and Surgical Reporter*.

"The subjects are treated in such a unique and attractive manner that they cannot fail to impress the mind and instruct in a lasting manner."—*Buffalo Medical and Surgical Journal*.

8, 9. ESSENTIALS OF PRACTICE OF MEDICINE. By HENRY MORRIS, M. D., Author of "Essentials of Materia Medica," etc., with an Appendix on the Clinical and Microscopical Examination of Urine, by LAWRENCE WOLFF, M. D., Author of "Essentials of Medical Chemistry," etc. Colored (Vogel) urine scale and numerous fine illustrations. Third edition, enlarged by some three hundred essential formulæ, selected from the writings of the most eminent authorities of the medical profession. Collected and arranged by WILLIAM M. POWELL, M. D., author of "Essentials of Diseases of Children." Crown 8vo, 460 pages. Price, Cloth, \$2.00.

"The teaching is sound, the presentation graphic, matter as full as might be desired, and the style attractive."—*American Practitioner and News*.

"A first-class practice of medicine boiled down, and giving the real essentials in as few words as is consistent with a thorough understanding of the subject."—*Medical Brief*.

10. ESSENTIALS OF GYNÆCOLOGY. By EDWIN B. CRAGIN, M. D., Attending Gynecologist, Roosevelt Hospital, Out-Patients' Department; Assistant Surgeon, New York Cancer Hospital, etc. Fourth edition, revised. Crown 8vo, 198 pages, 62 fine illustrations. Price, Cloth, \$1.00; interleaved for notes, \$1.25.

Specimen Illustration.

"This is a most excellent addition to this series of question compends. The style is concise, and at the same time the sentences are well rounded. This renders the book far more easy to read than most compends, and adds distinctly to its value."—*Medical and Surgical Reporter*.

11. ESSENTIALS OF DISEASES OF THE SKIN. By HENRY W. STELWAGON, M. D., Clinical Lecturer on Dermatology in the Jefferson Medical College, Philadelphia; Physician to the Skin Service of the Northern Dispensary; Dermatologist to Philadelphia Hospital; Physician to Skin Department of the Howard Hospital; Clinical Professor of Dermatology in the Woman's Medical College, Philadelphia, etc. Third edition. Crown 8vo, 270 pages, 86 illustrations, many of which are original. Price, Cloth, \$1.00; interleaved for notes, \$1.25 net.

Specimen Illustration.

"An immense amount of literature has been gone over and judiciously condensed by the writer's skill and experience."—*Medical Record*.

"The book admirably answers the purpose for which it is written. The experience of the reviewer has taught him that just such a book is needed."—*New York Medical Journal*.

12. **ESSENTIALS OF MINOR SURGERY, BANDAGING, AND VENEREAL DISEASES.** By EDWARD MARTIN, A. M., M. D., Author of "Essentials of Surgery," etc. Second edition. Crown 8vo, thoroughly revised and enlarged, 78 illustrations. Price, Cloth, \$1.00; interleaved for notes, \$1.25.

"Characterized by the same literary excellence that has distinguished previous numbers of this series of compends."—*American Practitioner and News*.

"The best condensation of the subjects of which it treats yet placed before the profession."—*Medical News*, Philadelphia.

Specimen Illustration.

13. **ESSENTIALS OF LEGAL MEDICINE, TOXICOLOGY, AND HYGIENE.** By C. E. ARMAND SEMPLE, M. D., Author of "Essentials of Pathology and Morbid Anatomy." Crown 8vo, 212 pages, 130 illustrations. Price, Cloth, \$1.00; interleaved for notes, \$1.25.

"The leading points, the essentials of this too much neglected portion of medical science, are here summed up systematically and clearly."—*Southern Practitioner*.

Specimen Illustration.

14. **ESSENTIALS OF REFRACTION AND DISEASES OF THE EYE.** By EDWARD JACKSON, A. M., M. D., Professor of Diseases of the Eye in the Philadelphia Polyclinic and College for Graduates in Medicine; Member of the American Ophthalmological Society; Fellow of the College of Physicians of Philadelphia; Fellow of the American Academy of Medicine, etc.; and **ESSENTIALS OF DISEASES OF THE NOSE AND THROAT.** By E. BALDWIN GLEASON, M. D., Surgeon in charge of the Nose, Throat, and Ear Department of the Northern Dispensary of Philadelphia; formerly Assistant in the Nose and Throat Dispensary of the Hospital of the University of Pennsylvania, and Assistant in the Nose and Throat Department of the Union Dispensary, etc. Two volumes in one. Second edition. Crown 8vo, 294 pages, 124 illustrations. Price, Cloth, \$1.00; interleaved for notes, \$1.25.

Specimen Illustrations.

"A valuable book to the beginner in these branches, to the student, to the busy practitioner, and as an adjunct to more thorough reading. The authors are capable men, and as successful teachers know what a student most needs."—*New York Medical Record*.

15. **ESSENTIALS OF DISEASES OF CHILDREN.** By WILLIAM M. POWELL, M. D., Attending Physician to the Mercer House for Invalid Women, at Atlantic City, N. J.; late Physician to the Clinic for the Diseases of Children in the Hospital of the University of Pennsylvania and St. Clement's Hospital; Instructor in Physical Diagnosis in the Medical Department of the University of Pennsylvania. Crown 8vo, 216 pages. Price, Cloth, \$1.00; interleaved for notes, \$1.25.

"This work is gotten up in the clear and attractive style that characterizes the Saunders' Series. It contains in appropriate form the gist of all the best works in the department to which it relates."—*American Practitioner and News*.

"The book contains a series of important questions and answers, which the student will find of great utility in the examination of children."—*Annals of Gynecology*.

16. **ESSENTIALS OF EXAMINATION OF URINE.** By LAWRENCE WOLFF, M. D., Author of "Essentials of Medical Chemistry," etc. Colored (Vogel) urine scale and numerous illustrations. Crown 8vo. Price, Cloth, 75 cents.

"A little work of decided value."—*University Medical Magazine*.

"A good manual for students, well written, and answers, categorically, many questions beginners are sure to ask."—*Medical Record*.

"The questions have been well chosen, and the answers are clear and brief. The book cannot fail to be useful to students."—*Medical and Surgical Reporter*.

Specimen illustration.

17. **ESSENTIALS OF DIAGNOSIS.** By SOLOMON SOLIS-COHEN, M. D., Professor of Clinical Medicine and Applied Therapeutics in the Philadelphia Polyclinic, and AUGUSTUS A. ESHNER, M. D., Instructor in Clinical Medicine, Jefferson Medical College, Philadelphia. Crown 8vo, 382 pages, 55 illustrations, some of which are colored, and a frontispiece. Price, \$1.50 net.

"A good book for the student, properly written from their standpoint, and confines itself well to its text."—*Medical Record*.

"Concise in the treatment of the subject, terse in expression of fact. . . . The work is reliable, and represents the accepted views of clinicians of to-day."—*American Journal of Medical Sciences*.

"The subjects are explained in a few well-selected words, and the required ground has been thoroughly gone over."—*International Medical Magazine*.

Specimen Illustration.

18. **ESSENTIALS OF PRACTICE OF PHARMACY.** By LUCIUS E. SAYRE, M. D., Professor of Pharmacy and Materia Medica in the University of Kansas. Second edition, revised and enlarged. Crown 8vo, 200 pages. Price, Cloth, \$1.00; interleaved for notes, \$1.25.

"Covers a great deal of ground in small compass. The matter is well digested and arranged. The research questions are a valuable feature of the book."—*Albany Medical Annals*.

"The best quiz on Pharmacy we have yet examined."—*National Drug Register*.

"The veteran pharmacist can peruse it with pleasure, because it emphasizes his grasp upon knowledge already gleaned."—*Western Drug Record*.

20. **ESSENTIALS OF BACTERIOLOGY:**
A Concise and Systematic Introduction to the Study of Micro-organisms. By M. V. BALL, M. D., Assistant in Microscopy, Niagara University, Buffalo, N. Y.; late Resident Physician, German Hospital, Philadelphia, etc. Second edition revised. Crown 8vo, 200 pages, 81 illustrations, some in colors, and 5 plates. Price, Cloth, \$1.00; interleaved for notes, \$1.25.

Specimen Illustration.

“The amount of material condensed in this little book is so great, and so accurate are the formulæ and methods, that it will be found useful as a laboratory hand-book.”—*Medical News*.

“Bacteriology is the keynote of future medicine, and every physician who expects success must familiarize himself with a knowledge of germ-life—the agents of disease. This little book, with its beautiful illustrations, will give the students, in brief, the results of years of study and research unaided.”—*Pacific Record of Medicine and Surgery*.

21. **ESSENTIALS OF NERVOUS DISEASES AND INSANITY, their Symptoms and Treatment.** By JOHN C. SHAW, M. D., Clinical Professor of Diseases of the Mind and Nervous System, Long Island College Hospital Medical School; Consulting Neurologist to St. Catherine’s Hospital and to the Long Island College Hospital; formerly Medical Superintendent King’s County Insane Asylum. Second edition. Crown 8vo, 186 pages, 48 original illustrations, mostly selected from the Author’s private practice. Price, Cloth, \$1.00; interleaved for notes, \$1.25.

Specimen Illustration.

“Clearly and intelligently written.”—*Boston Medical and Surgical Journal*.

“A valuable addition to this series of compends, and one that cannot fail to be appreciated by all physicians and students.”—*Medical Brief*.

“Dr. Shaw’s Primer is excellent. The engravings are well executed and very interesting.”—*Times and Register*.

22. **ESSENTIALS OF PHYSICS.** By FRED. J. BROCKWAY, M. D., Assistant Demonstrator of Anatomy in the College of Physicians and Surgeons, New York. Crown 8vo, 320 pages, 155 fine illustrations. Price, Cloth, \$1.00 net; interleaved for notes, \$1.25 net.

Specimen Illustration.

“The publisher has again shown himself as fortunate in his editor as he ever has been in the attractive style and make-up of his compends.”—*American Practitioner and News*.

“Contains all that one need know of the subject, is well written, and is copiously illustrated.”—*Medical Record*.

“The author has dealt with the subject in a manner that will make the theme not only comparatively easy, but also of interest.”—*Medical News*.

23. **ESSENTIALS OF MEDICAL ELECTRICITY.** By D. D. STEWART, M. D., Demonstrator of Diseases of the Nervous System, and Chief of the Neurological Clinic in the Jefferson Medical College; Physician to St. Mary's Hospital, and to St. Christopher's Hospital for Children, etc., and E. S. LAWRENCE, M. D., Chief of the Electrical Clinic, and Assistant Demonstrator of Diseases of the Nervous System in the Jefferson Medical College, etc. Crown 8vo, 148 pages, 65 illustrations. Price, Cloth, \$1.00; interleaved for notes, \$1.25.

"Clearly written, and affords a safe guide to the beginner in this subject."—*Medical and Surgical Journal*.

"The subject is presented in a lucid and pleasing manner."—*Medical Record*.

"A little work on an important subject, which will prove of great value to medical students and trained nurses who wish to study the scientific as well as the practical points of electricity."—*The Hospital*, London, England.

"The selection and arrangement of material are done in a skilful manner. It gives, in a condensed form, the principles and science of electricity and their application in the practice of medicine."—*Annals of Surgery*.

24. **ESSENTIALS OF DISEASES OF**

THE EAR. By E. B. GLEASON, S. B.,

M. D., Clinical Professor of Otology, Medico-Chirurgical College, Philadelphia; Surgeon in Charge of the Nose, Throat, and Ear Department of the Northern Dispensary of Philadelphia; formerly Assistant in the Nose and Throat Dispensary of the Hospital of the University of Pennsylvania, and Assistant in the Nose and Throat Department of the Union Dispensary. 89 illustrations. Price, Cloth, \$1.00; interleaved for notes, \$1.25.

Specimen illustration.

This latest addition to the Saunders Compend Series accurately represents the modern aspect of otological science. While small in compass, it is logically and capably written; it comprises upward of 150 pages, with 89 illustrations, mostly from original sources.

NURSE'S DICTIONARY of Medical Terms and Nursing Treat-

ment, containing Descriptions of the Principal Medical and Nursing Terms and Abbreviations; of the Instruments, Drugs, Diseases, Accidents, Treatments, Physiological Names, Operations, Foods, Appliances, etc. encountered in the ward or in the sick-room. Compiled for the use of nurses. By HONNOR MORTEN, Author of "How to Become a Nurse," "Sketches of Hospital Life," etc. 16mo, 140 pages. Price, Cloth, \$1.00.

This little volume is intended merely as a small reference-book which can be consulted at the bedside or in the ward. It gives sufficient explanation to the nurse to enable her to comprehend a case until she has leisure to look up larger and fuller works on the subject.

Announcement of Fortcoming Publications.

SURGICAL PATHOLOGY AND THERAPEUTICS. By J. COLLINS WARREN, M. D., Professor of Surgery, Harvard Medical School, etc. In one very handsome octavo volume of over 800 pages, with 135 illustrations, 33 of which are chromo-lithographs, and all of which are drawn from original specimens. (Passing through the press.)

A SYLLABUS OF GYNECOLOGY, arranged in conformity with **The American Text-Book of Gynecology.** By J. W. LONG, M. D., Professor of Diseases of Women and Children, Medical College of Virginia, etc. (Preparing.)

Based upon the teaching and methods laid down in the larger work, this will not only be useful as a supplementary volume, but to those who do not already possess the Text-Book it will also have an independent value as an aid to the practitioner in gynecological work, and to the student as a guide in the lecture-room, as the subject is presented in a manner at once systematic, clear, succinct, and practical.

TEMPERATURE CHART. Prepared by D. T. LAINÈ, M. D. Size 8×13½ inches. Price, per pad of 25 charts, 50 cents.

A conveniently arranged chart for recording Temperature, with columns for daily amounts of Urinary and Fecal Excretions, Food, Remarks, etc. On the back of each chart is given in full the method of Brand in the treatment of Typhoid Fever.

LABORATORY EXERCISES IN BOTANY. By EDSON S. BASTIN, M. A., Professor of Materia Medica and Botany in the Philadelphia College of Pharmacy. One handsome 8vo volume, with over 75 plates. (Passing through the press.)

A GUIDE TO THE BACTERIOLOGICAL LABORATORY. By LANGDON FROTHINGHAM, M. D. Illustrated. (In preparation.)

SAUNDERS' NEW AID SERIES OF MANUALS

IN ACTIVE PREPARATION.

PRACTICE OF MEDICINE. By GEORGE ROE LOCKWOOD, M. D.

Announcement of Forthcoming Publications.

An American Text-Book of Obstetrics

BY AMERICAN TEACHERS.

CONTRIBUTORS:

James C. Cameron, M. D., Edward P. Davis, M. D., Robert L. Dickinson, M. D., Charles Warrington Earle, M. D., James H. Etheridge, M. D., Henry J. Garrigues, M. D., Barton Cooke Hirst, M. D., Charles Jewett, M. D., Howard A. Kelly, M. D., Richard C. Norris, A. M., M. D., Chauncey D. Palmer, M. D., Theophilus Parvin, M. D., George A. Piersol, M. D., Edward Reynolds, M. D., Henry Schwarz, M. D.

In one very handsome imperial-octavo volume, with a large number of original illustrations, including full-page plates, and uniform in size with "The American Text-Book of Gynecology." (In active preparation.)

Such an array of well-known teachers is sufficient guarantee of the high character of the work. The illustrations will receive the most minute attention; the cuts interspersed throughout the text, and the full-page plates, which will reflect the highest attainments of the artist and engraver, will appeal at once to the eye as well as to the mind of the student and the practitioner.

An American Text-Book of Physiology

BY AMERICAN TEACHERS.

Edited by WILLIAM H. HOWELL, Ph. D., M. D.,

Professor of Physiology, Johns Hopkins University.

WITH THE COLLABORATION OF THE FOLLOWING EMINENT SPECIALISTS:

Henry P. Bowditch, M. D., John G. Curtis, M. D., Henry H. Donaldson, M. D., Frederick S. Lee, M. D., Warren P. Lombard, A. B., M. D., Graham Lusk, Ph. D., Edward T. Reichert, M. D., Henry Sewall, M. D., Joseph W. Warren, M. D.

In one imperial-octavo volume, with a large number of original illustrations. (In preparation for early publication.)

This work will be the most notable attempt yet made in America to combine in one volume the entire subject of Human Physiology by well-known teachers who have given especial study to that part of the subject upon which they write. The completed work will represent the present status of the science of Physiology, particularly from the standpoint of the student of medicine and of the medical practitioner.
