No. 1.

ORIGINAL ARTICLES.

THE MORBID PROCLIVITIES AND RETRO- GRESSIVE TENDENCIES IN THE OFF- SPRING OF MULATTOES.

Read in the Section of Diseases of Children, at the Forty-third Annual Meeting of the American Medical Association, held at Detroit, Mich., June 7, 1892.

BY W. A. DIXON, M.D.,
OF RIPLEY, O.

Observations extending over a period of more than thirty years have thoroughly impressed the conviction upon my mind that the offspring of mulattoes are the subjects of constitutional diseases to a greater degree than are those of unmixed blood, and that when confined strictly to their own class, they scarcely reach the fourth generation in descent, by reason of disease and sterility.

I have often wondered if others have had occasion to notice this feature in mulatto life, or whether the conclusions at which I have arrived are false and unwarranted from being based upon observations confined to a local district, yet rich in examples that go far to establish the view propounded. I believe that there is not much to be found in current medical writings upon the subject. Our locality is on the border between the free and the slave States of fifty years ago and more. It was then and long before had been, the custom of many wealthy planters, as they advanced to old age, to set free that portion of their estates which bore to them a filial relationship, and establish them in homes, in a section of country, where they would receive fair treatment, consideration and respect, as citizens and members of the community in which they should reside.

Such an opportunity was offered to them in our locality largely populated by abolitionists and sympathizers with the slave.

Thus, a community as it were of mulattoes, whose parents on the father's side were white men, mostly of great wealth and position, socially and politically, and principally of New England stock, existed near us.

The most of these people were complete types of physical perfection, tall, muscular and perfectly developed.

Many of them lived to old age, quite to one hundred years. Their wives were mulattoes. They were proud of their parentage and light color of skin. They made good citizens, and often were prosperous, as farmers. Their prosperity and pride almost separated them from their less fortunate brethren of darker color, and their children intermarried, that their color and race might continue.

I can trace some of these families through three or four generations. Those of the first cross were robust; those of the second were paler, more ashlike in com-

plexion, of slender form, plainly bearing many of the characteristics of predisposition or inevitable tendencies to special diseases, of the strumous type. The third union resulted in less fertility and greater predisposition to disease. Now, the children present the scrofulous physiognomy. The fourth union, still less fertile than the others, brings forth a progeny largely suffering from cutaneous affections, ophthalmia, rickets, dropsy of the head, white swelling of the knee joints, morbus coxarius, diseased glands, suppurating sores until the whole generation is quite extinct. I can scarcely find any of the fourth generation in good health.

These people have had all the advantages that their neighbors enjoyed. They had the best of schools, excellent religious privileges, were moral, upright, and highly respected.

They were able to maintain an academy of learning, from which their sons and daughters could go forth amply equipped to struggle in the unequal contest of life. All of these institutions succumbed to the waning constitutional vigor of their offspring. The academy is no more. The schools and churches, so ably maintained by their forefathers, are extinct.

The old family name is scarcely heard, and inquiry reveals the fact that their offspring were tuberculous, and either died in youth, or, if living, were so sterile that no descendants scarcely of the old families can be found.

This is true not only of one, but of many groups of families. The contrast between the histories of the mulatto and the white and the negro families residing side by side, as to health, as to power to resist disease, and as to longevity, is too great to escape notice, or to be regarded as merely incidental. It is now observable by the colored people themselves that if a mulatto marries back to the parent stock, the children escape to a greater degree scrofulous affections.

I have spoken to a number of physicians in this locality upon this subject, and they all agree that tuberculosis exists to an excessive degree among the mulattoes: that they are inferior in vitality, intelligence, and consequently morality, that they exhibit a mortality more considerable than that of the surrounding whites or negroes, and without reunion with the parent stock the mulattoes would soon become extinct. In the first generation they are quite prolific among themselves and arrive at maturity rather promisingly, but when these children intermarry they and their offspring are not prolific, a large portion being sterile, at even the second and third generations. It is noticeable that the mulatto girls develop in advance of both white and negro girls, but fade away as women, much sooner. It is noticeable also that in the second and third generations of pure mulatto intermixture, that quite all the children born are girls, which are noticeably sterile.

This fact I have observed so much that I believe it to be a physiologic truth. I would be pleased to learn if the observations of others who have given any notice to this subject confirm my own.

If this be true in one locality and in the mingling of the white and black races there, why not look for the same result in the cross of races elsewhere, and thus the introduction of the virus of constitutional diseases, which is transmitted through the succeeding generations?

I believe that ethnologists mainly agree that human hybridity cannot be maintained without reversion, or fresh supply from parent blood. Dr. Robert Knox, in his work on "The Races of Men," says: "I do not believe that any mulatto race can be maintained beyond the third or fourth generation by mulattoes merely; they must intermarry with the pure races or perish." M. Georges Pouchet, says "that such a race, such a type can only have an ephemeral existence." Dr. Paul Topinard refers to a record on this subject in North Carolina. "There the caste of free men was constituted entirely of mulattoes freed by their white fathers. The State, dismayed at the important position which they assumed, put a stop to this liberation. Left to themselves their number diminished at the rate of 29 per cent. decennially."

Ethnologists "have sought in vain among the nations of the earth for a race manifestly hybrid, with well defined characters, intermediate between two known races, perpetuating itself without the concurrence of the parent races."

Dr. Pritchard in his natural history of man, in his effort to find such, subsisting by themselves, could only point to three instances. The Griquas, the Cafuses, and the Papuans. Broca and others object to the truthfulness of these examples, and assert "that by no means do they prove that a mixed race can perpetuate itself separately."

If Dr. Pritchard, in his vast researches, finds it difficult to discover three examples only of hybrid races subsisting by themselves, and they so liable to objection that the other ethnologists deny the proof to be conclusive, then may we not inquire into a cause for the introduction and propagation of diseases, physical weakness, sterility and conditions unfavorable either for moral or physical development, beyond the microbe or bacillus.

The same causes that degenerated and brought to an ignoble end some of the royal lines and the most ancient blood of Europe are at work still, and in our midst also. Look, and wherever you see the greatest intermingling of races, there you see raging tuberculosis, carcinoma and struma in all their terrorizing forms, there you see an excessive mortality among the children, a disparity between the number of men and women, the women being in the majority; there you see the scientist with his microscope hunting for the enemy of life and health in the sputa, the excreta and the cell elements, when in fact the modification of the racial type, by the influence of some media not apparent in the cell elements themselves, altered in some way by the process of miscegenation, generates this virus—these microbes, these bacilli, which claim for their victims more than 25 per cent. of the dying.

Are there any races comparatively free from tuberculosis and all stumous affections? Wherever you see the purity of race maintained, in civilized or barbarous countries, there you see little or no tuberculo-

sis and scrofula. Do these affections prevail among the Jews and other unmixed races to anything like the extent, that we see in countries overrun by immigrants of every race, producing crossed races, without limit or regard to race affinities?

Broca mentions the assertion of several ethnological writers, "that the United States, where the Anglo-Saxon race is still predominant, but which is overrun by immigrants of various other races, is by that very circumstance, threatened with decay, inasmuch as this continuous immigration may have the effect of producing a hybrid race containing the germ of disease, decay and future sterility." There are serious men who have predicted from ethnologic causes, the overthrow of the United States, just as Ezekiel predicted the ruin of Alexandria."

The difficulty in finding instances in the past of nations surviving such influences may excite faith in the prediction, in spite of our unexampled growth, that the fundamental facts as to the perpetuation of crossed races, will ultimately prevail, even in our own country.

In conclusion, I am fully conscious of the fragmentary nature and narrow scope of this paper. I have made no attempt to go into the literature upon this subject, with which, indeed, I am too imperfectly acquainted. I have simply endeavored to briefly set forth these crude ideas which have been the outgrowth of my own observation. If they stimulate the profession to a livelier sense of the importance of looking back beyond the bacillus, and of teaching purity of race, in order to secure greater freedom from tuberculosis, greater immunity from cancer, less mortality, less imbecility and insanity, and greater longevity, than are found among any race of hybrids, it will fulfil the object for which it was written.

CONTAGION OF SCARLET FEVER.

Read in the Section of Diseases of Children at the Forty-third Annual Meeting of the American Medical Association, held in Detroit, Mich., June, 1892.

BY E. F. BRUSH, M.D.,
OF MOUNT VERNON, N. Y.

The two words, contagion and infection, are often used indiscriminately, and many a writer who starts with a definite idea of the word "contagion," will often before he gets through with what he has to say confuse it with the word "infection," and very few people who have not given the matter special study, can give the distinctive difference of definition between the two words. Our dictionaries are in the same confusing condition concerning these words. Thus: *The Century Dictionary*: In common use no precise discrimination of the two words "infection" and "contagion" is attempted. *Webster*: Infection, the transmission of affection without direct contact. In contradistinction to contagion. *Billings*: Contagion, capable of communication from one person to another either by actual contact or through the air. *Foster*: Contagion, the communication of disease from one individual to another by means of direct contact. Or as used as some writers (in the sense of infection) by effluvia. *Worcester*: Contagion, the communication of disease from one person to another by contact, direct or indirect. *Dunghison*: Contagion and infection are generally termed synonymous.

Dr. Pruden has recently tried to untangle the con-

fusion which exists in the common use of the terms, contagion and infection. He writes in a paper read before the New York Academy of Medicine, Jan. 21, 1892: "There should be among ourselves none of the old indefiniteness regarding the exact meaning of such terms as infection, infectious disease, contagium, contagiousness and the like."

The meaning of these terms was of necessity uncertain when the things themselves which they were intended to specify, were largely matters of speculation and conjecture. It were well, perhaps, if they were dropped wholly from our speech and replaced by new words coined in the new light. But as this may not be, the next best thing is to remodel the meaning, and with this to reinvest the words.

I think I do not err in saying that those who can justly speak most authoritatively in this matter are agreed that in the light of to-day, an infectious disease is one which is caused by the invasion and reproduction within the body of pathogenic microorganisms; not necessarily an invasion by bacteria, because in one case, at least, malaria, the invading pathogenic microorganism is not a bacterium, but belongs wholly to a different class. The invading microorganisms which we must assume to cause the exanthemata are wholly unknown to us, but the nature of these diseases justifies us in grouping them with those infectious diseases whose causative agent is definitely known. Infection is the condition produced by the entrance and multiplication of pathogenic microorganisms within the body.

The word contagious no longer covers infinite possibilities in the unknown, or carries with it the mysterious terrors of the unknowable. The contagium in any infectious disease is for us to-day the particular pathogenic microorganism itself, whose advent in the body ushers in those reactions of the body cells which we call disease. The contagium of an infectious disease is a particular thing, which has length, breadth and thickness, and weight and the varied powers of the lowly forms of life.

An infectious disease is contagious when its contagium, that is, the microorganism which causes it, under the ordinary conditions of life, can be freed from the body of a diseased person, and by whatever means conveyed to the body of another in a condition capable of lighting up the disease anew. The old indefinite distinction between infection and contagion, by which one strove to express, among other things a fundamental difference between the conveyance of disease by personal contact and by aerial transmission, has become impracticable and valueless now, because we know to-day that the differences in the mode of communicability of infectious diseases are largely dependent upon the physical qualities of the contagia, upon the places and ways in which these are freed from the body, and upon the places and ways in which they enter the bodies of the new victims.

The moment we know exactly what we mean when we speak of contagium, the moment we have learned to follow the movement of these particular contagia as they leave the bodies of their victims—in one case in the stools, in another from the skin, in others from the mucous membranes, and can trace their diffusion and life stories in earth, air or water; the moment, I say, that we can bring the light from these varied factors to bear on the clinical stories of infectious disease, we are not only in a condition to

talk plainly about the degrees of contagiousness, but to study the conditions under which degrees of contagiousness may vary in nature or be varied in art.

It is an unfortunate circumstance that the most common notion of a contagious disease is derived from those which are most dreaded and most liable to spread—from such diseases as the small-pox and scarlet fever—so that the common conception of a contagious disease is of one which necessarily taints the air about the victim—surrounding him, so to say, with an infectious atmosphere. But this notion is wholly groundless with any disease common with us outside the exanthemata, and is apparently reasonable here only because the contagia of these diseases are unknown to us, and are probably cast off through the skin, and so easily diffused.

The fact is that such infectious diseases as typhoid fever, diphtheria, and tuberculosis can be highly contagious or made scarcely at all so, depending upon the care or lack of care which is taken by the victims or their attendants in the disposal of their varying exudates or discharges.

Now, it does not seem to me that he has simplified the matter at all. Of course, if we are to consider bacteria as the prime cause of specific disease, then we must have a term to express the condition that arises from these agents and separate entirely from the bacterial diseases, the terms contagion and infection. There is an attempt just now to do this by the use of a new word, chemotaxis. Of course, before this word can be used it must be worked into tenses, for it has always appeared to me that one of the main difficulties with the term contagious is that it has no past tense, and the word infection has. We can say a person has become infected with an infectious disease, but when we wish to use the past tense with contagion, the only word I can think of is contamination. Now the word contaminated expresses a condition of soiling, or more vulgarly, dirtying, and really this is the sense in which it should be used. Thus, one becomes contaminated with syphilitic virus just as much as if he was contaminated with feces or any other matter. And from this point of view I have been teaching for some years that contagious diseases are those in which it is only possible to contract the disease by becoming contaminated either by coming in contact with the diseased person himself, or through something he has himself previously contaminated. Now, with this understanding of the term, the danger associated with a given disease would be clearly defined, because we would all know that a contagious disease would only be dangerous by contamination, either by food, clothing or any material thing that has been in actual contact with the diseased body. While the term infection should be used only with those affections that infect the atmosphere, like exanthemata, and it can also be used to express some of the nervous affections. Yawning often becomes infectious and in like manner hysteria does also. It is in this sense that Shakespeare used the word, "Infected be the air whereon they ride." With this view of the terms, we would classify scarlet fever as an infectious malady as are all the other exanthematous diseases. Of course all the dangers of a contagious disease are associated with the infectious diseases, but there is an extra danger in infectious diseases by reason of becoming affected without contact. But the vagaries of scarlet fever have been a stumbling block to everyone since the disease was first known.

Prof. Stiles in a recent correspondence in the *New York Medical Record*, writes: "Prof. Chapman, who held the Chair of Practice in the University of Pennsylvania from 1833-36, affirmed positively that scarlet fever was not contagious, and for some years the matter remained undecided. But with the disease in our time, I do not believe that any one holds this opinion now. From the best evidence we possess, the disease is comparatively new. It was not known in Europe until the time of the Crusades. It appeared first in Japan in 1610, and in America in 1735. It seems to be confined to the white thin skinned races as the negro and the Japanese are not affected, and it does not flourish in Hindostan. It is curious about the negro, he takes the measles in a very malignant form, but enjoys immunity from scarlet fever, a disease that until recent times was confounded with measles, and both diseases came to America from Asia daring or immediately following the Crusades.

Scarlet fever was a very rare disease in America during the last and beginning of the present century. So much so that Dr. Rush, about the beginning of the present century, makes the remark, "that no physician here would be likely to see it more than once in a lifetime." Just to give an idea of the views prevailing in this country forty years ago, I quote from a Systematic Treatise, Historical, Etiological and Practical, "On the Principal Diseases of the Interior Valley of North America," by Daniel Drake, edited by Hanbury Smith, and Francis Smith, M.D., 1854. "A malignant form of scarlet fever affected the first settlers of Kentucky and Ohio in 1793. It was always fatal at Marietta and Belpree, the oldest settlements of the State of Ohio. It was most dreadfully destructive among the children and young persons, attacking and destroying nearly all the former. It is worthy of remark that at the time of this epidemic the country was an almost unbroken forest, and the emigrants lived in open cabins, and subsisted on a simple diet, very often deficient in quantity. From this time until 1803 I do not know that any form of scarlet fever appeared in the valley of the Ohio, but since this date, that is, for the last twenty-five years, it may be regarded as one of our epidemics, having at no time been absent from the valley of the Mississippi, and the Lakes. In my personal intercourse with physicians, I scarcely conversed with one north of the 33d degree of latitude who had not seen the disease once or several times, though many south of that parallel had never met with it. Of its introduction into most of the localities in which it has pervaded, we absolutely know nothing. I have never been able to trace up a single case at Cincinnati to importation by patients or families, nor as far as I know, has a case of that kind been made out.

Pervading for several months or a year one place, the people of surrounding places although they maintained the usual intercourse with it will remain exempt. When it appears in a family, it seldom attacks all the liable at the same time, but more commonly does so progressively, while one child in each of a number of neighboring families may be seized simultaneously. Presenting such habitudes, we need not be surprised that our physicians, like those of other countries, differ in opinion as to the course in which it propagated itself. A part believe it is never infectious, another part, as appearing and

spreading solely by infection. A third and a larger portion, consider it to have originated de-Novo, but to be capable of propagating itself, and the truth probably lies between them. Thus we see how many different opinions there are regarding scarlet fever, and the disease will continue to puzzle us until we know vastly more about infection and susceptibility than we do at present. I have seen cases arise in children that could not by any possible means have been exposed to infection of recent origin, and I have seen children exposed to the disease in its most malignant form and not take the infection. If the materia morbi retains its virility for the long period it has been supposed to do, then we may in any ordinary house get some infected material in our homes through the ordinary supplies of food or clothing, etc.

A very remarkable case is cited in the *Times and Register*, March 12, 1892. Dr. W. E. Holland writes as follows:

"The following is an accurate statement of a case which came under my charge some four months ago. I was called to see a boy fourteen years of age. His mother said he had a strange eruption appearing on his face and body. After inquiring and making an examination of the case, my mind at once reverted back to the hours that I had the pleasure of listening to your lectures on the practice of medicine, and especially your lectures on scarlet fever, and hearing you say the germ would live for years in the laid away clothes of persons who had suffered from the disease. At the time of this case there were no cases of scarlet fever anywhere within a radius of twenty miles. I carefully inquired of my professional brothers of the section, and they said they had no cases of scarlet fever. I then made a very careful examination of the house all through, and in the garret in the corner stood an old chest, which had been handed down from one generation to another, and had been used to store away old clothes. I then asked the mother if any of the family had been sick with, or had died with the scarlet fever. She replied that her father had come home sick, and the physicians said he had scarlet fever. He laid sick for some weeks and died. I then asked what had become of his clothes. She said they had been stored in the old chest in the garret for thirty-five years, but that she had recently taken a pair of her father's pants and made out of them a pair to fit his grandson. The latter had only worn them a few days when the rash made its appearance."

In the same journal, Dr. Backwood, of Philadelphia, writes:

"I know beyond question that a suit of clothes which the patient outgrew during his illness, was the cause of giving the disease to a poor child to whom the articles were given, a year after the original patient had gotten well, and the garments were kept in camphor, etc., all that time to preserve them from moths."

Now, in contrast to this let me cite a recent occurrence that came under my own observation. A lady sent for me one afternoon a few weeks ago. When I reached the house I found her in a state of excitement. Three of her children were ill with ordinary functional stomach trouble. One of the children was complaining, and requiring the mother's constant attention, and several times the servant girl, who had been in the family only a few days, came

into the bedroom to do some errand, and each time she would say, "That is just the way my brother acted." As the servant had only been in the family a short time, the lady took no notice of the remarks at first, but finally asked what was the matter with her brother, "Sure, ma'am, he died of scarlet fever two weeks ago." Then the lady questioned her closely, and found that the servant was one of eleven who lived in a tenement house in one of the lower wards of New York City. Four of them had scarlet fever, and one boy of twelve had died. And the girl came from that infected tenement house with the same clothes she wore during the prevalence of scarlet fever. The lady, of course, ordered her out of the house in a lively manner, but still none of the children took scarlet fever. A circumstance like this proves nothing, and is only interesting, as is the following taken from the *Times and Register*, March 12, 1892. Dr. R. V. Salmon, of Dadeville, Alabama, writes as follows:

"Your letter of the 18th inst. received asking for a letter from me on scarlatina. My reply may sound a little queer, but we have had no scarlatina in this section since 1856, though it has been thirty miles on the same railroad."

The question as to what gives immunity, is, of course, the interesting point in the discussion of this disease. The black and dark thick-skinned inhabitants of the earth are immune. We must infer by means of this difference in their skins, because as far as we know, there is no other physiological difference. The question that occurred to me, and in fact, my reason for studying the subject at all was to settle in my own mind, whether or not in a case of scarlet fever occurring in one of a family of children, is it advisable for the unaffected children to remain at home, or ought they to be sent away? This question came to me personally during a sorrowful experience, and I was unable to settle it fully. I remember three instances, one several years ago, before I had studied medicine. A Presbyterian minister had three children, two boys and one girl. The girl was attacked with scarlet fever, and at once the boys were sent away from home. The girl made a good recovery. Everything that could be done to make the house clean with disinfectants, etc., was completed, and several weeks elapsed after the girl's recovery when the boys came home. They both took the disease, and one died. I have known personally the occurrence just like this. Then on the other hand, a family living on the same street with me in Mount Vernon. Four children, one was attacked with scarlet fever, the other three children remained in the house. The mother took care of the sick boy until he died; she mingled with them and with other members of the family, but none of the others sickened.

Dr. Campbell related to me a case that occurred in his practice. Of a family of eight children, one sickened with scarlet fever, and was isolated in an attic room. The case progressed favorably. During the peeling stage the sick child was left alone by the nurse for a few moments, and when she returned to her charge, she found the seven well children in the room playing with the desquamating case of scarlet fever. Not one of them took the infection. If these children had been taking belladonna as a prophylactic, what would the verdict be? These and many others of like nature, make me think that there may

be some sort of immunity by reason of a child living constantly in an infected atmosphere, if it has escaped the first infective influences.

We have an analogy in some of the cattle diseases. There is an infection in cattle known as Texan fever. It belongs to the anthracoid class of diseases, and the native cattle of Texas can have the affection and not be disturbed in their general health, but if one of these affected Texan cattle mingle with any bovines not natives of Texas, or if some of the non-natives cross a track previously travelled by Texan cattle, they are attacked with the disease, and ninety per cent. of them die.

There is also an endemic affection among the cattle on the steppes of Russia, known as petechial typhus, which is so mild with the natives as to call for little or no attention. But if any animals not natives come in contact with the diseased cattle, they take the affection and die. So, I believe many diseases create by their own virulence an immunity in individuals who have lived in the infected area. And so I believe from the facts that have presented themselves to me, after years of close observation, that the children in a household, who have escaped the first infective influences of an invasion of scarlet fever, are safer to remain in the infected area than they would be if removed to another house or region. I am willing to admit that this is largely a matter of opinion, but the question often arises, and will continue to be a serious subject to the practitioner. Therefore, it is worthy of further study. As a prophylactic measure with children unaffected, and in a household where the disease exists, I recommend the skin and entire body to be anointed with a weak solution of carbolic acid in olive or cotton seed oil, morning and night, and a gargle composed of half an ounce of fluid hydragric, in a tumbler of water, used three or four times daily. For I believe the site of invasion of all the exanthematous diseases to be the skin, and sometimes the mucous membrane lining of the upper air passage, and hence the reason for the prophylactic measures recommended.

A PLEA FOR EXTRACTION AND REPLANTATION, AS A MEANS OF CURE IN OBSTINATE ALVEOLAR ABSCESS.

Read in the Section on Oral and Dental Surgery, at the Forty-third Annual Meeting of the American Medical Association, held at Detroit, Mich., June, 1892.

BY JOHN S. MARSHALL, M.D.,
OF CHICAGO, ILL.

Mr. Chairman and Gentlemen of the Section:—In the presentation of this subject I make no claim to a new discovery, for the operation is an old one and has been occasionally practiced with varying success for many years. I trust, therefore, that I shall be pardoned for introducing a subject in this presence which cannot be classed as a new operation, or an entirely new method of treatment. Methods, however, are sometimes improved and I shall be content to leave to your good judgment whether the line of treatment to be presently indicated is rational and justifiable, and any improvement over the methods generally pursued.

One of the first and most important principles of surgery is the conservation of diseased organs and tissues, provided they can be restored to a healthy condition, rendered more or less useful for the pur-

poses for which they were created, and incapable of harm to other members or the general system.

In these days of antiseptic surgery, many things are accomplished which a few years ago would have been considered highly dangerous or impossible. The abdominal cavity is now opened with impunity, and operations made upon the enclosed viscera, that to say the least, are startling: The chest is explored and portions of the lung removed; the cranium is perforated, and tumors extracted from the superficial and deeper portions of the brain; and yet the individuals operated upon live to tell the tale.

In no department of minor surgery has greater advancement been made than in dentistry. Most of the diseases of the mouth and associated parts are now more successfully managed, and thousands of diseased teeth are restored to health and usefulness every year, that were formerly consigned to the forceps, and this has been largely the result of a better knowledge of the causation of many diseases and how to prevent and to combat the inflammatory processes by aseptic methods.

I was led to adopt the practice of extracting and replanting teeth for the cure of obstinate or persistent alveolar abscess on account of the failure—in my own hands and those of others—to cure a considerable percentage of these cases by the ordinary means at our command.

By obstinate or persistent alveolar abscess, I mean those cases of alveolitis in which the inflammatory symptoms persist after all the ordinary means of disinfecting and filling the root canals, etc., have been faithfully tried without avail.

This form of alveolar abscess is usually the result of a crooked root or an abnormally small root canal, making it impossible in either case to remove the putrescent pulp or render innocuous the retained septic material; or perforations of the root made in attempts to open small root canals; or erosion of the apical end of the root; or the presence of broaches, filling material or dressings, which have passed the apical foramen; it is accompanied by a more or less persistent discharge of pus, either through the external or internal plate of the alveolar process, or through the alveolus at the neck of the tooth. Occasionally cases will be found in which no discharges are present, but instead, a chronic induration of the surrounding tissues, or as in the superior teeth, the discharges may find their way into the antrum of Highmore or the anterior nasal passages, and possibly mislead the surgeon.

These teeth are usually sooner or later condemned as harmful or worthless members of the body and are removed.

It is this class of teeth for which I make my plea, and I believe from a practical experience extending over a period of several years with this method of treatment, that a majority of them may be rendered healthy and useful for an indefinite period.

It is perhaps hardly necessary to say that replantation is only admissible in the anterior teeth, including the bicuspids. The molars are not capable of being replanted only in exceptional cases, when there is fusion of the roots, and they assume a conical form, and occasionally a lower molar, where the roots are perpendicular to the crown.

I think it will be generally conceded that attempts to cure *in situ* such cases as those just mentioned, usually prove unsuccessful, and that eventually the

teeth are lost. This, I believe, results from the fact that such operations are largely, *per force*, only guess-work. If the root is curved at a more or less acute angle, it is difficult to follow the canal with the broach, and many times quite impossible; or if the canal is abnormally small, the finest broach may not enter at all. Drilling is unsafe; and under these conditions the various antiseptics and liquified filling materials are unsatisfactory; because they do not always penetrate to the end of the canal, and consequently septic material remains in the root and keeps up a constant irritation.

In cases of erosion of the apical end of the root, amputation of this portion *in situ* is rarely successful in curing the disease, owing to the difficulties in smoothing the stump and perfectly filling the apical foramen. The same may be said of attempts to plug perforations of the sides of the root. In those cases where broaches, filling material or dressings have passed the apical foramen diagnosis is difficult, except by trephining the alveolar plate and this has no advantage over extraction and replantation.

Roughened surfaces and foreign substances are not kindly borne by the tissues which surround the roots of the teeth. It is therefore imperative that all such hindrances to a return to the normal condition be reduced to a minimum.

For these reasons it would seem preferable to extract and replant such teeth if they do not speedily prove amenable to treatment by the usual methods; for, with the tooth in the hand, the root can be minutely inspected and any eroded portion amputated; and the surfaces finely polished. The root canal can be reamed out and cleansed without fear of perforating its sides; the canal and the apical foramen or a perforation, plugged with gold and carefully finished, and the whole thoroughly sterilized by immersion in bichloride of mercury solution 1 to 500 of water (tepid) for thirty minutes.

None of these operations are possible with the same degree of perfection while the tooth is *in situ*; they must be more or less imperfect; and just in that degree will they produce irritation, and the more serious inflammatory processes.

The question might be very properly asked, "Are the operations of replantation and transplantation of freshly extracted teeth having the pericementum attached, founded upon physiological law and sound surgical principles?" I answer, yes! Quite as much so as are the operations of skin and bone grafting, and no one condemns these. Union with the tissues with which they are placed in contact is the result of the same vital processes; the surgical conditions are nearly identical in each of them and success is as certain in the one as in the other; provided the same aseptic conditions can be maintained until union is complete. Failure of replanted teeth to unite with their alveoli is much less common than with transplanted and implanted teeth; at least my personal observation bears out this statement. The immediate cause of failure in replanted, transplanted and implanted teeth is usually suppurative inflammation induced either by mobility of the tooth which constantly breaks up the attachment of the plastic exudate; or septic condition of the tooth, or its alveolus at the time of the operation; or inoculation afterwards from a filthy condition of the mouth.

The failures which occur later, viz.: after attachment has taken place, are more difficult to under-

stand. In these cases the surfaces of the roots are attacked by the osteoclasts and gradually honey-combed; or masses of tissue are dissolved at various locations, leaving large cavernous excavations with sharp edges; suppuration accompanies or follows the work of the osteoclasts; the tooth becomes loose, and is sooner or later expelled from the jaw as a foreign substance.

In explanation I would venture the opinion that these phenomena are due to irritation induced by a septic condition of the dentine, resulting from decomposition of the organic material contained in it, and that in the form of a gas or effluvium it penetrates the cementum, and, coming in contact with the pericementum and surrounding tissues, sets up this retrograde metamorphosis.

There are certain individuals for whom it would not be wise to undertake the operation, viz.: those suffering from general anæmia, tuberculosis and syphilis. Such people are never good subjects for surgical operations, as their tissues are very irritable. They do not as a rule heal readily, and are prone to suppuration and sloughing, consequently replantation, transplantation and implantation, if performed upon such persons, are likely to prove unsuccessful.

Many of the failures from these operations that have come under my notice, have been associated with one or the other of these diseases. Great care should therefore be exercised in the selection of the cases upon which to operate. Carelessness in this regard can only result in failure.

Of the many operations which it has been my privilege to perform, it has not thus far been my misfortune to be obliged to record a single failure, although they have comprised all grades of the disease, several of long standing, and ranging in duration from a few months to fifteen years. But I refrain from mentioning individual cases, for fear of wearying you.

The after treatment consists in frequent irrigations of the mouth with antiseptic solutions; among the best of which are the Thiersch solution composed of boric acid, 12 parts; salicylic acid, 4 parts; water, 1000 parts; and another consists of listerine, 1 part; water, 3 parts.

Bichloride of mercury solutions are not permissible on account of the danger from poisoning and the blackening of the teeth.

We are all no doubt interested to know the character of the union which takes place between the root of the replanted tooth and its alveolus, but so far it has not been positively demonstrated. I would therefore like to offer a few thoughts which I trust may end towards the elucidation of this question.

Applying the methods employed in physical diagnosis to these cases, we find that percussion gives the most marked signs. Taking the percussion note of normal teeth, produced by striking the tooth with a steel instrument as the standard of pitch, we find that as inflammatory conditions of the alveolus advance, the percussion note becomes lower and duller; while on the other hand, as these symptoms subside, the note assumes a clearer and higher pitch. This lowering of the tone is doubtless the result of a thickening of the pericemental membrane, and its increased vascularity.

The percussion note given by a large percentage of replanted teeth a few months after the operation or

when union is complete, is much clearer and higher pitched than that of the adjoining teeth. This is more noticeable in the superior than the inferior teeth, on account of the greater resonance of the superior maxilla.

These facts would seem to indicate that a bony union takes place in these cases between the root and its alveolus. It would also seem probable that the locations at which this ankylosis would most likely occur, would be where the pericementum had been destroyed, or the cement tissue partially removed, and I can see no reason why under these conditions union may not take place in the same manner as with fractured bones. In other cases the percussion note is normal. This would indicate a normal reunion of the pericementum with the alveolus; but where the percussion note is lower and duller, it would be certain evidence of an indurated pericementum, or other inflammatory symptoms.

In conclusion, let me emphasize the following points as necessary to insure success in these operations:

1. Exclude anemic, tubercular and syphilitic cases.
2. Secure thorough aseptic conditions of the surfaces of the root and pulp canal, by washing and immersing in bichloride of mercury solution 1 to 500 of water.
3. Amputate and smooth all eroded surfaces but sacrifice as little of the pericementum as possible. This is very important.
4. Hermetically seal the pulp canal, and apical foramen, and any perforations that may exist, with gold fillings.
5. Curette the abscess cavity, remove the blood clot from the alveolus, and wash both with the bichloride of mercury solution before replanting the tooth.
6. Secure immobility of the tooth by a ligature or an interdental splint, until union has taken place.

Venetian Building.

DISCUSSION OF DR. GRADLE'S PAPER.

(Concluded from page 774, Vol. XIX.)

Dr. Fletcher asked if the peculiarity of the extent or position of the antrum was indicated in any way by the shape of the face. For instance, is the antrum farther back in a face with high cheek-bones, or is there any similar indication in regard to it?

Dr. Talbot said that as far as he knew there was nothing to indicate the extent or position of the antrum from the form or character of the bones of the face.

Dr. J. S. Marshall hoped that something would be said of antral disease following the grip. He had had four cases, in each of which there had been discharges into the nasal cavity of thick mucus,—not bad smelling, nor was it pus, but simply apparently an excess of mucus which had filled the cavity and was discharged through the nose. He thought it advisable to open into the antrum between the roots of the second and third molars, as this is usually the most dependent part of the cavity. He usually used, as an antiseptic, Thiersch's solution,—a bland antiseptic, and very satisfactory.:

Boric acid, 12 parts;
Salicylic acid, 4 parts;
Water, 1000 parts.

Dr. Talbot reported a case where, after the opening had been made, there was no immediate flow of pus; but such a flow did occur a day or two after the operation.

Dr. Gradle, in reply, stated that this had happened in a case of his where he had opened into the antrum, supposing a formation of pus there was responsible for a train of neuralgic troubles. He found no pus at the time of the opera-

tion, but in a day or two afterward there was a flow, which he was at first inclined to charge to infection from the instrument used in the operation; but the history of the case convinced him that the disease was the cause of the original trouble, as after the antrum was cleaned out the neuralgic troubles ceased. It is possible sometimes that there may be infection by the instrument or if there be morbid fluid already present, piercing the wall and allowing the entrance of air might cause the formation of pus.

Dr. Taft asked Dr. Gradle what per cent. of diseases of the antrum were caused by diseased teeth.

Dr. Gradle thought between forty and fifty per cent.

Dr. Taft raised the question whether the micro-organisms in the pus from such positions as the antrum and the seat of a whitlow, for instance, where there was no opportunity for the microbes to obtain entrance from without, were the cause of the pus-formation, or whether they were merely an accompaniment, and asked where they came from and how they obtained access to such closed-in positions.

Dr. Gradle thought that the blood was possibly the vehicle which carried the microbes.

Dr. A. E. Baldwin said if this was so, and the blood carried these micro-organisms, there was certainly no safety in any measures which we could devise to keep them out of the system.

Dr. Clifford thought it better to pay more attention to systemic treatment in diseases of the antrum rather than to depend altogether on local treatment. The cause must in many cases be systemic, and we cannot reasonably expect to effect a permanent cure unless we remove the cause. He had had cases which he relieved without opening into the antrum or establishing any drainage, by paying attention to remedial measures applied to the system at large.

they may display widely varying degrees of brain power—from genius to idiocy.

Inebriety is often only developmental disease, beginning in embryonic life, and manifest in various degrees of malformations. A child with organic defects at birth is switched on the road to inebriety, insanity and perhaps idiocy. Hairlip, cleft or deformed palate, talipes, rickets and other abnormalities are unmistakable hints.

A child in infancy who has convulsions at dentition, strabismus, and later chorea, epilepsy, asthma, who at puberty suffers from hysteria, arrested growths, stupidity, or abnormal sensitiveness is on the same road with the same destination.

If to this is added malformed maxillaries and palate arches, together with defective teeth, the evidence is complete.

It is an important question, however, how far a deformed palate or defective teeth can be accepted as evidence of neurotic or alcoholic diathesis. If the question is confined to the teeth, some curious facts appear.

It may be said to be an established fact that the teeth of hereditary neurotics vary in shape and structure from those of persons of different heredity. Probably they are not any more marked in many cases than any other organic degenerations. Some of these defects do not appear in organic form or structure, but in the power and quality of force displayed.

The effect of alcohol in excess on the teeth is within the observation of all persons. This may be described in general terms to be that of an irritant, impairing the vitality of the mucous membranes and developing a grade of chronic inflammation that is continuous. The stomach, throat, and mouth all become the seat of degenerative processes, by which the nerves of the teeth are quickly affected. The nutrition of the teeth is impaired and the pulp dies, the gums retract, often leaving a red line of demarcation.

The effect of alcohol on the system is to paralyze and impoverish the nutritive system. Conditions of practical starvation supervene, affecting all growth. Hence, degenerate teeth and gums are the natural outcome.

It is a fact that inebriates, as a rule, suffer from early disease and death of the teeth. A large proportion of cases under my care seek the aid of the dentist early in the treatment. When the teeth are destroyed and replaced by others, carelessness in the quality of food, in mastication, and methods of eating are sources of irritation that farther predispose to the use of spirits. The neurotic diathesis that is seen in the early decay of the teeth will, in many cases develop inebriety, as the result of impoverished brain nutrition.

Irregularity of the teeth is also very prominent in inebriates. Projecting incisors and molars that crowd past each other and various other deformities are common. I have in a few cases noticed what seemed to me a very unusual absorption of the bone where teeth had been withdrawn, leaving great cavities, usually seen only in advanced age. This has appeared to me to be a part of the customary alcoholic degeneration.

Some years ago a very large, broad shouldered, muscular inebriate came under my care. He had a hin, piping voice. Examination revealed a very

SOME FACTS RELATIVE TO DISEASES OF THE TEETH AND JAWS IN INEBRIETY.

Read in the Section of Oral and Dental Surgery, at the Forty-third Annual Meeting of the American Medical Association, held at Detroit, Mich., June, 1892.

BY T. D. CROTHERS, M.D.,
OF HARTFORD, CONN.

Seen from the clinical and neurological standpoint, a large proportion of the hereditary cases of inebriety have defects and degenerations of the face, jaws and teeth.

Up to the present time, no studies have indicated any *specific* degeneration that can be traced to alcohol as the sole cause. Nevertheless, the inebriate from heredity or other causes has defects, malformations and retarded growths of various organs of the body that are hints of continued organic degeneration. The inebriety or any associated disease in the parents may appear very prominently in defects of the face, head and jaws. These widely differing variations from the normal symmetries are almost infinite in diversity and degree. The same variations in quality and capacity exist in the brain.

How far the bony structure of the calvarium is controlled by the brain itself or how far external defects influence the internal development, is not yet clearly understood.

The frequency with which congenital defects of the head and face appear in inebriates suggests a pathological relation, which is fully in accord with other facts, and are also true of other degenerative processes. The complex degenerations from the excessive use of alcohol are always transmitted in some form to the children.

Low vitality and defective cell growth and nutrition appear in the descendants in aggravated forms.

The children of such parents are always noted for physical defects of structure and type, although

high, narrow palate arch, with a projecting lower maxillary. He was an hereditary neurotic from an insane and moderate drinking family. His father had the same high vaulted palate, but a retreating, imperfectly developed lower maxillary. He had two brothers, one a famous tenor singer, with striking astigmatic face, and no doubt had a high palate arch. The second had a high arch with a flat dome and irregular teeth and jaws.

Within a year I have seen two children of this patient, both with deformed palate arches and teeth. They are markedly neurotic and have strongly marked degenerative heredity.

It is a common observation that a thin, high-pitched voice is a possible hint of hereditary degeneration when seen in inebriates, and it is often associated with deformed mouth or maxillaries.

This observation of Dr. Talbot appears to be amply confirmed in my experience. Reasoning from the general history of these cases, I should expect to find many deformed palates and teeth, and other marks of physical defects, such as cranial deformities, facial irregularities, together with ill-shaped hands, feet, arms and legs.

Retarded growths and over-growths, associated with mental defects, are often very prominent.

From a clinical point of view, a deformed palate may be taken as an unmistakable sign of neurotic degeneration, which may or may not develop into a distinct form of disease. If with this are associated bad teeth, a tendency to break out into inebriety doubtless exists, due to nerve and cell starvation, with consequent exhaustion, for which alcohol is a most seductive narcotic. In a large per cent. of inebriates, where a deformed palate is found, it can be taken as a sign of nerve and brain degeneration, and will be accompanied by other physical signs of like import. Further study of these cases will reveal mental defects of reason, conduct, and character.

The inebriate who has this peculiar arch with defective maxillary growths has received from his ancestors a pathological bias which will make a cure difficult.

I shall close this brief note with a quotation from Dr. Clouston's work on the "Neuroses of Development:"

"If the skull in its growth, its size and its shape, its dome and base, is actually dominated by the brain it defends and contains, then the brain growth will in this way secondarily determine the shape of the upper maxillary bone and the palate.

"The brain unquestionably deriving its shape, size, and qualities from ancestry and a bad heredity, determining a bad brain, we see how a bad nervous heredity would naturally determine an abnormal palate. The theory that a high palate may be a "reversion" to a lower animal form or to the form in lower races of mankind seemed to be largely disproved by a careful examination of the palates of most classes of animals and of different races from the Europeans to the extinct Americans, the Australians and the Hottentots, which I made in the Anatomical Museum of Edinburgh University.

Where dolicocephaly and brachiocephaly is a matter of race and not of disease or degeneration, they make no difference in the palate dome.

There is no such thing as a high V-shaped palate in any animal or in any race from the Australian aborigines upward. In one way only can the V-

shaped palate be connected with a reversion to the animal type. Apart from prognathism, the sides of the palate, that is, the lines of the bicuspid and molar teeth on each side tend to run parallel to each other.

Now, supposing the lines of the teeth in man during development were approximated and made parallel by a formative reversionary process, the palate would be pushed up in the center,—the line of the least resistance—into the nasal cavity.

Those palates where the deformity consisted in a ridge down the center antero-posteriorly, seem to show that in them the deformity took place at a later period than in the other deformed palates when the nasal septum was getting stronger and kept the center of the palate down, while on each side of it the palate was drawn up making two palate vaults instead of one.

The theory that the shape of the palate is dependent on the nasal cavity of which it is the floor seems to me without any valid foundation whatever.

The upper maxillary bone is related to three functions, viz.: alimantation, smell, and facial expression.

There is no proof that either smell or mastication is interfered with by a high dome, but unquestionably facial expression is greatly influenced by any change in its form, and facial expression is naturally related directly to the development of the mental part of the brain and is dependent on it. Speech I found, is affected slightly by the shape of the palate.

The theory that deformed palates are due to thumb-sucking in infancy is utterly baseless. Idiots notoriously don't suck well.

Prognathous jaws certainly seem to be a reversion to an animal and lower human type, but they do not necessarily imply a high palate.

Virchow's theory of premature or irregular ossification of the skull sutures,—though it may explain some few cases of idiocy—does not seem to me to explain the high palate any more than I think it explains the dolicocephalic, or brachiocephalic types of head or the types of cerebral sulci.

The deformity of the palate occurs during brain growth, early in life, probably in utero.

We must refer the high palate to a bad initial neurotic heredity, just as we refer a bad type of face or irregular teeth or an asymmetrical head to such heredity.

Mere accidental changes in the head shape are quite consistent with good brain development. The brain in its growth, if artificially confined in one direction will expand in another, and not suffer in function thereby.

The savages who make their children's heads square by pressure do not alter the mental or motor functions of the brain thereby.

The vaulted palates and altered dental arch must be taken with other changes in the head and especially in the face expression. As one of the morphological indications that show a tendency in the person to whom it belongs and in his family to developmental neurotic diseases—notably idiocy, congenital imbecility, stuntedness of growth, deformity, epilepsy, adolescent insanity, and that organic lawlessness and lack of mental inhibition or weakness of mind that distinguish the criminal classes. It is thereby one of the marks of a family that is tending toward mental death and extinction.

As regards the exact mode in which the palate deformity arises, I cannot find any help in a study of the mode of ossification of the upper maxillary bone, except in the cases where deformity consists in a depression or two depressions where the four centres of ossification meet. If the anterior lobes of the brain, —and that is the part of the brain that lies above the palate—become contracted through hereditary brain deficiency, and the skull base in front is therefore narrowed while the jaw must remain large enough to hold a normal number of teeth, it might naturally assume more the shape of the bow of a boat than a horse-shoe.

The alveoli of the bicuspid and molars on each side being drawn together by the narrow skull-base from which they hang and this process would throw up and deform the palate.

Clayshaw's measurements of the skull-base and pterygoid arch give much support to this hypothesis.

In congenital mental defect it is the anterior lobes that are found chiefly deficient, and in the microcephalic and Kalmuck class of idiots—where the brain has undergone most developmental lessening, the palate is found to be highest and most deformed.

Taking all the facts into account, it seems proved that the condition of the palate may be a most important index of brain development and of liability to developmental neurosis.

My second class of neurotic palates is apt to go with a nervous temperament—often with a neurotic diathesis; often with high mental qualities, but not all-roundness of capacity; often with keen sensitiveness or supersensitiveness of bodily feeling or emotion, and frequently with liability to the lesser functional neuroses—such as hysteria, neuralgia, migranes, headaches, etc.

It seemed to me that the consumptives are more apt to have neurotic and, many of them, deformed palates, than the sound in body.

I did not find any connection, hereditarily or otherwise, between my "deformed" palate and cleft palate.

They seem in a way to represent formative tendencies "in utero" in opposite directions.

In the case of the ossifying centres in cleft palates they had not been able to meet in the center and close in the floor of the nares, through perhaps excessive width of skull base; while in the latter, as we have seen, there was a greater width of palate bone than was needed to stretch across, and so it had to rise up in the center and form an acute angle or high arch.

Discussion.

Dr. J. Taft said the most remarkable effects noted in the paper were on the shape of the jaw and mouth due to hereditary transmission. These effects were important and undeniable, but the question arose in his mind whether the inebriate suffered any change in the conformation of these parts induced by the habit of drinking.

Dr. Crothers said there were very marked changes, but chiefly those resembling the changes usually brought about in the process of aging.

Dr. Barrett said he understood the essayist to refer to the V-shaped vault as a reversion to the animal type. He thought this was a mistake, as the high or V-shaped vault is not found among animals. It, however, might be true in regard to the V-shaped arch, as this, or rather the saddle-shaped arch, is common in animals, more especially those nearest correlated to man.

Dr. E. S. Talbot:—I am much interested in the paper of Dr. Crothers, especially as the author's long connection with an inebriate asylum gives him peculiar advantages for

observing these conditions. I will have to take issue, however, with his statements that these peculiarities of the mouth and jaws extend back to uterine life. Every observing dentist knows better than that. The author being a medical man, has not the opportunity for observing the mouths of all classes which we of the dental profession have. We know that this condition is never found during the existence of the first set of teeth. The deformity begins in the sixth or seventh year.

For several years I have been making a study of these peculiarities in the mouths of idiots, mutes, inebriates and criminals. In that time I have examined about seven hundred and fifty mouths of inebriates, and have found a larger percentage of badly formed mouths than among any criminal, idiot, or other defective class; but the defects are not so marked. There are fewer absolutely V-shaped arches among inebriates, but more of what might be called partial V-shaped arches; but I find plenty of V-shaped arches among criminals, idiots, the deaf and the blind. Now another singular thing: there are twice as many high vaults among inebriates as among any other class of degenerates. This proves that the inebriate is born; that it is impossible for him to live a straight, ordinary life. One born with the qualities that this formation indicates will become either an extreme egotist, a genius in business or some other direction, or he will be deaf and dumb, idiotic, blind, or an inebriate. I will show this in a paper I am to read before the Neurological Section, and will show that the inebriate is diseased.

If we examine a skull, we find quite a space between the hard palate and the brain. If the brain is arrested in its development, the osseous system will likewise be undeveloped, but the arrest of development in the osseous system will be caused by the want of development in the brain. I may say, however, that the lower jaw is developed independently of the rest of the face.

Dr. Fletcher asked whether the fact that both the teeth and the brain were developed from the epiblast had any bearing upon the defective teeth in the classes spoken of?

Dr. Talbot thought that as the arrest of development was from causes back of the birth of the child, it was reasonable to suppose that there was a defect in the tissue from which the organs originated.

CLINICAL LECTURE ON THE TREATMENT OF DIFFERENT FORMS OF BRIGHT'S DISEASE OF THE KIDNEYS.

Delivered at the Pennsylvania Hospital, Philadelphia, November 19, 1892.

BY J. M. DA COSTA, M.D., LL.D.
OF PHILADELPHIA, PA.

Gentlemen:—I shall this morning bring before you a series of cases of Bright's disease, illustrating several varieties of this affection. After discussing their clinical features and diagnosis, I shall make some remarks upon treatment. It happens that the wards are now rich in cases of kidney disease; so that I am enabled to group for you cases suffering with different types of the disorder.

Case I is a boy 16 years old, who was before you two weeks ago. I pointed out to you at that time the striking phenomena. I told you that he had the characteristic look of the affection. He was pale; his face was oedematous, as were his limbs; his mind was dull, and examination of his urine revealed the cause to be chronic parenchymatous nephritis. Not to repeat at length what we then discussed, I will merely speak of the treatment. I said that we should treat the case with the lactate of strontium, a remedy which is new in the treatment of these Bright's affections, and which, both last year and this, I have been testing clinically. Now here is a case returned after two weeks, and we may ask ourselves if this plan of treatment has been followed by any striking results; in fact, by any result that would make it worth while to continue the remedy. We observe that his general condition has improved; he looks

brighter, but there is still pallor and puffiness of the face. He passes from forty-two to sixty ounces of urine daily, and last week it ranged from sixty to ninety ounces. Nevertheless, the proportion of albumen remains high. The precipitate upon boiling the urine in a test tube is from sixty to seventy per cent. in bulk; and this proportion was found in the urine during the preceding week, even when he was passing such a large quantity. We further observe that his tongue is slightly coated; the bowels are daily moved; his appetite is good. His diet consists of milk, oysters, fish, vegetables, bread, and some tea and coffee. He has not been allowed to eat meat. He has been taking milk six ounces every two hours, and the other articles of food at meal times, so that milk forms the greater part of his nourishment; as his appetite is good, he gets quite enough in the way of food. You probably wish to be told what has been the result of the remedy in this case. The strontium has acted the part of a powerful diuretic; the urine at one time, as you observe by this chart, went up to ninety ounces. Nevertheless, the amount of albumen has not been decreased. His general health is fair; at all events it is not apparently suffering much at present.

The pathology of this case has been already referred to; it is recognized as one of parenchymatous nephritis. There is now very little dropsical swelling remaining. Under these circumstances, should we consider that he has had enough of the remedy? Or what conclusion can we form in reference to it? First, let me call your attention to the fact that the dose was even increased from thirty to forty grains, three times a day (or two drachms daily). I do not believe it proper to increase this dose or even to continue the remedy. I think, after two weeks trial, that we may conclude that this agent will not produce any specific effect upon the albuminuria. This is not my first experience of the kind with the strontium salts: I tried them last year, when they were first brought forward, and I may state that I had very much the same results last winter as we have had in this case. The effects of the lactate of strontium have been carefully studied in these cases. It is an admirable diuretic it is true, but as far as any specific effect upon the kidney or upon the excretion of albumen is concerned I cannot say that we have yet obtained any decided results. I therefore conclude that it is in cases of Bright's disease with scanty secretion that it is most applicable, since it will increase the amount of the urine passed without causing any irritation of the kidneys; but as for diminishing the amount of albumen, I do not think it will maintain the reputation it had at first, or accomplish what was then claimed for it; for you are aware that the French clinicians who introduced it did not do so because it possessed diuretic properties, but on account of its alleged effect in diminishing the amount of albumen. You have already heard that albumen still exists in large proportion in this boy's urine, associated with epithelial casts, that are largely granular. I will now give him some other remedy that I hope may prove more useful in diminishing the albumen. I will here try a remedy that I have found of benefit in similar cases; it is nitro-glycerine. We will begin with two drops of the one per cent. solution in alcohol, and gradually increase it as high as ten drops, given three times each day, carefully observing the effects. In one

case, I went above this as high as thirty drops three times a day; but I think that for the most part it is better to confine ourselves to smaller doses, say not over ten drops of the centesimal alcoholic solution. Its best results are shown in reducing the excretion of the albumen, thus diminishing the amount of drain from the blood of this important constituent. The diet of the patient will remain the same.

Case II is a man 65 years of age (carried in on a bed). Now, gentlemen, here is a case with which I am not so familiar; barring a short conversation with him yesterday, I see him now for the first time. The resident physician tells me that this patient has been in the hospital once before for the same malady, so that we may learn something of the early history of the illness. This also is a case of Bright's disease of the kidneys. His present attack began three weeks ago, or it may be more correct to say that he grew worse three weeks ago, for the doctor says that he was in this hospital from May until last June, and then went out better but not cured. He was dropsical upon admission on the former occasion, and his urine was scanty, eighteen to twenty ounces a day; it contained small quantities of albumen with granular casts. In his previous history I find a note of eye-changes; whitish, glistening spots seen in the right eye, and similar spots, but less marked, in the left eye—in other words the characteristic retinal changes of Bright's disease. Under treatment in the hospital, with digitalis, elaterium, followed by Basham's mixture, his dropsy disappeared. He was so much better that he considered himself cured and left the hospital; but he was not well. This was his previous history; now we come to his present illness. Three weeks ago he became worse; he complained of pains in the lumbar region, and of some dizziness, but had no dropsy at this time. He came back to be treated for his pain in the lumbar region and for vertigo. The dropsy has not reappeared. The urine has been examined since his re-admission two days ago. On the 17th it was 1020, clear, of alkaline reaction, and amounted to fifty-four ounces; yesterday (the 18th) it was thirty ounces. The proportion of coagulum after boiling in the test tube was two per cent. The small white sedimentary deposit consisted principally of phosphates; no casts were found.

His tongue is clean; the bowels are moved daily. His pulse is distinctly rigid, showing increased arterial tension, and his temporal arteries are prominent and throbbing. The heart has a sharply accentuated, second sound; the apex impulse is, however, to be felt within and under the left nipple. Notwithstanding this extraordinary accentuation of the second sound, and the forcible impulse which may be felt all over the cardiac region, I do not find any evidence of decided cardiac disease. There is no enlargement of the liver, nor of the spleen, and no œdema of the chest or extremities. Now, what is the matter with this man? This case is entirely different from the one you saw before. This patient has a cirrhotic or contracted kidney. The condition is readily recognized by three signs. In the first place, the absence of dropsy, or only its occasional appearance, and even that I infer from his history rather than from anything that we see at present. Secondly, the retinal changes found upon ophthalmoscopic examination. Thirdly, the signs of

increase of arterial tension shown in the pulse and the very markedly accentuated second cardiac sound. Finally, the urine record is most significant. The two per cent. of coagulated albumen we have here, is in marked contrast with the sixty to seventy per cent. in the other case. In that patient we had parenchymatous nephritis, in this cirrhotic kidney; in the former there was enlargement and in the latter contraction of these organs. This is the form which has been called chronic, interstitial nephritis. The urine usually has the specific gravity of 1005 to 1015; here it is a little higher, but this does not impair the general features of the case. Let me direct your attention to one more point. You recall the fact that casts were so frequently found in the other case that every examination showed them in profusion; here they are rare. Yesterday the resident examined four slides without meeting with a single cast. But this is not altogether a typical case. Is there anything lacking? Yes, the heart condition. When you have a case lasting as long as this, it is common to have more than mere increase of arterial tension, and accentuated second sound and marked impulse. It is common to find cardiac hypertrophy, and its absence here will give us a point of prognosis. On account of the absence of this lesion in the heart, the patient is very likely to have a longer life before him, and better health than if this change had taken place. Except for the accidental occurrence of uræmia or uræmic convulsions, the cases of interstitial nephritis which do best in the long run are just these cases that are free from cardiac lesion.

As regards treatment, it is very important to keep the bowels in a soluble condition. The cardiac overaction and the condition of the blood-vessels make it incumbent upon us to administer laxatives. Rochelle salts, repeated several times a week, may be given. We will avoid a routine treatment such as the administration of infusion of digitalis, because while it would affect favorably the dropsy, where it exists, it would aggravate the arterial tension. If we increase the heart's action, we run the risk of rupturing the vessels and bringing on an attack of apoplexy. What class of remedies would then be likely to do good in this case? I should not consider that the treatment by nitro-glycerine, given to the preceding case, would be of any value here, simply because the amount of albumen is extremely small, as it usually is in contracted kidney, though the nitro-glycerine would be of service for the arterial tension. If we could find some remedy which would reduce the amount of fibrous tissue forming in the kidney it would strike at the root of the malady. Corrosive sublimate is such a remedy, and I will therefore give this patient bichloride of mercury in increasing doses. I have tried iodide of potassium, but found it of certain efficacy: in some cases I have seen increased irritation and injury of the kidney following its administration. I believe that the bichloride is a safer remedy, and will commence with a dose of one-thirtieth of a grain three times a day, increasing it gradually to one-eighth of a grain.

Now, gentlemen, at the same time that we give the bichloride for the condition of the kidneys, we must pay some attention to securing the free action of these organs. The patient is now passing hardly urine enough, only thirty ounces a day. I will, temporarily at least, give him cream of tartar in the form of lemonade (made by dissolving the

cream of tartar in sweetened water, half an ounce or more to the pint), which he shall take daily until the secretion is freer. As a rule, you will not have much difficulty in keeping up the secretion in instances of contracted kidney; indeed, it is apt to be a little more than normal. He may also drink some mild diuretic mineral water, such as Poland water.

The diet is a very important part of the treatment of a case of Bright's disease. This patient has been put upon a milk diet almost exclusively. Is it essential that a patient with contracted kidney should be exclusively upon a milk diet? I answer, No. It is a nourishing, bland diet, and has diuretic properties, but in cases of contracted kidney where there is so little albumen as there is here, I give milk mainly, but I also allow toast, the yolks of eggs, and other light articles of food, such as oysters, fish and poultry. While keeping to milk diet as the main line of treatment, I do not make the patient's life miserable by insisting strictly upon milk as the sole article of diet.

We will watch the progress of these cases; one having a large amount of albumen, casts and dropsy, a case of parenchymatous nephritis; the other with a small amount of albumen, no casts, no dropsy, a case of interstitial nephritis, and the latter on a different plan of treatment from the former.

Case III.—Here, gentlemen, is yet another case of Bright's disease of still different character. It is fortunate that the rich material now in the wards will enable me to exhibit to you the principal forms of this protean malady in a series of cases, and to point out the different indications for treatment in each and the best course to pursue in the general management to secure the most benefit to the patient.

This man is about 70 years of age, of spare frame and at present confined to bed. He had a brother, he says, who died with dropsy. He himself, prior to his present attack, has been a well man, or at least in his ordinary health, as he is a chronic sufferer from hæmorrhoids, to which he attributes all his illness. We get the following history from the physician who attended him outside of the hospital: during last winter he had an attack of what was considered acute nephritis, from which he entirely recovered. He then was well as ever until six weeks ago, when he began to complain of shortness of breath, weakness, and swelling of his legs.

As you see his legs are œdematous; they pit upon pressure, although since he has been in the hospital, the enforced rest in bed has done him much good, and the swelling is less marked than when he came in. There is no abdominal dropsy; no disease of the heart can be detected upon auscultation of the chest. There is feeble respiration with slight relative dullness at the back of the lungs especially upon the left side, where I can hear some moist râles. His tongue is clean except towards the back, where it is slightly coated. The bowels are costive. The urine has a specific gravity of 1022, and it is acid this morning, but was not so yesterday. It contains albumen and a sediment composed of abundant epithelial casts and urates, but no blood.

Now what is the matter with this man? He is suffering from an attack of acute or subacute nephritis. The fact that he was in his usual health—for his ill-health before was his usual condition and due to hæmorrhoids which seem to have embittered his existence—it is fair to say, I think, that he was in

his usual health, when he suddenly became short of breath and dropsical with albumen in the urine, and casts. The only question is, Is the present attack one which can be traced back to the seizure which we learn from the physician who attended him he had last year, or is it a distinct attack? It is difficult to say, as we know nothing at all about the condition of the urine in the meantime, since he passed from medical observation until he applied here for treatment. If you ask my opinion as to the probabilities of the case I would say, that there has been since the former attack a slight amount of latent kidney disorder, and that the present is really a subacute attack of nephritis. If this were entirely an acute attack, we should have more albumen and perhaps some blood in the urine.

What is to be done for the patient in the way of treatment? We must first relieve the present condition of dropsy. His shortness of breath is due to dropsy of the lungs or serous effusion into the pulmonary areolar tissue. There is pulmonary congestion with effusion. There is no disease of the heart and we must look to the kidneys for the cause of the disorder. On account of the coated tongue, costiveness and congested internal organs, laxatives are indicated here as in the preceding case. Let him have half an ounce of bitartrate of potash every other day, and if it does not produce results, give it every day. Let him have diuretic mineral waters freely; He shall have infusion of digitalis, half an ounce every four hours, its effects being watched. We will dry-cup his lungs to relieve the pulmonary congestion, and he shall also have a few dry cups over each kidney. After the irritation from this has subsided, croton oil or tincture of iodine may be applied over the kidneys in the lumbar region. As this is an acute, or at least a subacute attack, we will put him upon a milk diet. He may have some toast with his milk because it will make his diet less monotonous; but the more strictly he keeps to the milk diet the better.

We have here indicated a different line of treatment from that of the two other cases—milk diet, diuretics, digitalis and laxatives. Under these precautions the acute condition will pass away and then we will be able to decide whether there was anything left from the preceding attack, or whether this was an entirely new seizure.

I have been enabled this morning to place before you, in these three patients, three different forms of Bright's disease of the kidneys, and to show you how they differed in their clinical characters, how they required different forms of treatment, and also how they differed in their prognosis and ultimate consequences.

[The treatment in Case III was followed by the happiest results. When he was shown to the class a week later, the albumen was reduced to a mere trace and all the dropsy had gone. In the first case shown, scanty urine coming on and symptoms of mild uræmia, the nitro-glycerine in a few days had to be discontinued, and pilocarpine, laxatives, caffeine and benzoate of sodium were substituted, under which he rapidly improved.—*Rep.*]

RICKETS, AND THE TREATMENT OF ITS RESULTING DEFORMITIES.

BY WM. E. WIRT, A.M., M.D., Ph.D.,

PROFESSOR OF ORTHOPAEDIC SURGERY, WOOSTER UNIVERSITY, CLEVELAND, OHIO.

In the consideration of a medical topic we must recognize its importance as depending on: first, the frequency with which the disease occurs, and secondly, the severity of the disease if left untreated. Taking this as our standard of test we must recognize in rickets a disease of considerable importance.

Frequency.—In Europe the disease is very common, especially is this so in England, and to such an extent that in some countries it is known as the "English disease." The proportion of all children attending certain clinics, having rickets is given as follows: Dresden, 25 per cent.; Berlin, 11 per cent., Parague, 31 per cent. In the higher classes the proportion is much smaller.

Merei states that in Manchester one in five children of well-to-do families had rickets, and the proportion is about that great in the wealthier classes.

Its severity when left untreated varies considerably. In the milder cases the lesions are insignificant, and the ultimate damage done is of little importance. But in the severer cases the results are quite different; the changes in the spinal column and extremities modify seriously the contour of the body, and may even prevent locomotion; the changes in the thorax interfere seriously with the function of vital organs; the changes in the bones of the skull may even endanger the life of the child; while the deformities produced in the pelvis are a menace to future generations.

Climate.—It is stated by various observers that it is a disease more especially of northern climates, it being particularly common in Germany, Denmark, Sweden and England. But my own observations lead me to think that it is more common among the Italians and negroes than any other class of people. In the city of Cleveland the disease is quite common among the former, and I recently had a death among them from this cause.

Occurrence.—Rickets is mostly a disease of early childhood though it is observed at other periods of life. Enough cases of fetal rickets have been observed and recorded to establish its possibility. At the age of puberty changes may take place in the bones which are recognized as due to rickets. In girls at this age the preparation for the catamenial flow causes disturbances of nutrition, and if to this we add a sedentary life we have conditions favoring this disease. Vincent, of Lyons, considers the scoliosis of adolescence as late vertebral rickets.

A form known as senile rickets has been described, but the condition thus found is probably the same as that known as ossium mollities. But by far the greater proportion of cases are seen in children between the ages of six months and two years.

Pathological anatomy.—The pathological changes noted in rickets are mostly to be found in the ends of bone, in the cartilage and in the periosteum. Chemically, there is a change in the proportion of the organic to inorganic material, in the normal bone the organic matter constitutes about one-third of the bone. In rickets the organic material may compose as much as four-fifths of the bone.

Histologically there are many changes, the most

marked of which is seen in the cartilage between the epiphesis and diaphesis. This cartilage normally contains a zone of proliferation, consisting of one or two layers of cells, while in rickets it is composed of many layers of cells involving nearly the whole intervening cartilage. The cells are much enlarged and the matrix is diminished. Therefore, the proliferating zone is much increased in size, is soft, and of a grayish translucent appearance. This increase of the proliferating zone accounts for the epiphiseal enlargements. The process of ossification is arrested. The Haversian canals extend from the bone into the proliferating zone by a process of absorption and appropriation. Attempts at ossification are shown by granules of lime being scattered through the cartilage, and here and there are found nodules of true bone. Increase in thickness of bone occurs from the under layer of the periosteum. In rickets this *subperiosteal* layer is increased in vascularity, and in appearance much resembles spleen pulp, so that the older observers mistook this condition for a subperiosteal hæmorrhage. The bones affected are the skull, jaw, teeth, spine, extremities and pelvis.

The effects on the skull are a direct sequence of the non-ossification of the bones. The sutures and fontanelles remain open much longer than they should and resulting from this are changes in the shape of the head. The diameters are changed, the head being lengthened and flattened latterly. The contour of the head is rectangular with prominent frontal and parietal eminences. The forehead is prominent, and in some cases even to the extent of overhanging. Authorities differ as to the relative size of the head, some claiming that it is larger, and some that it is smaller than normal. The London Pathological Society reported in the *Lancet* of 1880 that in seventeen children of average age of 4.72 years the average circumference was 21.22 inches, while in an equal number of non-rachitic children with average age of 6.05 years the average circumference was 19.95 inches.

On the other hand Ritter von Rittersheim, on the ground of careful comparative measurements, denies that there is any enlargement. As for my own opinion, my experience would lead me to think that the head is enlarged in rickets. I have measured few rachitic children whose heads measured less than 20 inches, while the vast majority measure more than this.

In regard to the effect of this disease on cerebral development as apart from the size of the head, Trusseau held that cerebral development was favored, while Gee maintained that there was retarded cerebral growth. My opinion inclines toward the former view the vast majority of rachitic children certainly seem above the average in intelligence.

A condition of the skull known as craniotabes, which consists of a softening and thinning of the bones, was until recently considered to belong particularly to rickets; but syphilographers claim to find this condition more or less common in syphilis. One argument advanced by Goodhart in favor of its common connection with rickets is that craniotabes is almost invariably associated with laryngismus stridulus; again laryngismus stridulus is universally admitted to be almost always due to rickets; so that if the two are thus closely associated, the evidence is clearly in favor of the rachitic nature of craniotabes.

The thinning of the skull in craniotabes is due to the pressure of an external object, as the pillow, from without, and the pressure of the brain within. It is usually found on the posterior aspect of the skull, due to the child lying more commonly on that part. On pressure of the hand the impression conveyed is likened to that of parchment paper.

Other parts of the head affected are the jaws and teeth. The whole face is smaller than normal, and this is particularly seen in the lower jaw which is shortened and becomes polygonal in shape. Fleishman claims that the upper jaw is lengthened.

The process of dentition suffers severely. The incisors may not appear until ten months or later, and when they do appear they are deficient in enamel and crumble readily. Delayed dentition is of great diagnostic importance.

In the trunk we find various changes. The ribs are early affected, and changes take place in the contour of the thorax. The so-called "rachitic rosary" consists of a beading or enlargement of the ribs at their anterior ends where they unite with the costal cartilages, and it is a most characteristic symptom of the disease. The atmospheric pressure combined with muscular force acting on the softened ribs causes a change in the contour of the thorax. The most common deformity is a flattening in the sides and a pushing forward of the sternum producing the condition known as pigeon breast. Sometimes the reverse takes place, and the sternum is sunken in instead of protruding and forms what has been called the bird-nest breast. In severe cases these changes in the chest interfere seriously with the action of the heart and lungs. Changes in the arteries may and do result from these abnormalities in the shape of the chest.

In marked cases the abdomen becomes quite protuberant. The spine very commonly suffers from the disease, the bones being softened and the ligaments weakened, and following this condition we have kyphosis or lordosis, the former being the more frequent.

In its effects on the bones of the pelvis of woman rickets verily threatens man's posterity, and on this account the rachitic pelvic deformities are considered the most serious to which the skeleton is subjected. They are produced by the downward pressure of pelvic organs which tend to flare out the brim; by the pressure of the trunk, transmitted through the spinal column, which, acting on the sacrum presses forwards its promontory, thus shortening the antero-posterior diameter; by the action of the heads of the femora in standing and the pushing in of the tubercles of the ischia in sitting, both acting to narrow the outlet of the pelvis. Serious consequences may follow from the marriage of a woman who had rickets of any severity.

The deformities of the skeleton the most apparent are those of the extremities, the most marked of which are found in the lower extremities. In the upper extremity we find the humerus usually bent only slightly with the convexity outward, the point of greatest curve being at the insertion of the deltoid; the radius and ulna are bent with convexity outward. Sometimes the bend is quite marked just posterior to the wrist, and is thought to be due to creeping. The natural curves of the clavical are increased, and frequently the scapula is found slightly warped with its edges thickened. In the

lower extremities we find the femur bent with convexity outward; the most common curve for the tibia and fibula is the simple outward curve recognized as bow-legs. In severe cases the lower limbs are so twisted as to have received the name of grape-vine legs. In these cases the femora at the upper portion are bent outward, at the lower portion they are bent inward forming a marked knock-knee: the tibiae are bent outward forming a marked bow-leg or frequently in the severer cases they are bent backwards, that is, with the convexity forwards. In a few rare cases the tibiae are flattened just below the knee with a marked convexity posteriorly.

Etiology.—The cause of rickets may be summed up in the word malnutrition, and may occur as Vincent has said: "In the very bosom of abundance"; but it is seen in its severe types among the children of the poor in large cities. There seems to be an inherited predisposition to the disease. Defective assimilation and enfeebled digestion which have a causative relation, can often be traced to diseased and cachectic conditions of the parents. The relation of syphilis to rickets has long been a mooted question. Certain it is that the impaired nutrition accompanying inherited syphilis must necessarily predispose to rickets. But the claim of M. Parrot that rickets is a manifestation of infantile syphilis is not borne out by the history and indisputable facts in many cases. Again, as against the syphilitic origin of rickets someone (whom, I cannot recall) has attracted attention to the fact that syphilis shows itself most markedly on the first children born in a family, while rickets manifests itself most markedly in the last child or children born.

Hygiene is recognized as of great importance in this disease, and Fournier considers the principles of hygiene as the most important factor in its cure. As for myself, I have been able to trace the cause of rickets in more cases to improper feeding than to anything else. It is the common answer to inquiry in this regard as to what the child has been fed: "Oh, the child has been eating just what the rest of the family eat," and this is said of a child a few months old.

Hand-fed infants are extremely liable to the disease, and especially is this so when fed starchy food. It has been said that rickets could be produced in an animal by feeding lactic acid, at the same time restricting the amount of calcareous matter, but it would seem that the want of calcareous matter in the food was the more important element, and not so much is made of this point as formerly.

A form of this disease, which has not received much attention, is called by Eugene Vincent "local inflammatory rickets." He describes it as produced at one end of a long bone by inflammation at the other end. I have seen a few cases that might be classed under this head.

Symptoms.—The symptoms of rickets have many of them been described under the head of pathological anatomy. The disease so often follows a spell of sickness that it is difficult to say when the disease began. It will be noticed that the child is peevish and cross; it is restless at night with a tendency to kick off the bed clothes; there is often flatulence with pasty stool. A symptom often observable is tenderness of the whole body. The child seems to dread to be handled. The healthy child delights in exercise and loves to be dangled in the air; the rickety

child dreads exercise and seems most contented when left alone; the rickety child perspires freely, both when asleep and awake, especially is this so about the head. Later on the bone changes take place. The ribs are beaded; the chest changes its shape; the fontanelles remain open much longer than normal; the contour of the head is changed; craniotabes is noticed; dentition is delayed, the epiphyses of the extremities are enlarged; the limbs are deformed; walking is delayed, the child assumes peculiar attitudes—the spine sometimes in kyphosis, sometimes lordosed, if able to stand the limbs are spread apart. To these symptoms may be added the symptoms of broncho-pneumonia. With this array of symptoms the diagnosis becomes easy.

Prognosis.—The prognosis of rickets as to life is very good. Only a few of the more severe cases die. I recently had a very severe case of rickets in a child of fifteen months, that died of broncho-pneumonia complicated by diarrhoeal troubles. This child had never walked, its limbs being very soft and pliable, and accompanying this were all the marked signs of rickets. In the mild cases the diagnosis is often not made out and yet the child entirely recovers. In the moderately severe cases the bones soften and become deformed, then arrest of the disease takes place, and the bones harden in the deformed position. Children so affected never reach full size and they always bear marks of the disease. It is only in the mild cases that the child outgrows the deformity, so that it is a serious mistake to let these children go untreated, often at the recommendation of the physician, being assured that the child will grow straight. At this stage they only require mild treatment for the deformity, and this mild treatment they should have.

The complicating diseases which these children are liable to are those of the respiratory tract, and these diseases they bear badly especially if the chest is much deformed. Bronchial catarrh and broncho-pneumonia are especially to be feared. Whooping-cough is badly borne, and measles if attended by bronchitis or broncho-pneumonia is a dangerous complication.

Treatment.—The treatment of rickets is clearly indicated by the pathology and etiology. Healthy nutrition must be restored. The child of a sick mother with milk of poor quality and small of quantity must have additional food; if two years old it should be weaned. Naturally the diet of a rickety child must vary with its age. The following diet is given by Erastus Smith, and for the average case can not be much improved: breakfast, a cupful of milk with a teaspoonful of Mellins' food dissolved therein; at 11 A.M., a cupful of milk containing fifteen drops of saccharated solution of lime; dinner at 2 P.M., a tablespoonful of pounded mutton chops with stale bread and gravy; or, a tablespoonful of the flower of brocoli, well stewed with gravy, bread and butter, and toast water. Supper at 6 P.M., same as breakfast, or a soft boiled yolk of egg provided no meat has been eaten. If the child is a year old or younger and is hand fed the milk should be diluted with lime water or barley water. The proportion is two parts of milk to one of water, or in some cases it may be reduced to equal parts of milk and barley water.

Of nearly equal importance with the food is the hygienic measures. Strict cleanliness must be ob-

served in connection with the feeding apparatus and the food. Every day the child should receive a tepid bath; cleanliness must be observed in dressing the child, there being no stint in the changes of its linen and napkins. It should be dressed warmly but not bundled up. The child should be kept in a warm and light room with plenty of ventilation; in pleasant weather the child should be kept out doors as much as possible.

Among the therapeutic measures cod liver oil, iron and the hypophosphites rank high. Phosphorous is highly spoken of by many. Jacobi, of New York, gives the official oleum phosphoratum ($\frac{3}{8}$ gr.) Ledeschi makes applications of galvanism to the spine and claims better results than with phosphorous alone.

Treatment of Deformities.—The treatment of the deformities resulting from rickets falls within the province of the orthopedic surgeon. For the milder cases mild treatment only is required, the simplest of which is the building up of the sole of the shoe. For bow-legs the shoe is built up from one-eighth to three-eighths of an inch on the outside of the shoe; for a knock-knee the shoe is built up on the inside. Before beginning the treatment a tracing is taken of the deformity and after wearing the built up shoes for several weeks the tracing is again taken. If improvement is noted the treatment is continued to a perfect cure. If the deformity is increasing, or after eight weeks there is no improvement, this form of treatment is abandoned and braces are used. Of course, the above method is only indicated in the milder cases. For the severer cases braces are indicated in the start. The idea to be carried out in these braces in rickety deformities is three point pressure—two on concave side of the limb and one on convex side and at the point of greatest convexity. To have these pressure points always at the same place the brace must be carried down to a foot plate, or up to a pelvic band; the former is usually the simpler method. Pressure is obtained at the point of greatest convexity by means of a lacing. If by the use of braces correction of the deformity is not obtained there remains osteo-clasis and osteotomy. Since the days of antiseptic surgery osteotomy has been found to be a perfectly safe procedure and on account of its precision is preferred by most operators. By means of a small osteotome the bone is easily broken, the deformity corrected, the parts dressed antiseptically and the limb fixed in plaster of paris. At the end of four or five weeks the plaster is removed and the union is found firm.

As a safeguard braces are sometimes worn for several weeks or perhaps a month or two after removing the plaster.

In the lower extremities we find the femur bent with convexity outward; the most common curve for the tibia and fibula is the simple outward curve recognized as bow-legs. In severe cases the lower limbs are so twisted as to have received the name of grapevine legs. In these cases the femora at the upper portion are bent outward, at the lower portion they are bent inward forming a marked knock-knee: the tibiae are bent, etc.

To remove nitrate of silver stains from the fingers, paint the blackened parts with tincture of iodine: by applying ammonia, the iodine will be bleached, leaving white instead of black stains.

THE REMOVAL OF THE TOOTH PULP BY THE USE OF COCAINE.

Read in the Section of Oral and Dental Surgery, at the Forty-third Annual Meeting of the American Medical Association, held in Detroit, Mich., June, 1892.

BY EDWARD C. BRIGGS, M.D.,
OF BOSTON, MASS.

In October, 1890, I read a paper on this subject before a society in Boston and recounted many successful operations done since the preceding May. Since then I and some of my neighboring associates have been so successful that I feel constrained to bring the matter before this Association for a wider field in which to sow such good seed. In almost all cases of exposed pulps the pulp can be paralyzed and removed with no pain or discomfort to the patient. Cases which would seem most antagonistic to any radical treatment yield most gracefully to this.

Pulps of known irritability which would resist arsenious acid are satisfactorily disposed of by this method. Teeth are not "devitalized" by this treatment, as is so often the case with strong caustics, but are simply made "pulpless"—retaining their color and vital connection with the jaw.

The immediate root filling which is a part of the operation seals the tooth before germs can get in, and there is no abscess to be feared.

To operate it is necessary to have, 1, a tightly packed, smoothly running hypodermic syringe, with a flexible, blunt point. This latter condition I obtain by putting the point of a Dunn syringe into a hypodermic syringe.

2. A freshly prepared 20 per cent. solution of hydrochlorate of cocaine. (I have not yet had the opportunity to experiment with so-called milk of cocaine, which is suggested as being better.) Having an exposure of the pulp (the smaller the better), first apply on cotton some of the cocaine solution. This in a few moments makes the exposed part approachable, and if the opening through the dentine into the pulp is not as large as the end of the syringe point the syringe can be immediately placed over the point of exposure.

Having adjusted the syringe point, the piston is then to be firmly and steadily pressed down slowly at first and with increasing pressure, finally to be pressed down with considerable force, carrying the solution up and around the pulp to its extreme end. At the first impact of the liquid against the pulp the patient sometimes feels a shock—not worse, however, than one gives the patient when feeling with a probe to see if previous application of arsenious acid has done its work. If now the syringe point has been properly directed and fits over the exposure or into the opening in dentine so as to allow but little back flow, the operator can immediately open freely into pulp chamber with a bur, remove the pulp from the canals with barbed broaches; or even better when possible, enlarge the canals and remove the pulp at same time with a Gates-Glidden drill.

The advantage of this latter method lies in the fact that after the pulp has been entirely removed by a broach, if there is any delay in putting in the filling the inner walls of root or roots become sensitive again and it is as impossible to pass a probe into them as when the pulp was *in situ*.

A case or two by way of illustration:

Miss L. had been in Philadelphia during the winter, and

having gone away without the usual autumn examination a capped pulp had come to grief and an eminent dentist in Philadelphia had applied, presumably, arsenious acid. The patient returned to Boston with cotton dressing in the tooth and reported to me the day before departing for Europe, wishing to have the tooth filled. She said the tooth was "dead," but when I passed a probe into the distal root, I found it very much alive. It took but a moment, however, to pass a small syringe point down into the root, inject the cocaine rather forcibly, and then with barbed broach remove quite a sizable piece of root pulp. The roots were then washed with antiseptics, dried, and filled with gutta percha.

This case is typical of a large class, and we all of us have or have had teeth with "life in the end of the roots" which have baffled our efforts to completely remove, and which therefore we have had to keep dressed and temporarily filled for months and even years waiting for complete death. As a fellow practitioner remarked to me the other day, the operation was worth everything to us for just those cases alone.

Mrs. R. is a patient of my brother's. He was called to see her for the first time in her sick room where she had been a nervous invalid for over a year. Two or three teeth presented exposed pulps. My brother thought to disturb her least by making application of arsenious acid. It was with the too often result—inflammation, pain, and no destruction of pulp. He then tried the method described here, and removed the pulps of two teeth without the slightest shock or pain to the patient. This too under the most disadvantageous circumstances at the residence of the patient. I have the records of fifty or more cases almost all of which can be classed as perfectly successful. Where failure has been the result it has been due to defect in carrying out the detail of the operation as described. Failure to get syringe point directly over exposure; failure to have syringe in perfect working order; failure to use at least a 20 per cent. solution; and last but not least, neglect to have a fresh solution of the drug.

The operation must be done carefully, methodically, exactly—as we specialists have to do our work. When so done it will prove a success and a great boon to the profession. It is hardly necessary to add that proper care must be taken to prevent the patient swallowing any of the drug, using, as is necessary, so strong a solution.

PNEUMONIC FEVER—ITS SYMPTOMATOLOGY.

BY EDWARD F. WELLS, M.D.,
OF CHICAGO.

INTRODUCTORY.

From 1874 to 1886, a period of twelve years there passed under my observation four hundred ninety-eight cases of pneumonic fever. These were encountered in private family practice and in a rural neighborhood, inhabited by natives of the North of Germany and their descendants. They were, almost without exception, members of families in good circumstances, occupied comfortable dwellings, dressed and lived well and were exposed, to an extent much less than ordinarily, to the inclemencies of the weather, the hardships of excessive toil and the cares of want. They were, moreover, of a parentage largely free from pulmonary consumption and cancer and wholly free from syphilitic taint.

Carefully kept clinical histories of the cases above referred to have been preserved and it is an analysis

of these which serves as a basis for this study. In addition to this original material I have not hesitated to compare my observations and conclusions with those published by others.

The symptoms of pneumonic fever are usually clear and unequivocal, yet they are not rigid and immutable, but are endlessly modified by a great variety of circumstances. They are, for the most part, highly suggestive but not pathognomonic. In this, as in so many of the fields of medical science, we find that immediately we have accumulated an assemblage of affirmatory truths sufficiently large to serve as a basis for the formulation of a rule, numerous contradictory facts of more or less weight spring up to create distrust or compel exceptions. Nature persistently refuses to be confined in her marvelous operations by the restricting regulations of the conventionalist. Disease, of whatsoever name or character, should be viewed as an expansive, and not fully explored whole, and in an inquiring and liberal spirit. There can be no question as to the value to be placed upon the study of the ordinary and typical cases of an ailment, but if we do not desire to too narrowly confine our views we must not overlook and ignore the unusual, the complicated and the anomalous cases—and it will be found that in these varieties are comprehended a very large contingent of those encountered. Entering now upon the consideration of the clinical features of pneumonic fever in such an elastic mood we will quickly discover that the "exceptions to the rule" will engage quite as much of our attention as the law itself.

In viewing this malady from a clinical standpoint we are at once and irresistibly impressed by the fact that we are not looking upon a picture of still life, but that the patient is in the midst of a raging, momentous and terribly real conflict, in which the opposing forces are pitted against each other in an endless succession of varying combinations.

PRODROMATA.

Although an abrupt accession is the rule in pneumonic fever, yet a distinctly appreciable prodromal stage is present in a very considerable proportion of cases. This feature is particularly noticeable in some years, localities or epidemics. Thus in the great North American epidemic of the second decade of the present century a prolonged initiatory stage was the rule, and the same has been true of some other outbreaks.

An examination into the nature of the premonitory symptoms as they have been recorded in the histories of my cases leads to the conclusion that they are so varying as to almost defy analysis, and so equivocal that a diagnosis of approaching pneumonic fever can not be made from them. When present there is nothing peculiar about them:—nothing, indeed, which could lead the observer to a just conclusion as to whether the patient was to be the subject of a nameless slight indisposition, typhoid fever, variola, malarial ague, dysentery or—pneumonic fever. In short they are those peculiar to infectious diseases in general and are not particularly distinctive of the one under special consideration. The patient may complain of anorexia, nausea, vomiting, constipation or diarrhoea and other gastro-intestinal disorders; of headache, drowsiness or sleeplessness, irritability and fretfulness, restlessness and listlessness and other cerebral symptoms; of cough, op-

pression and thoracic soreness; of epistaxis, coryza and sneezing; of languor, lassitude and weakness; of chilliness and feverishness; of fixed and fleeting pains in the back, limbs, chest, muscles, etc.:¹ of anemia, sallowness and jaundice, and of many other symptoms, continuing for a shorter or longer period until the disease declares itself in unmistakable character.

Premonitory symptoms, in a diagnostic point of view, are of greater value in the aged than in the young. A dull headache, with drowsiness, irritability, sallowness, relaxation of the masseters, general weakness, anorexia and slight febrile movement has been, in my experience, so often the forerunner of an attack of pneumonic fever in elderly persons that I view it with suspicion and apprehension. One other symptom has particularly attracted my attention and that is an indefinite anxiety or alarm—a feeling of impending danger. This I have seldom observed as premonitory to any other disease—the nearest approach to it being the anxious restlessness which sometimes precedes gastric hæmorrhage.

My 72nd case is a good example of an assemblage of premonitory symptoms:—A young man, aged 20, of German parentage, and of excellent general health, was taken, May 16, 1879, with epistaxis and lassitude. Of an energetic nature he could now scarcely prevail upon himself to arise in the morning or to give up his chair after being seated—it was a task for him to move about, although he was not, as yet, weak. In a day or two his appetite failed and the sight of food became obnoxious. His tongue became coated and a foul mucous secretion accumulated in his mouth, especially in the morning. After a few days he became feverish, with suffusion of the eyes, slight deafness, dryness of the lips and restlessness. His bowels became confined and his urine was scanty, high-colored and deposited a copious sediment upon cooling. He was ill—too sick to be up and not prostrated enough to willingly lie in bed—yet careful examinations, repeated daily, failed to show any local cause for the symptoms, which were, in turn too indefinite to permit the diagnosis of any systemic disease, until, on the 26th inst., a severe chill was followed by all the ordinary symptoms of a severe attack of pneumonic fever, terminating in convalescence on the seventh day.

Andral's twelfth case is also a good illustration of this feature:—A man, aged 33, of a full and plethoric habit, for some time experienced headache, transient dizziness and epistaxis. On Dec. 16, 1822, when arising in the morning, he felt generally ill, with violent headache, tinnitus aurium, a sensation of burning heat over the entire body, etc. These symptoms continued and the face became flushed, eyes injected, pulse accelerated, tongue coated, etc. There was exaggerated pulsation of the temporal arteries, general debility, dullness of the intellectual faculties, anorexia, thirst, constipation, scanty urine and a slight cough. After an attentive examination the disease could not be located—all the organs seemed to be excited and upon the verge of inflammation, but in none was this an actual fact. These symptoms continued until the night of the 20th, when he awoke with a severe pain in the right side of the chest, which became almost insupportable when he inspired deeply or made the slightest movement. From this time the case assumed ordinary features and the patient died on the night of the 29th.²

This stage may be modified by peculiarities of the prevailing medical influences, the presence in the system of the germs of other diseases, etc. Thus in the case of persons residing in malarious regions there may be chilliness, followed by febrile reaction, recurring at regular intervals for several days before the pneumonic disease is fully established.

A girl of 12 years had a chill on the morning of April 25,

¹ Pause—Lungenentzündung, Leipzig, 1861, S. 67.—especially noticed aching of the joints in the afternoon and at night, but in my experience this was not observed oftener at this period of the day than at other times—beyond the evening exacerbations noticeable in nearly all cases.

² Andral, Clin. Med., Vol. ii, p. 132.

1881, followed by fever and profuse perspiration. In the afternoon she was up and at play, ate heartily and slept well during the night. On the following morning she had a second attack, accompanied by bilious vomiting, delirium and convulsions. This exacerbation continued until after midnight, but ended as the first in a complete intermission. On the third morning fever again recurred and became continuous. It was not, however, until the following day that the disease assumed a pulmonary aspect and could be recognised as pneumonic fever—the lower lobe of the left lung being the seat of the local inflammation.

A lady, aged 74, was taken with tertian ague in Sept., 1884. After having been three weeks ill she came under my observation on Oct. 10. Under treatment the ague promptly ceased and the patient soon regained her usual health. On Nov. 2 she had a chill at 10 A.M., followed by fever and profound prostration. On the following morning she felt better, arose and walked about the house, but was seized by a second chill at 11 A.M. This was more severe than the first and was followed by a higher fever and even greater prostration. During the night she was delirious. Next morning she expressed herself as feeling better, yet she preferred remaining in bed. At noon she had a third profound chill, followed by ardent fever, delirium, coma and consolidation of the entire right lung. She coughed a few times and expectorated characteristic sputa, but she remained in a dazed stupor until death occurred two days later. At the autopsy the entire right lung was found hepatized (red), with the markings of the ribs plainly shown.³

INVASION.

The invasion of pneumonic fever is, in the majority of cases, sudden. The patient is usually taken with a chill, accompanied or quickly followed by fever, cough, dyspnoea and thoracic pain⁴. This⁵ was the mode of access in nearly two-thirds of my cases, and the experience of other observers has been similar.

Thus in the Plague of Athens, "in general the persons were attacked by it suddenly, while in full health and without ostensible cause,"⁶ and such has been the language of the historians of a majority of the epidemics which have occurred and of the observers of individual cases⁷. Fox⁸ says that "in a large proportion of cases the disease commences suddenly and without previous warning, in persons who up to the moment of seizure had felt perfectly well, and it is not unusual⁹ for the invasion to occur during the night after the patient has gone to bed in his usual health.

To the patient there is something very alarming in the remarkable suddenness—like an electric shock from a concealed battery—with which the initial chill of pneumonic fever interrupts the course of health. Without feeling in the least unwell he retires to bed, to be awakened in the middle of the night to find himself the central figure in the midst of a raging storm of rigors. His teeth chatter; his feet freeze; his knees knock together; frigid trains speed up and down his back and spread out over the surface; his breathing is oppressed; some demon weighing tons sits upon his breast: he breathes deeply, he coughs, and is horrified at the keen pain which shoots through his side; he clasps the painful spot and coughs again, but all in vain for the agonizing pain is not lessened; his head aches—throbs to the

³ In studying these cases in which malaria evidently played an important rôle in the prodromal stage, we must not lose sight of the fact that distinctly intermittent or remittent symptoms may be present without the slightest suspicion of malarial infection. See Green, Quain's Dic. Med., N. Y., 1883, p. 880; Huss, Lungenentzündung, Leipzig, 1861, S. 37; Kottwitz, Inaug. Dissert., Halle, 1882, S. 33; Taylor, N. Y. Med. Jour., 1887; Thieme, Inaug. Dis-ert., Jena, 1865, and many others.

⁴ Satterthwaite, Phila. Med. News, Jan. 5, 1889, p. 3, places the order of events as follows:—(1) Pain, prostration, cough; (2) severe chill; (3) nausea, and (4) rise of temperature. This has not been the case in my experience.

⁵ I refer to the sudden onset of the disease.

⁶ Collins' Translation of Thucydides, N. Y., 1883, p. 49.

⁷ See Cleghorn, Epidem. Dis. Minoræ, London, 1762, p. 261; Huxham, Epidemic Diseases, London, 1748, Vol. ii, p. 59; Stokes, Med. Times and Gaz., May 26, 1855; et al.

⁸ Reynolds's Syst. Med., Phila., 1880, Vol. ii, p. 163.

⁹ In my experience nocturnal invasion has been very common.

point of bursting, he will say—and all his joints are racked with pain; he is dizzy; his brain reels, and all his sufferings are aggravated by the vomiting which ensues. The scene rapidly changes. Soon ardent fever is developed; the face is flushed; the cheeks glow; the skin is dry and burning hot; the pulse bounds excitedly; the dyspnoea continues; thirst is intense; the cough is acutely painful; the expectoration becomes bloody, and the hapless victim, with an expression of alarm, anxiously appeals, with his eye, to each one visiting his bedside. Thus the patient reposes in bed in a constrained posture, a picture of alarm, suppressed excitement and human suffering, and awaits with dread each coming event until, in a few hours, the disease has reached its height.

Usually the pulmonary symptoms declare themselves at once, but in a certain proportion of cases we have all the indications of a severe illness without any discoverable local manifestation. There is the sudden or gradual access of febrile symptoms but absolutely no trace of pneumonic changes can be discovered, until, after the lapse of a more or less prolonged period, they disclose themselves by the development of characteristic local symptoms and signs. We have, in these instances, systemic fever without local changes, as we have, at the end of the attack, local affection without fever.¹⁰ That this is, in the majority of instances, a late localization of the disease, and not merely an obscuration of the early physical signs, is clearly proven by the fact that in these cases the local affection pursues an ordinary course as to duration and sequence of the signs, which would evidently not be the case if they were only hidden.

A girl of 14 years was attacked during the night with a chill, followed by fever, delirium, muscular tremor, etc. The fever was continuous and all the symptoms indicated that the patient was laboring under a grave disease. The breathing was peculiarly oppressed and there was a slight cough, yet daily attentive examinations of the chest failed to detect any signs indicative of local affection until the fourth day when it was possible to demonstrate a beginning consolidation of the base of the left lung. On the next day the local phenomena were unmistakable, and the case pursued an ordinary course toward recovery.

Bolles' case was as follows:¹¹—A young man was taken ill, June 17, 1880, with febrile symptoms, chilliness, some cough, quick pulse and flushed cheeks. By the third day he was so low that two competent physicians expected him to die. At this time his lungs were carefully examined and absolutely nothing abnormal discovered. The chest expanded and contracted perfectly and the respirations were only 20 per minute. On the fifth day there was noted a patch of bronchial respiration and bronchophony, not very well marked, at the inner border, of the left scapula. On the sixth day this patch was enlarged and there was dullness on percussion, and on the seventh day the disease was fully developed.¹²

The late localization of the disease has an important bearing upon our conception of its nature, inasmuch as it affords strong presumptive evidence that it is a general disorder with a local manifestation.

¹⁰ Cases of this description are in my collection and they have been observed by Andral, *Op. cit.*, p. 181;—Baginsky, *Pneumonie u. Pleuritis*, Tübingen, 1880, S. 10;—Bolles, *Boston Med. and Surg. Jour.*, Feb. 3, 1881, p. 105;—Cincinnati *Lancet and Clinic*, Nov. 3, 1883, p. 398;—Cleghorn, *Epidem. Dis. Minorit.*, p. 261;—Heiss, *Inaug. Diss.*, München, 1857, S. 6;—Sturges, *London Lancet*, N. Y., 1881, Vol. 1, p. 287;—Tyson, *Ibid.*, 1881, Vol. 1, p. 233;—*et al.*

¹¹ *Boston Med. and Surg. Jour.*, Feb. 3, 1881, p. 105.

¹² Grisolles, *Traité de la pneumonie*, p. 181, speaking of these cases says that in some he has "noticed for four days intense febrility without being able to discover on the part of any organ, and especially on the part of the lungs, any lesion explaining it," and Andral, *Sup. cit.*, makes a similar statement.

By some writers who consider cold an efficient cause of the malady it has been thought that the period intervening between the exposure and the development of the attack is a reasonably exact measure of the duration of the stage of incubation.

Thus a gentleman riding against a raw wind felt chilly, and upon arriving at his residence, an hour later, was seized with a rigor which ushered in an attack of pneumonic fever.

A farmer engaged, at noon, in shocking wheat exerted himself greatly, in order that he might complete his work before the advent of a threatened storm, and perspired freely. In this condition he was overtaken by a shower of cold rain and hail and became thoroughly wetted. Although he quickly exchanged his dripping garments for others which were warm and dry, yet he was taken with a pneumonic chill six hours later.

A man engaged in chopping wood and perspiring freely, ceased work and sat down for a long talk with a neighbor. The March day was cold, raw and windy and the laborer's chest was covered only with a thin cotton shirt. Upon rising he felt tired, stiff, sore and chilly. This was about 4 p.m. During the night he was restless, slept but little and had frightful dreams. All next day he felt badly, and had headache, articular pains, anorexia, vomiting, irritability of temper, thoracic soreness and an insignificant cough. In the evening he had a rigor, followed by a severe attack of pneumonic fever.

A woman at the wash-tub perspired freely and exposed herself, with scanty clothing, to a cold wintry wind. Three hours later a severe pneumonic chill sent her to bed for a ten day's illness.

I might multiply these instances from my own records and from the published experience of others¹³ but the result would be simply a tedious repetition of similar cases. In all my cases, however, the attack followed quickly upon the exposure.

This is in exact accord with the experience of LaRoche¹⁴ who, speaking of the vicinity of Philadelphia, says that a prolonged incubation may have been noticed elsewhere "but so far as the experience of the physicians of this section of the country extends, it may be safely averred that nothing of the sort has occurred, and I tax my memory in vain for a reference bearing on this point to some of the many publications, foreign and native, that have passed through my hands. Never and nowhere have I seen, heard or read of a case in which the attack has come on, whether abruptly or preceded by premonitory symptoms, more than a few days after exposure."

The fallacy of all this is, however, obvious. Pneumonic fever is certainly caused by a *materies morbi, sui generis*. That exposure to cold may, and probably does, place the system in a condition favorable for the reception and action of the specific cause may be admitted, but this exposure is not the essential element. Now, if it be granted that another, and a special agent, besides cold, is necessary for the production of the disease, we can never be certain whether the specific germ has previously entered the economy and, lying dormant and awaiting a favorable opportunity to begin its work, or whether it enters the system at the identical moment of "catching cold," or, finally, whether the entrance is subsequently effected.

In this connection it may be mentioned that patients often mistake the initial chilliness or rigor of pneumonic fever for exposure to cold, and this source of error and fallacy must be born in mind when considering this question.

The disease has also been considered contagious, and it has likewise been proposed to measure the period of incubation by estimating the interval between the contact with other cases and the outbreak

¹³ Ziemssen, *Pleuritis u. Pneumonie*, 1862, S. 159, gives a long list of cases.

¹⁴ *Pneumonia*, Phila., 1854, p. 391.

in the patient. Here, again, arise the same doubts as in the preceding series of cases.

It follows, then, that we are, as yet, unable to state, with any degree of certainty, the duration of the stage of incubation. Such stage, nevertheless, does exist, and the future may delineate its characteristics and measure its exact duration.

CHILL.

A chill is almost always the initial symptom of the sudden invasion of pneumonic fever. It is usually accompanied by rigors and is generally more intense and pronounced than in any other malady except pyæmia¹⁵ and malarial ague. The duration of the chill varies from a few minutes to several hours;¹⁶ its decline being gradual.¹⁷ In some cases the chill is replaced by a sense of chilliness, alternating with flashes of heat—if the patient is in bed and quiet he feels feverish, but with the slightest jar or movement chilly sensations course up and down the back, spreading thence, as from a centre, to various parts of the body. This continues for a short time and is replaced by a sensation of heat until another movement causes the chilliness to reappear. The profound chill often passes off with this sort of chilliness. The duration of this recurrent chilliness is usually longer than that of the decided chill—sometimes being twelve or more hours. There is usually a single chill, although there are occasionally multiple recurrences.¹⁸ It usually immediately precedes the development of the local symptoms, but in some cases it may precede these by several hours or days. The initiatory chill was present in 86 per cent. of my cases. In 199 cases the chill was noted as being severe; in 97 there was "a chill;" in 76 there was "a light chill," and in 56 there was simply "chilliness."¹⁹

The initiatory chill was present in 92.6 per cent. of Fisser's¹⁹ cases; in 92.5 per cent. of Lebert's²⁰ cases; in 82 per cent. of Chomel's²¹ cases; in 80 per cent. of Huss' cases²²; in 79 per cent. of Grisolle's cases;²³ in 60 per cent. of Speck's²⁴ cases; in 37 per cent. of those analyzed by Stortz;²⁵ in 63 per cent. of Schapira's²⁶ cases; in 94 per cent. of Wunderlich's²⁷ cases; in 65 per cent. of Fenwick's²⁸ cases; in 77 per cent. of Louis's²⁹ cases; in 75 per cent. of Lépine's³⁰ cases; in 72 per cent. of Kocher's³¹ cases; in 69 per cent. of Bleuler's³² cases; in 64 per cent. of Fox's³³ cases; in 60 per cent. of Durand-Fardel's³⁴ cases; in 50 per cent. of Juergensen's³⁵ cases; in most of Gerhard's³⁶ cases and in all of the 63 cases of the Loberg epidemic.³⁷

As to the severity of the chill Fisser³⁸ found that of 219 cases, 84 had rigors, 41 had a chill, 42 had a light chill, 35 had a very light chill and in 17 the chill was lacking.³⁹

Scheffels⁴⁰ in describing the appearance of the chill says that the patient suddenly felt a sensation of

warmth, then heat, and, a short time afterwards a chill.

Chomel⁴¹ thought that when the attack began at night the chill was generally absent. This, however, is contrary to my experience. Early in my professional career I was impressed with the remarkable frequency with which the pneumonic chill occurred at night and during the hours of sleep, and subsequent observation has only confirmed my early conclusions; for of 428 cases the chill occurred between the hours of 9 P.M., and 6 A.M., in no less than 231.⁴²

Chill is, however, absent in certain forms of the disease or conditions of the patient. Thus in the case of young children it is usually replaced by slight chilliness, coldness of the extremities, nose and ears, paleness of the surface, blueness of the nails, etc.⁴³ In the aged, also, an initial chill is less frequent than in adults, but when a chill occurs it is more distinctive of pneumonic origin. In the weak, cachectic and diseased it is also often lacking.⁴⁴ This is also true of some epidemics.

Juergensen⁴⁵ states that very fleshy persons escape the chill, but I can not confirm the statement, it so happening that every fleshy person whom I have observed with this disease had a very distinct initiatory chill.

Chills may occur after the disease has been fully established⁴⁶ and even during convalescence.⁴⁷

A young lady, 17 years of age, was taken, Apr., 28, 1880, with a chill, followed by cough, pain in the right side, sanguineous expectoration and the ordinary signs and symptoms of pneumonic fever locally affecting the apex of the right lung. Crisis occurred on the seventh day and convalescence seemed fully established, when, three days later, she had a second severe chill and rigor, followed by a pulse of 116 and a temperature rising to 102.5°. The febrile symptoms continued only a few hours, after which convalescence was uninterrupted.

A CASE OF SPINA BIFIDA WITH CURIOUS DISTURBANCES OF THE SEXUAL FUNCTIONS.

BY SYDNEY KUH, M.D.,

FROM CHICAGO.

ASSISTANT AT THE CLINIC OF PROF. ERB, IN HEIDELBERG.

Philipp Eller, twenty-six years of age, a tailor, was admitted into my ward on the 9th of July, 1891. His father had died from dropsy, there was perhaps some case of phthisis in the family, certainly no nervous taint in the ancestry. The patient has ever since the time of his birth, a slight prominence in the sacral region of the spinal column upon which hair grew ever since he can remember. It cannot be ascer-

¹⁵ Including puerperal fever.

¹⁶ In my cases the duration was from a few minutes to six hours. Andral, *Med. Clin.*, Vol. ii, p. 140, mentions a case in which shivering continued for more than five hours. See also Schuyler, *N. Y. Med. Jour.*, Oct. 13, 1883, p. 406.

¹⁷ This point seems to have escaped the notice of writers.

It has been supposed that chills occurring after the disease has been established were indicative of the involvement of fresh pulmonary territory, but my cases afford no evidence in favor of this view.

⁴⁷ Several such cases are in my collection.

tained at what time he learned to walk, but he is positive that he could go to school without assistance at the age of six years. He could not, however, walk as well and as long as other boys of his age, the legs, especially the left one tiring rapidly. Later on the lower extremities, particularly below the knee, remained unproportionately thin, and the toes stood in abnormal position, all of these symptoms being more pronounced on the left side. There was no spontaneous pain. Sensation had always been impaired somewhat in left leg and foot. It can not be ascertained with any degree of certainty whether vaso-motor or secretory disturbances existed.

The discharge of urine had always been impaired, and there had been chronic constipation; both excretions invariably pass off together, so that the patient is compelled to sit on the water-closet whenever he wishes to pass his urine. The sexual impulse was but very slight. He had never attempted cohabitation. Up to about a year ago he had occasionally ejaculations of semen accompanied by slight erections of very short duration, especially when he was compelled to move rapidly or to do fatiguing, heavy work. These erections were also very frequent while the patient was being shaved, came on regularly whenever the barber went over his face twice (gave him a "close shave") and also came now and then when he had his hair cut. There was never more than one ejaculation during one shaving or hair-cutting.

During his boyhood he suffered a good deal from headaches, which were accompanied by exhaustion and a sensation "similar to fever." During one of these attacks he, in his words, lost consciousness "and ran about the room, shrieking." There never had been any epileptic fits. He made but slow progress in school, learned with great difficulty. Strong odors immediately gave rise to headaches.

It happened now and then that somebody struck the prominence on his back. Immediately his lower extremities would fly from under him, he would fall on his buttocks, the legs taking the tailor position, and being utterly powerless. At the same time he had the sensation of something piercing his head, he would shriek and become unconscious for a few moments. His falling was connected with a sudden very intense pain in the legs and the head. For some time he could not succeed in arising, the entire body trembled, and he yelled loudly. For two days thereafter he would feel as though he had been whipped; as soon as anybody approached him he would begin to tremble in the apprehension that something might happen to his back.

There were never any signs of an affection of the cerebral nerves or of those of the upper extremities. The power of speaking was quite normal. No polyuria, but he had to urinate more frequently than other people, especially after having received a blow in the small of the back.

There had been no stiffness of the legs up to December 27, 1889, on which day he was taken with influenza, and on the following morning he noticed that his legs had become stiff and showed spasmodic contractions. No pain, no disturbance of sensation. After this attack of influenza the spastic symptoms increased in intensity, and since a year there is also tremor of the right, rarely also of the left arm after work. There has not been an erection or ejaculation for one year. When he was sewing the fingers of the right hand would occasionally spread asunder. This

exacerbation had been progressive up to the date of admittance to the hospital.

During the last year electricity and warm baths had been used, under which treatment his troubles grew worse. In the month of May, 1891, he suffered from an unknown disease, accompanied by fever.

State on admission.—Well built man of medium size. Muscles well developed. The intelligence of the patient is rather below the average; he is very talkative. The skull is very narrow in its anterior portion, very broad in the parietal region. The greatest circumference measures 57.3 cm., somewhat more than the average.

The cerebral nerves, the upper extremities and the thoracic and abdominal viscera are normal.

In the region of the sacrum in the median line there is a tumor approximately of the size and form of half an orange lying immediately below the skin and fluctuating. This part is very sensitive to pressure. The posterior osseous wall of the spinal canal is absent in the entire length of the sacrum. The tumor is covered with a dense growth of long black hair, its centre being occupied by a horizontal retraction of the skin. Below the prominence, corresponding to the point of the os coccyx the skin is adherent to the bone and retracted in the form of a funnel. Directly above the tumor, *i. e.*, in the lower part of the lumbar region, the spine is somewhat sensitive to pressure.

There is no marked atrophy of the lower extremities, the left being but slightly thinner than the right. There are fibrillary contractions in the muscles of both legs, more pronounced on the left than on the right side. The patient is able to move the limbs in all joints. The left knee is slightly flexed, cannot be extended completely, either voluntarily or passively. The *M. ileo-psoas*, the *quadriceps cruris* and *peroneal* muscles are parietic on the left side. There are marked tonic muscular spasms in the left, slighter ones in the right limb, especially in the flexors of the knee and the adductors. There is no disturbance of coördination, no intention-tremor. Both mechanical and electrical irritability of the muscles are unchanged, only that mechanical stimuli produce marked fibrillary vibrations. *Pes equinovarus*, more pronounced on the left than on the right side.

Sensibility.—There is a diminution of sensibility to touch in the right thigh, and in the left leg below the knee; of the sensibility to pain in the entire right lower extremity; of the sensibility to temperature in the left leg below the knee. The patient locates the sensations correctly.

Reflexes.—The abdominal and cremaster reflexes are normal on both sides, the right plantar reflex is not so marked as that of the left. No reflex from the *tendo achillis*. There is a reflex upon tapping the tendon of the *M. tibialis posticus*, also stronger on the left side. Adductor reflexes rather excessive on both sides.

The lower extremities perspire less than the rest of the body. They are covered with short black hair.

The urine contains neither albumen nor sugar. The temperature is normal; the pulse is strong, its rate varies from 80 to 112.

Treatment.—Galvanic current applied to the spinal cord and the lower extremities. *Kalium iodatum* 0.75–1.5 gr. pro die. After three days the patient is able to ascend steps without assistance, which he had

been unable to do. Later on he did not stand kalium iodat. well, and the medicine was changed to pills of argent. nitric.

On the 17th of September, 1891, Eller was discharged from the hospital. There were then no clonic contractions of the muscles nor pain. The patient was able to walk with greater ease, to ascend steps without difficulty. His weight had been increased by 6.5 pounds.

Remarks.—As to the diagnosis there can be no doubt that the patient suffers from spina bifida. The tumor of the sacral region covered by long hairs, fluctuating and evidently in connection with the central nervous system, the pes equino-varus, the disturbance of sensibility and of the functions of the sphincters are conclusive proofs. The trouble grew worse after an attack of influenza. Experience has taught that la grippe is both very liable to produce nervous disease of all kind and to aggravate existing ones. The curious disturbances of the sexual functions, especially their irritability to abnormal stimuli have to my knowledge, not been previously observed in cases of this kind.

A STUDY OF THE REQUIREMENTS OF THE AVERAGE PROSPECTIVE MEDICAL STUDENT IN 1892.

BY BAYARD HOLMES, M.D.

SECRETARY OF THE COLLEGE OF PHYSICIANS AND SURGEONS OF CHICAGO.

It has been often questioned whether the average medical student is better educated to-day than ten years ago or not. Not knowing the species then, I cannot answer.

I happen to have in my possession evidence of the scholarship of the average man who proposes to study medicine to-day. This evidence has come in the course of my regular correspondence during the past year. For the purpose of this paper I have selected one thousand consecutive correspondents and tabulated their educational qualifications. These are a continuous series and they include every correspondent, who gave me the necessary information, going back far enough to secure a necessary decimal, one thousand. None of them go further than one year back.

1. Number of prospective medical students having A.B., B.S., or other corresponding or succeeding degrees	185
2. Graduates of High Schools which are accredited to State Universities	211
3. Graduates of State Normal Schools or City Normal	80
4. Graduates of Dental or Pharmaceutical Schools	69
5. Holders of certificates of completion of pre-Medical course in universities	25
6. Other adequate education but without diploma	252
7. Total number who present evidence of sufficient education for admission to the College of Physicians and Surgeons, or of any college requiring only the minimum of the Association of American Medical Colleges	822
8. Number who do not present evidence of such education though filling out the blanks in other particulars	198
Total consecutive correspondents considered	1000

Many of the best educated men are to be found in class 6. These men cannot present any diploma, but are in many instances better educated than the graduates of scientific or high schools. We would conclude then that less than twenty per cent. (18.5) of

prospective medical students are graduates of colleges with the bachelor's degree, that a little more than twenty per cent. (21.1) are graduates of accredited high schools, that two and a half per cent. only are graduates of pre-medical courses in universities, and twenty-five per cent. are able to pass an examination in English, mathematics, physics and Latin, as presented by the rules of the Association of American Medical Colleges. Thus it appears that only twenty per cent. of prospective medical students are shut out by the requirements of the Association. These statistics may encourage some timid schools to insist on this requirement of the Association.

It may be asked, are these statistics fair and reliable? So far as the students are concerned they are probably sufficiently reliable for our purpose. It may be reasonably premised that students who have the required education more readily fill out the blanks than those who cannot answer the questions in the affirmative. The blank was as follows:

Name. Age. Nativity.
 Education.
 Have you a degree? What?
 Where obtained? Time required
 Have you graduated at a high school?
 If so, what did your course cover in Mathematics, Physics and Latin?
 Have you studied in a medical college? What one? When?

 Address. P. O.
 County. State

Another source of error is to be found in the fact the correspondence was usually begun through physicians and educators and the names of those only were asked for who had "a good preliminary education." These statistics are derived largely from the six States surrounding Chicago.

With these facts before us it may be seriously asked if it is advisable to make the degree A.B. or B.S. a requirement for admission to the medical school. It is certain that all our schools could not make such a requirement. It would probably pay one or two favorably located schools to re-organize their methods and conclusions so as to give a course adapted to the educated student. Such schools would have a hard struggle for a few years, and would need a temporary or permanent endowment, but in time they would secure their own. Their course would be shorter. It would be conducted on different plans and by a different sort of men, but the success would be enviable.

At the college that I represent one hundred and twelve students asked for entrance certificates in October 1892; of these, one hundred and one presented evidence of scholarship from colleges or accredited high schools, eleven wrote the examination. One failed and was refused. Seven were unable to write the examination in Latin satisfactorily, and were conditioned in that study. Three wrote the whole examination satisfactorily.

THE laws of Michigan forbid any railroad within its borders to employ other than total abstainers from alcoholics as engineers, train-dispatchers, firemen, brakemen, or other railroad servants. The penalty is said to be \$500 for each offence. Yet many of the passenger boats in said State have open bars on board for the patronage of all.—American Lancet.

THE
Journal of the American Medical Association
PUBLISHED WEEKLY.

SUBSCRIPTION PRICE, INCLUDING POSTAGE:
PER ANNUM, IN ADVANCE \$5.00
SINGLE COPIES 10 CENTS.

Subscriptions may begin at any time and be sent to

THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION,
No. 68 WABASH AVE., CHICAGO, ILLINOIS.

All members of the Association should send their Annual Dues to the
Treasurer, RICHARD J. DUNGLISON, M.D., Lock Box 1271, Philadelphia, Pa.

MEMBERSHIP IN THE AMERICAN MEDICAL ASSOCIATION.

This is obtainable, at any time, by a member of any State or local Medical Society which is entitled to send delegates to the Association. All that is necessary is for the applicant to write to the Treasurer of the Association, Dr. Richard J. Dunglison, Lock Box 1271, Philadelphia, Pa., sending him a certificate or statement that he is in good standing in his own Society, signed by the President and Secretary of said Society, with five dollars for annual dues and subscription for THE JOURNAL. Attendance as a delegate at an annual meeting of the Association is not necessary to obtain membership. On receipt of the above amount the weekly JOURNAL of the Association will be forwarded regularly.

SATURDAY, JANUARY 7, 1893.

THE ORGANISMS OF MALARIA.

LAVERAN'S discovery in 1880 of organisms in the blood of malarial patients has been verified and elaborated by pathologists and clinicians the world over. In Italy the study of LAVERAN'S organisms has been pursued with great enthusiasm and persistence, and we owe much of our knowledge of their nature, and of their relation to the various forms of malaria, to the labors of such men as GOLGI, MARCHIAFAVA, CELLI, FILETTI and GRASSI. The researches of the last two upon the structure of the organisms leave no doubt as to their animal nature, demonstrating conclusively the presence of vesicular nuclei, and it is now universally accepted that they belong to the protozoa, and their faculty of amœboid movement brings them under the rhizopoda. In the United States COUNCILMAN in Baltimore, OSLER in Philadelphia and in Baltimore, WALTER JAMES in New York, DICK in Galveston and Ann Abor, as well as many others, have been able to fully corroborate the results obtained by the European investigators. In India VANDYKE CARTER, Professor in the Grant Medical School of Bombay, has studied the organisms elaborately and found their demonstration to be of great value in the differentiation of malarial from other forms of fever. At the present time all modern clinicians make routine blood examinations in all doubtful fevers, and the diagnostic importance of the malarial parasites has been repeatedly emphasized by the report of cases from the clinics of America, Germany, the Scandinavian countries and elsewhere, many of them in regions where malaria is practically unknown, only imported cases occurring. The amœbæ have not yet been successfully cultivated artificially, but their etiological relation to malaria is considered quite evident because of their constant presence in its various clinical forms; because of the relation which GOLGI and other Ital-

ians have shown to exist between the phases of the development of the organism and the malarial paroxysm; because the morbid anatomy of malaria corresponds entirely to what would be expected from the distinctive effects of the parasites upon the red cells, namely: corpuscular disintegration and pigment accumulation, and their results such as capillary obstruction with organisms and detritus in all the important organs of the body in acutely fatal cases, and pigmentation, connective tissue increase and anæmia in chronic cases; and also because quinine, in arresting the clinical manifestations of malaria, appears to have a specific effect upon the amœbæ, which completely disappear from the blood.

There is considerable difference of opinion among the investigators as to the relation to each other of the varieties of amœbæ observed in malaria. It will be recalled that GOLGI and others have shown that the regular intermittents depend upon amœbæ with quite distinct morphological differences, all of which, however, are endoglobular and grow and become pigmented during the intermission, so that at the time of the paroxysm they nearly or quite fill the decolorized red cell, the pigment being in the centre of the amœba; as the paroxysm occurs the amœba undergoes segmentation into from six to twenty spores. The apyretic stage corresponds to the vegetative, the paroxysm to the proliferative phase in the evolution of the amœba. If the vegetative phase occupy twenty-four hours then fever will assume a quotidian, if forty-eight hours a tertian, if seventy-two hours a quartan type. In the remittent and pernicious forms a small amœba is described, and in malarial cachexia intercellular and free variously shaped organisms are found. In all types of malaria are found atypical organisms, ciliated and crescent-shaped, whose relation to the essential amœba present is not yet understood. Now LAVERAN maintains that the various clinical forms of malaria depend on the same single polymorphous amœba, the various types of fever being the expression of the individual reaction of the person into whose blood the amœba gains entrance. This simple and fascinating theory is opposed by GOLGI, who maintains that the various malarial fevers depend on three varieties of amœbæ, and FILETTI and GRASSI describe five distinct malarial blood parasites. This question is yet unsettled, and so are many others in regard to the etiology of malaria: we do not know anything in regard to the amœbæ outside the body, nor how they enter the body or leave it, but we do know positively that in malaria there are found typical organisms in the blood by means of which we are able to distinguish between this and other fevers. In the tropical and subtropical regions this fact should be utilized and attempts should be made to more definitely define the large number of fevers there occur-

ring by studying them thoroughly in the light of LAVERAN'S discovery. In the United States it is now possible to demonstrate precisely whether such a thing as typho-malarial fever exists or not; routine blood examinations during life and careful anatomical studies after death would soon settle the question permanently. The demonstration of the amœbæ of malaria is not laborious and they should be looked for by the general practitioner everywhere in all obscure cases of fever, so often imperfectly diagnosed, with the assurance that in a fair number of instances positive results will be obtained.

THE PRESENT STATUS OF MEDICAL EDUCATION IN THE UNITED STATES.

Indications point to a pronouncedly higher standard of requirements upon the part of the medical colleges of this country. The year just closed has witnessed a change of the curriculum of fully 25 per cent. of the entire number of colleges. This change has consisted in extending the course of instruction from two to three courses of lectures before conferring the degree of M.D. The number of colleges that will graduate students at the end of their second course of lectures the coming spring are less than ten per cent. of the whole number of schools in the country. With the exception of two schools they are confined to a limited section of the country. Even these schools will in the near future extend their course by an additional year. The experience of these schools raising their standard by requiring four courses of lectures before graduation has been all that their faculties or friends would anticipate. Instead of a falling off in the number of students there is an actual increase in attendance. The University of Michigan, Harvard, University of Pennsylvania, and Chicago Medical Colleges have lost nothing by their change of policy.

Their course has met the approval and admiration of every friend of scientific medicine in the country. Their new curriculum enables them to afford a thorough scientific and practical course of medical instruction upon a par with the very best schools of Europe. The product of their labors will bear fruit in better material. The experience of all colleges that have extended their course of instruction the last few years, has been an increased income from fees of students. Instead of the schools, requiring four courses of lectures before graduation, losing in numbers they will rapidly gain. This situation is due to various causes. The result of the public school system of this republic has been to make the masses of the people at least friends of a thorough education: as a result of the agitation of the subject of higher medical education the attention of the public has been repeatedly directed to our shortcomings and there has resulted in consequence thereof most

efficient medical legislation. The result of this legislation has been most beneficial both to the public and the profession. As the result of several thousand examinations the last few years, they have revealed the character of work being done by the low grade colleges. Fully 25 per cent. of their students have failed to receive a license while the students hailing from the higher grade colleges have very rarely failed. About .985 per cent. of their number being licensed.

There are at the present time fifteen States with practice acts that require an examination of all persons desiring to practice medicine in the respective commonwealths. These States include nearly 50 per cent. of the entire population. From present indications all the States will be equipped against the products of the "Commercial Medical College" in the near future. The result of these changes is quite obvious. The intelligent young man realizes that he can only obtain a scientific medical education in those schools having the facilities to teach and that have a thorough curriculum. In consequence of these changed conditions the high grade school of the future will reap the harvest at the expense of their weaker competitors. The increase of requirements will lessen the number of men entering the profession but not to that extent desirable. The total income of the colleges however, will be increased by extending the requirements to four years. We anticipate many changes for the better the present year. The attention of the profession is being centered on a few of our great metropolitan schools the last few months. The result of their deliberations is awaited with interest. Concert of action upon the part of less than a half dozen of the stronger schools would result in the adoption of the four year requirement by every school in the country in a remarkably brief period of time. In the consideration of this important and vexed problem, to both the public and colleges, it may as well be recognized first as last, that the character of your labors will be revealed in the future, by your students in the examinations before the various State boards. If these examinations reveal a failure of a large percentage of your students before various State boards, your halls will be deserted. This has been the experience of schools in Europe and it will be the experience here. Believing it in your power we appeal to the colleges of the country to solve this burning question in a business-like, intelligent and conscientious manner.

SURGEON GENERAL ILLINOIS STATE NATIONAL GUARD.
—Gov. Altgeld has selected for Surgeon-General of the Illinois National Guards, Dr. N. Senn of this city. This appointment will give general satisfaction to the physicians of the State who are interested in the elevation of the Medical Service of the

National Guards to a high standard of excellence. Doctor Senn has had a large practical experience in this line of work. He is the founder of the National Association of Military Surgeons of the National Guards of the United States and President of that Association since its organization. The Association is composed of the medical officers of the regular Army and the National Guards, and has the official recognition of the General Government. The third annual meeting will be held in this city during the month of August in connection with the Worlds Fair.

DOMESTIC CORRESPONDENCE.

To the Editor of the JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION:

The following letter has been received from an esteemed correspondent, and as it refers to an item that appeared in the JOURNAL of December 24th, 1892, I copy it for the benefit of any others among your readers who may have been disturbed by the statements quoted.

—INDIANA DEC., 28, 1892.

DR. G. BETTON MASSEY.—*Dear Sir:*—I hope you will not think me presumptuous in asking you how long you have been insane? I refer you to the JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION. Vol. XIX, No. 26, quoted from the *National Medical Review*. Is Price insane? Or is he suffering from—
Yours very respectfully,
—M.D.

I have thanked the Doctor for his kindly solicitude, and have assured him that I am at least sane enough not to venture to answer the last question in his letter. Since, however, the item quoted from Dr. Price appeared in the JOURNAL of Dec. 24th, page 756, under the head of "Selections" rather than "Medical Humor," it may be well to point out the absurd nature of the reasons alleged in it by Dr. Price as a basis for his opinion that "it is utterly incomprehensible how any sane man can advocate the use of electricity" in pelvic troubles. He asks "Why not apply this all-powerful, this infallible and omnipotent curative effect of electricity to the resolution of abscesses found in the neck of strumous children?" and rightly says that mothers would pay well for such relief for their little ones. I beg to reply that there is no analogy between an abscess such as referred to and a purulent collection within a natural cavity. No one ever claimed to cure such abscesses by electricity, though many of us have had cases of veritable pus tubes get well under it by natural drainage through the uterus after the inflammatory occlusion had been removed by absorption. I am personally aware of three children who have been born after the electrical resolution of pyosalpinx, and in two of these cases several competent surgeons diagnosed double pyosalpinx.

The allusion to "strumous" glands of the neck reminds me though, that they are not so refractory to electricity as Dr. Price supposes, provided treatment is instituted before suppuration. Some recent cases yet unreported have proven to me that they may be reduced in size to a very material extent by being brought at intervals under the influence of the negative pole (with a clay electrode) of powerful galvanic currents.

The immediate effect is to cause so great a determination of blood to the enlarged gland as to temporarily increase its bulk, at the subsidence of which the tumor will generally be found smaller. Since it is now known that these so-called "strumous" glands are in reality tuberculous, a

permanent reduction in their size, which has resulted in some of my cases, may well be accepted as a favorable result. Whether the bacilli are affected themselves or merely their products, is uncertain, but the probabilities are that decrease in size is due to the absorption of the products and irritative consequences of microbic action in this case, as well as in the hyperplastic pelvic disorders now so largely treated by the interpolar action of electric energy. If it were possible for me to disbelieve in germs like Dr. Price I would have greater faith in the resolving power of galvanic currents in these "strumous" glands, for a daily experience begets increasing confidence in our ability to use currents that will stimulate tissue changes to an extent fully equal to clearing up mere glandular infarctions; and even a lymphatic gland should be restored to function if possible, rather than removed from the body.

This excursion of Dr. Price's outside the pelvis is to be commended, for no one can deny that the present views of abdominal surgeons need a healthy comparison with the work being done in less abused portions of the body.

G. BETTON MASSEY.

Wanted.—A Word.

The medical profession in general, and the surgical instrument dealers in particular, are much in need of a word that will properly describe a surgical instrument that has been so constructed that it may be rendered aseptic. Such instruments are usually called aseptic, but as they are septic until rendered *aseptic* by antiseptic methods, it follows that the name as now applied is a misnomer, because an instrument can hardly be both septic and aseptic at the same time. Will some one kindly supply this "long felt want?"

BOOK REVIEWS.

HYGIENE AND PUBLIC HEALTH. By LOUIS C. PARKES, M.D., D.P.H., London University, etc. Third edition, with seventy-eight illustrations. Philadelphia: Blakiston, Son & Co. 1892. \$2.75.

This is a work of 523 pages replete with invaluable information. In a small space it covers nearly the whole field of sanitary science. While it is intended primarily for students and medical men, every intelligent householder could profitably make the acquaintance of most of its contents. If the general public would do itself the favor to become conversant with the chapters on house drainage, water, heating, lighting, ventilation, smoke prevention, food, beverages, clothing, etc., it could reap benefits that would repay for the time and money invested a thousand fold.

In the prefaces to the first and third editions Dr. Parkes professes to have reworked the most recent advances of bacteriological and etiological investigation, but this edition bears internal evidence that not all the parts that bear directly on these subjects have been rewritten, for the nature of these rapidly developing sciences quickly reveals such neglect. There are discrepancies in the different sections that have to do with bacteriological data that can be accounted for on that hypothesis only, for in some places the reader is conscious of perusing a back number, while in others the facts are brought down to date. On page 68 he says: "Whether the choleraic diarrhoea is due to the presence of a living germ in the water, or to dead and decayed organic matter in solution or suspension, is not yet certain." On page 413 he insists that bacteriological

investigation "does not prove that the microbe is an indispensable antecedent (cause), or even an antecedent of the disease, or indeed that it is anything more than a consequence." He makes no effort to reconcile his position with the fact that a community may drink water from the same source year after year without the incidence of cholera or enteric fever until the characteristic bacilli infect the supply. On page 91 he concludes "that the biological test (of water) is valuable only for the confirmation it gives of the results of chemical analysis, and not because it is capable of throwing any further light on its dangerous or harmless qualities." Page 72: "Cholera epidemics appear to have been rendered practically harmless (in England) by ensuring an abundant supply of pure water." Page 443: "The comma bacillus may be regarded as pathognomonic of the disease (Asiatic cholera); and its presence when detected in the stools may be considered as sufficient to establish the diagnosis, etc." He emphasizes the danger of disseminating such diseases as cholera, typhoid fever and diphtheria through drainage channels and the necessity of preventing the entrance into sewers of the excreta from persons suffering with these maladies.

On the question of quarantine the author agrees with the position taken by Dr. Elmer Lee and denounces it as neither useful nor practicable. It cannot be denied that the experience of England during last summer's epidemic of cholera supports his view, and his recommendations are certainly humane. In this connection it is interesting to observe that the Illinois State Board of Health adopted resolutions at its last meeting precisely in line with Dr. Parkes' teachings at the University College.

Arsenical poisoning from inhaling particles of arsenic and the vapor of arseniuretted hydrogen from wall paper is explained.

The smoke nuisance in London, he concludes, cannot be abated except by the substitution of cheap coal gas for coal for domestic consumption. A lucid explanation of the manner and prevention of deaths from the use of odorless fuel gas is given, and it ought to prove highly interesting to the residents of Hyde Park, the home of the English aristocracy of Chicago.

Epidemic influenza is accorded the important consideration that its crippling and fatal effects demand. The death-rate in England was raised by nearly two per 1,000 by this disease, and the epidemic of 1892 was much more severe than it was in 1890 or 1891.

The book is a credit to the publishers and is deserving of popularity with the profession and the people.

SELECTIONS.

HYDROCHLORIC ACID IN THE STOMACH.—According to Ewald (*Berlin Klin. Woch.*) a deficiency of hydrochloric acid in the stomach has, in recent years, been considered as indicating disturbed function and is not diagnostic of any definite organic lesion. During the first stage of digestion the acid present in the stomach is used up in neutralizing the different bases contained in the food. Later, the free hydrochloric acid increases in amount until it reaches from one and a half to two and a half parts in the thousand of gastric contents. The absence of free hydrochloric acid does not necessarily mean that the secreting power of the stomach is entirely lost. A certain amount of digestion can take place by the help of unstable compounds of the acid which are present in partially digested food. In three conditions free hydrochloric acid is absent: gastric carcinoma; chronic catarrh leading to atrophy of the mucous membrane; and

severe nervous depression. Atrophy of the gastric mucous membrane is most common in old persons who have suffered from dyspepsia. The contents of the stomach contain no free hydrochloric acid, no pepsin, and no rennet ferment. Cancer may exist for a long time without being suspected, the symptoms pointing to a severe neurosis. To improve the muscular tone of the stomach, strychnine, belladonna, and physostigmine may be used. Good results may be obtained from exercise and massage, and from internal faradization. To prevent fermentative changes, the contents of the digestive tract should be made as far as possible unsuitable for the growth of micro-organisms. Resorein, naphthalin, salicylate of bismuth and benzo-naphthol are recommended. The author especially recommends the latter in doses of from two to five grains a day. It is tasteless and non-irritant, and remains unacted upon in the stomach, but is split up in the intestine into naphthol and benzoic acid.—*Boston Medical and Surgical Journal*.

THE EXAMINATIONS FOR THE MEDICAL DEPARTMENT OF THE UNITED STATES ARMY.—The examination of candidates for commissions in the medical department of the army, recently held at the army headquarters in New York, was not, says a writer in *The Tribune*, prolific in its results. Only four of the twenty-two who appeared before the Medical Board succeeded in filling the rigid requirements, professional and physical, for appointment as assistant surgeons. The officials of the Medical Department are gratified for the few successful candidates, considering their high qualifications, but they are also disappointed at the small percentage of the successful ones. On the other hand the applicants who failed in the examinations, and also their friends, feel their disappointment more keenly and complain bitterly about the severity of the examinations. The Surgeon-General's Department, however, prefers to go short-handed rather than reduce the standard of the examination, and soon another examination will be ordered to fill the six vacancies still remaining.—*Medical Record*.

BRIDGEPORT, CONN., prohibits the practice of irregular physicians within its limits. As Connecticut has no law regulating the practice of medicine, this municipal ordinance may stimulate it to the recognition of its duty.

MISCELLANY.

MIDDLETON GOLDSMITH LECTURE.—Dr. William P. Northrup has been invited by the trustees to deliver the above lecture before the New York Pathological Society in April next; subject to be later announced.

OFFICIAL LIST OF CHANGES in the Stations and Duties of Officers Serving in the Medical Department, U. S. Army, from December 24, 1892, to December 30, 1892.

Capt. Louis W. Crampton, Asst. Surgeon U. S. A., leave of absence granted is extended three months.

Capt. Marcus E. Taylor, Asst. Surgeon U. S. A., is granted two months ordinary leave of absence, to take effect upon the expiration of his present sick leave. By direction of the Secretary of War.

First Lieut. Frank T. Meriwether, Asst. Surgeon U. S. A., leave of absence for seven days granted is hereby extended ten days.

First Lieut. Benjamin L. Ten Eyck, Asst. Surgeon U. S. A., is relieved from duty at Ft. Leavenworth, Kan., and will proceed at once to San Antonio, Tex., and report to the commanding General, Dept. of Texas, for duty with the troops now in the field.

First Lieut. James D. Glennan, Asst. Surgeon U. S. A., will upon his arrival at his station (Ft. Sill, Oklahoma Ter.) from leave of absence, proceed immediately to San Antonio, Tex., and report in person to the commanding General, Dept. of Texas, for temporary duty in the field with troops operating on the Mexican border.

ORIGINAL ARTICLES.

A BIRD'S EYE VIEW OF NEW MEXICO.

Read in the Section of State Medicine at the Forty-third Annual Meeting of the American Medical Association, held at Detroit, Mich., June, 1892.

BY FRANCIS H. ATKINS, MD.,

OF LAS VEGAS, N. M.

MEMBER NEW MEXICO MEDICAL SOCIETY, AMERICAN CLIMATOLOGICAL ASSOCIATION AND AMERICAN MEDICAL ASSOCIATION.

My doubt lest any audience I might have in Detroit might know more of New Mexico than I myself after a dozen years' residence within its borders was measurably lulled last evening when a member exclaimed on learning my home, "Oh! that is just above Peru."

I am sure the gentleman did not pertain to the Section on State Medicine, but the incident emboldens me in displaying this bird's-eye view of the territory I represent, the land of the undying sun, the purple grape and the plaintive burro.

There being no apparent provision for climatology in the several sections, by the courtesy of the officers of the Section on State Medicine, I am permitted to read here a few notes upon the characteristics of New Mexico and their climatic bearing upon the great problems of the prevention of disease.

Since the Hon. Jacob H. Gallinger of New Hampshire, less than two months ago, introduced a joint resolution in the Senate of the United States providing for a commission to select a suitable site for the establishment of a great national sanatorium in one of the territories for the treatment of pulmonary diseases, and especially as the bulk of his corroborating testimony relates to New Mexico, I feel that a paper bearing on that territory, its merits and demerits, may fairly be ranged under the title of State Medicine.

New Mexico, oldest named of American regions marked by the infrequency of phthisis, has, by reason of its inaccessibility and of its slow social development, been greatly neglected as a field of resort for phthisical and other invalids. Whatever claim Colorado has to your patronage, New Mexico has in equal force, with the added advantage of a lower latitude and hence warmer winters. This has not been justly appreciated, and the superior social features of the Centennial State have given it a position in eastern thought above our Sunshine State not justly merited when the question is one of saving the life of the tuberculous and not of furnishing them luxuries.

So vast is New Mexico that England, Scotland, Wales and Ireland could be placed within its borders, I am told by our nimble arithmetician, while in altitude it varies from 3,800 feet, on the plains of its south and east borders, to lofty mountain ranges over 12,000 feet high. Necessarily, here is variety

to suit a multitude of varying cases. So much misconception exists concerning this wide combination of mountain and plateau that I hasten to briefly mention the leading features of its climate.

The mean annual temperature of Santa Fé at 7,000 feet altitude is 48° and that of Las Vegas at 6,450 feet 51°—the latter corresponding with Peoria and Indianapolis.

That of the plains is considerably higher, being 55° to 60° toward the south.

As to moisture—the dryness of New Mexico is notorious. The annual precipitation in 30 odd years at Fort Union not far from Las Vegas—in the northern part—averaged 18 inches, but at Santa Fé only 15 and at El Paso, just below our southern border, but 12 inches. When it is remembered that one half of this falls in midsummer and but six to eight per cent in winter—and this wholly as snow—it will be seen that invalids here escape the dreaded combination of wet and cold.¹

The figures for percentage of moisture are low, the annual mean for many years at Santa Fé being but 45, the monthly mean not passing above 54 in winter and often falling to 30 (and even 20 at Las Vegas) in spring and early summer.

Our governor when asked to give New Mexico a name of sentiment dubbed it the Sunshine State. The sky seems infinitely high above our heads there as contrasted with that of Detroit or New York, and we bask in the sun's rays to a degree hardly known elsewhere. A Signal Bureau analysis placed El Paso, Tex., and Fort Stanton, New Mexico, in a short preferred list for least average cloudiness, with but 29 and 25 days respectively per annum reported cloudy. In one recent year I noticed Santa Fé accredited with 27 cloudy days, while Detroit had 123 and Chicago 116, while the proportion of days rated clear in New Mexico to days called fair is immensely greater than in the lake cities.

New Mexico is often spoken of as a windy state and visitors carp at us because we do not report our winds. Let me say that the much visited Colorado quite equals us in the annual mileage of wind. Government observers at Santa Fé and Fort Stanton report an annual movement of about 60,000 miles. That of Colorado Springs has been observed as high as 90,000 miles in a year, and especially do this highly favored resort and Denver report winds exceeding in maximum velocity those in New Mexico, a signal advantage to the latter region.

In average velocity Santa Fé wind ranks with the soothing Jacksonville, Fla., as well as in total mileage, while as a matter of fact the whole east slope of the Rocky Mountains is wind swept to about a similar extent—as to annual mileage—the wind movement of New Mexico is actually less than that

¹ The average total precipitation in three winter months at Fort Union for 10 years was 1.69 inches of water, all as snow.

of Detroit and St Paul by one sixth, less than that of Boston and New York by one fourth. It is the dust incident to the dryness (as in the other southwestern states) that has given New Mexico a bad name by accentuating its winds. But this is chiefly annoying in the streets of our towns and here is being combatted by sprinkling as is done in the towns of California and Colorado.

A mean annual temperature of 48 to 51 degrees should sufficiently assure eastern physicians and their patients that the winters in the higher altitudes, as at Santa Fé and Las Vegas, cannot pass without occasional zero temperatures, on one or two days only in some winters, in others for two or three weeks, in January the air being as still, clear and crisp as that of Minnesota (but dryer), and the public health rising to a maximum. I dwell on these facts because still invalids stream into New Mexico expecting, by the delusive suggestions of its last name, to find a tropical climate with the fruits and flowers of the same. Even in the southern sections, at lowest altitudes, it is far from tropical.

We offer simply a very dry air, a vast amount of sunshine, a breeze that never is warped into cyclonic effects, altitudes from 3,000 to 7,000 feet with towns providing constantly improving shelter and comforts for invalid visitors, or even 9,000 feet, with occasional dwellings, for more tolerant cases. Necessarily the air is pure, for except to a small extent in the Rio Grande valley, there is no malaria, and water is too scarce to waste it in making swamps.

Visiting doctors wonder how the New Mexican doctors live, so meagre is the practice afforded, so healthful the climate. The Las Vegas doctor often has long spells of enforced idleness when he cultivates philanthropy and the softer virtues. During the past year many months saw our physicians but lightly employed, while our well equipped druggists were subsisting by selling perfumery and cigars. We have no regular seasonal diseases, as abdominal diseases in summer, malarial in autumn or pulmonary in winter—the light pharyngitis and bronchitis of the country is naturally more prevalent in December and January. Pleurisy is extremely rare; croupous pneumonia not at all common, catarrhal pneumonia but little more so. Acute articular rheumatism is uncommon. The renal degenerations are practically unknown. In nineteen years on the plains and mountain borders, I have not seen one genuine case of Bright's disease, and but a single case where an acute nephritis perhaps of zymotic origin—lingered and was fatal. If kidney degenerations can be foreseen or if they tend to prevail in certain families, certainly New Mexico is the place for resort and residence in such instances.

Indeed, the only really prevalent disorder is the lithæmia or concealed gouty diathesis, of which there is a curious abundance—at least in higher altitudes—but proper hygiene prevents or cures this.

The three inroads of influenza, though visiting us, made no deeper impression than our simplest winter visitation of sore throat. In the first no consumptives in Las Vegas were touched by it; in the second a few visiting invalids felt its force but recovered without apparent detriment. In fact no American death in any way attributable to the influenza has occurred in my part of New Mexico.

The climate of New Mexico is especially adapted to the restoration of phthisical cases in the earlier

stages—for instance, Mrs. A. of Chicago, age 23 years, continuously coughing for six months, sputa examined by a well known specialist and contained bacilli, history of increasing weakness. Ten weeks after reaching Las Vegas, New Mexico, all cough had ceased, no pus was expectorated, and she could run up long flights of stairs rapidly. Mrs. B. came to same place 14 years ago for cough, hemorrhages and emaciation. Within three years all symptoms disappeared, she married, bore healthy children, and has lived with impunity the past three years in New England, a robust woman. These are sample cases, hardly scientifically reported, of which our territory can furnish many.

Cases with cavity, if not progressing too rapidly, on arrival will mend, but in the name of all honest Rocky Mountain doctors and tender hearted lodging house keepers let me beg that cases with advanced destruction of the lungs, high temperature and persistently rapid pulse be not sent to this country—or, at least, not to the higher localities.

On the other extreme there is no better climate in which persons who are merely weak, or who are lacking robust development, especially such as are of tuberculous stock, or in markedly delicate families, may secure safety from phthisis or develop more robust bodies. Such families escape in New Mexico the sickness and premature death so likely to seize them in the damper states.

Scrutiny of the annual reports of a vast benevolent order reveals a remarkably lower death rate and sick list for this territory than for a string of central and eastern states, while the time lost per member by sickness was singularly less than in those states—attesting the great salubrity of the climate.

The death rate of the resident American population, which I have studied a number of years, is low, ranging in Las Vegas from 12 to 6 per thousand per annum. As illuminating the unpleasant side of sending moribund consumptives to New Mexico, our gross death rate was increased from 22 to 56 per cent each year (in a series of years) by the deaths of these forlorn visitors. Moderate cardiac valvular disease need not bar a visitor, while occasionally extreme valvular obstruction may exist for years without detriment to health and comfort.

The visiting consumptives show a very minimum of the ordinary incidents of phthisis. Hamoptysis is rare; I have prescribed for night sweats but twice in seven years; cough and expectoration generally diminish.

As to advancement in medical legislation, New Mexico has a Medical Examining Board under an old and clumsy statute. Efforts of our medical society to secure its remodelling on the best in other states have been baffled by politicians in our own profession. Similar fate befell bills concerning expert testimony and privileged witnesses among medical men. Formerly small-pox corpses were carried through the streets on boards by daylight for public burial, and not a few such were laid by the native faithful under the floors of the Catholic churches. Modern legislation has abolished all this. An excellent school law, now one year in successful operation, has quite taken the fancy of the natives and bids fair to be the first entering wedge for sanitary ideas. A recent curious statute forbids graveyards to lie nearer than 50 feet to any river; the former limit was 25 feet!

There is no territorial board of health, but local health officers do efficient service in a few towns. Hospitals exist in several towns. Our medical society constantly agitates sanitary subjects. The fatalism of the Mexicans and their utter lack of appreciation of the sanctity of human life (when disease is in question) are the chief hindrances to sanitary reform. In a few weeks it will be my privilege to lecture before a summer normal school, chiefly of native teachers, on the prevention of disease. But from the start I shall be handicapped, for my prospective hearers do not dread or attempt to prevent the contagious diseases, and, when God wills it, all their little brothers may die and they will not complain.

Finally, we denizens of New Mexico marvel that eastern people do not make our higher altitudes a summer resort. All who have lived here unite in pronouncing the summers the nearest to ideally perfect that they have ever seen. The young people complain that the evenings are too cool to let them sit freely on the piazzas; the nights are always cool; the heat of the day—rarely touching 90°—is so tempered by the dryness as not to be oppressive; sun-strokes, like the cyclone, malaria, the flea, the mosquito, are unknown. High temperatures with high percentage of humidity are very rarely seen, and then but for an hour in the morning.

ARRESTS OF DEVELOPMENT AND DECALCIFICATION OF THE ENAMEL AND DENTINE.

Read in the Section of Oral and Dental Surgery, at the Forty-third Annual Meeting of the American Medical Association, held at Detroit, Mich., June, 1892.

BY EUGENE S. TALBOT, M.D.,
OF CHICAGO.

I wish to call your attention to a few observations which I have made in regard to a want of calcification and decalcification of the enamel and dentine. The conclusions arrived at are the result of the study of three cases which have presented themselves to me for treatment.

The first case is that of Miss C., 24 years of age. Her jaws have gradually come closer together, owing to a wearing away of the teeth. The front teeth have exceeded the back ones so that considerable space was noticed between her front teeth. The articulation was so poor that she was unable to chew her food and mastication was imperfectly performed with the vault of her mouth and tongue. Owing to the constant use of her tongue for purpose of mastication, hypertrophy had taken place to such an extent that her speech had become impaired. She was a constant sufferer from indigestion due to improper mastication, which was readily detected by the thick white coating on her tongue. Upon examination of her teeth, I found them of a dark yellowish color, containing grooves and pits, indicating arrest of development due to some of the eruptive fevers early in life. The bicusps were the only teeth that had any semblance of normal contour, although the second molars were fairly well developed. None however, were smooth like ordinary teeth. The roots of the second molars upon the right side of the jaw still remained, while the first molars had been extracted. The anterior teeth, both upper and lower, were worn away from one-third to one-half the length of their crowns. I judge that this was not due to friction by mechanical attrition for two reasons: first, the present teeth were very rough upon their cutting surfaces. If it had been due to attrition they would have been smooth; 2, the roots of the second molars were smooth and polished. They did not occlude with the upper molars. Hence, abrasion by attrition is wholly out of the question. In order to improve the appearance of the face and make the teeth

serviceable for mastication, it was necessary to crown all the teeth except the six lower anterior ones. Upon scratching and shaving the crowns and roots, the enamel and dentine could be shaved off like horn or old cheese. The inclination of the crowns and roots of the upper anterior teeth when the jaws were in their proper position was such that the anterior and labial surface had to be shaved and ground down to such an extent that the pulp chamber was ground nearly to the cervical margin, without exposing the pulp, thus showing that the pulps had receded entirely from the crowns. This was also the case with the molars; no canals could be found in the roots. A sister of the patient had also similar teeth; she died at the age of five, of membranous croup. Her mother said that she had tried to have her children eat oatmeal for the purpose of improving the tooth structure, thus showing that she was not unmindful of the bad condition of the children's teeth. The father's teeth were in a similar condition although not quite so bad. The grandfather and grandmother on her father's side were both of a nervous temperament. Tartar accumulated early upon the teeth of all. The teeth of these girls erupted at an earlier age than usual.

Case 2, is that of a girl, aged 11 years, who was sent to me by her physician for an opinion as to the cause of her trouble and also for the purpose of treating her mouth and teeth. I found her an exceedingly nervous child, she would cry upon the slightest provocation. Her bones were small in diameter and she was rather short for her age. Upon examining her mouth I found the teeth covered with tartar of a bright yellow color. The tartar formed a continuous band extending from the second molar of one side to the second molar of the opposite side—this was upon both jaws. To such an extent had this accumulation taken place that it was impossible to locate the individual teeth until the tartar was removed. This was very difficult to accomplish because the slightest grating of the instrument upon the teeth would produce such a sensation upon her nervous system that she would nearly go into spasms. I could operate only about five minutes at a time. Upon the removal of the tartar, I found that the crowns, including the enamel and dentine were as soft and cut like horn. The tartar accumulates upon her teeth to such an extent that in two week's time, they will be completely covered. The child has occasionally nervous spells at which times all her teeth will ache. She suffered the most excruciating pain for about ten minutes after the impressions were taken for the models which are here presented. No cavities were found in her teeth. The child takes plenty of nourishment but the phosphates and carbonates are not assimilated, which is also indicated by the small bones and nervous condition. Believing from the large amount of tartar which is excreted by the salivary glands that an excessive amount must also be excreted by the kidneys, I submitted a quantity of urine to Prof. Walter Haines of Rush Medical College for an examination. The following is his report: "From 100 cc. I obtain 0.0775 grams of the calcium phosphate ($\text{Ca}_2\text{P}_2\text{O}_7$), from which I calculate that the entire amount of calcium phosphate eliminated by the urine in 24 hours is 0.9168 grams. All the calcium in the urine existed as phosphate and none as carbonate. Gautier gives the average amount of calcium phosphate in the urine of an adult for 24 hours as 0.40 grams."

When we take into consideration, the age of this patient, and the fact that children are not in the habit of excreting the phosphates as grown people are, it will be found that this child is excreting through the kidneys four times as much as normal individuals at 30 years of age. None of the carbonates were present which shows that a large drainage was taking place from the system.

Case 3, is that of a gentleman, a lawyer, 42 years of age. He complained of sensitiveness of his teeth whenever food was taken into his mouth, he suffered no pain at other times. I found that all the teeth were arrested in their development, with pits and groves running across the anterior teeth and clear around the bicusps and first molars, and above and below these grooves, constrictions and irregularities of structure occurred, extending to and including the grinding surfaces. These conditions were the result of arrest of development due to the exanthemata—he informed me that he had had all the children's diseases. In all these teeth the enamel was imperfect and the cavities had been constantly excavated and filled. Upon examining these sensitive places in the molars, which were deep, I found that the

structure cut like horn or old cheese-rind, and extended into the dentine an eighth of an inch below the soft decay. The color was dark brown. We frequently find these spots of a darker hue in the molars, but still soft when cut with the excavator. No enamel or rather hard organized enamel is present. Believing from the depth of the cavity and the character of the pain that the pulp was exposed, I cut into floor of the cavity with an excavator and finally with the bur until I was afraid of going through into the alveolar process without finding the canals. The tooth was afterwards filled with cement and has remained quiet for four months. The secretion of the mouth is alkaline.

Case 4. is one which comes under the care of Dr. W. C. Barrett of Buffalo, N. Y., and was presented before the Illinois State Dental Society in 1882. The following letter accompanied the models. "The casts were made from impressions of the dentition of a young man, a resident of this city, of otherwise full development, in excellent general health, with no marks of inherited disease, and who comes of a sturdy race, the family occupying high social and business positions. Nearly two years elapsed between the periods of taking the lower and upper impressions, which accounts for an inexact occlusion.

When I first saw him, the possessor of this denture was about 18 years of age. The maxilla, as might be seen in the casts, were well developed, and there was nothing approaching deformity, as the mouth presented a full and natural appearance although of course no teeth were visible. I counseled him to refrain from any meddling, as his condition could not, in my opinion, be bettered by the dentist. At that age young men are very solicitous about their appearance, and, annoyed I suppose at his peculiarity he applied to another practitioner who gave a different opinion, removed all the upper roots, and inserted a rubber denture which the young man is now wearing. I subsequently extracted some of the father's teeth and have made a microscopical examination of them.

It will be seen that there are absolutely no crowns to the teeth, their summits being for the most part upon a level with the gum and this was also the case with the deciduous dentition. The only vestige of enamel was some minute nodules or kind of bead-work around the cervical edges of two or three of the molars. The gum had a dense, glistening appearance, hard, unyielding, with apparently less than normal vascularity, and seemed admirably adapted to assist in mastication, reminding one of the maxillary appearance presented by the gramnivora that have incisors upon only one jaw. Of course there was nothing like a pulp chamber, but the roots of the teeth have nerve canals, which, however, are obliterated at the cervix. The exposed dentine, before extraction of the teeth, seemed very dense and hard, and when tried with an excavator was about as sensitive as ordinary enamel. The color of the exposed ends of the teeth was of a rich, dark amber hue, approaching mahogany, and they were smooth and polished by attrition.

This peculiarity is not the result of disease, nor is there anything simulating the appearance of the atrophied crown which is sometimes the mark of arrested development, due to some functional derangement; it seems the result of hereditary transmission. The father had precisely the same dentition, though the son is the only one among several children, who has inherited this peculiarity. The father was also the only one in a large family who possessed this dentition. Beyond this I have no certain data, but I am informed that the mark has been persistent in the family as far back as they have any knowledge, although it has seldom appeared in more than one member at a time, some generations escaping entirely, while it cropped out occasionally in a collateral branch without being transmitted to descendants at all. In the direct line of descent it has, as well as I can determine, usually appeared in at least one mem-

ber of the family, and that without material modifications. The young man of whose jaws these casts are fac similes, may then reasonably be expected to transmit his denture to one out of a number of possible children, while the others will escape. His brothers and sisters may perhaps have children among whom will be found this lack of development, but the peculiarity will probably end there in their cases, while it is indefinitely continued in the direct line of descent.

When the father first presented himself to me, he had but two or three of these incomplete teeth left. These were worn down to mere points, and he had for years done his mastication upon the unprotected gum. The alveolus was so much absorbed that artificial substitutes had become a necessity and under my directions he was supplied with an entire new set. The roots, or the remainder of them which I removed, were of a dark mahogany color, due to staining of the dentine, and the nerve canal was entirely obliterated. They had once doubtless been of nearly the normal size, as are those of the son, but had been worn down to the point by mastication, having been gradually raised in their sockets to meet the demands of nature.

I made microscopical sections of some of the son's teeth and mounted them for examination. At the cervix of the teeth—the surface presented for mastication—very few marks of the dentinal tubules remained, they seeming to have been obliterated by an infiltration or deposition of calcareous dentinal matter. As I neared the apex of the roots the sections presented a more perfect dentinal arrangement, and the tubules more of the usual appearance though the whole structure of the tooth was loose and showed numbers of minute chambers, some of them apparently communicating by what appeared to be abnormally large dentinal tubules. The nerve canal, entirely obliterated upon the grinding surface, (though from the direction and arrangement of the few tubules visible it had once existed) farther towards the apex of the root made its appearance and was of nearly normal size. The ends of the roots were well formed, and the apical foramen had the appearance of fully developed and well grown teeth. The cementum was much less in proportion than is usual, the dentine at most being invested with but a very thin layer, but what there was, presented no unusual appearance. The enamel which was found in minute nodules at the cervix of two of the teeth, was extraordinary in appearance. It did not present the usual relation to the dentine, and at the junction of the two there was not the frequent reaching over of some of the tubules. The enamel rods had not the usual regular appearance, but the substance of the enamel seemed twisted and contorted. It existed in minute aggregations, and seemed to have little of the usual relations with dentine. The most of the teeth had no enamel whatever. I can do little by way of accounting for this abnormal dentition. The entire absence of enamel in most of the teeth must have been due to a lack of enamel organ, or to its functional inactivity. The teeth erupted about the usual period, though perhaps a little later than usual. They have never shown any signs of caries, those of the father wearing out without decay, and those of the son being perfectly sound and quite exempt from disease. The case has been one of interest to me, and I should be glad to know if any other dentist has met with a like peculiarity."

Such conditions are frequently observed in connection with one or two or even three and four teeth. I can recall a number of cases where the lower central and the lateral incisors of both sets are in the same condition, while all the other teeth are normal. I can also recall a case where the bicuspid upon both sides are in the same condition and the other teeth are normal: and also other cases where the first molars upon both sides are in the same condition and also the roots of the second lower right molar, although I am not quite certain of this; the other teeth are normal. I have frequently seen and you have all observed the first permanent molars in that soft condition, contracted at different points, presenting holes and grooves which run in all directions. The decay extends deeply and is of a dark brown color resembling spunk or the decay of the heart of a tree; the tooth is exceedingly sensitive to touch and painful when food of different qualities come in contact with it. The secretions of the mouth are usually perverted, and when these teeth are excavated, the softness of the enamel and dentine is readily noticed. The pulp recedes frequently, obliterating the pulp chamber.

The roots of the case illustrated by Dr. Barrett, seem to be covered at the cervical margin with dentine which would also indicate that the pulp had also receded. I have observed this in the roots of molars, bicuspid and incisors when in a similar condition.

When this condition takes place in old people the enamel and dentine become exceedingly hard, and no sensation is experienced when the tooth is excavated. You will therefore observe that while the recession of the pulp is precisely the same in both cases the results are directly opposite. We have all observed teeth of a dark color, and so worn down that occlusion is impossible, while the teeth anterior and posterior to them, are in a healthy condition—this is frequently the case with the first permanent molar.

Their surfaces are smooth and polished. The color of the crowns of these teeth are not unlike that of the roots and teeth already illustrated in the cases presented.

I should class under the head of abrasion and erosion cases where one, two or even all the teeth are affected and where the color of the enamel and dentine is normal. Many theories have been advanced of the etiology of abrasion and erosion but I think that all these cases can to a certain extent be classed under the same condition, namely, primarily a want of calcification and a decalcification of the enamel and dentine. We frequently find that the first permanent molar and sometimes the second and third are worn away, and all the other teeth are normal. These mouths sometimes present strange conditions. First, decay is rarely present. Dr. Barrett very aptly says in his case, "That the teeth showed no signs of decay, those of the father wearing out without decay. The secretion of the mouth is most always alkaline and quantities of tartar are usually present. In ordinary mouths when the secretions are acid decay would take place because of the recession of the pulps—usually tartar in large quantities is present. These conditions render decay almost impossible. These teeth are always soft, cut readily under the bur and the pulps recede so that in many cases the pulp chamber is entirely filled. The anterior teeth upon the upper and lower jaw will wear away frequent-

ly, leaving a space of from one-fourth to three-fourths of an inch between them, while the teeth posterior to them occlude. The enamel although nearly twice as dense as the dentine wears away as readily as the dentine. What conclusion can we draw from these facts? We have already shown that in some cases the phosphates and carbonates are not assimilated. This to my mind is the cause of erosion and abrasion. We instinctively make the remark to a patient that it is better for teeth to erupt late because the tooth structure will be of a better quality. I have frequently observed this in irregularities of the teeth—when these teeth are slow in coming through, they are larger, more dense in structure and set more deeply in the jaw. The reverse is the case when they erupt early. The structure of the tooth is not well nourished. This condition can also occur in utero, the mother not giving sufficient nourishment to her child. Dr. Marshall in his paper entitled "The Oral Cavity of Pregnant Women" read at Newport, 1889, alludes to "certain cases of pregnancy in which the nutrition was impaired and as a result the bones and dentine became abnormally soft and that thus this softening of the dentine predisposes the teeth to decay." The child after birth may be poorly nourished and thus the bone, teeth as well as other tissues of the body suffer as a result. You are all familiar with the fact that the teeth suffer from a want of nourishment, and arrest of development will take place when the child is afflicted with the constitutional diseases. These teeth are soft and when the enamel is lost decay attacks them. After the teeth are formed they frequently decalcify. This is well illustrated in the case of pregnant women—the teeth seem to lose their vitality and decay early. If the teeth disintegrate under these conditions why will they not in constitutional diseases, as consumption, typhoid fever, etc? We know that this is the case so far as decay is concerned. I have called your attention to the fact that in some cases especially in children between 12 and 20 the phosphates and carbonates do not assimilate and hence there is a softening of the teeth and bones. We find that these substances which are taken in the system in the form of food for the nourishment of the body are deposited, unorganized upon the teeth, being excreted by the salivary glands. These substances are also excreted by the kidneys. The brain is not properly nourished, and as a result the child becomes very nervous, or again the child may possess a very active brain and the phosphates are entirely used up in its nourishment, the bones and teeth suffering in consequence. I have plenty of material that could be brought forward to sustain this theory, but the paper is now so long that I will not weary you with any further data. I have tried to find some mode of treatment but at the present time have been unable to lay down any fixed rule. Plenty of outdoor exercise and good nutritious food are about all the measures that can be suggested. It is possible that if the child lives long enough he may outgrow this want of assimilation.

Discussion.

Dr. W. C. Barret: We should try to determine the reason of the want of enamel in these cases. In one case there was a total lack of crowns to the teeth, and no enamel at all, except some little nodules at the gingival portion. In my report, quoted by Dr. Talbot, I stated that the dental tubules were not entirely normal. I believe this was because there were no crowns to protect them, and being normal at first, the modifications were caused by the want of the pro-

tection of the enamel. The roots were perfect, and mastication was performed upon the tops of the roots. Of course there was a cause for this absence of enamel. Could it be an entire failure of the enamel-membrane derived from the epiblast while the mesoblast performed its office correctly? The deciduous teeth of these patients had some kind of crowns. I do not know and could not learn just how near to normal they were.

We should take up and make a study of the pits and cracks often found in enamel. No one has as yet demonstrated the reason for them. They have been ascribed to the diseases of childhood, but if that is true why do they not occur all over the enamel? The enamel is all formed at one time, and these pits and marks should be in all parts of it. We all know that this is not generally the case, and we cannot prove that they are connected with the eruptive diseases of childhood. If every child who had eruptive diseases had these defects in its teeth, then it might prove that they were the cause, but it is not so.

Dr. Gish reported a case of a child, seven years old, whose temporary teeth were in a condition very much resembling the teeth described by Drs. Talbot and Barrett, only that they had had crowns. When he first saw the case, every one of the deciduous teeth was worn off even with the gums, and the roots were of a polished mahogany-brown appearance. He watched the case with a great deal of interest. He had to remove the roots of the premolars, as they were so firm that the permanent teeth could not erupt. When the permanent teeth did come in, they were quite perfect. What factor could cause such a condition in the deciduous teeth which still would not affect the permanent set?

Dr. Fletcher asked Dr. Barrett how many generations of the family—the subject of his report—he had positive knowledge of.

Dr. Barrett said he had positive knowledge only of the father and son. As for the preceding generations, he knew nothing only that it was an accepted tradition in the family that there had for a long time been one or more with short teeth in each generation.

Dr. Allport spoke of three girls in one family, who were patients of his, whose teeth were quite short and of a light slate color; in two of the girls the back teeth only were affected, in the third even the front teeth were of the same color. He learned that the grandfather had teeth of the same character, though the boys in the same family had perfectly natural and well-formed teeth. The peculiarity was evidently hereditary.

Dr. Talbot said, in closing the discussion, he wished to call the attention of the section to the prevalence of cases of a want of assimilation of the phosphates and carbonates in the food, and the consequent lack of these elements in the teeth, bone, and brain. We will find a child, say of twelve or fourteen years,—likely a girl,—very nervous; eats everything, beefsteak, milk, etc., yet is so nervous that she cannot control herself,—perhaps cannot hold her urine. She will be a bright child, with small bones. Upon examination her teeth will be found full of tartar, and her urine loaded with carbonates and phosphates. This material, so badly needed to supply the bones, teeth, and nervous system, is not assimilated, but is excreted by the salivary glands and in the urine.

Similar conditions are found in pregnancy; the teeth decay more rapidly than they would otherwise, and if a limb is broken the bones cannot be gotten to unite. These cases show that the phosphates and carbonates are appropriated by the fetus. We know, too, that in many diseases the teeth do not receive sufficient nourishment. The teeth show erosions arising from the constitutional condition which produces softening, and the attrition of the food and the adjacent parts wears the teeth away. Dr. Truman says that in erosion the structure of the teeth is harder than usual, but I think it is softer.

We all have these patients, but none of us know how to treat them successfully. We are advised to take the child from school, keep her out of doors, on a farm, with horse-back or bicycle riding. We will try all these and many other measures, but with little prospects of success. The probability is that such a child will die of consumption within a few years.

Another condition of the system which affects the teeth is gout. A gouty patient will almost invariably, if not quite show a softening and erosion of the teeth.

Dr. Fletcher said he had a case, a patient about 45 or 50 years old, whose incisors were entirely denuded of enamel on the labial side. The appearance was not as if it had dissolved away, but rather as if it had split off, as the edges were distinct.

Dr. Clifford asked if there was any peculiar diathesis in this case.

Dr. Fletcher said he did not know of any.

Dr. Barrett reported a case somewhat similar, with the enamel all gone from the labial surface, leaving it smooth. The teeth came to a sharp edge and crumbled away. He did not know what to do with them, unless he put crowns on them. The enamel on the lingual surface was intact. They were just the reverse of the teeth of rodentia.

On motion, the subject was passed, and Dr. J. L. Gish read a paper on "The Diseases of the Gums."

Dr. Gish's paper included a classification of the various pathological disturbances of nutrition as they are expressed in the soft tissues of the mouth. He described clearly and fully the several types of inflammation, from simple acute to chronic suppurative inflammation, as well as the cellular changes expressed as morbid growths. The pathological processes, as well as the clinical appearances in their different phases, were fully set forth, and the paper was a fair résumé of present knowledge in this department of pathology.

Its great length, and our lack of available space, coupled with the fact that we have recently presented our readers with similar matter somewhat *in extenso*, precludes a fuller abstract.

Dr. Fletcher related an experiment which he had made to show the influence of the faradic current in the circulation. He isolated the mesentery of a frog, and under the microscope watched the circulation until stasis had set in in a few of the vessels; then, by turning on the faradic current, he cleared up the whole zone. The shock stirred up the white blood-corpuscles and started up the circulation. He had found the use of the current in diseases of the gums very satisfactory, as described in the paper.

Dr. Curtis said the essayist had ably described the pathological conditions of diseased gums, and he regretted that the treatment had not been described more fully. He believed electricity was a great remedy for these diseases, and as we get to understand the use of it better, we will be better able to treat them.

Dr. Marshall, said, in regard to the use of the electrical current, if the positive pole is placed over a location where hyperemia exists, and the negative pole over the base of the brain, the hyperemia will be decreased. If the poles are reversed, the hyperemia will be increased. His treatment had been mostly in cases of hyperemia of the pulp. When the tooth does not positively pain the patient, but feels as if toothache were imminent, by applying the current and repeating for a day or two the condition will be passed, and the necessity for further treatment averted.

THE GENERAL AND THE LOCAL IN DENTAL PATHOLOGY.

Read in the Section of Oral and Dental Surgery, at the Forty-third Annual Meeting of the American Medical Association, held at Detroit, Mich., June, 1892.

BY J. SMITH DODGE, Jr., M.D., D.D.S.

OF NEW YORK, N. Y.

The whole field of pathology is divisible into the general and the local; and the opinions of pathologists have fluctuated many times in assigning the controlling power to the one or the other.

Ignorant minds necessarily look at the seat of pain or other disturbance as containing the disease. It was considered a great scientific advance when disease was pronounced an affection of "the humors," meaning all the liquids of the body, and therefore conceived as general with local manifestations. In our time the cellular pathology of Virchow has given a strong impulse again toward the more local conception, and bacteriology seemed for awhile about to convert all pathology into the local action of microbes. But the opinion grows that it is not so much the bacteria as their ptomaines, diffused by the hæmatic and lymphatic circulations, which cause disease; and this may bring us back again to the humoral theories, with the great advantage that we have discovered the *materies morbi*.

Dental pathology is so recent that it can hardly be said to have shared all these fluctuations; but it has room enough for them all, and its short history shows now the general and now the local view predominant.

The earliest modern dentists were first of all physicians, several of them among the great lights of medicine, and they naturally viewed all affections of the teeth not of mechanical origin, as symptomatic of general disorder. But when dental operations had been invented the processes were so obviously local both in causes and in results, that they fell speedily into the hands of men who were merely skilled mechanics, and the general relations of the art were almost neglected or treated in the most empirical manner.

A great change resulted from the labors of Dr. Harris and the founding of the Baltimore College of Dentistry, which was the birth of dental education. For many years the constant effort of educated dentists was to remove the stigma of a mechanical art and to assert their affiliation with medical men. This effort naturally brought forward again whatever could be alleged as connecting the teeth with the general system, whether as exerting or suffering pathological influences. And there was a time, midway in this struggle, when cautious men were inclined to think that the manual skill and the practical usefulness of a dentist were pretty certainly in inverse ratio to his scientific knowledge of medicine. Indeed, a contrast used to be drawn between European and American dentists along this line; the Europeans being confessed the more scientific, but the Americans far more practical.

Such work as Harris', however, could not fail, and by slow degrees dentistry has come to its own. We no longer need to ransack the records of medicine for rare and doubtful cases which may show the reciprocal relation of teeth and nerve-centres, in order to prove that we deal with vital organs intimately associated with the general welfare of the system. Every division of the dental field is now known to demonstrate this abundantly; and a suggestive outline of the familiar facts is all we shall need here.

It is not worth while to dwell on mere curiosities. Almost every organ of the body has at some time been reported as having pathological relations with the teeth; but it may be doubted whether all these cases could have stood the test of modern research. At any rate the very rare ones can never be anticipated and seldom recognized, and may well be left out of our view.

Neither need we take up the sequels of inflammatory action produced by diseased teeth in the adjacent tissues; the periosteal tumor which sometimes long precedes the breaking of a chronic alveolar abscess; burrowing fistulae which occasionally open far from the tooth; alveolar necrosis; affections of the antrum, etc. There is no mystery about these results and there can be no advantage in going over them here.

The remote relations of the teeth which still need study are effected either by the nerves, (whether the teeth are on the causative or the resultant side), or by general cachexias not well understood.

There can be no doubt that the constitution and the structure of the teeth partake of the general conditions of the system during the formative stage.

This relation is a little obscured by the fact that the internal condition of teeth does not so readily fluctuate with changes of the general health as do most other tissues; because the process of nutrition and interstitial change is exceedingly slow. But during the formation of the teeth they are as easily influenced as other organs, and their subsequent condition, especially the difference often found in the same mouth between teeth of different periods, may frequently be accounted for by inquiring into the health of the child at the time when each order of teeth was forming.

A relation so easily established authorizes us to believe that a similar cause may some day be made out for more mysterious deficiencies of dental constitution, and pathological conditions be thus explained from within for which no study of their surroundings shows any cause.

But the history of teeth is not wholly determined by the circumstances of their formation. Many observations have proved that a slow circulation pervades the dentine, maintaining a correspondingly slow process of renewal and interstitial growth. This process certainly produces at times increased density, and the presumption almost amounts to certainty that it sometimes retrogrades and causes deterioration. The evidence of this is not easy to disentangle, but it grows in distinctness. It has long been observed that the teeth rapidly decay during or immediately after some attacks of prostrating sickness and some pregnancies. The cause usually assigned has been a pathological acidity of the buccal fluids; but it is now established by researches in bacteriology, that except at the very beginning caries depends very little on external conditions; and therefore, if the long recognized effects of sickness and pregnancy are facts, some cause must exist which acts within the tooth. And such a cause does exist which is exactly in the line of our present study. Experiments made by the writer some years ago, but never published, showed that when decay occurs in fairly well-formed teeth, a zone of dentine immediately surrounding the cavity of decay has a higher specific gravity and yields more ash than a similar section from a sound side of the same tooth. This necessarily means a new deposit of lime salts apparently resulting from the irritation of decay. Now such a deposit in itself is of course a local affair, but it implies a heightening of vital activity which must be traced back to nerve centres. And it may well be assumed that besides the increase of density, the increased vitality of the dentine hinders, *pro tanto*, the ravages of the bacteria. If then this be the normal check upon decay, anything which so cripples the nerve-centres as to prevent this opposition, leaves the tooth defenseless to its enemies, and destruction is far more rapid. Now to this failure of normal inhibition rather than to any local cause, the quick decay accompanying disease and pregnancy must be ascribed.

Another field of quick decay reinforces this conclusion. In advanced life, when the general strength is impaired, teeth which have borne the strain of a lifetime are seen to give way suddenly to decay, so that in a few months there will be little left of the crown except the enamel, the dentine being decalcified in mass. Of course something must have happened to make this possible and not only general reasoning but the fact that these teeth are remarka-

bly insensible under the excavator, indicates that the nerves which supply them have almost ceased to work.

From all these considerations it seems fair to conclude that the decay of teeth is far from being a purely local matter, and is greatly determined by the nerve-centres from which the teeth are supplied.

Another branch of dental pathology which was long treated as merely local, has come to appear still more dependent on general conditions—the whole group of pericemental affections loosely classed as Riggs's disease. Once every condition, from a slight marginal congestion to the suppurative inflammation of the whole membrane was called the result of "tartar;" and under this name were included both salivary calculus and the scales and stars of pericemental exudate which occur at all parts of an affected root. With this view of the cause it could not be doubted that some kind of local treatment would cure the disease; and the remedies warranted never to fail have been countless.

The fact is, however, that extreme deposits of salivary calculus, even masses as large as the tooth, are frequently found to have caused no worse trouble than a superficial inflammation with some absorption of the gum; while deep-seated lesions of the most fatal kind occur in mouths which have been kept carefully clean. There is some cause farther back. Of course bacteria are invoked to explain it all, and they doubtless play a large and aggravating part. But they cannot explain why one mouth welcomes and another rejects them under the same visible conditions.

This writing has been interrupted to see a case which perfectly illustrates. Two molars have been driven apart by the blow of a wedge-shaped antagonist. At every meal food packs tightly against the intervening gum, till it has receded far beyond the original level of the alveolus, forming a deep pocket between the teeth. Could any conditions be more inviting to bacteria—the deep, protected nidus, the ever renewed supply of food never quite removed, the air and heat and moisture of the mouth? And yet neither tooth shows the least sign of pericemental disease, and the depressed surface of the interdental gum is pale and healthy as the hard palate. Such cases, not very infrequent, prove that the whole is not stated when we have spoken of bacteria. The opinion of dentists is therefore inclining towards one or another constitutional state as the predisposing and sustaining cause of pericemental trouble. We do not yet know much about it. Perhaps gout or rheumatism is at the bottom of it; perhaps the condition, not well understood, which promotes nasal catarrh.

To these two conspicuous topics might be added odontalgia: but of this so much is superficially known and so little profoundly, that it is hardly profitable for discussion. It is enough to say that the pains of the teeth are as frequently unaccountable as any others. The great majority, it is true, are due to local irritation traceable if sufficient diligence is used. But the commonest perplexity of dental practice is that one may do so much in one month without painful sequels, while so small a portion of similar treatment in the next month will prove disastrous.

Nor has as much been anywhere said as might be of fugitive and unaccountable pains in the teeth. It

often happens that the most searching examination discovers no local cause and that nothing in the subsequent history throws any light on the matter. Of course such phenomena are to be referred to reflex-action. The fifth pair present so many points of possible irritation, and this is known to pass so readily from one branch to another, that it would be strange indeed if the teeth did not often complain of disturbances quite remote from them.

Irregularities of position constitute another topic which might occupy us. When all the cases have been subtracted which can be explained by mechanical causes, a few remain which are partly ascribed to heredity and partly left without any explanation. It is probable that further study of these will bring to light constitutional causes, perhaps reaching back to foetal life. But the whole matter waits for patient investigation.

This review, then, while it shows very much yet to be accounted for, also shows that dental pathology is but a part of general pathology and can by no means be studied alone.

And yet when we turn to the dentist's daily practice, we are surprised to find how much all this may be left out of account, how overwhelmingly the troubles which he treats admit of purely local explanation and cure. Indeed, the man who broods beside his operating chair over remote causes and turns his best attention to general remedies, will by-and-by find that chair empty, and will learn that he is a practical failure.

Let us next view the matter, therefore, from this side and see to how great a degree dental pathology is local.

Nobody doubts that uncleanness of the mouth promotes decay: and no theory of electro-chemical action nor any discovery in bacteriology can shake this long established result of observation. It is equally certain that the careful excavation and filling of any given cavity always retards and frequently ends forever the morbid process.

It is worth while to add that when filling is unsuccessful and the question is raised whether the tooth or the operation is at fault, most practical dentists will incline, (if the operation is not their own), to suspect a fault in the filling.

One cannot speak quite so forcibly of local causes in pericemental disease. And yet the results of local treatment are so often beneficial that local causes must play a large part, and the attempt to trace these disorders back wholly to constitutional causes must not only fail but must seriously interfere with the discovery of improved local treatment.

As for the local causes of odontalgia, they are very numerous and sometimes so hidden that a diagnosis of remote causation is always to be looked on with suspicion and most rigorously questioned. And this, with a little less emphasis, is to be said of dental irregularities.

It might seem that such a survey as has been here made leaves the whole subject in confusion, and dentists must again divide into two opposing camps as in earlier days—the medical dentists and the operators.

But this can never be. There is no room for such strife, and if it could be attempted, the contest would be too unequal and would be speedily fought out. For all theories are subject to the test of facts; and the fact is that the reason of our existence as dentists,

the warrant for the high estimation in which our art has finally come to stand, is the possibility of relieving dental troubles by local operations. No amount of diagnostic acumen or of scientific learning will make a man a successful dentist who cannot give prompt comfort and safe assurance of future usefulness to the mouths of his patients.

The writer hopes to be particularly understood as building, whether at the chair or in an essay, on the intelligent, patient, and skillful performance of dental operations, as the corner-stone of dentistry. Whatever we may discover or invent, the day will not come in our time when there will not be ravages of past disease to repair and conditions of present disorder to cure.

It will be indeed a happy day for the science of the teeth if there ever arise men with the leisure and the learning necessary to work out the meaning of innumerable facts separately collected and recorded by practicing dentists. A single such man devoting his life to this study and to the verification of such conclusions as might be drawn, would make for himself a name and for dental science new means of usefulness, so great that we can as yet hardly estimate them. But no man can possibly do this who is tied to the operating chair; and the zeal that works without fee combined with the fortune which makes this possible, does not yet seem to have fixed its attention on dental science.

Meanwhile what can we, who must do our daily tasks, also do towards broadening the horizon of dentistry, towards hastening the happy day when dental disorder shall be rather prevented than cured?

Dentists have long nursed this hope, and the present paper aims to add another impulse in that direction.

It is no violent exercise of imagination to fancy the dentist of the future receiving a new patient. The chair, the mouthglass, the probes will all be there, and the examination, tooth by tooth, as minute as now. Then will follow a series of questions covering the ancestry, the habitual surroundings, the personal history and habits of the patient, and at last the dentist will give his judgment. "You have such and such defects of the teeth," he will say, "which will all be duly corrected. You have this or that constitutional weakness which has caused or promoted your dental troubles. Or your diet, your occupation your habits are at fault, and it will be necessary to make changes thus and thus." After six months perhaps the patient will return, the examination will be repeated, the regimen approved or changed as results may have appeared. In a few months or years the patient will have ceased to have any further dental disasters beyond the inevitable wear and tear of hard used organs; and after two or three generations a race will be produced in whom dental disorders will rank with pulmonary or ocular diseases, always possible but commonly escaped.

No thoughtful dentist will say the picture is too flattering, yet how delightful it is. And how are we to realize it? By holding fast the conviction that behind the local cause and effect there are powerful general causes; that these are not simple and manifest but difficult to trace and much interwoven; and that therefore they are not to be discovered by catching up some theory of phosphates, or rheumatism, or bacteria, but by the most patient accumulation and comparison of cases which now and then give some

valuable hint, and a slow induction of broad facts and general principles. As it will take several generations of patients properly guided to produce the dentition of the future, so it will take several generations of educated, diligent dentists to acquire the wisdom which may guide.

Perhaps it will seem a scanty outcome of so many words, but the conclusion of the whole matter is this: Besides the patient work of local treatment and repair from which we cannot escape, we must vigilantly watch and search for remote causes, we must question and compare unweariedly, we must nurse a wholesome suspicion of theories which explain too easily or too much; and we must count it a life well spent if, besides innumerable daily ministrations of comfort to our patients, we can at last contribute to our profession one step forward in a knowledge of the fundamental causes of dental pathology.

Discussion.

Dr. Talbot agreed with the essayist that the diseases of the teeth were often intimately connected with diseases of the system, and instanced two cases of patients suffering with pyorrhœa alveolaris who had been under his care, but for whom he had not found it possible to effect any permanent good. The disease of the teeth affects the general system, and the disease of the system affects the teeth. In both cases he had advised long ago that the teeth should all be extracted and artificial dentures inserted in their place. All the teeth are sound, and the patients would not consent to lose them, though it is the only course by which they can expect to enjoy life. The patients have now become so physically run down that it is scarcely possible for them to get from their homes to their offices. They were of gouty diathesis, and when they had excess of acid in the urine the teeth would be surrounded with pus, and so loose that they scarcely could be kept in their sockets. The age of the patients was about thirty-five to forty-two years, and the trouble had been running on for fifteen or more years.

To understand such cases it is necessary to study the whole systemic condition. So also in neuralgia we often find the cause in a distant part of the body; for instance, it may be in the uterus, it may be from dyspepsia or a gouty or rheumatic condition.

Dr. Marshall said that one of the patients of whom Dr. Talbot spoke had come into his hands. He first looked for constitutional cause for the trouble. There was no tartar on the teeth. He made up his mind the patient was gouty, and upon examining the urine found a large excess of uric acid. Upon inquiring into his habits it was learned that he was an excessive meat-eater. Being advised to limit himself in this regard he improved, but he will not give up his meat to the extent necessary to avoid the trouble, so now and then he returns for local treatment, which is given, and he is told to return the next day, but he never does. When he has the severe suppuration there is always excess of uric acid; no doubt the excess of uric acid or the gouty condition affects the suppuration as a cause.

ORAL MANIFESTATIONS IN METALLIC POISONINGS.

Read in the Section of Oral and Dental Surgery, at the Forty-third Annual Meeting of the American Medical Association, held at Detroit, Michigan, June 18, 1892.

BY G. S. JUNKERMAN, M.D., D.D.S.

PROFESSOR OF COOPERATIVE DENTISTRY AND DENTAL CLINICAL STUDY IN THE DENTAL DEPARTMENT OF THE UNIVERSITY OF PENNSYLVANIA, PHILADELPHIA, AND SURGEON AND PROFESSOR OF CLINICAL DENTISTRY IN THE DENTAL DEPARTMENT OF THE SAME UNIVERSITY.

Many metallic poisons which are non-corrosive in character show the limit of their exhibition in the human system by manifestations of some nature in the oral cavity. Some of the corrosive metallic poisons also show this limit in the mouth. This is especially the case with the escharotic corrosive metallic poisons. In both acute and chronic metallic poisonings are found oral manifestations; but this

paper wishes to direct the attention to the oral manifestations arising from chronic metallic poisonings. There is a slight suspicion that the prolonged exhibition of arsenic, in proper doses to produce medicinal effects, may result in the death of the pulp of one or more of the teeth in the individual so treated. There is no authenticated case of this nature, but the theory of it, based upon a knowledge of the accumulative nature of arsenic, is a good one. Arsenic in its action has a predilection for glandular tissue, and if it accumulates in the liver, spleen, kidneys and lymphatics, why should it not use the lymphatics of the pulps of the teeth as storehouses? Upon the hypothesis of these pulp manifestations of arsenical poisonings can be explained the twofold nature of the drug arsenic, viz.: the corrosive and the neurotic; both of these effects being produced when the drug is applied locally, and only the neurotic effect being present from the internal administration of the drug and its subsequent accumulation.

Arsenic does not always destroy by corrosion but may, as it must in these cases, produce death of the pulp by over-stimulation.

If arsenical poisoning endangers the inner vitality of the teeth, their external vitality has also an agent of destruction in mercurial poisoning. Manifestations of mercurial poisoning are particularly marked in the oral cavity. Mercury has a selective action for the lymphatic glandular system, and the first indication of the presence of mercury is an increased flow from the salivary glands. Mercurial poisoning is very destructive to the peridental membrane. This destruction is usually permanent and is exhibited by soreness and subsequent looseness of the teeth. Mercury in all its forms is synergistic to a destructive metamorphosis. The vitality of the general system is lowered by its internal administration, and the general action of the drug is rather to destroy than to build up the human tissues. The death of pulps too often results from mercurial poisoning. This arises from the placing in too close proximity to the pulp of so-called *fillings* (?) made of amalgam. The most skilled operator cannot possibly give to a certainty the prognosis of a tooth treated with an amalgam filling. If the tooth escape mercurial poisoning it is solely due to the degree of vitality possessed by it or the diminutive size of the filling, preventing a sufficient supply of the poison to produce death to the pulp. Many cases of chronic mercurial poisonings require several years to manifest themselves finally in the destruction of the pulps. Teeth into which have been stored large quantities of mercury in the form of amalgam rarely retain the vitality of their pulps for any length of time. Unfortunately for future generations the tooth does not die the day and often not the year that it is killed. I do not wish to deviate from the proper course of this paper to enter upon a discussion on amalgam as a filling material. Most of us use it, and it seems to be a necessary evil; but it must not be denied that many pulps are destroyed by mercurial poisoning caused by its use. The injury from the much vaunted external evaporation and subsequent absorption in the oral cavity of the mercury from amalgam fillings, pales into insignificance aside of the cases of the absorption of mercury by the canaliculi from the inner walls of the fillings. There is no doubt that many obscure cases of a neuralgic nature might be explained from mercurial poisoning of this kind. The

evaporation of mercury from fillings after they have become perfectly set is a theory and founded mostly upon the imagination. The absorption of mercury by the dental tubuli is a well authenticated fact which can be verified at all times. The specialist therefore as well as the general practitioner must shoulder the responsibilities arising from the administration of mercury; local mercurial poisoning destroying the internal vitality, and systemic mercurial poisoning destroying the external vitality of the teeth. The oral manifestation of lead poisoning is characterized by a blue line at the margin of the gums, usually on the inferior central incisors. In the internal administration of the drug the slightest appearance of this line marks the beginning of plumbism, and where the administration should be stopped. It is claimed by some good authorities that this blue line is due to the deposition of sulphide of lead and is only found in the mouths of individuals suffering from lead poisoning and who do not use tooth brushes.

If this is sometimes true it is not always the case, for I have found the line in persons with scrupulously clean mouths, and where all attempts to remove it by mechanical means were futile. The blue line must be explained upon some other hypothesis than a mechanical one. The mucous membrane seems to have a selective action for lead and the blue line is the inflammatory result of the deposition of this irritant. An argument against the mechanical theory also is that the deposition, if it proves to be such, is found in a place very freely bathed in saliva; while those parts of the teeth comparatively free from saliva show no signs at all. The blue line cannot always be taken as proof positive of lead poisoning. Mercurial poisoning will often produce the same condition; but a differential diagnosis can be made, if not by the history of the case by the number of teeth affected, the lead poisoning being restricted to the front teeth. What is more difficult is a differential diagnosis between lead poisoning and pyorrhœa-alveolaris in its first stage. The blue line in both conditions is frequently identical and we are compelled to depend upon the history of the case. This history often becomes very obscure from the patient's unwillingness to divulge the secret of her beautiful complexion or his brown or black metamorphosed head of hair. Time clearly determines the diagnosis, however, lead manifesting its characteristic constitutional symptoms and the arrival of the pyorrhœa-alveolaris at the pus stage.

The specialist is frequently the first called upon on account of the unsightly appearance of these blue lines; and this local symptom may for a long time remain the only sign of the trouble, there being no systemic symptom marked enough to attract the attention. This local lead poisoning may be brought about by the use of tooth powder. What occasion there is for making lead an ingredient of tooth powder may not appear clear to the intelligent practitioner; but that it has been found there is an authenticated fact. Powdered acetate of lead is usually the compound used, and its virtue to the stupid and unprincipled tooth powder-charlatan lies in its styptic and hæmostatic properties. If you have a case of lead poisoning do not be satisfied with examining the face powder and hair dye, but examine also the tooth powder used by the patient. There may be other metals that would manifest their poisonous properties in the mouth; but there are none which

on account of their use are capable of abuse and manifest their abuse in the oral cavity more than arsenic, mercury and lead.

Discussion.

Dr. Fletcher said he had not used any of the poisonous substances, with the exception of arsenic, for the devitalization of pulps, and had never seen the blue line on the gums indicating lead-poisoning.

Dr. Barrett did not think the death of the pulp caused by the application of arsenic could be due to over-stimulation, or to anything else than the corrosive effect of the drug. It has been claimed that it is caused by strangulation of the pulp, by causing a swelling of the pulp and a consequent constriction of the apical foramen. The falsity of this idea is proven by the fact that the effect is produced in children's teeth as well as adults', and it is well known that there is no apical foramen in children's teeth; and it produces the same effect on other tissues where there is no possibility of strangulation. As to mercury, we know that this substance has toxicological possibilities which no other substance has; that it is very unstable in its compounds, and apt to unite in new combinations when brought into contact with various substances, and so we need not be surprised at any effect produced by it, provided there be anything with which it could combine to produce a new compound; but he could not conceive that the mercury from an amalgam filling should be absorbed by the tubuli and go back into the system to work harm.

Dr. Talbot asked Dr. Barrett how he explained the dark color in and around teeth having amalgam fillings.

Dr. Barrett thought that in some cases at least it was caused by the union of some of the other components of the amalgam with the fluids of the mouth or teeth.

Dr. A. E. Baldwin said he was ignorant of the use of acetate of lead as an ingredient of tooth-powder, and thought such a reckless use of such a dangerous substance could not be too severely condemned. In regard to the argument of Dr. Barrett that the action of arsenic in the teeth of children proved that this drug does not effect the death of the pulp by means of strangulation, he did not think the proof was conclusive. There might be a strangulation in the blood-vessels, a constriction sufficient to cause the death of the pulp. And in regard to the statement in the paper of the absorption of mercury into the system through the canaliculi of the teeth, we can hardly accept that either. Amalgam is a chemical union of two or more metals, an alloy having peculiarities differing from those of any of the constituent metals, and the mercury could only be absorbed as a vapor. There are more idiosyncrasies of patients in regard to the use of mercury than of any other material. Some are disastrously affected by the mere contact of mercury with any of the membranes, even in small quantities.

Dr. W. W. Allport:—Just what the process is by which arsenic effects the death of the pulp is a mooted question; yet he has been inclined to believe that the theory advanced by Dr. Flagg several years ago, that it was by strangulation, is nearly correct. It seemed to him that a little thought would satisfy Dr. Barrett that the effects of arsenic on the pulp of a tooth and upon the soft parts of the mouth were entirely different. When arsenic is applied to the gum, the effect is continuous; applied to the pulp, death occurs within an hour. Another thing: it usually takes longer to destroy the pulp in the tooth of a child than in an adult.

As to the effect of mercury, we all know that teeth long filled with amalgam become brittle, showing that the mercury has affected the structure. This effect, it seems, must be from the evaporation of the mercury, and the vapor would naturally be in the direction of the least resistance—that is, between the filling and the tooth itself.

Dr. J. Taft said there could be no question of the effect of arsenic upon the soft tissue. A very minute quantity coming in contact with the gum will devitalize that portion of the gum and cause a slough. Some years ago a dentist announced a discovery by which a tooth firmly held in the jaw could be made so the extraction would be an easy matter. His plan was to take a line string, moisten it, and after drawing it through arsenious acid, tie it around the neck of the tooth just below the edge of the gum. The action on the gum was such as to make the tooth easy of removal, but the after-effects of course were serious.

We cannot explain just how arsenic acts on the pulp; but the fact that the pulp to which it is applied is found to be disintegrated proves that the action is not strangulation.

In regard to the action of mercury on a tooth, when a

tooth receives an amalgam filling the tooth-substance may be stained. This staining is not superficial; it penetrates the dentine; sometimes it is not very marked, and sometimes the dentine is blackened through and through from even a very small amalgam filling. This effect is produced by the penetration of the vapor of mercury into the tubules and its oxidation there.

It has been argued here that as amalgam is a chemical union of metals, it does not have the same characteristics of any of its component parts; but we all know that there is always an excess of mercury, so there is no doubt that the material for evaporation is there. Mercury will always vaporize at the temperature of the mouth, or even at a much lower temperature, down to freezing point. This may be tested by exposing a piece of gold foil where there is free mercury; within a few days the surface of the gold foil will be covered with mercury. The distance the vapor will penetrate into the dentine will be determined by the density of the structure. The vapor of mercury is so subtle that it is scarcely possible to get a joint tight enough to hold it. So we see that when teeth are filled with amalgam we have free mercury, and that the vapor will come from it, as the circumstances are in every way favorable. In very susceptible constitutions it is reasonable to believe that it may exert an influence on the general system. I think there are cases in which it does.

Dr. Talbot related experiments by which he had proved that the vapor of mercury was constantly given off even by very old amalgam fillings. He had had patients who had been injuriously affected by amalgam fillings. When the amalgam was removed and gold inserted, they had recovered. He said that he himself was an instance of unusual susceptibility to mercurial poisoning, and that if he should rub up two amalgam fillings in the palm of his hand each day for three successive days, he would be attacked by paralysis agitans.

Dr. Junkerman, in closing the discussion, said that the corrosive effects of arsenic when brought into contact with the soft tissues were well known, as shown when it is accidentally placed in contact with the gum. The stimulating effect upon the system is also well known, and can be tested any time by taking a dose of Fowler's solution. The effect is stimulating and exhilarating, but he thought the effect on the pulp was a corrosive one, as the disintegration of the pulp indicated.

That mercury is absorbed by the tubules of the teeth has been proven by extracting the globules from the dentine of teeth which have been long filled with amalgam.

As to the use of acetate of lead in tooth-powder, he had discovered it from the fact that he had a patient, a lady, who showed indications of lead-poisoning. To try to find the cause of the trouble, he asked her for a sample of her face-powder. This was furnished, and also a sample of her tooth-powder. The face-powder was found to be harmless, but on testing the tooth-powder he was astonished to find that it had the acetate of lead in it.

Dr. Clifford asked why, when mercury was used in excess in copper amalgam, the filling becomes black, but the teeth are not discolored?

Dr. Junkerman said it was possible that the oxide of copper formed, and prevented the absorption of the mercury by the teeth.

REMARKABLE SEQUENCE OF OPERATION FOR NECROSIS AT BASE OF SKULL: A NEW METHOD OF RESECTING THE THIRD BRANCH OF THE FIFTH NERVE.

Read before the American Medical Association, at Detroit, June, 1892.

BY G. LENOX CURTIS, M.D.,
OF NEW YORK.

About a year ago a case came into my hands for operation, which presented unusual features of interest from the surgical standpoint, not merely on account of the immediate results, but because of the suggestion which it afforded of a decided improvement in an important surgical operation.

On May 15, 1891, the patient, Miss M., aged 25, a professional nurse by occupation, presented a note from Charles

M. Magee, M.D., of Syracuse, N. Y., asking me to make a careful examination of her symptoms and condition, and stating his opinion that she had been suffering for the preceding five months from confined pus, somewhere at the base of the skull. He had, the note added, sent the patient to her dentist some two months before, but no trouble was found, though on the day previous to her coming to me the dentist had discovered pus coming from around one of the teeth.

The right side of the face was considerably swollen. The eye on that side protruded from its socket. The sight of the eye was, however, normal, while the left eye, which retained its normal position and was apparently not involved in, or related to, the trouble which had forced its companion out of position, was almost totally blind. With the right eye closed, the patient could merely distinguish the difference between daylight and darkness. Questioning her it was brought out that, as far as she knew, she had never had the use of the left eye. She had first detected the fact that it was useless to her at the age of seven years, and she had always supposed that its ecuity had dated from her birth. She had no recollection of any traumatic injury to which the disability of the eye could be referred. Clearly there could be no connection between the present condition of the patient and the blindness, which was therefore dismissed from the consideration.

The history of the case from the time serious symptoms were first observed, is perhaps best told in the following statement of the patient:

"First appearance of head trouble was in the latter part of January, 1890, when I had an attack of la grippe; was confined to bed two days; in the louse a week. Had more or less headache afterward, but no serious trouble until July of the same year, while in charge of a patient in the country; I was taken in the night with a severe chill, followed by headache and bone-ache. There was also a watery discharge from the eyes and nose, and I lost all sense of taste and smell. Did not seem to get over what appeared to be a cold in the head, but at the end of the second week after the chill, I went on duty again. The pain and fullness seemed to increase until the fourth day, when I was obliged to take to my bed. Had more or less ear-ache and faint turns and dizziness, and was brought home on my bed. Expected to have an operation performed, but on reaching home, it was decided that this was not best. Was confined to the house with this attack seven weeks, and was not able to work until the latter part of October. In January face was somewhat swollen, followed in February by a discharge from the right nostril; head was relieved as long as the discharge kept up, but when it stopped the pain and pressure were intense."

Examination confirmed the suspicion of Dr. Magee. On passing the electric lamp into the nostrils and posterior pharynx, marked opacity was observed throughout the entire right superior maxillary region, and extending far back in the direction of the ear, indicating disease of the antrum of Highmore and congestion of the surrounding tissues. The patient's physical condition was so unfavorable, however, that it was decided to defer operation until she could be strengthened for the ordeal. She was accordingly placed on an anti-pyemic treatment, with such good results that on June 2, the operation was performed with the aid of Dr. Magee, who also administered the anæsthetic, and my regular assistant. As in most of these cases, the operation was performed through the mouth, so as to avoid a scar on the face. The first step was the extraction of the second molar on the left side, the second bicuspid and the first molar having already been lost. The wisdom-tooth, or third molar, was allowed to remain, as its removal was unnecessary and it would serve a good purpose as an anchorage in case a bridge piece of artificial teeth should be required. A flap of gum having been turned back the bone was cut away from between the anterior surface of the wisdom tooth and the distal surface of the second bicuspid, the alveolar process being removed with it, and the cut extending along the buccal surface of the superior maxillary bone about a half inch.

On entering the antrum, that cavity was found to be entirely filled with multiple mucous cysts, pus, and granulations, but there was no evidence as to the origin of the accumulation. The posterior wall was absent, and the edges of the bone surrounding the opening were rough and dead, showing that necrosis had occurred. In exploring beyond this opening an accumulation similar to that in the antrum itself was discovered, except that it contained no mucous cysts, being composed entirely of pus and granulations, extending as far back as the junction of the sphenoid and

temporal and up on the zygomatic arch. The external surface of the pterygoid process and two-thirds of the greater wing of the sphenoid bone were entirely denuded of periosteum.

In all nearly a half-pint of diseased tissue was removed. The surface of the wing of the sphenoid, which was denuded, was necrosed, necessitating its removal with the bur and curette. As the necrosis involved the foramen ovale the nerve and artery were pressed aside to allow of the removal of the necrosis around the foramen. The necrosed bone removed, extended over the lower two-thirds of the external surface of the great wing of the sphenoid bone, the zygomatic surface of the external pterygoid plate, the entire zygomatic surface of the superior maxillary bone, and throughout most of the surface of the antrum, though the necrosis was less marked in this territory. Thorough cleansing was secured with carbolated solution followed by solution of bichloride of mercury. The entire wound was then packed with iodoform lint, which was not changed until the fourth day. Fever was very slight, there having been only two degrees rise in temperature, and this subsided upon the redressing. The wound was dressed in the same way for two weeks, after which the dressing consisted of injections of bichloride of mercury and peroxide of hydrogen, twice a day, and carbolated solution every two hours. A gold tube was finally put in the antrum, attached to the wisdom tooth, to facilitate syringing out the closing wound, and as a drainage outlet, and in due time was removed. The patient was able to attend to the dressing of the wound herself after four weeks following the operation, and the case progressed favorably and rapidly. The wound in the jaw soon closed almost entirely, there remaining only an opening just large enough to pass a probe through with difficulty. There is no deformity of the face. The right eye, with the removal of the cause of its protrusion, has returned to its normal position. The patient's health and strength have been entirely restored, she having gained twenty pounds in weight since the operation, and having a greater degree of vigor than for years previous. She has been able to pursue her accustomed vocation for some ten months.

The remarkable feature of the progress of the case after operation was the establishment of sight in the left eye. It will be remembered that the patient had no recollection of ever having had any degree of useful vision with this eye, that, so far as she was aware, it had been blind from her birth. The first indication of incipient visual power in this eye was observed on the third day. On the fourth or fifth day the patient could count with the left eye unassisted, the fingers on a hand held at a distance of four feet. In two weeks she was able to distinguish objects with some degree of clearness, and could recognize those about her. By September the sight had strengthened so that she could read the head-lines in a newspaper, two months later even small capital letters were easily read, and gradually, with the aid of a strong glass, ordinary print could be deciphered without difficulty.

This surprising and gratifying result opens up a wide field for speculation as to the ultimate and proximate causes of the previous blindness of the eye, and, as well, the *rationale* of the removal of this defect. Little is hazarded in the conjecture that the point of interference with the natural office of the optic nerve, was probably at some portion of the optic tract on the right side, since this region was involved in the territory of diseased tissue, and the affected eye was on the opposite side from the lesion operated for. It is, perhaps, not necessary to rehearse here the anatomy of the parts, a brief study of which will show that it is scarcely possible that the malign influence could have been exerted elsewhere.

As to the character of the interference, it would seem to have been in the nature of pressure producing a form of strangulation, which inhibited the normal function of the optic nerve. The history would lead also to the suggestion that the beginning of the

formation of broken-down tissue was made very early in the life of the patient, perhaps from a tumor at birth, which impinged upon the optic tract, and thence extended slowly, passing downward through the sphenomaxillary fissure, and by pressure absorbing and destroying the soft and hard tissues in its course, until the posterior wall of the antrum was broken down, and the antral cavity itself became choked with the products, the attack of *la grippe* acting simply as the spark to fire the mine which had been so long preparing. The subsequent train of symptoms is self-explanatory in the light of the condition shown by the operation.

Of course, it would be interesting and instructive to be able to determine exactly what was the primal factor in setting up the disturbance. The hypothesis above advanced seems the more reasonable in view of the fact that the idea of traumatism is scarcely admissible. The possibility of adenoids being at the bottom of the mischief may also be advanced, but guesses at the remote origin of the difficulty would now be futile.

It would be vastly more profitable to consider a fact which the operation conclusively demonstrated, namely, that resection of the third branch of the great trifacial at the foramen ovale, can be accomplished in a much more skillful manner than that now commonly employed. As is well known to you, the usual method is to cut from the outside, and the equally usual sequence is an unsightly scar upon the face. In the case described I did not resect the inferior maxillary nerve, but I did curette the necrosed bone away from around it, and I could distinctly see the nerve and most of the bone which was curetted. This would indicate the entire feasibility of reaching the third division of the fifth nerve when it is necessary to resect it at the foramen ovale by operating within the mouth. The parts are as readily accessible as by external operation, the wound heals readily, and no deformity will be caused. In operating after the suggested method, it should be borne in mind that the wounds in the mucous tissue of the mouth are liable to become niduses for the propagation of infectious bacteria, and it will therefore be necessary to guard against such a possibility by the adoption of the proper precautions. This, however, is no more than is requisite in the external operation.

THE FORTHCOMING REPORT OF THE BUREAU OF EDUCATION ON PROFESSIONAL EDUCATION IN THE UNITED STATES.

BY BAYARD HOLMES, B.S., M.D.

SECRETARY OF THE COLLEGE OF PHYSICIANS AND SURGEONS OF CHICAGO.

It has been my pleasure and rare opportunity to look over the proof sheets of chapters IX and X in the forthcoming *Education Report 1889-90* on professional schools. These chapters have been prepared by Wellford Addis of the Bureau.

MEDICAL SECTS.

One is pleased to see the diagrams which show such gratifying improvement in many directions. Thus, at this time, when the question of "the code or no code," is separating the American Medical Association into two factions with age and dignity on one side and youth and humanity on the other, a

glance at Diagram 11, which is here reproduced will convince the most fearful that the abuse and misinterpretation of a single clause in the code need not shatter that almost inspired document. The equitable adjustment of the "medical sect" question can be furthered by devotion to higher objects in medical education. Some of these objects will be set forth in this article.

DIAGRAMS OF PROFESSIONAL EDUCATION.

DIAGRAM 11.—Showing fluctuation of attendance at the schools of each of the three medical sects in the United States during the period 1880-90.

In looking over the statistics of the medical schools in Germany and France, one is surprised to see the strong advance of medicine in Germany during the past fifteen years. The actual fact of this advance is put forth by Diagram 1. To appreciate what this increase in the number of medical students in comparison with students of law and theology means, it must be remembered that in Germany the professional schools are integral parts of the University. Entrance to the professional schools depends on the previous completion of the course in philosophy, *i. e.* it depends on completion of a course at least equal to that represented by the A.B. or B.S. degree with us. Notice the fact that as medicine became more a science and especially as pathology became more carefully studied (1876 *et seq.*) and as surgery became under the use of antiseptic methods more successfully practiced, that the number of aspirants for a medical career rapidly increased. As we all know, medical literature has been enriched more by German labor during this period than by the labors of all other nations. The same activity is not to be found in any other department of University educa-

tion though there is a similar though lesser wave in the attendance in theology. This parallel between medicine and theology is to be found in almost any table.

In France, where education is bureaucratic from Kindergarten to the National Academy, much the same increase in attendance in the medical schools is to be seen. But, as I believe, because medicine was relatively in a much better condition in France at the beginning of the antiseptic period than in Ger-

838 EDUCATION REPORT, 1889-90.

DIAGRAM 1.—Showing movement of the enrollment in the faculties of law, medicine, and theology, in twenty-two German universities during thirteen years.

" " " 1889	13	13	13

many, this rise is not so noticeable. Law is relatively more prominent in the University in France than in Germany. In 1880, in each 100,000 inhabitants in France, there were 11 students of medicine and 14 students of law. At about the same time, in Germany, there were 8 students of medicine and 11 students of law to the same unit of population. This changed so that in 1888, France had 17 students of medicine and 14 students of law, and Germany had 18 students of medicine and 13 students of law to each 100,000 population.

It is interesting to compare the attendance of American professional schools with the preceding statistics. It must be remembered that the American professional schools are not parts of Universities

in any such sense as they are in Germany. Most schools of law, medicine and theology are open to any applicant with even the rudiments of a "common school education." The course of study is shorter and, in medicine, graduation entitles the holder of the diploma to license to practice. From all of these causes and because our people require and pay for more, if not for better, medical service than the Germans and French, the ratio of medical students is, with us, absolutely and relatively greater than in either of these countries. Thus in 1881, in the United States, there were 25 students of medicine, 6 students of law and 9 students of theology to each 100,000 inhabitants, while in 1890 there were 24 students of medicine, 7 students of law and 11 students of theology in the same unit of population.

ENDOWMENT OF PROFESSIONAL SCHOOLS.

We have complained in these columns and elsewhere of the neglect of medicine by the Universities of the United States.¹ This becomes apparent when we consider the amount of financial support schools of medicine receive from University corporations and from States.

The *productive funds* in the hands of medical schools, both those connected with and those independent of Universities in the United States was in 1889, \$249,200 while at the same time there was in the hands of schools of theology, productive funds to the amount of \$11,939,631. The value of buildings and grounds used by medical schools at the same time was \$4,047,618, and the theological schools were accommodated with buildings and grounds

¹ V. Article by the author, Journal Am. Med. Assn, July, 1892 and University Magazine October, 1892.

valued at \$7,762,095. It must be remembered that in the case of the medical schools these buildings and grounds were covered with mortgages. This was not often the case with the theological schools.

The contrast is still greater when we consider the number of students, the receipts from fees, and the expense of these schools outside of salaries of teachers. Unfortunately it is impossible to give

The theological schools report productive funds amounting to \$17,599,979, and stated, at the same time, the value of their buildings and grounds was \$10,720,860. They had 7,672 students in attendance.

Technological schools report productive funds amounting to \$13,229,940. These institutions received from State appropriations or municipal aid in 1891-92, \$747,504, which, if capitalized at 5 per cent., would be equivalent to an endowment of

842 EDUCATION REPORT, 1889-90.

DIAGRAM 3.—Showing movement of enrollment in schools of law, medicine, and theology in the United States during the period 1880-90.

For every 100,000 inhabitants in the United States, there were in 1881:

Year	Law	Medicine	Theology
1881	7	25	9
1889	7	21	13

this last item, as private corporations are not ready to open to the public their financial affairs. The medical schools had in 1889, 12,238 students who paid tuitions to the amount of \$763,761, while at the same time the theological schools enrolled 6,989 students.

I am able to reinforce these figures by an abstract of the statistics for medicine, theology and technology as reported to the Bureau in June, 1892. The medical schools possessed buildings and grounds in 1892 valued at \$7,507,937, and productive funds amounting to \$611,214. Medical departments of State universities also received State aid in 1892 amounting to \$40,500, which, if capitalized at 5 per cent., would be equal to an endowment of \$810,000; making a total endowment of \$1,421,214. There were 16,731 medical students in attendance.

DIAGRAM 13.—Showing enrollment and graduates for the period 1880-90 in medical schools of the United States.

\$14,950,080; making a total endowment for schools of technology of \$28,180,020. There were enrolled in the schools of technology 10,921 students, about one-third of whom were in preparatory courses. It will thus be seen that the endowment of theology is increasing at the rate of about two million dollars a year. The technological schools are well provided for but medicine has scarcely raised its endowment, even at the most liberal estimate, to a million and a half.

COURSE OF STUDY.

Diagram 13 shows that, making allowances for ordinary loss of students from year to year, the length of the medical course was hardly three years in 1890; as the graduations are thirty per cent. of the enrollments. This allows a loss of only three per

cent. in two years. This experience has shown is quite five per cent. a year.

The course of study is again abbreviated by the absurd custom of having medical schools open only one half the year. This means that almost 5,000,000 of dollars lie unproductive one half the year. In dollars, this is a loss of \$250,000 a year. In educational units, it means that students receive only two-thirds the training they are supposed to receive. In plain English it means that in the United States in 1890, 4,500 men were given the degree of Doctor of Medicine after studying, on an average, less than eighteen months in medical school. When we consider what the average medical schools offers each winter this is truly an appalling statement.

PRELIMINARY EDUCATION.

Is it any wonder then that educated men, who are trained in our better class of colleges and scientific schools, turn away from medicine in disgust. Diagram 15 shows the relation between total matriculates in reporting medical schools and those having degrees in letters and science in the same schools.

856

EDUCATION REPORT 1889-90.

DIAGRAM 15.—Showing relation betw. the number of students in certain medical schools of the United States, and the number of these students holding degrees in letters and science, during the period 1880-90.

That portion of the report which deals with this subject is worthy of reproduction here.

“Of the 96 institutions reporting to the Bureau in 1881, 42 returned 1,111 students having a degree in letters or science,

and three reported definitely that they had no scholar with a degree. In these 45 institutions there were 6,625 students. Thus in every 100 students there were 17 who it may be said had been liberally educated. If the other institutions (51) had reported specifically that they had no students who had received a degree in letters or science the whole attendance as far as reported to this Bureau (11,399) could be, and no error occur, compared with the number of students who were reported as having obtained a degree by the schools which answer the question definitely in the affirmative or negative. If we assume, however, that these 50 institutions had no matriculate in attendance having a degree in letters or science, then to do justice to the several parts of the country, comparison may take the following form:

	1881.			
	New Eng. and Mid. States.	South Atlantic States.	South Central States.	North Central States.
Ratio of Matriculates having a degree in letters to students in all medical schools in each section of the country	11	6	2	7
Ratio of matriculates having degrees in letters or science to students in medical schools that reported students with such degrees in each section of the country	20	11	8	15

Continuing this sifting process by considering eleven schools of medicine which are departments of a university, it happens that at:

1881.	Had deg. in letters or science.	
	Attend-ance.	Per cent.
Harvard Medical School	243	49
Yale Medical School	21	48
Coll. Physicians and Surgeons (Columbia College)	547	31
Medical Department of the University of Penn'a	375	26
Medical School of Maine (Bowdoin College)	112	20
Medical Dept of the University of City of New York	623	19
Medical Department of the University of Vermont	50	12
New Hampshire Med. Institution (Dartmouth Coll.)	91	7
Dept of Medicine and Surgery, University of Mich.	380	16
Medical School of the University of Missouri	40	43
Chicago Med. Coll., Northwestern University	150	20
Total	2,635	Average, 22

Considering the statistics of the eleven individual medical schools as before at

1889-90.	Had deg. in letters or science.	
	Attend-ance.	Per cent.
Harvard Medical School	290	43
Yale Medical School	55	30
College of Physicians and Surgeons (Columbia Coll.)	619	36
University of Pennsylvania, Medical Department	485	26
Medical School of Maine (Bowdoin College)	81	21
Medical Dept of the University of City of New York	633	17
Medical Department of the University of Vermont	205	19
New Hampshire Med. Institution (Dartmouth Coll.)	83	15
Chicago Med. College, Northwestern University	237	3
Dept of Medicine and Surgery, University of Mich.	372	10
Medical School of the University of Missouri	21	6
Total	3,081	Average, 23

Finally let us consider the statistics of the year 1889-90. 110 institutions have reported to this Bureau, 78 of which reported definitely the number of students having a degree in letters or science, or they have no student possessing such a degree. In these 78 schools 15 per cent. of the matriculates had obtained a degree before entering upon the study of medicine. The absolute figures are, sixteen schools with no students enrolled who had obtained a literary or scientific degree, 62 schools with 1,382 students having a degree; total enrollment in the 78 schools 9,389. Adding to the enrollment of the 78 schools the enrollment of the 32 which answered “don't know” no data, etc., the total enrollment of the 110 schools reporting is 13,793. Comparing the enrollment in these 110 schools with the number of matriculates reported by the 78 schools as having degrees, the result is that 10 per cent. of the enrollment in the medical schools of the country were possessors of a degree in letters or science. Considering the States by sections and including only the 78 schools which reported

15 per cent. of their matriculates having a degree in letters or science it is found that 18 per cent. of the matriculates in the medical schools of the North Atlantic division had a degree in letters or science, 13 per cent. of the South Atlantic division, and 18 per cent. of the South Central division (including Tulane University estimated at 25 per cent.), of the North Central division, and 9 per cent. of the Western division. These figures show a diminution for the schools of the North and an increase for those of the South.

From the foregoing statements it appears that there has been a slight *reduction* in the number of matriculates (17 in every 100 in 1881, 15 in every 100 in 1890) at medical schools, who had received a degree in letters or science; while the statistics of the eleven departments of universities (where one would expect a large per cent. of the matriculates to have obtained degrees) show that there has been an increase of but 1 per cent. in the matriculates who had obtained a degree in letters or science. Indeed in the instance of the College of Physicians and Surgeons (the medical department of Columbia College) of New York City a decrease of 2 per cent. is shown when the per cent. of enrollment for the decade 1870-80 (37 per cent.) is compared with that for 1880-90 (35 per cent.); or comparing the per cent. for the first half of the decade 1880-90 with the second half, a reduction of over 3 per cent. is shown.

The question then is: Has there been no improvement in the scholarship of the matriculates at medical schools?

The first of several questions asked on the form of inquiry sent out at the close of the school year 1889-90 was "Have you noticed during the last decade that the students of later years were, in a scholastic sense, better prepared to enter upon the study of medicine than those who preceded them?" Of the 86 regular schools reporting, 75 answered the question, 67 in the affirmative and 8 in the negative. Of 7 eclectic schools only one answered "No." Of 13 homoeopathic schools 12 answered "Yes," one fails to answer.

How are these facts to be reconciled? Statistics show that the number of matriculates having a degree is not increasing relatively to attendance. (page 879. See diagram I5), and yet the medical schools are almost unanimous in asserting that there has been an advance in the scholarship of the matriculates. Is this unanimous report as to the advanced scholarship to be attributed to an increased attendance at the medical schools of the country? Are more graduates of high schools matriculating at medical schools? If we compare the attendance of secondary schools (exclusive of public schools and departments of normal schools and of institutions for superior instruction) for 1880-81 with that for 1888-89 we find that there has been an increase in the attendance of schools for secondary instruction of 13 per cent. If we compare the attendance at the public high schools of 132 cities for 1880-81 with the attendance in the public high schools of these cities in 1887-88 an increase of 37 per cent., is shown. Or, speaking upon the subject from the still more general standpoint of population and considering that the public high school is always a feature of urban life, it may be concluded that the increase in urban population during the decade 1880-90 has increased the high school attendance of the country at large.

Some confirmation of the idea that the improvement in the scholarship of matriculates at medical schools is due to the high school, is found in the great protest against secondary and collegiate education because it tends to overcrowd the learned professions, especially those of law and medicine. But a protest is entirely too insecure a foundation to build a theory upon. What is necessary is information as to the localities whence the matriculates of medical schools come, whether from towns and cities or from the rural districts, for public high schools with few exceptions are located in the centers of population and rest on a system of grades beneath them from which they are fed. The public high school of the rural districts it should be said is in many cases the State normal school or agricultural college.

In examining the reports made to the Bureau some expressions are found that corroborate what has been suggested above. A medical school of California in answering the question as to the better scholarship, answers "Decidedly so," and adds, "18 had attended universities, academies, or colleges, 12 were graduates of high schools, 17 were graduates of the State Normal school or held educational diplomas or first grade certificates, and 40 passed examinations." A Southern school in denying improvement, adds, "The common school system has destroyed the private schools, and only an elementary education can be had outside." (There is no normal school in this correspondent's state). The

medical department of the celebrated University of the Northwest replies, "Our students average far better now than formerly, and nearly all who enter now (who are not possessors of a degree) are graduates of high schools." While one of the foremost universities of the Southwest reports in the affirmative, adding, "Many of our matriculates being graduates of high schools or universities." A college of Ohio makes a very striking answer in saying, "Yes, as to students who enter under 25 years of age, no, to those who enter above 25 years." And a Southern college answers, "I have noticed an improvement in this respect, but it must be remembered that the students from the South now seeking admission to our colleges received their education (literary) during the decade following the war when educational matters were chaotic.

Of 110 schools, 86 answer the question: "Has the average age of matriculates advanced?" Two-thirds of these answered no, and ten of them say the average age has diminished. The Hospital College of Medicine (Central University) reports the age of seniors in 1880 as 26, in 1885 as 28, in 1890 as 27. One college reports, "Age diminished, mental calibre advanced."

It cannot, then, be doubted that relatively a smaller number of medical students have the bachelor's degree than in 1880, though the education of the average medical student is superior to the education of the average medical student ten years ago.

Last summer, many of the college journals gave in the June number the statistics of the graduating class. I selected out seven such compilations and noticed an astonishing series of figures under the caption "Prospective Calling." Almost forty per cent. of the June graduates were put down for law, about the same number for theology, while only about five per cent. had selected medicine for their future study.

This shows evidently that medicine is not attractive to the college-bred man. In this connection we must consider the following propositions:

1. Medicine does not pay.
2. The study of medicine is not attractive. *a.* The subject is inherently repulsive and uninteresting. *b.* The conduct of medical schools makes medical education repulsive and uncongenial to an educated man.
3. The instructors in colleges and universities do not encourage men to take post-graduate study in medicine.
4. University corporations do not credit work done in medicine and reward it as they do work in other departments.

Let me consider the propositions one by one.

1. Medicine does pay as compared with theology for the average man. The reward comes slowly because there is less opportunity for a physician to distinguish himself and attain an acquaintance and reputation rapidly. But the financial reward of the best men in medicine is about five times as great as in the ministry. The financial reward in medicine all the way down the scale is greater, as evidenced by the number of aspirants for medicine among the uncultured as compared with the number of aspirants from the same class for theology. Figures are not at hand to show the exact income of physicians and theologians, but in any community examples can easily be recalled sustaining these assertions.

We must admit that financially law pays better than medicine to the superior man. But here medicine has an advantage in that constant incentive to the cultivation of the best qualities of character which it affords, while law, more than mercantile or commercial pursuits, tends to undermine the best qualities of man and crystallize the best emotions,

sentiments and aspirations. Still it seems to me medicine pays too well to secure only five or ten per cent. of the annual output of college graduates. We must look elsewhere for the cause of this movement.

2. The study of medicine may be unattractive from two different causes. *a.* It may be inherently unattractive to college-bred men. We may safely assert that this is not the case, but that on the contrary it has combined in it all the attractions of the natural sciences with the personal interest which adds so much to the humanities. Again, by consulting Diagram I it will be noticed that medicine is the most popular profession in the opinion of the graduates of the German universities. A knowledge of the thesis literature of the German universities gives one the opinion that medicine furnishes the ideal field of scientific study.

But if medicine is sought by the educated German and is neglected by the educated American, may it not be the fault of the medical schools themselves? Largely I believe it is. This has happened from many and from widely separated causes. Medical education has not been controlled by educators, but by clinicians. The antique methods of the Revolutionary period prevail in the great majority of medical schools to-day. Even in those medical schools that are most intimately connected with State or private universities, other rules and other methods than those of the literary and technological departments prevail. In the report which furnishes the material for this article, we are astonished to find that in one of our university medical schools the course of lectures is so arranged that each student hears every lecture repeated the second year of his attendance and then passes his examination and graduates. Can any educated man endure this, in this last decade of the nineteenth century! The fact is apparent to any student that medical schools are run for the good and profit if not for the glory of the professors. These men want quick returns and they adapt their instruction to the unevolved mental maws of the students that come in the greatest numbers. Such pap the college-bred man does not relish. To such instruction the university teachers do not recommend men for post-graduate work. To such instruction the American university too often gives its name though withholding its support. Let me omit to speak on propositions 3 and 4.

In conclusion, let me make the following deductions:

1. The average course of study in the United States is still less than three years; *i. e.*, eighteen months.

2. The antiquated method of repetition still prevails in the majority of medical schools.

3. The number of students of medicine is absolutely increasing but (in relation to population) relatively diminishing. The homoeopathic and eclectic schools are hardly holding their own.

4. The education of the average medical student is superior to that of ten years ago, but the ratio of matriculates having degrees in science or art is actually diminishing even in the richest, best located and only endowed medical schools.

5. The medical department is, so far as we know, neglected by every university in the United States, it is farmed out or left to shift for itself on half rations, or in the best instances, treated from an educational standpoint in an exceptional manner.

6. Medicine is neglected by the benevolent and by the State. From the former it has received almost nothing and from the latter not a tithe of what has been lavished on technological schools, and this in spite of the fact that the State and all benevolent institutions have put a heavy task of gratuitous and often compulsory service on the medical profession.

7. The medical schools are wasting their substance by keeping their doors shut half the year, and they are degrading the profession by allowing uneducated men to matriculate and uncultured men to graduate.

8. The laws which allow the diploma to become a license to practice, put the short-term-no requirement schools in a position to dictate to the schools that offer a medical education in place of a degree.

EYE TROUBLES WHICH CONSTITUTE A FREQUENT SOURCE OF HEADACHE, VERTIGO AND NAUSEA, AND OTHER NERVOUS DISORDERS.

Series of four lectures delivered at the Fourth Special Course of the Chicago Polyclinic.

BY F. C. HOTZ, M.D.,
PROFESSOR OF OPHTHALMOLOGY.

FIRST LECTURE—ANOMALIES OF REFRACTION.

It has of late years become more and more generally understood that certain affections of the eye have a far reaching effect upon the nervous system, and are a prolific source of nervous disorders. The clinical evidence now in our possession is so abundant and strong that this causative relation between the eye and certain neuroses can no longer be treated as a mere theory, but must be accepted as a positive fact. As the clear understanding of this relation is of the greatest consequence in the successful management of numerous nervous complaints you are called upon every day to relieve, I thought in looking for a practical subject for these lectures I could not choose any that would interest you as much as the "Ocular Affections which Constitute a Frequent Source of Headache, Vertigo, Nausea, and other Nervous Disorders."

For this purpose I have arranged these ocular troubles into four groups.

1. *The first group* embraces those cases in which the cause of nervous troubles can be traced to an abnormal state of the refraction of the eye.

In order to make clear this connection of the nervous system with the refraction of the eye, it will be necessary to devote a few minutes of our time to a consideration of what we call refraction and accommodation.

By *refraction* is meant the optical condition of the eye when in a state of absolute rest; by *accommodation*, the faculty of altering the refraction to suit the varying optical requirements of the eye to see with equal clearness at varying distances.

Refraction is a power the eye has in common with any convex glass lens; it is the power of changing the course of rays of light passing through it in such a manner that eventually they will all come together in one point called focus. The normal eye (Fig. 1) is so constructed that parallel rays of light (*i. e.*, rays coming from a very long distance) are united in a focus (*f*) exactly on the retina; and this state of refraction is called normal, or *emmetropia*. But the refraction departs so often from the emmetropic

state that if you examine any 100 eyes you will always find the emmetropic eye in the minority; the majority of eyes will show either of the following conditions of abnormal refraction:

FIG 1

1. *Myopia* (Fig. 2): the rays of light are brought to a focus, (*f*) before they reach the retina:

FIG 2

2. *Hypermetropia* (Fig. 3): the rays reach the retina before they are focalized:

FIG 3

3. *Astigmatism*: the rays cannot be united in a single focus at all, but the surface of the cornea being differently curved in two opposite directions or meridians (which are perpendicular to each other), there is a marked difference in the refractions of these two meridians, and the rays passing into the eye through the one meridian are brought to a focus sooner than the rays entering through the other meridian. By this peculiar inequality of the corneal meridians, the following kinds of astigmatism are possible:

ξ. 1. *Simple myopic astigmatism*—refraction in one meridian emmetropic, in the other meridian myopic.

2. *Compound myopic astigmatism*—refraction in both meridians myopic, but the myopia of the one meridian greater than the myopia of the other.

3. *Simple hypermetropic astigmatism*—emmetropia in one and hypermetropia in the other meridian.

4. *Compound hypermetropic astigmatism*—hypermetropia in both meridians; but greater in the one than in the other.

5. *Mixed astigmatism*—myopia in one, and hypermetropia in the other meridian.

The degree of abnormal refraction is determined by the optical value of lenses. If we place a convex lens before a hypermetropic eye, (which as you have learned by Fig. 3, cannot bring parallel rays to a focus on its retina) the rays are made convergent before they enter the eye, and therefore are brought to an earlier focus; thus, convex lenses as it were increase the refractive power of the eye and there-

fore we can find for every hypermetropic eye a convex lens which will increase its refraction just so much that the rays are focalized exactly in the retina. The value of this convex lens represents the amount of refractive power the eye is wanting in order to be emmetropic; in other words it expresses the refractive deficiency or the degree of hypermetropia. In a similar manner we can find for every myopic eye a concave lens which makes the rays just divergent enough before their entrance into the eye, that they will now be focalized in the retina. The value of this concave lens indicates the amount of refractive power the myopic eye has too much to be emmetropic; or in other words, it indicates the degree of myopia.

In order to have a definite and uniform scale of optical values, oculists have adopted as the unit a lens of one meter focal length, which is called a *dioptry*. A lens which shortens the focal length to half a meter, must of course have twice the refractive power of one dioptry, and therefore is numbered 2 (2 D.), while a lens with a focal length of two meters can be only half as strong a one dioptry, and is called one-half dioptry (.50 D.); and now such symbols as M 2 D., or H. 4.50 D., will be no hieroglyphics for you any longer; you will understand them at once to mean: myopia of two dioptries, or hypermetropia of 4½ dioptries.

If you throw the rays of a gas jet through a convex lens upon a cardboard, and slowly move the cardboard away from the lens, you will see a distinct inverted image of the flame appear upon the card when it is removed to a certain distance from the lens. This distance corresponds with the focal length of the convex lens, and if in the experiment the card is brought nearer to or farther away from the lens than the focal distance, the image of the gas flame becomes indistinct. Just as this convex glass lens produces an inverted image upon the card, so do the refractive substances of the eye (cornea, lens and vitreous) produce inverted images of outward objects upon the retina.

If these retinal images are sharp and distinct, we see the objects well; if the images are indistinct, our sight will be blurred. As these retinal images are distinct only when the rays are focalized on the retina, and as this is only done by the emmetropic refraction, the emmetropic eye is the only eye which sees a distant object distinctly by means of its refraction alone. But the clear sight of the emmetropic eye even would be limited to long distances: it would be very imperfect at a short range if it had not the power of accommodation. That an emmetrope can see an object distinctly whether it be 60 feet or 6 inches from his eye; that you can recognize a friend several blocks away, and can read small print, this extensive range of clear vision you owe to the power of accommodation by which the eye is enabled to increase the refractive power just so much as it is necessary for the production of a sharp retinal image of the nearer object.

These variations of the refraction are produced by alterations of the convexity of the crystalline lens through the action of the ciliary muscle; when its fibres are contracted, the lens becomes more convex and thereby more refractive; hence, whenever in the interest of distinct vision an increase of the refraction is needed, this demand is met by a corresponding contraction of the ciliary muscle. In the emme-

tropic eye: this action of the ciliary muscle is needed for near vision only, because as you have seen, distant vision is perfect under the effect of the natural state of the refraction.

The myope also uses his accommodation in near vision only, because his distant vision cannot be improved by any effort of accommodation.

In the emmetropic and myopic eyes, therefore, the ciliary muscles are constantly changing between contraction and relaxation, and can perform with ease and regularity the work imposed upon them by the acts of vision.

But we find different conditions in a large number of hypermetropic and astigmatic eyes. I have shown you that the hypermetropic eye needs the assistance of a convex lens to focalize parallel rays of light on the retina. Now whether a convex lens be placed *before* the hypermetropic eye or whether the same refractive value of such lens be added to the crystalline lens *in* the eye by an effort of accommodation—the optical effect would be the same; in either case the defect of refraction would be removed; the eye would be put in the condition of an emmetropic eye and have clear distant vision. Many hypermetropes enjoy this perfect vision, because they succeed very well in correcting their refractive error by the efforts of accommodation. And in astigmatic eyes it is also possible within certain limits, to overcome the abnormal refraction by special efforts on the part of the ciliary muscle.

Every hypermetrope and every astigmatic person who can see with his unaided eye as clearly as an emmetrope, enjoys this good vision at the expense of the ciliary muscles; they are working at a high tension all day long. But this incessant tension of the ciliary muscles can be maintained only by the expenditure of a large amount of nerve energy; and if the nerve force is consumed quicker than it can be replenished, this abnormal wear and tear will eventually cause an exhausted and irritable state of the nervous system, which manifests itself in various ways in different persons. The most prominent among the nervous symptoms induced by the strained efforts of accommodation, are severe pain in the forehead, or occiput, typical attacks of migraine, vertigo, nausea, vomiting, a sense of weariness coming over the person after a shorter or longer use of the eyes.

In many instances patients connect their nervous trouble with the eyes, because it always begins with a dull pain or a strained feeling over the eyes; or because they cannot read or write without getting a violent headache; but in a number of cases the patient does not connect his headache with his eyes because he can see apparently as well as any body, and claims he can read without feeling any discomfort in his eyes. Such patients think their eyes are perfect, and probably they are inclined to laugh at your suggestions to have their eyes examined, because you suspect the eyes to be the cause of the frequent headaches you have tried in vain to relieve by medical treatment. Among the last hundred refraction cases examined in my office, 46 patients mentioned headache as their chief complaint, and as the main reason for having their eyes examined. Five of those 46 patients had hypermetropia, 7 myopic astigm., and 34 hypermetropic astigmatism. That the hypermetropic astigmatism is so predominant among those cases will not surprise you if you remember that this is just the refractive error which

embarrasses the vision the most, and causes the eyes to make the greatest effort for its correction.

And here I wish to emphasize the fact that in many cases the refractive errors are of comparatively small degrees, often detected only after a searching examination. Let me give you a few illustrations: Here is a boy 12 years old, sent to me two months ago because he had more or less headache every day since last fall. He had complained in the same way during the previous winter and spring; but had been entirely free from headache during the vacation. He is a bright healthy boy, and the family physician searched in vain for some palpable cause for those persistent dull headaches. And if the boy was not himself only too eager to go to school, he might, and probably would have been suspected as shamming sickness in order to be excused from school. His vision was apparently perfect ($\frac{20}{20}$), with normal refraction; but after the ciliary muscle had been thoroughly paralyzed, the right eye showed hypermetropic as. of $\frac{1}{2}$ D. and the left eye, hypermetropic astigmatism of only $\frac{1}{4}$ D. The proper glasses for the correction of these small degrees of astigmatism were given for schoolwork, and they have relieved the boy from his school-headache. He has not had any sign of a headache, and has not lost one hour of school since he got his spectacles.

Here is another striking example: In January a gentleman, 36 years of age, a book-keeper, healthy, temperate and very regular in all his habits, called to have his eyes examined. As a boy, he was often taken out of school on account of his eyes; and the past 18 years (*i.e.*, since he began book-keeping) he had been troubled by occasional attacks of headache (starting over the eyes and going all around the head) and vertigo. These attacks gradually became more frequent, and lately he was often obliged to quit work at noon on account of severe headache and dizziness. The examination revealed $\frac{1}{2}$ D. of hypermetropic astigmatism in each eye. He got the correcting glasses, and he reports now he has been attending to his office work every day from morning till night, and has not felt the faintest indication of headache or vertigo.

When for the first time you were told that headaches, nervous dyspepsia, etc., could be cured by a pair of spectacles, you probably had your serious doubts of the veracity of the person who told you this story: for you could not very well conceive how a pair of glasses should in any way influence the nervous system. And you were right; the glasses have no direct influence on the nervous system. The glasses only correct the error of refraction, that is to say, they put the eye in the condition of the emmetropic eye, and thereby relieve the ciliary muscle of the necessity of excessive work. Take for instance hypermetropia of 2 dioptries: to see well this eye has to increase the refractive power of its crystalline lens by 2 dioptries through the action of the ciliary muscle; and *this perpetual tension of the ciliary muscle is the connecting link by which the hypermetropia reaches the nervous system*. Now if we place the 2 dioptries of needed increase of refraction before the eye in the shape of convex glasses, the deficiency in refractive power is mended by them as well as the tension of the ciliary muscle did it before; and the hypermetropia corrected and its disturbing effect upon vision removed, there is no more need for the continuous efforts of accommodation. You now un-

derstand the *modus operandi*: the glasses relieve the muscular tension and, this muscle strain being the source of the nervous disturbances, the glasses in eliminating the disturbing cause indirectly relieve the nervous system.

Whether an error of refraction will cause any nervous disturbance, and how violent symptoms it will produce, does not depend on the degree of refractive anomaly, but on the condition of the nervous system. It is a great mistake to think severe nervous symptoms cannot be produced by small refractive errors, because their correction by accommodative efforts requires only a proportionately slight strain of the ciliary muscles—on the contrary, as I have said before, in the majority of these cases we find comparatively small degrees of refractive errors, especially often slight degrees of hyperopic astigmatism. For these slight anomalies can be corrected by an amount of muscular tension which the ciliary muscles can easily afford to continue without getting quickly exhausted, and under these circumstances the eye will make this special effort to correct the abnormal refraction in the interest of clear vision. But if the refraction departs much from emmetropia; if, for instance, the degree of hypermetropia is so great that its correction would require nearly all the available power of accommodation, you understand that the ciliary muscles could not meet this demand but for a few minutes; it would quickly be exhausted; its tension would be relaxed, and the sight grow dim in proportion to the degree of the existing ametropia. The correction of these higher degrees of refractive errors being impossible by a reasonable and continued effort of accommodation, the eye gives up the attempt; and therefore these patients do not enjoy very clear distant vision, but on the other hand do not suffer from the secondary effects of the eye strain. This is one reason why not every hypermetrope or astigmatic person exhibits symptoms of nervous disturbance. But you may also meet two persons showing the same degree of astigmatism; but while the one is suffering severely from the effects of the ciliary muscle strain upon the nervous system, the other is perfectly unconscious of straining his ciliary muscles. This fact does not argue against the existence of the relationship between eye-strain and nervous disturbances; but it only shows that one person can endure an amount of wear and tear of the nerve forces, which the other person cannot. The nervous organization of no two persons is alike; the reserve force is not dealt out to all with the same measure; one person has very little of it; another person is endowed very liberally with it; and it is this difference in the reserve nervous force which explains that the same cause which in one person will raise a tremendous nerve storm, will produce but the faintest ripple of disturbance in the nervous system of another person.

AUDIBLE NERVE CURRENTS.—Dr. Wedensky, of St. Petersburg, at the recent physiological congress held in Liège, contributed a series of telephonic demonstrations of the currents of action in nerves.

The Alabama State medical examining board rejects forty-one and sixteen one-hundredths per cent. of candidates who apply for a license.

SOCIETY PROCEEDINGS.

American Electro-Therapeutic Association.

Second Annual Meeting, held in New York, October 4, 5 and 6, 1892.

WILLIAM J. MORTON, M.D., PRESIDENT.

FIRST DAY, OCTOBER 4—MORNING SESSION.

The Association was called to order in the New York Academy of Medicine, by the President, at 10:30 A.M. The first order of business was the election of new members.

LIST OF NEW MEMBERS.

- Dr. Floyd B. Crego, Detroit, Mich.
 Dr. H. H. Hahn, Youngstown, O.
 Dr. A. G. Henry, Courtland, N. Y.
 Dr. Thos. W. Poole Lindsay, Ontario, Can.
 Dr. W. J. Herdman, Ann Arbor, Mich.
 Dr. D. S. Campbell, 9 Washington Ave., Detroit, Mich.
 Dr. Emil Heuel, 352 Willis Ave., New York, N. Y.
 Dr. Wm. Davis, Omaha, Neb.
 Dr. J. T. Harvey, Boston, Mass.
 Dr. C. W. Martin, Topeka, Kan.
 Dr. E. B. Sangree, 744 S. Fifteenth St., Philadelphia, Pa.
 Dr. G. M. Hammond, 58 W. Forty-fifth St., New York, N. Y.
 Dr. Robert L. Watkins, 320 W. 145th St., New York, N. Y.
 Dr. Lucy M. Hall Brown, 134 Montague St., Brooklyn, N. Y.
 Dr. Chas. R. Dickson, 263 Victoria St., Toronto, Ontario, Can.
 Dr. Howard Smith, Surgeon U. S. N. (Retired).
 Dr. F. Schayoir, S. Atlantic St., Stamford, Conn.
 Dr. Ernest Wende, 174 Franklin St., Buffalo, N. Y.
 Dr. O. S. Phelps, 143 W. 131st St., New York, N. Y.
 Dr. S. T. Anderson, Bloomington, Ill.
 Dr. Spencer M. Free, Dubois, Pa.
 Dr. F. Semeleder, Caille Sur I, No. 1018, Mexico, Mex.
 Dr. J. Mount Bleyer, 118 E. Sixteenth St., New York, N. Y.
 Dr. Willis E. Ford, 266 Geneva St., Utica, N. Y.
 Dr. G. E. Percy, 9 Benevolent St., Providence, R. I.
 Dr. D. J. Neylan, 172 Hope St., Bristol, R. I.
 Dr. F. H. Wallace, Boston, Mass.
 Dr. W. T. Bishop, Harrisburg, Pa.
 Dr. Halford Walker, 56 Isabella St., Toronto, Ontario, Can.
 Honorary Fellow—Dr. Bruce Clark, M.A., M.B., F.R.C.S.,
 46 Harley St., Cavendish Square West, London, Eng.

President William James Morton, M.D., read his address on

ELECTRICITY AND MEDICAL ART AND SCIENCE.

Fellow Members of the American Electro-Therapeutic Association:—It falls to my fortunate lot to have the honor and the privilege of declaring this, the second annual meeting of the American Electro-Therapeutic Association, formally open.

In accordance with precedent, a few words are, I believe, expected from your presiding officer at this stage of our proceedings.

I might content myself with selecting some special subject, but it seems to me that our programme is already richly laden with these; moreover I divine that there are thoughts of a more general scope in the minds of all of us present who have watched the steady growth of this young organization and who have at heart its welfare. It is to some of these thoughts that I will attempt to give expression—how inadequately, no one is more conscious of than myself—under the general heading of Electricity and Medical Art and Science.

From more than one point of view this assemblage of medical practitioners especially interested in the applica-

tion of electricity in medicine is an unusual event. Electro-therapy has too long, hung, so to speak, on the outskirts of medicine. Never has a nobler agency for cure been more ignobly treated. Seldom has a branch of science which requires man's highest intelligence to comprehend been so sedulously relegated by professional neglect to the hands of those least gifted by mental qualifications or by integrity of character to pursue it. I do not speak too strongly when I say that with exceptions only the more brilliant for their isolation, electro-therapy has been too long left to the designing, the ignorant and the incompetent. The reasons for this state of affairs are manifest; they are inherent to the nature of the subject and to the nature of the medical profession. Among some of the more obvious of these reasons are:

1. The difficulty of comprehending the agency itself.
2. Our inadequate knowledge of the nature of disease.
3. A traditional adherence to medicines and drugs as remedies, to the exclusion of natural agencies.
4. A skepticism as to the value of all strictly therapeutic measures—a consequent neglect of such measures and an accompanying perversion of the function of the physician from the art of healing to that of scientific explorer.
5. The natural contempt felt for the ignorant methods of the class of men (generally not physicians) who extensively treated disease by electricity.
6. The stupidity and ignorance of the public who buy electric nostrums, think that electricity is the vital principle itself, and regard it as the great "cure-all."
7. The unfortunate appellation, for a physician, of the term "electrician" with the idea that he is a mere administrator and consequently a subordinate. It is safe to say, to-day, that those who use electricity as a means of cure would repel the title as having no special application to themselves. They use not alone electricity but also all measures that seem applicable; they are in short physicians.

These reasons for the present position of electricity are too obvious to require discussion. Such of them as relate to the nature of the agent and to the nature of disease only incite us to profounder study, while such as refer to the relations of electricity to the medical profession will disappear with the higher education of the profession and with a corresponding purging of electro-therapy from mystery and humbuggery by those whose labors are undertaken in a purely scientific spirit.

And now a word as to where we stand to-day—a glance as it were, and that a brief one, at the evolution, so to speak, of electro-therapy.

The single observation of the workman who noticed twenty years ago that the dynamo machine was reversible into the motor has wrought a wondrous change in the relations of electricity to the affairs of mankind—a change which naturally worked itself out in commercial and industrial directions where self-interest and gain were at stake and where capital was available. As a result there has sprung up a new class of experts—the electrical engineers—self-taught and acquiring their science as the need arose in the first instance, and now scholastically trained.

Always in advance of them the new science sprang into being; its demands strained their highest intelligence and highest energies. Electricity had emerged from its thrall-dom; had cast aside the pedagogic flummery of the classroom and the text-book, and had become a part of warring, hard and practical life. A giant had arisen from his cradle; his followers thronged after him and multiplied.

Electricity had revolutionized physics when it made the conception of the identity of light and itself the only tenable one, had revolutionized chemistry when Faraday established his "voltametric law" and law of electro-chemical

equivalence. To-day it has revolutionized the arts, communication and transportation, and the period has just arrived when its influence is beginning to be felt in medicine.

Partially satiated with his conquests over inanimate wires and iron, the electrical engineer is already turning his attention to the action of electricity upon living things—is invading the realm of biology and medicine, and is just to that degree a help to the medical man.

On the other hand the medical man is turning to the physics of electricity and acquiring the lore of the electrical engineer—a happy direction for both and a happy combination for the welfare of electro-therapy. Medicine welcomes the electrical expert; we welcome his presence among us to-day.

It is this great stride of electricity into the other affairs of life that has again forced it into prominence in medicine. When first it invaded medicine it was under false colors of identity with the "vital principle" and "nervous force;" its empirical results were registered from a false point of view. To-day an exact science knocks at the doors of medicine—an inexact science—and demands a hearing. On the one hand is living protoplasm, differing only from dead protoplasm in that it exercises chemical affinities by the inexplicable law of "life;" on the other, a rate of motion capable of affecting gross substance, living as well as dead, and of exhibiting in it the phenomena we term electric. Can we hesitate to believe that it is a great study and worthy of our best thought to ascertain what is the effect of this manifestation of energy called electric and electricity upon living human tissue, in health and in disease? It is this pursuit which has brought us together to-day, and under advantages which our predecessors, even in recent years, were infinitely far from possessing.

Not far distant we may catch the gleam of a new electro-therapeutics arising in the wake of the new electrical science. It requires but little prophetic spirit to watch its growth, founded upon the exact physics of electricity, upon biological study, upon an ever increasingly exact pathology and upon rigid clinical observation.

Electricity is a science, born new every day, and its votaries daily form a new school. The observation of yesterday put in practice today, shelves a hundred well used tomes and saves as many and more lives.

In the onward march of measures for the relief and cure of crippled and wounded humanity I see electro-therapeutics struggling with more and more powerful pace to the vanguard.

You ask—the skeptic asks for the basis of the faith that is in us. It consists broadly: 1. in the known, exact, and remarkable power of the agency itself. Electricity, as exhibited in the familiar physical phenomena of heating, lighting, chemical and mechanical effects, and 2, in its known, exact and remarkable actions upon living tissue.

There are positive pillars of fact upon which we build our faith; among these are,

1. *Excitation of living protoplasm*: Electricity causes protoplasm, animal and vegetable, to contract or otherwise exhibit its characteristic functional excitability. Both nerve and muscle tissue respond to the electric stimulus, dependently and independently. The parts of the human body beneath the skin can be excited in no other manner in a corresponding degree.

(To be continued.)

DOCTOR OF MEDICAL SCIENCES is a new medical degree proposed for establishment in France by the French Minister of Public Instruction. This title will be superior to the ordinary M.D.

THE
Journal of the American Medical Association
PUBLISHED WEEKLY.

SUBSCRIPTION PRICE, INCLUDING POSTAGE:
PER ANNUM, IN ADVANCE \$5.00
SINGLE COPIES 10 CENTS.

Subscriptions may begin at any time and be sent to

THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION,
No. 68 WABASH AVE., CHICAGO, ILLINOIS.

All members of the Association should send their Annual Dues to the
Treasurer, RICHARD J. DUNGLISON, M.D., Lock Box 1274, Philadelphia, Pa.

MEMBERSHIP IN THE AMERICAN MEDICAL ASSOCIATION.

This is obtainable, at any time, by a member of any State or local Medical Society which is entitled to send delegates to the Association. All that is necessary is for the applicant to write to the Treasurer of the Association, Dr. Richard J. Dunglison, Lock Box 1274, Philadelphia, Pa., sending him a certificate or statement that he is in good standing in his own Society, signed by the President and Secretary of said Society, with five dollars for annual dues and subscription for THE JOURNAL. Attendance as a delegate at an annual meeting of the Association is not necessary to obtain membership. On receipt of the above amount the weekly JOURNAL of the Association will be forwarded regularly.

SATURDAY, JANUARY 14, 1893.

THE PARASITE OF CARCINOMA.

During the last few years a whole literature has come into existence on the alleged parasite of carcinoma. In every laboratory this obscure branch of pathological histology has been studied with zeal and persistence. COHNHEIM'S theory that tumors are due to exaggerated growth of primary remnants of the embryonal folds, gone astray in various parts of the body, has been severely criticised by the enthusiastic believers in the parasitic origin of carcinoma; it has been characterized as purely speculative, as founded only upon probability. It has been shown that embryonal folds exist in all multi-cellular organisms and that consequently invertebrates, theoretically considered, would be just as much liable to various forms of tumors as the higher animals, but such a thing as a carcinoma has never been described in the inferior animals up to the present time although they are very liable to parasitic tumors of various kinds. COHNHEIM stated that carcinoma is not contagious and this statement still holds good; but the opponents of the embryonal misplacement theory are not slow to point out that many diseases, proven absolutely to be of infectious and parasitic origin, are not in any sense contagious. The question continually forced to the front by the bio-pathologists consequently reads: Is it not possible that in man and the higher animals malignant neoplasms are of parasitic origin just as in the lower animal scale where all tumors are parasitic? Many authoritative scientists believe that this question has already been answered in the affirmative by the actual demonstration of cancer organisms. Others again, equally prominent, believe that Cohnheim's theory is for the present the only acceptable, and probably also the only true, theory. Then again, many pathologists have placed themselves in an attitude of critical expectancy, ready to give every result of continued

investigation fair and unprejudiced consideration refusing, however, at the present to take any positive stand on the question. The solution of this problem appears to hinge largely upon the interpretation of the various bodies found by means of recently improved technique in the interior of carcinomatous cells. These bodies have been variously interpreted: Some regarding them to be, wholly or partly, as VIRCHOW did in 1851, the products of endogenous cell division, others as dead red corpuscles, or as dead leucocytes, or as due to the invagination of one cell into another, or to degenerative changes of various kinds in the protoplasm and nuclei of the carcinoma cells. NOEGGERATH states that he has been able to show that all the mysterious bodies found in carcinomas could be traced to pathological alterations in the nuclei. Recent technical modifications resulted in such marked differentiation of the cell and its nucleus from the inclusion so-called that, according to many investigators, doubt could no longer be entertained as to the fact that the included mass has the structure of a true cell presenting no appearance suggestive of degeneration either of the protoplasm or of the nucleus of the epithelial cell proper. Thus PUFFER and WALKER following in the foot-steps of SJÖBRING, FOÁ, SOUDAKEWITCH and others employed the BIONDI-EHRLICH triple stain and found the nucleus of the carcinoma cell to stain green, the protoplasm orange-red, while the nucleus of the parasite stained red and its protoplasm light blue, the resulting picture being so characteristic that the inclusions were unhesitatingly pronounced to be true parasites. METSCHNIKOFF in a recent and interesting argument entitled: "Remarks on Carcinomata and Coccidia" (*Revue Générale Sciences Pures et Appliquées*) states it as his opinion that these so called parasites have the greatest analogy with coccidia; he compares carcinoma with coccidiosis, as seen in the rabbit's liver, and finds many points of great and striking similarity between the two diseases. Coccidiosis is an infectious, parasitic disease, not contagious, the lesion consisting of nodules of varying size, composed of proliferating biliary ducts whose epithelial cells contain the coccidia, voluminous sporozoic organisms concerning whose role in this disease there is now no longer any doubt. Like coccidiosis carcinoma is characterized by epithelial cell proliferation; like coccidiosis carcinoma is not contagious; and finally, METSCHNIKOFF concludes as already stated that some of the peculiar bodies demonstrated in carcinoma cells by recent investigation present the closest resemblance to coccidia and this conclusion he regards as sufficiently reliable to serve as the starting point for new researches. VITALIS MUELLER (*Virchow's Archiv.*), on the other hand, suggests that these coccidioid parasites are but the products of indirect nuclear fragmentation in dropsical carcinoma-

tous cells; he was not able to find any karyomitotic figures in the nucleus of the alleged parasite but he did find the nuclei in the epithelial cells containing this parasite undergoing indirect fragmentation. Unanimity of interpretation of these interesting appearances is consequently not yet achieved, but it can, without much fear of contradiction, be stated that the concensus of opinion of a very large number of scientists is to regard the recent bodies referred to as parasitic in nature. The beginning already made in the microbic study of carcinoma is certainly encouraging, but it is quite evident that part of the investigation must be conducted along new lines in order to completely solve this deeply obscure but important problem regarding the etiology of carcinoma.

THE COMING MEETING AND ITS WORK.

The superior character of the papers which have appeared in *THE JOURNAL* has been very gratifying to both the managers and members of the Association. It furnishes the strongest possible proof of our oft repeated statements, that to raise the character and tone of *THE JOURNAL*, the members must prepare and read better papers. The officers of each Section must exercise care and discrimination in the selection of such papers. The old method of gathering every paper offered, read personally or by title, and sending them indiscriminately to the editor for publication, making *THE JOURNAL* a practical dumping ground, is perilous to any publication, no matter who manages it. Happily this is rapidly passing away, and although many papers are yet received by the editor, from the Section officers, that are not creditable to the authors or the Association, the number is growing less every year. This is true in the British Medical Association journal. Recently some severe complaints have been made and questions asked why carelessly written, elementary papers of no value to science should fill up the paper? The editor calls on the Section secretaries to cull out and send abstracts of such papers if worth it, and announces his willingness to discriminate if sustained by vote of the Association.

Our Association is far more tractable and inclined to adapt itself to new conditions and demands than our foreign brothers. Hence both the Association and its Journal should be among the most advanced of scientific workers. This can only be accomplished by hard, exact work; members who expect to read papers at the coming meeting, should exercise the same painstaking care they would in the most delicate surgical operations. Every part of the paper should be most carefully considered and studied, and every theory and conclusion worked out as exactly as that of a brief to the consideration of a group of judges. Writers and readers of papers before the

Associations often make the fatal mistake, that their experience and personal reputation will carry conviction above all faults of facts and methods of expression. To their admirers this may be true, but every year the circle of sharp critical readers is increasing; critics who are discerning and unsparing in their judgment, and who form clear conceptions on many topics that they are not personally familiar with. Foreign critics complain that American writers are careless in expression, and hasty in conclusions, and fall into the weakness of explaining minutely, what is not understood only in the most general way. This critical readers of *THE JOURNAL* see illustrated in many ways. The remedy for this is more time and study to the papers that are to be presented. Readers should remember that they are addressing a large unknown audience, of both this and the generations to come. If they have anything of value to say, it will be remembered, and be heard far down in the coming century. Medical science is awakening from its long sleep of theory and formalism. It has become aggressive, imperious and exacting, and demands the clearest, best sustained facts above all generalities. Any physician from college centers or lonely country practice, who has new observations and facts of science, is called to contribute them. As a duty they owe to others, such facts should be carefully studied and presented in the briefest possible way compatible with clearness. It should be assumed that the audience understands all the elementary principles bearing on such truths, and that the varied theories held by others pro and con relating to this topic are of little or no interest. The audience of the Association and its Journal have neither the time or space to follow exhaustively any subject of science. Its purpose is to keep its members in sympathy and touch with all advances of science, and stimulate pioneer work, pointing out new lines and avenues into the unknown. The few months to come is little enough time to prepare papers for the next meeting. If our friends and well wishers, and also captions critics, will spend their energies on papers which will be read, *THE JOURNAL* will be raised immeasurably and be less open to fault-finding.

A united effort along this line will soon place *THE JOURNAL* among the great periodicals of the world. This is not extravagance, for the material and the scientific men are here, to lead in the very front ranks of science. The first great want or need, is mobilization and concentration of study and effort, sifting out the facts and presenting them in the most available form, to stimulate and rouse others to correct or confirm them. This *JOURNAL* appeals to all its readers, and to every member who expects to present a paper at the coming meeting, to aid in securing a higher standard in the study and methods of presentation of the facts.

THE NEED OF NATIONAL QUARANTINE.—John S. Billings, surgeon U. S. A., writing from Washington, says:

"In reply I would say, in my opinion a system of national quarantine or maritime sanitary inspection can be organized and enforced in such a manner as to afford greater security to the country and cause less restrictions upon traffic and travel than result from the present State and municipal systems. Such a national system would cost more than the present systems, because it would have larger and better plants and better paid officials, but the cost, being defrayed from the national Treasury, would be much more fairly distributed."

Economy, in the face of cholera even now existent in Hamburg, may be said to occupy a "very secondary place" in the minds of the prudent citizen as well as of the experienced sanitarian.—*Baltimore Medical Journal*.

DOMESTIC CORRESPONDENCE.

Revision of the Code of Ethics.

To the Editor of the JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION:

Dear Sir:—In THE JOURNAL of December 31 1892, "INQUIRER" asks if the writer has read the editorial of the *Medical News* of September 27, 1892.

1. The writer has read carefully the article in question, but its perusal has not convinced him that it would be wise to make any alteration in the Code; on the contrary this editorial would have had the effect of convincing him of the wisdom of leaving the Code intact had he entertained any doubts on that score, for the editor of a journal of the high standing of the *Medical News* is doubtless sure of his facts when he declares the general sense of the profession to be that the Code is an excellent guide for professional conduct, which is the same as saying that the majority of physicians are against any change.

2. The following is precisely the language of a part of the first paragraph of the editorial: "We think the general sense of the profession would answer that while the Code, as it now stands, is an excellent guide for professional conduct, it is wise to subject it to revision for two reasons: 1, it contains much that is unnecessary and useless; and 2, a respectable number of members of the profession demands its revision and is dissatisfied with certain of its provisions." If it is the general sense of the profession that the Code, as it stands, is an excellent guide for professional conduct, surely there is no need of change, for what excels cannot be bettered, and if the Code is excellent it cannot contain anything unnecessary or useless. The Code being an excellent guide for professional conduct, the demand for its alteration does not seem just, and dissatisfaction with any of its provisions is not consistent with the acknowledgment of its excellence. It would therefore be gracious for the minority to abide by the general sense of the profession and allow the Code to stand as it is, for it wrongs no man. The two reasons given in favor of revision do not appear to be valid, unless the language of the editorial has been wrongly interpreted.

3. In THE JOURNAL of December 24, 1892, is a letter by "IOWA," who thinks "it is safe to affirm that nine-tenths of the regular profession heartily agree with the views stated by 'CONSERVATIVE' in his letter to THE JOURNAL of the 10th inst., as to any change in the Code. . . ." The tenor of "IOWA'S" letter indicates that he is well informed on the subject he discusses, and he will doubtless gratify many readers by again giving his views, but more in detail, respecting the inadvisability of making changes in the Code.

4. "INQUIRER" seems to imply that the style of the Code

bears some resemblance to the exuberant manner of some of the writers of the last two centuries, but this is scarcely just, for even the Johnsonian method is less objectionable than the loose style of Cervantes with its tiresome repetition of adjectives and its many other tautologies. Percival, who wrote after the admirable style of Addison, used less adjectives and adverbs, and the committee of 1847 improved upon the style of Percival. But is there any writing in which some literary blemishes may not be detected? Are not all mortals erring in many ways? If this were not the case there would be no necessity for laws of any kind. Whatever may be the blemishes of the Code, all its teachings are so salutary that not a word in any of its phrases should be expunged.

5. "INQUIRER" quotes from four of the writer's reasons for non-revision stated in THE JOURNAL of December 10, 1892, as though he thinks these reasons are stated too generally. Perhaps he is right. Perhaps the writer was wrong in taking it for granted that the readers of THE JOURNAL are all thoroughly well acquainted with the Code in all its details. In any event a brief sketch of the origin, lofty aims, extent and arrangement of the Code may not be out of season.

6. It is well known that the framers of the American Code modeled it upon the "MEDICAL ETHICS" prepared by Dr. Thomas Percival of Manchester, for the guidance of physicians and surgeons, and particularly for a son who was about to enter the profession but who died before the completion of the work. Certain parts of the American Code are especially designed for the information of beginners, while other parts are for the guidance of physicians throughout their professional career, and the remainder for patients and the general public. All these parts are essential to the consistency of the Code in its entirety, and not a part can be altered or expunged without seriously mutilating the document. The committee of 1847, of which Dr. Isaac Hays was chairman, appended a note to their report to the effect that "on examining a great number of codes of ethics adopted by different societies in the United States, it was found that they were all based upon that by Dr. Percival, and that the phrases of this writer were preserved to a considerable extent in all of them. Believing that language so often examined and adopted must possess the greatest of merits . . . clearness and precision . . . the committee . . . have carefully preserved the words of Dr. Percival whenever they convey the precepts it is wished to inculcate." Dr. Percival dedicated his work, published in 1803, to Sir George Baker and to another son who was then a student of medicine, and said, in this dedication, that in the composition of the Code his thoughts had been directed to his deceased son "with the tenderest impulse of paternal love, and not a single moral rule was framed without a secret view to his designation, and an anxious wish that it might influence his future conduct." In this same dedication Dr. Percival says: "The relations in which a physician stands to his patients, to his brethren, and to the public, are complicated and multifarious, involving much knowledge of human nature and extensive moral duties. The study of professional ethics, therefore, cannot fail to invigorate and enlarge your understanding, while the observance of the duties which they enjoin will soften your manners, expand your affections, and form you to that propriety and dignity of conduct which are essential to the character of a gentleman."

7. It is not unlikely that they who now wish to expunge the first chapter of the American Code, will soon change their opinion after reading carefully the able commentaries of the late Dr. Austin Flint upon the Code. This precious little volume, bearing the title of "MEDICAL ETHICS AND

ENIGMATIC," published by the Appletons, of New York, should be diligently studied by every physician in the land, and should also be in the hands of the laity, for it concerns all men. In it every article of the Code is embodied and is eloquently commented upon, and the best reasons are given for its composition. Those who study these commentaries cannot fail to be impressed with the fact that there is no necessity to curtail the Code, that every word it contains is in its proper place, that the language is not redundant, and that the moral principles it inculcates are of the most exalted character.

8. The absence from the Code of high sounding words, of attempts at embellishment, or of what is often called fine writing, is remarkable. The document is characterized by the skilful and judicious use of such parts of speech as exactly convey the desired ideas, by the most precise phraseology, by great lucidity of statement, by the soundest moral principles, and by an excellent arrangement into chapters, articles, sections and subsections. It contains 5,240 words or thereabouts, and can be read in an hour and a half. Percival's code contains about 20,000 words and has not generally been considered too long.

9. The American Code, as shown above, is a short abstract of Percival's code, but the editorial of the *Medical News* of September 17 offers a proportionately shorter abstract of this abstract, but the seventeen sections, containing in all about 889 words, suggested in this editorial, do not constitute a sufficient amplification of the golden maxim, be just—the fundamental principle of the ethics of all the relations of men with their fellows.

10. The writer of the editorial in question may, for a time, have lost sight of the fact that the Code is intended as well for the instruction of beginners in medicine as for the guidance of physicians of experience, for patients, and for the general public. His ground that the public "has nothing to do with acts on the part of physicians that render them amenable to penal law" is not tenable. Laws are framed by individuals, but are never operative until they have the sanction of the public or of those members of the public delegated to examine and enact them. The more the public knows of the Code of medical morals in its various relations, the better it will be for that public and for the profession.

11. The cry of want of conciseness in the Code is as unfounded as are all the other objections. Conciseness in the Code need not consist merely in economy of words, but in clearness and precision of statement, in absolute freedom from ambiguity, and in the fullest and most unmistakable directions without superfluous phrases. All these qualities exist in the Code as it now stands.

12. The *News* editorial says: "The Code need not, and should not, include exhortations and maxims that go without saying." If all men were just these exhortations would be unnecessary. Be just, should "go without saying," but it does not. Men are unjust often from mere thoughtlessness, and need reminding to be just and sometimes how to be just. Hence the Code, which is a commentary upon the maxims that "go without saying." No "clear-cut" set of dry short rules will answer. The perusal of the Code as it now stands gives pleasure as well as instruction, because the document is an attractive literary production of high order.

13. The American Code is an excellent amplification of the golden maxim, and is so well arranged as to be time-saving while it gives the fullest information to the different classes for which it was framed, and tells young physicians under what circumstances they may fail to be just to themselves and to others.

14. When the revision committee examine the Code critically in reference to its adaptation to the several classes of

persons for which it is intended, they may not find in it superfluous articles or redundant language.

A CONSERVATIVE MEMBER.

The Regulation of Quacks by Local Legislation.

MANSFIELD, O.

To the Editor of the JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION:

Sir:—Since the announcement of the passage of the ordinance in this city entitled "The Registering of Physicians, Midwives and Pharmacists," I have been flooded with letters from all parts of the country asking for a copy of the ordinance which I have been unable to supply, and consequently take this method of reaching the profession at the earliest possible moment with a copy of the ordinance, which is as follows:

Registering of Physicians, Midwives and Pharmacists, in the City of Mansfield, O.—It shall be the duty of every physician, midwife and pharmacist practicing in the City of Mansfield, Ohio, to register in a suitable book prepared therefor by the Health Officer; which register shall contain the name, the street address, the college at which said physician, midwife and pharmacist graduated, and date of said graduation; and further, that on and after the adoption of this ordinance, no person shall be permitted to practice the art of medicine, surgery, midwifery, pharmacy or dentistry, or sell medicine or drugs from house to house, or on the streets, without registering with the Health Officer, and furnishing him, when so required, a sample bottle of the medicine to be sold for analysis; and displaying to him their certificate from the State Board of Pharmacy in the case of druggists, or their diploma of graduation from a recognized chartered medical or dental school in the case of a physician, surgeon, midwife or dentist.

And that such person shall not be eligible to receive a license from any city officer, until he has displayed the above mentioned documents or drugs, as the case may be, to the Health Officer, and received a certificate from him to the proper city officer, who shall then have the privilege of issuing the said person the necessary license, which shall not be for less than \$10 or more than \$50 a day.

And further, that any person violating this ordinance shall be subject to a fine of not less than \$50 or more than \$100 for each offense.

In the selling of drugs, this ordinance is not intended to apply to regularly recognized traveling salesmen who deal directly with the physicians or druggists of the city.

Attested: F. M. REAMY,

JOHN V. VANNATA,

City Clerk.

Pres. City Council.

To the Editor of the JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION:

I regret exceedingly that your printers changed two letters in the title to my little article in the last issue of THE JOURNAL, making "A Study of the Acquirements of the Average Prospective Medical Student," into "A Study of the Requirements, etc." You will readily see that this makes the title absurd. I am, very respectfully,

BAYARD HOLMES, Sec'y.

Chicago, January 7, 1893.

SELECTIONS.

HEMOLYSIS—In the exhaustive and erudite study of the process of blood destruction or hæmolysis, which was chosen by Dr. Wm. Hunter for his recent lectures in connection with the Grocers' Company Research Scholarship, the proposition that the blood acts in its physiological and pathological relations similarly to other tissues is one which will at the present day be accepted without demur; but, although there is no doubt of the waste and renewal of all tissues and cells, the blood is singularly adapted for observing the method of such changes owing to the special colored element that it contains. It was then mainly an exposition of the destiny of hemoglobin that the lecturer made, and

the facts and arguments which he adduced from observation of normal changes on the one hand, and of abnormal—whether induced experimentally or as the result of morbid action—on the other, were both numerous and sufficient. It would hardly be fair to Dr. Hunter to attempt a critical survey of the elaborate details of his work. He was dealing, as he said, with a comparatively novel subject, and no criticism could rightly be passed by any one who had not traversed the same ground. It may, however, be permitted to indicate a few of the salient points which are to be gathered from his exposition. In the first place, the derivation of bile-pigment from hæmoglobin is unquestioned, and it is to be noted that this conversion is not entirely limited to the liver cells, whither the products of effete red corpuscles are conveyed by leucocytes. For leucocytes and connective tissue cells can also produce pigments identical with bilirubin and biliverdin from hæmoglobin, although in the main the conversion is effected in the liver. The red corpuscles may, however, part with their hæmoglobin under the influence of changes created in the blood plasma, and the coloring matter thus set free may come to be deposited in the spleen, liver and bone marrow. That the portal area of the circulation is the region where this liberation of blood pigment (active hemolysis) mainly takes place is a view which was, we believe, originally propounded by Dr. Hunter, who has still further elaborated it. He shows that this hæmolysis may occur in health, during digestion, in the spleen and gastro-intestinal capillaries; that it may be effected, in the same area, by the action of toluylendiamine; and that it probably occurs here in pernicious anæmia and malignant jaundice. The resulting free blood pigment is deposited to a large extent in the liver and to a lesser degree in the spleen, and even in the kidney—as evidenced by micro-chemical examination. The subject embraces, however, many other questions than these which we have indicated; and we only regret that Dr. Hunter had no opportunity to gather up the fruits of his labors in a few general propositions.—*The Lancet*.

FILTERED OR BOILED WATER?—M. A. J. Martin, under this title, presents a very carefully studied paper. Recognizing the fact that many filters, so far from separating the bacteria, may even make the water richer in these organisms, this method cannot be recommended. Boiled water has lost its carbonic acid gas, and the salts of lime and magnesia are precipitated; the taste is flat, although on standing in a cool place it reabsorbs the greater portion of the lost gas. Even boiled water ought not to be long preserved. The problem apparently was solved in heating the water without loss of air, cooling it mechanically, and adding oxygen by means of an air-pump; or it can be boiled in closed bottles. Various ingenious apparatus have been devised for boiling water in closed vessels under pressure, and cooling it in the same apparatus. Investigations have shown that the slight differences observed in the chemical composition of the water before and after sterilization have not altered its potability. With a filter, one can drink only the water of which he knows the source; with boiling, one can use any water. Boiling, then, should be the procedure of choice as soon as any suspicion arises, it should be the rule, especially in large cities, during the progress of any epidemic.—*Gazette Hebdomadaire de Médecine et de Chirurgie*, 1892, No. 37, p. 433 (*American Journal of the Medical Sciences*.)

CONDITION OF THE BLOOD IN GASTRIC AFFECTIONS.—A considerable amount of uncertainty has hitherto existed in reference to the condition of the blood in connection with gastric affections, especially in ulcer and malignant disease of the stomach, and authors differ greatly in their state-

ments on the subject. Orterspey *Berlin Klin. Wochenschr.* etc. has made some careful experiments in order to clear up these doubts, and the following are the results he has obtained: In nine cases of ulcer of the stomach the results were very uniform—diminution in the amount of hæmoglobin and in the number of red blood corpuscles, these changes being particularly marked in those patients who had had hæmatemesis. These results of course correspond with the anæmic state so constantly met with in connection with this disease, and all previous investigators have found the same condition. Out of twelve cases of cancer of the stomach, in one the blood was perfectly normal, in eight the number of red discs was diminished, in eleven there was a diminution in the amount of hæmoglobin present, in five there was an increase in the number of leucocytes, whilst in two, although the hæmoglobin was diminished, the red corpuscles were about normal in number. All these changes are neither characteristic of the cancerous cachexia generally nor of cancer of the stomach in particular, as they also occur to a similar degree in the course of many other affections. There is therefore no diagnostic difference in the blood to be noted in the two diseases, ulcer and carcinoma of the stomach. There is, perhaps, more value in the examination of the blood in doubtful cases, when there is uncertainty as to the case being one of malignant disease or chronic catarrh or a neurosis of the stomach, as the last two sometimes lead in extreme cases to the absence of hydrochloric acid in the gastric juice.—*The Lancet*.

BOOK REVIEWS.

INTERNATIONAL CLINICS: A QUARTERLY OF CLINICAL LECTURES ON MEDICINE, NEUROLOGY, PEDIATRICS, SURGERY, GENITO-URINARY SURGERY, GYNECOLOGY, OPHTHALMOLOGY, LARYNGOLOGY, OTOTOLOGY, AND DERMATOLOGY. By Professors and Lecturers in the Leading Medical Colleges of the United States, Great Britain, and Canada: Edited by JOHN M. KEATING, M.D., Colorado Springs, Col., Fellow of the College of Physicians, Philadelphia, etc.; JUDSON DALAND, M.D., Philadelphia, Instructor in Clinical Medicine, and Lecturer on Physical Diagnosis and Symptomatology in the University of Pennsylvania, etc.; J. MITCHELL BRUN, M.D., F. R. C.P., London, England, Physician and Lecturer on Therapeutics at the Charing Cross Hospital, D. W. FINLAY, M.D., F. R. C.P., Aberdeen, Scotland, Professor of Practice of Medicine in the University of Aberdeen, etc. Vol. 1, Second Series, 1892. Philadelphia. J. B. Lippincott & Co.

This is a cloth bound book of 363 pages containing clinical lectures by 38 teachers and embracing 56 subjects. The number of authors to each country represented is as follows: United States 27, England 6, Canada 2, Scotland, Ireland and France, 1 each. The three leading cities of our own country furnish the following distribution of writers: Philadelphia, 8, New York 6, Chicago 2, nearly one-half of the whole number of contributors. The subject of general medicine occupies 192 pages, surgery, 60, neurology, 50, genito-urinary and venereal surgery 38, gynecology and obstetrics 37, pediatrics 20, ophthalmology and dermatology each 10, laryngology 9, otology 0. There are seven well executed plates and 33 figures or cuts. The table of contents could be improved by grouping the lectures under appropriate headings corresponding to the sections in which they are found. There is a very complete index.

The first 22 pages are filled by an exceedingly instructive lecture by Dr. J. M. Da Costa, on the pulmonary complications of influenza. The epidemics of this disease have been so flippantly treated by the people, the public press and even by the profession, in many instances, that it is a source of satisfaction to have the subject presented by an able

authority and with the dignity and thoroughness that its importance demands. The histories of six cases are detailed together with the results of quite extensive variations in treatment.

Dr. Arthur Wynne Foot, of Dublin, fills 18 pages with a lecture on Graves' disease. He endorses Sattler's theory that the starting point is in the medulla oblongata, near the origin of the vagus. Exactly one page, out of the 18, is devoted to the general subject of treatment. The practitioner who looks for any advancement, or even anything encouraging, in the management of this affection will be disappointed. It is to be hoped that such antiquated terms as Graves' and Basedow's disease, which have no medical significance in themselves, will soon give place to names of inherent scientific meaning, like ophthalmic goitre, that suggests two of the three prominent symptoms.

There is a short talk by Dr. P. Blaikie Smith, of the Aberdeen Royal Infirmary, on acute intestinal obstruction and peritonitis the result of enteric fever (?). In its ultra-conservatism it presents striking contrasts to the advanced teachings of the American leaders in abdominal surgery, of whom Dr. Senn is a strong type.

Dr. Wm. Henry Porter has entered on a series of lectures on syphilis. The first one is deeply interesting and full of promise.

The paper on ocular symptoms in Bright's disease by Dr. Thos. R. Pooley is one of the greatest practical value to every general practitioner.

Dr. Ohmann-Dumesnil, of St. Louis, contributes one of the most helpful articles in the series, on herpes zoster.

Six pages are devoted to general paresis, by Dr. B. Sachs, of New York. The differential diagnosis of this disease from paranoia and multiple cerebro-spinal syphilis is given. It is to be regretted that this entertaining writer stopped short of a consideration of the management of this disease.

Another excellent article that deserves mention is from the pen of Dr. R. Marcas Gunn, of London, on eye diseases in children. It is misplaced in the section on pediatrics, although there is no essential difference between ocular affections in children and the same disease in adults.

The book is the production of such a large number of authors, and comprises such a varied list of subjects that it is not practicable to give a comprehensive idea of its contents within the reasonable limits of a journal review.

It is sufficient to say that such names as Ashurst, Casselberry, Charcot, Goodell, Loffert, Mundé and Parkes are a guarantee of the worth of the work.

THE CHEMICAL BASIS OF THE ANIMAL BODY. AN APPENDIX TO FOSTER'S TEXT-BOOK OF PHYSIOLOGY. (Sixth Edition.) By A. SHERIDAN LEA, M.A., D. Sc., F. R. S., University Lecturer in Physiology in the University of Cambridge; Fellow of Caius College, Cambridge. New York: MacMillan & Co. 1893. (All rights reserved). Pages 288. Price \$1.75.

This appendix, written upon the same lines as those found in the former editions of Foster's well known book of physiology, has been so enlarged that it now in reality constitutes a distinct treatise on the chemical substances occurring in the animal body; the volume is consequently paged separately from the rest of the text-book and it has an index of its own and it may be regarded as an independent work entirely. The chemical features of the more important of the various substances that occur in the body are briefly considered, such characters only being described as possess physiological interest. The chemistry of the several proteids is first taken up and then follows a section on the enzymes or soluble ferments, the more important of which, such as ptyalin, the amylolytic enzyme of the pancreas, pepsin, fibrin ferment, urea ferment and others are

given a special description. The carbohydrates, fats, the various saline, crystalline and pigment substances found in the tissues, the excretions and secretions of the body are all described from the standpoint of physiological chemistry; as a rule brief but succinct statement is made regarding the practical uses made of many of these substance as, for instance, the preparation of hamin crystals from minute quantities of hæmoglobin and methæmoglobin for medico-legal purposes. Extensive references are given throughout the book in the shape of foot-notes; the references to recent work appear exhaustive and complete; at the end of the volume is a list of authorities quoted which, arranged in double columns, occupies nearly eight pages. The publisher's work is well done; there are forty-one black and white figures illustrating the various crystals and the spectra of hæmoglobin and its derivatives or combinations. The statement can safely be made that this work on the chemistry of the animal body by Dr. Lea forms an in every way worthy appendix to Foster's standard book; at the same time it may be regarded as independent work of equal merit.

REPORT OF THE SURGEON-GENERAL OF THE ARMY TO THE SECRETARY OF WAR FOR THE FISCAL YEAR ENDING JUNE 30, 1892. Washington: Government Printing Office, 1892.

This report of 126 pages contains the usual amount of statistical material as well as the necessary financial statements. It is interesting to note that the library of the Surgeon-General's office now contains 166 006 publications of all kinds, of which 13 781 were added during the year. Of 77 candidates for medical officers invited to appear before various examining boards only 13 were found qualified to enter the service; there are now eleven vacancies in the medical department. The medical department of the National Guard has received considerable attention from the Surgeon-General's office with the wise view to secure its effective coöperation in time of war. At the end of the report are eleven excellent photographs illustrative of the field equipment now in vogue in the U. S. Army Medical Department.

MISCELLANY.

WANTED.—No. 2, Vol. XIX, of THE JOURNAL.

MASSACHUSETTS has a record as a sterile State. One-fifth of the married women are childless. In Suffolk county the percentage is one-fourth. So says the last census.

OFFICIAL LIST OF CHANGES in the Stations and Duties of Officers Serving in the Medical Department, U. S. Army, from December 31, 1892, to January 6, 1893.

First Lieut. Isaac P. Ware, Asst. Surgeon U. S. A., is assigned to duty at Ft. Sill, Oklahoma Ter., until further orders.

Capt. Adrian S. Polhemus, Asst. Surgeon U. S. A., leave of absence granted for two weeks, on surgeon's certificate of disability, is hereby extended fourteen days from December 30, 1892, on surgeon's certificate of disability.

First Lieut. Frank T. Meriwether, Asst. Surgeon, is relieved from further duty at Ft. Adams, R. I., and assigned to duty at Madison Bks., New York.

PROMOTIONS.

Lieut.-Col. Charles H. Alden, Deputy Surgeon-General U. S. A., to be Asst. Surgeon-General with the rank of Colonel, December 4, 1892, vice Heger, retired.

Major Albert Hartsuff, Surgeon, to be Deputy Surgeon-General with rank of Lieut.-Col., December 4, 1892, vice Alden, promoted.

Capt. Louis M. Maus, Asst. Surgeon, to be Surgeon with the rank of Major, December 4, 1892, vice Hartsuff, promoted.

No. 3.

ORIGINAL ARTICLES.

A UNIVERSAL MENTO-DENTAL SPLINT, WITH REPORT OF CASE.

Read in the Section of Dental and Oral Surgery, at the Forty-third Annual Meeting of the American Medical Association, held at Detroit, Mich., June, 1892.

BY M. H. FLETCHER, M.D., D.D.S.,
OF CINCINNATI, O.

Before showing the splint and reporting the case in question, it may be well to review in some degree splints and bandages for broken lower jaws, and in particular mento-dental splints.

Heath divides appliances for the jaw into two classes, external and internal to the mouth, though he says "it may be necessary to combine the two methods in a few cases."

The simplest and most effective form of external apparatus, and by far the best in a very large majority of cases, is the four-tailed bandage, two of the tails being carried over and tied on top of the head, the other two carried back and tied around the nape of the neck, the part covering the chin oft-times

Fig. 1.

being reinforced by pasteboard or sheets of gutta-percha. This method with its variations is no doubt familiar to you all, and when the fracture is simple with no displacement is undoubtedly the best, since it brings the lower teeth in perfect occlusion with their antagonists and holds them in their proper places, as well as puts the fractured ends of the bone in direct apposition, so that when the fracture is healed the jaw is in every way in its proper and normal condition, both for use and appearance. The great objection to this form of apparatus, also in inter-dental splints, is that the patient must be fed on liquid foods. Gross says, "I have known great emaciation to arise from inability of the patient to take appropriate nourishment during the long confinement of the parts." All inter-dental splints, also wires and ligatures, are usually accompanied by external bandages to hold the lower jaw against the splint and against the upper teeth, so that the ina-

bility to take proper nourishment enters largely into the objection to these forms. Dr. E. H. Angle's method is a most excellent one. It consists of buttons or short pipes soldered to bands which are fitted to the appropriate teeth and these bands are tied, wired, or fastened together with rods thrust through the short pipes on the bands and held at one end with a hook on the rod and a nut screwed on to the other end.

This method has the very great objection of complication, for one is certainly safe in saying that hardly any surgeon and very few dentists are prepared to or can fit a band to a tooth firmly enough to withstand much strain, even after long experience. The writer has used Angle's apparatus in a number of cases of regulating, and to fit them firmly to the

Fig. 2.

teeth in the case of a fractured and inflamed jaw would certainly be difficult.

Mento-dental splints or appliances made to grasp the lower jaw, are not new. They are made with one part fitting the crowns of the teeth, the other part the chin and lower border of the jaw.

In 1799 Rutenich, a German surgeon, used such an appliance. Bush in 1822, Houzelot in 1826, Lonsdale in 1867, Hill in 1866, and Moon at a later date. These all used mento-dental splints and all with reasonably good results. These splints have the great advantage of allowing the patient to take nourishment of any kind demanded. They also have the disadvantage of becoming foul after being worn awhile.

Heath remarks: "The great difficulty in using all forms of rigid splints to the jaw is the tendency of the support for the chin to produce abscesses and

ulceration by the pressure upon the sharp border of the bone." These splints do not seem practicable used back of the second molar, but certainly work well with fractures anterior to that point.

Our own experience coincides with what Heath says, for in the case to be reported abscesses made their appearance and the splint was obliged to be removed much earlier than desired on that account. The case resulted reasonably well however, as the model will show, but we have a form of a chin support to present which is designed to do away with the objection spoken of, by using a canvas instead

Fig. 3.

of a metal support for the chin. (See Figs. 1 and 2.) The case we have to report is as follows:

Mr. B. H., age 36, on the 23d of last December was attacked by three highwaymen for purposes of robbery, but being a good fighter he laid out the three robbers and proceeded to his home. After having somewhat subsided from the excitement of the melee he felt a pain in the lower jaw. The next morning he proceeded to a surgeon and found that his jaw was fractured, one of the men having struck him a heavy blow on the chin with his fist. There being no displacement the jaw was dressed in the usual way with a four-tailed bandage and in three weeks he was back to his work again. Mr. H. is a wood-worker in a carriage factory.

On the 15th of January, twenty-six days after the first accident and three days after he had gone to work, Mr. H. with five other workmen was called to test a

Fig. 4.

new fire ladder, and being the first to mount he was at the top, about thirty feet from the ground, when the ladder broke, and falling, he struck the pavement with terrific force, breaking both arms below the elbow and crushing the jaw in a frightful manner, breaking it through the old fracture. The nearest surgeon was called, who dressed the wounds and sent the men to their respective homes. Mr. H.'s jaw was dressed in the usual manner with a four-tailed bandage. Ten days after, finding the jaw was not doing well and that the fracture had not been reduced, the writer was sent for by the attending surgeons to see what could be done with some different kind of apparatus. After examination it was found that the jaws were so closely set together that it seemed impracticable to take an impression for the

purpose of making a plaster model with the idea of breaking and resetting it in normal position for the purpose of making an inter-dental splint, as suggested by Heath and others. So we conceived the idea of making a mento-dental splint of two block-tin impression trays such as every dentist has at hand. This splint was worn for five weeks but had to be removed on account of two abscesses forming, one on either side of the chin, where the chin support pressed hardest on the soft tissues. The fracture was comminuted and compounded on the inside under the left bicusps, the point of the right half and some of the bone being through the flesh at that place. The left lateral and the right alveolar process, which had surrounded it, was taken away with the fingers from the front side, and afterwards some smaller pieces of bone were removed from the wound in the same

Fig. 5.

place. There was about one quarter of an inch of the bone lost and the left central now stands adjoining the left cuspid. (See Fig. 3.) The remaining incisors were all loose.

Twelve days after the accident, the splint being ready, such plastic adhesions as had formed were broken up, the left lateral and loose pieces of bone removed as stated, the two halves of the bone were reduced and ligated as nearly to their normal position as possible, and while being held firmly in this position by an assistant the impression tray used on top of the lower teeth was filled with plaster of Paris, which had been mixed with a one grain to the ounce solution of bichloride of mercury (for antiseptic purposes), the splint (see Fig. 4) was applied and the parts held firmly in this position with the hands until the plaster had time to set, the screw of the splint being tightened at the same time, and tightened from time to time as necessary.

The fracture was obliquely across the chin from the neck of the left cuspid across the symphysis to a point below the right cuspid, as shown in the plaster model. The result is to be seen in another model made after the fracture had healed. (See Fig. 5.)

[Fig. 1 represents the ideal universal splint, the chin-support being made of a fork of stiff wire, across which is stretched heavy canvas, the margin of canvas being allowed to stand up long enough to pin or sew the head and neck bandages to, thereby gaining the advantage of a four-tailed bandage in addition to the mento-dental feature of the splint. In the early stages of the case the tails can be kept tied, excepting at the times of feeding, or left off altogether, as the case may require. Additional trays of different sizes may be made to suit the case; they are inserted into the splint by removing the screw, and withdrawing from the slot the one in place and inserting the one desired. The size and shape are further modified by bending the cup (which is made of block tin) to any shape desired. The part of the splint coming down and fitting on the crowns of the lower teeth is designed to be filled (when applied) with plaster of Paris, softened gutta-percha, or other material suitable for holding the teeth firmly in position. This splint is designed to be made and kept on sale with other surgical supplies, one outfit being sufficient for all cases where it may in any way be demanded.

Fig. 2 represents the splint in position. The splint represented in Fig. 1 would not need the cotton packing, and can have the four tails attached or detached at pleasure.

Fig. 3 represents a plaster model of the jaw-bone, as near like the jaw when found as could be constructed; the projecting left lateral incisor and the amount of bone, as represented by the line, were lost.

Fig. 4 represents the splint used in the case, which is constructed out of the ordinary block-tin impression trays, the fittings being made of brass plates and wire soldered together with soft solder; the screw is an ordinary stove or carriage bolt, made to cut its own thread in the soft solder

which has run in the hole in the lower part of the apparatus, and is to be tightened or loosened with an ordinary screw-driver. The chin-support was packed with cotton wool.

Fig. 5 represents the case after recovery.]

June 1, 1892.

Discussion.

Dr. John S. Marshall said he was interested in the splint, and that while it served its purpose admirably, he thought the better way to treat fractures of the inferior maxilla was to wire the parts firmly together with a silver wire, as the mouth is so much easier to keep clean than when a splint is worn. In such cases he dissects down the tissues till the edges of the bone are reached, the tissues and the periosteum being laid back. A drill is then passed through near the end of the bone, care being taken to avoid the roots of the teeth and the inferior dental canal. A silver wire is then passed through the holes in the ends of the bone, and the parts brought together. Two or more such sutures are made, and secured until the fractured parts are immovable. He has treated many such cases in this way without any bandages. No after-treatment is required except frequent washings with an antiseptic mouth-wash, for which he prefers Thiersch's solution, as follows:

Boracic acid, 12 parts;
Salicylic acid, 4 parts;
Water, 1000 parts.

This is a good antiseptic: is not dangerous, nor unpleasant to the taste, only a little bitter.

He related the cases reported on pages 575-6 of the *Dental Cosmos* for 1892, and in reply to a question said it was usually necessary to leave the wires in place from four to eight weeks, the time depending upon circumstances. In nearly all cases suppuration will take place and retard the knitting of the bone.

Dr. Curtis said the results of the case reported by Dr. Fletcher are exceptionally good, and the splint is very well adapted to the class of injuries it was designed for. He thought in hospital cases the plaster bandage was perhaps as good as anything,—that is, where there are teeth in both sets; but before it was applied several layers of cotton should be placed under the chin whenever the bandage will come in contact, to lessen the liability of abscesses forming.

Dr. Marshall said that the evidence of all surgeons to whom he had talked upon the subject was that a splint of this character was always a failure where there was any displacement, and that the system of wiring was always used.

Dr. Allport said that he agreed with Dr. Marshall that wiring was better than any splint. He believed that he himself was the first man who used wire for this purpose. It was about thirty years ago, and he got good results. He related the case of a lady who fell from a step and broke each jaw in four pieces. He wired all the pieces in place, and the bones united perfectly, and the result was in every way satisfactory. He thought that oral surgeons were better able to handle such cases than the general surgeon.

Dr. Barrett reported a case of a boy who was run over by a heavy wagon in such a way as to crumble the lower jaw frightfully. He was brought to the city and put in the hands of a competent and skillful surgeon, who wired the pieces together by wire around the teeth. When the mouth was open the parts were kept in proper position, but when shut the jaw went away around to one side. Dr. Barrett, being called in consultation, found four physicians there, all of whom confessed that the injury was beyond their skill to repair, hence they had called him in as a specialist in these things. The boy had been under an anesthetic for most of the time for four hours.

Reasoning by exclusion, as there was no crepitation and no fixation, he concluded that there was no luxation, and no complete fractures that were not securely wired, and that there was only one possible cause for the condition: an incomplete or "green stick" fracture across the angle of the ramus. With the muscles relaxed the jaws fell directly down, but when the boy attempted to close his mouth the temporal and internal pterygoid, with some of the fibres of the masseter, not being counteracted on the other side, drew the jaw to one side, it bending or yielding at the point of the incomplete fracture.

The boy was taken to Dr. Barrett's office, and gutta-percha impressions taken of both jaws. The impressions were trimmed to the proper shape, and a notch cut in front

for feeding through, and the boy having been again anesthetized, the occluding surfaces of the gutta-percha impressions that were to serve as splints were warmed until they were adhesive, and placed upon the teeth; then by main force the jaw was carried to its proper place, the two gutta-percha splints stuck together, and the whole was fastened with a two-tailed bandage. The operation was a perfect success.

Dr. Fletcher said that though wiring was undoubtedly to be preferred in many cases, it was not admissible in such as he described, because in his case at least a quarter of an inch of the bone was lost by comminution, and to wire the bone together would make proper occlusion of the teeth impossible.

DISEASES OF THE GUMS.

Read in the section of Oral and Dental Surgery, at the Forty-third Annual Meeting of the American Medical Association, held at Detroit, Mich., June, 1892.

BY JOHN L. GISH, M.D., D.D.S.,
OF JACKSON, MICH.

It is not my purpose to try and cover the whole field of pathological conditions that would naturally come under the above heading, but simply take up such parts as are more common in our general work.

So far as the anatomy, histology and normal conditions of the gums are concerned, I will pass over that division, and not consume time by repeating that which we must know, in order to fully appreciate any abnormal conditions or changes that may take place in the gums.

When you deal with pathological conditions, let them exist wherever they may, in our body, we at once encounter the problems of growth and development, nutrition and assimilation. So here, when we find diseased conditions of the gums, we know that the laws that govern the process of growth and development, and the functions of nutrition and assimilation, have been changed to a greater or less extent, with the corresponding resultant of active or passive congestion, hypertrophied or atrophied conditions or increased cell growth of the tissues involved.

When we take up active or passive congestions or the acute and chronic inflammations of the gums we consider the type of cases that come to our notice more often, and cause more trouble to our patients, than is made manifest by the hypertrophied, atrophied and cell growth conditions combined. Under the section of acute inflammation of the gums, we have to contend with the acute or inflammatory œdema, marked by its rapidity of development, severe pain, tumefaction and great tension of the tissues, due to some chemical or traumatic lesion, and closely connected to this pathological condition, we do encounter gangrene of the mouth (or noma), which is less rapid in its development and attended with a less degree of pain, but far more destructive in its results, and much more obstinate in yielding to treatment. Under this division we may also include the acute catarrhal, herpetic and croupous inflammations.

Under division second, or passive congestions where the circulation is slowed in its course, affording an opportunity for the red blood corpuscles to accumulate in the arteries, and the white blood corpuscles to find their way into the veins, whose anatomical structure, viz.: their thin walls, affords an easy escape of the white blood corpuscles, by their amoeboid movements, into the surrounding structures, and at the same time with the passage of the white blood corpuscles, or leucocytes, there is also

the transudation of the liquor sanguinis, forming the serous effusion, which together with the leucocytes, dividing and multiplying, excite the tissues into cell-proliferation. This in turn causes a greater nutritive activity with the formation of a cell growth, which is very unstable in its composition and soon passes into retrogression, or the breaking down stage, with the formation of pus, which dissolves alike the alveolar process, the dental organs and the soft structure, thus completely destroying the involved tissues and ending a cycle of changes, only again to be renewed, and cause further destruction of the parts by continuity and contiguity, as is done in chronic catarrhal inflammations, phlegmonous and suppurative inflammations or abscesses, and fistulae of the gums.

Under division three we will include hypertrophied and atrophied conditions, and under division four such cell growths as the fibrous, papillary, and vascular tumors and epitheliomata of the gums.

Division four including as it does, the variety of cases that come to our notice the least, have pathological conditions in common, varying only in the elements involved, and I cannot do as well in giving their pathology, as I can to repeat the words of Wedl, who regards papillomata of the gums as essentially localized hypertrophies of the papillary portion; generally associated with caries and located upon the facial surface of the gum; their diminutive conical elevations form dome-shaped enlargements and present an analogy with acuminate condylomata.

Fibromata of the gum occur in the submucous connective tissue in the form of projecting, superficially smooth, compact tubercles, which slope away towards the surrounding tissues: they are by no means of rare occurrence, especially those of smaller dimensions, and are composed of firm bundles of connective tissue with numerous interlacements, and imbedded cells. Linhart extirpated a fibroma of the submucous connective tissue nearly as large as a hen's egg.

Angiomata (vascular tumors) are of rare occurrence, and some give rise to hæmorrhage which endangers life. Salter reported a new-formation of this kind which was composed of numerous convoluted blood-vessels and connective tissue. The surface of the tumor, which was lobulated, located upon the neck of a tooth and as large as the berry of the common winter cherry, was covered with papillæ like those of the gum and with epithelium. The latter condition serves to indicate that the new-formation was seated in the submucous connective tissue of the gum and not, as alleged, in the dental periosteum.

Epithelial cancer sometimes occurs primarily in the gum and knotty elevations are developed, which increase in number and extent and spread to the submucous connective tissue, dental periosteum, alveolus and alveolar process. The epithelium undergoes notable proliferation and imparts a brighter color to the knots; it also dips down to a considerable depth into the substance, where the familiar rosette-shaped, nest-like groups of flattened, often distinctly ribbed cells are met with. Sometimes the papillæ of the gum also grow considerably in length and breadth, and the cancer acquires the appearance of a succulent wart which finally ulcerates. Schuh observed the origin of the epithelial cancer upon the buccal surface, usually in the vicinity of the last molars. Here also, he says, it maintains for a time the char-

acter of the broad cancer; that is, of a form of cancer which increases only in its extent of surface, not in depth, remains superficial, therefore, resembling a granulating surface, and slowly destroys the organic parts.

The hypertrophied and atrophied conditions, or division three of this paper, are more often met with than the conditions under division four, and of the two types of conditions under division three, the hypertrophied is far more common.

Atrophy, as the name implies, is a progressive and morbid diminution of the bulk of tissues of which the gum is composed. Atrophy is generally symptomatic, but it may be due to a local cause. Now inasmuch as atrophy from a pathological standpoint is just the reverse of hypertrophy, it will not be necessary to review its general pathology in order to state the changes that take place, but the general pathology of hypertrophy of the gums as given by Wedl, will serve the double purpose; hence, hypertrophy of the gums occurs frequently among the sequela of a chronic inflammatory condition of the root membrane following caries of the teeth, and is induced, also, by the irritation of the gums produced by the products of the degeneration of the hard tissues of the teeth.

The sharp edges of the stumps, too, which remain after the destruction of the coronal portions and necks of the teeth, become the sources of irritations.

The hypertrophy occurs both in the papillary portion and beneath the latter, in the corium of the mucous membrane. When it occurs in the former, it is most conspicuous upon the facial surface of the gums and is confined to the region of one tooth or a few teeth, or acquires more extended limits in cases of caries involving the crowns or roots of several teeth.

The epithelium, also, participates in the hypertrophy which affects the papillary portion.

The secretion of mucous usually is increased in connection with papillary hypertrophy, and partial exfoliations of the epithelium occur, leaving superficial erosions. Bleeding readily occurs from the painless swellings, even from slight mechanical irritations. Sometimes the papillary portion is not involved and the proliferation is confined to the corium, occasioning a swelling of the gum, which has a smooth exterior. In these cases, which are more protracted, the cellular infiltrations rise to a tendinous connective tissue; in other words, the hypertrophic gum becomes sclerosed, and, consequently, it presents an increased power of resistance and a diminished succulency. The gradually obliterated papillary portion is covered by a common, thick, superficially smooth layer of epithelium. Notwithstanding the increased consistence of the corium, cellular-infiltrates are met with in the form of long chain-like rows or clusters, of ovoid cells, which are enclosed with a capsule of fibrous tissue. Since the periosteum, also, beneath the indurated gum is thickened, it is by no means strange that cross sections of the latter sometimes present slender trabeculae in the process of growth, together with young bone-corpuscles," while the above has given us the general pathology of hypertrophic conditions of the gums, there is yet another subdivision of this type of cases, that does come to our notice quite frequently and I mean the hypertrophied conditions of the tissues that often times surrounds, or accom-

panies the eruptions of the wisdom tooth. It is true that in this particular type of cases, we have a greater degree of pain, more swelling, and inflammatory action extending to the surrounding tissues, than is the case in true hypertrophy of the gums, but the difference in the exciting cause, will explain the difference in symptomatic results.

In true hypertrophy, usually the result of some chronic inflammation of a root membrane, or the irritation of the gums produced by the products of the degeneration of the hard tissues of the teeth, we have the train of symptoms or conditions as above given; but in this particular type of cases caused by undue pressure on the surrounding tissues, and still further augmented by the close relations of the parts, and the mechanical action of mastication we account for the difference in subjective symptoms.

In chronic catarrhal inflammation, included under division second, or passive congestions we find the mucous membrane thickened and of a rose color with white spots which appear and disappear with the exfoliation of the epithelium. The patient complains of unpleasant sensations such as burning, itching and tickling, and as a result of this congestion there is a grey mucilaginous, and at times a puriform secretion poured out upon the surface of the gums. Of course the degree of this inflammation is modified to a greater or less extent, according to the time that the lesion is allowed to run, and as to whether the patient is suffering from other systemic troubles, or from catarrhal inflammations of surrounding membranes.

Phlegmonous inflammation, is somewhat sudden in its onset, but is attended with but little or no fever. The congestion is confined to both the corium and submucous connective tissue, with ulcerations occurring in small, shallow, yellowish spots or in the form of one large phagedenic ulcer. If this ulceration is allowed to continue, we will have necrosis of the osseous substance, beneath. Recovery is very slow and the surrounding membrane is spongy, from infiltration of the liquor sanguinis, very sensitive and bleeds easily. This type of cases is common, and is found in the well nourished, as well as in those who have systemic complications.

Suppurative inflammation, is where the lesion has been such, as to cause the passive congestion to result in the formation of pus, this pus may find its way to an external opening, or it may undergo, resorption. If the exciting cause has been mechanical such as compression, contusion, or laceration, the recovery is speedy with suppuration, but if on the other hand the exciting cause is a diseased root membrane of a chronic character, and the irritant becomes extended to the gum a fistula is formed, which will continue to discharge its secretion, until the parts are made healthy within.

Again referring to division one, under which we consider inflammatory œdema, acute catarrhal, herpetic and croupous inflammations, there is in common the rapidity of onset, severe pain, tumefaction and sponginess of gums, attended with the unpleasant sensation of itching and burning, in addition to this, the herpetic inflammation is characterized by the formation of vesicles, which rupture and remain a superficial erosion healing without cicatrization; closely allied to the herpetic condition is the inflammatory affection of the gums, developed during the course of an acute exanthemata, such as scarlet fever, measles etc.

The croupous inflammation, not only has the subjective symptoms that attend all active congestions, but it is characterized by the greyish structureless membraniform exudation, which may be very easily detached. This exudation takes place very rapidly and as rapidly undergoes degeneration with the production of an offensive, sanious mass, which dips down between the gum and the tooth thus exciting the root membrane into an active congestion with the corresponding loosening of the tooth. If the action is not checked the alveolar process is destroyed, and the teeth are lost.

In considering the treatment of the above pathological conditions, it must be governed according to the nature and type of the case in hand. But to generalize, I will say that in treating division first, or active congestions, with the exception of those cases due to acute exanthemata, I have found in galvanic and faradic electricity my most valuable agent, and it is so valuable, from the fact that by the proper manipulation of this subtle agent, we can correct circulatory disturbances, promote absorption of the transudated fluids, and cause the secretions and excretions to be changed into their normal condition.

Take for instance a case of noma, destructive in its results, and obstinate to cure, here by an application of electro-chemical cauterization from the positive pole, we can arrest the superficial destruction of tissue, and produce a healthy restoration of the parts beneath.

In treating the passive congestions I can apply electricity with benefit, only to the chronic catarrhal inflammations, the other types of cases of the second division are treated according to the principles of good surgery.

In dealing with hypertrophies, fibrous tumors and epitheliomata the electro cautery has been my best and most successful remedy. In order to cope with the papillary and vascular tumors, the galvanic current has been my most potent agent.

THE CONDITION OF THE DENTINE IN PULPLESS TEETH.

Read in the Section of Oral and Dental Surgery, at the Forty-third Annual Meeting of the American Medical Association, held at Detroit, Mich., June, 1892.

BY W. C. BARRETT, M.D., D.D.S.,
OF BUFFALO, N. Y.

I had promised the Secretary of this Section that I would prepare and read a paper at this meeting upon the "Condition of the Dentine in Pulpless Teeth." It was a subject upon which I had bestowed some thought, but with the literature of which I had not made myself thoroughly acquainted. I had read Prof. Miller's work on "The Microorganisms of the Human Mouth," and his communications to the various journals, notably *The Dental Cosmos*, but not with this special subject in mind. I had not collated his writings on this theme, and hence had not collated them. When this had been done, I was astonished at the thorough manner in which the ground had been covered. Had I examined my subject earlier, I should not have attempted an excursion in the field, but having engaged to present this paper, I will endeavor to redeem my promise, premising that I can do little save to call attention to the great work done by Prof. Miller in this direction, a work

which does not seem to be fully appreciated, and which perhaps will not be until each attempts, like me, specially to study it for himself.

In view of his exhaustive experiments, one can but wonder at the seemingly crude theories now held and taught by some men to whom we naturally turn for illumination. Perhaps I shall do more good by placing Dr. Miller's comprehensive studies before you for discussion than I would by effort in any other direction, for it must be remembered that his are not mere generalizations, such as mine must necessarily be; they are the result of long series of conclusive, scientifically conducted, original experiments and observations, and they are not to be overthrown by any inductive reasoning whatever. In view of the overwhelming original testimony which he introduces, no man has the right to dispute his deductions until he is fortified by a like mass of opposing facts, deduced from like carefully conducted experiments; or until he can indisputably demonstrate that the conclusions reached by Dr. Miller are not warranted by the results obtained.

The dentine, deriving its nutriment from the pulp of the tooth through the dentinal fibrillæ, is separated from all the other tissues of the body, through investment by the cementum and the enamel. The latter tissue is not only practically devoid of living matter, but it is not in direct relation with any tissues save the dentine itself. For our present purposes then, the enamel may be looked upon as a simple protecting cap, whose office it is to preserve the dentine and pulp from injury.

The cementum is of a different character. It is but slightly differentiated from true bone. It is in relation with a periosteal membrane, and it is nourished like bone through a system of lacunal corpuscles, connected by canaliculi.

In young teeth it is not infrequently the case that there is even a kind of system of Haversian canals, traversing the cementum and dentine between the pericementum and pulp, whose office it is to assist in maintaining the vascular supply, and incidentally, perhaps, to afford nutriment to the deeper cementum corpuscles.

The dentine is yet more differentiated, and in its structure has lost the lacunal corpuscles, while the canaliculi are modified into the dental fibrillæ. Their office is not materially changed, nor are we to suppose that the contents of the dental tubuli differ very widely from the canaliculi of true bone. They form the living portion of the dentine, as the lacunal corpuscles and the canaliculi form that of true bone. The dentinal fibrillæ are in connection with the vascular pulp, and from it derive the nutriment necessary to their continued life. The corpuscles found in true bone and in cementum are absent, and hence there is little that bears a resemblance to that concentric texture of true bone which forms its lamellated structure. At the extremities of the dentinal fibrillæ, we have the irregular inter-tissual spaces which mark the boundary line between dentine and cementum, and which may perhaps be considered as modifications of the cementum corpuscles, but they are not intimately connected with the dentinal structures.

The dentinal fibrillæ, depending as they do on the vascular pulp for nutrition, certainly lose their protoplasmic vitality when separated from it. Let us consider for a moment the condition of the dentine in a tooth the pulp of which has, without medica-

tion, just been removed. The fibrillæ have been freshly torn from their relations with the pulp, and remain filling the dental tubuli as before their violent separation. Like all protoplasmic material, they are composed of the great quaternary of elements which enter into the composition of all organic elementary structures.

But the dentinal fibrillæ probably also contain other elements, such as sulphur and phosphorus, which make it more near the nature of albumen. Indeed, it is probable that if we consider it as clearly albuminous, we shall not do much violence to nature. Carpenter says that this substance is the proper pabulum of the animal tissues generally, and so the dental fibrillæ, possibly modified somewhat, may be looked upon as albuminous in their nature.

The dentinal tubules which contain the fibrillæ are exceedingly minute. For the putrefaction of the contents of the tubuli it would be essential that putrefactive organisms should enter them. While it is quite possible that these may penetrate the tubuli, it must be to but a limited extent. In an article in the *Dental Cosmos* for May, 1890, upon "The Decomposition of the Contents of the Dental Tubuli," Dr. Miller shows that from their minute size and the very small amount of nutriment for the microorganisms which they contain, any bacteria which enter them must soon perish from want of pabulum, to say nothing of the fact that they are mostly aerobic, and so could not possibly live in the tubuli for any length of time.

But not satisfied with *a priori* reasoning, he commences a rather remarkable series of experiments and observations, from which he incontestably deduces the conclusion that bacteria do not penetrate the tubuli of undecayed dentine to any marked extent; certainly not enough to cause any necessity for the disinfection of the dentinal substance in teeth in which there has been no decay within the pulp canals.

I need not enlarge upon this. The record is open to the inspection of all, and no one has yet dared to take issue with Dr. Miller upon this point. It must be accepted that in the dentine of the roots of the teeth in which decay has made no progress, there is no infection of dentine that demands any antiseptic treatment aside from that usual in pulp canals.

What then becomes of the contents of the dentinal tubuli? It is but necessary to consider their character to form a clear estimate of this. The dentinal fibers cannot be considered as pure albumen, for that is only found in connection with other substances in the body. But whatever its exact composition it presents certain characteristics, one of which is its tendency, when at rest and separated from living tissue, to dissociate the watery portion, and to form a dried residuum which is insoluble. This condition may also be produced by most acids, by the metallic salts and by creosote.

The natural tendency then, for an albuminoid fibril, would be to assume a mummified condition, most conducive to its indefinite preservation, when kept in the state in which it will be found in the dentine of a tooth root.

Fibrine is but comparatively slightly differentiated from albumen. It contains the same elements, but it offers certain physical characteristics that distinguish it. Albumen is coagulated by heat, and by certain agents. Fibrine coagulates spontaneously

when exposed to the air. If then the fibrille of the dentine approach fibrine in their characteristics, they will undergo the change called coagulation without the intervention of any medicinal agent whatever. It is in this condition that, if sealed up from external influences, they present the very best state for the preservation of the tissue in which they are found. Hence the condition of the dentine is best in which the contents of the tubuli have been coagulated, or separated from the watery elements, and permitted to become a kind of minute mummy within their investing sheaths.

But the investigations of Miller, to which I have already referred, determine another matter. He did not find that the mouths of the dental tubuli, in teeth from which the pulp had been removed, were opened toward the pulp chamber.

He had under examination nineteen teeth. In ten of the roots of them he found the canals to be completely or partially lined with a homogeneous structure, containing few or no tubuli, but occasionally a formation resembling a bone lacuna, and bearing a much more near resemblance to cementum than to dentine. This layer is impenetrable to microorganisms, and therefore forms a protection to that tissue when the pulp has been removed. We find then, that the dentine is not only protected by the cementum on its external aspect, but very often by a modification of this tissue on its inner surface.

There is, therefore, little danger of infection of the contents of the dental tubuli. But even if this were possible, I cannot conceive that it would matter much. The amount of infectious matter would be so small, and the chance for the penetration of the gaseous products of decomposition through the dentinal tubuli, past the zone of demarcation between dentine and cementum, and finally through the cementum corpuscles and canaliculi which are themselves filled with living matter, would be so remote, and its influence upon the pericementum so infinitesimally small, that it seems folly to take it into consideration in the presence of so much more potent factors.

Clinical experience too, as is so plainly stated by Dr. Miller in the article to which reference has been made, does not sustain the theories of those who insist upon the possibility of infection from dentine. If the contents of the pulp canal be completely removed, the territory made thoroughly aseptic and the space finally filled, there is, so far as I am aware, no record of any trouble from the dentine. Even admitting that there exists within the dental tubuli matter which is susceptible to putrefactive changes, it is too small in amount to induce any disturbing conditions in the presence of a pulp canal carefully filled with a material which must seal the exceedingly minute mouths of the tubules wherever they are not already stopped by the modified dentinal layer of which Miller speaks. In the presence of much more important things, it seems like bad judgment to elevate such a mole-hill into a mountain, for it has a tendency to carelessness in things that need more attention. I doubt whether there has ever been a case of re-infection of the tissues about a tooth that has had its root filled after antiseptic treatment, that cannot be directly traced to some imperfection in the manipulation, or to some infected pockets outside the tooth itself. It is well known that the usual place for the formation of an infected

pocket is at or near the apex, and that there may be a penetration of the microorganisms and the formation of infected pockets for some distance back in the bone. I have myself seen at least three such, extending back from the point of an incisor tooth until the last one was over the second bicuspid, and each of these separate pockets connected with the original one at the apex of the incisor.

They were only reached by a long incision through the gum and external alveolus, extending from one to the other until the last one had been reached. If the infection had been from the dentine, it would have manifested itself quite differently.

Undoubtedly there are cases in which the infected spot is at some point in the pericementum between the gingival margin and the apex of the root. But this does not by any means prove that it came from infected dentine. Perhaps after the apical foramen, the most usual place for the formation of an abscess is at the bifurcation of the roots of a bicuspid or molar. I believe this to be due to the fact mentioned earlier in this paper, that something analogous to an Haversian canal there may penetrate the cementum and dentine, from the pericementum to the pulp. I have demonstrated such many times.

Not infrequently an abscess refuses to yield to the usual treatment through the pulp canal, and for the reason that the medicaments fail to reach the infected point. But such instances cannot be said to be produced by infected dentine.

There is, in truth, another foramen analogous to that at the apex, and it becomes septic in precisely the same manner as does the latter.

In what I have previously urged, we have presupposed that caries has not commenced within the pulp canal. And yet we are all well aware that in cases in which the pulp had been long dead, and there has been extensive decay of the coronal portion of the tooth, there was caries of the dentine commencing within the pulp chamber and extending down the canal.

In instances like this, of course there will be thorough infection of the dentine. It will not, however, be due to decomposition of the contents of the dental tubuli, but to infectious matter which may find its way into the hollow from external sources. It would be as manifestly improper to fill such a canal without removing the carious portion, as it would be to fill a cavity from the outside without careful excavation.

Here would be an instance in which the reaming out of the canal to the depth to which caries had penetrated would be eminently proper practice. It is very seldom that this decay will extend far down the root canal, or be very deep, without such destruction of the crown and cervical portions of the root as to make preservation practically impossible.

As regards the use of coagulating agents in the treatment of root canals, I cannot conceive of any objection to them. If by any it be thought necessary that dentine should be disinfected and made more aseptic, this can only be accomplished by agents which have the power of penetration in a marked degree. These are usually coagulants, like chloride of zinc, bichloride of mercury, etc. Upon this subject I can only refer to the experiments and observations reported by Dr. Miller, in an article on "The Relative Rapidity with which various Antiseptics Penetrate Pulp Tissue," published in the *Dental Cosmos* for May, 1891.

Discussion.

Dr. E. J. Clifford said the discoloration found in dead teeth was probably caused by the formation of sulphides of some of the different metallic agents used in medicaments. The less we treat the teeth in the vast majority of cases, the better will be the results. No law can be laid down to which exceptions could not be found, but in the majority of cases the quicker we fill a root-canal and the cavity over it, the more satisfactory the operation will be. Two things, however, work against immediate root-filling: first, the difficulty of drying the root; and second, soreness of the tissues about the root. If there is no way to dry it thoroughly, or if it is too sore to work on, then it is better to wait. In all favorable cases he advocated immediate filling.

Dr. W. W. Allport said the Section was under obligation to Dr. Barrett for a most excellent paper.

In our practice we have two classes of pulpless teeth to treat. Those we devitalize leaving the dentinal fibers in the condition when devitalization took place, are in the most favorable condition for successful treatment. The other class is where the nerve has been dead for a long time. Here the condition is different, and the treatment must be adapted to the altered condition.

Our aim should be to prevent discoloration of the dentine. Whether this can best be done by the use of oils or of chlorine, or by thoroughly drying the cavity and canal, so as to leave the fibers in a mummified condition that will prevent decomposition, is the question to decide. In old cases we should use every means in our power to restore the normal color, but in freshly devitalized teeth little or no treatment is necessary.

Dr. Gish said that whatever treatment was necessary could as well be done in one sitting as in twenty, and that the duty of the dentist to his patient calls for the course of treatment necessitating the least trouble and pain, therefore he advocated immediate filling.

Dr. M. H. Fletcher said that to him it seemed that the pulp-canal before filling must be surgically clean; that is, it should have all substances removed which might contain or support any spores or bacteria. In a case reported by Dr. H. A. Smith in a paper read before the Mississippi Valley Dental Society, trouble arose at the apex of a tooth that had been filled for fourteen or fifteen years. In the discussion it was said that there had been a continual effort at the apex of the root to dissolve the root as a foreign material. This will always happen if there should be an excess of filling-material forced through the end of the root, and if the tubuli had not been thoroughly disinfected the septic matter contained in them would set up suppuration.

In regard to the substance covering the tubules from the pulp-chamber, he had learned that after the tooth is fully formed there is a deposit, as it has been called, a translucent zone, lining the chamber and pulp-canal, but the deposit as he had seen it is penetrated by the tubuli. This must be so or the deposit could not take place, and he thought the tubuli were sufficiently numerous to need disinfection.

Dr. G. L. Curtis said the paper was an argument in favor of removing the pulp while it was healthy, and not destroying it by any substances that would enter the tubules. He could understand how in teeth so treated the deposit spoken of would occur, but in teeth dead for a long time it would not be there.

Dr. A. E. Baldwin did not agree with Dr. Barrett's idea that anything was so well proven that a dentist should finally accept it as a truth without satisfying himself by independent investigation. Because another had formed a theory and by experiment satisfied himself of the truth of it, was no reason anyone else should accept it. In regard to bacteria and microbes, and the necessity of making our root-canals aseptic, he disagreed with the paper. He did not think we could get them in better condition than by desiccation. He seldom uses anything in the way of antiseptics except carbolic acid in five per cent. solution, and has very good success. If he can get the root cleaned out, in an ordinary sense, whether it is, "surgically clean" or not, and get it thoroughly dry, he did not worry about the success of the filling. He thought a great deal of the irritation about the end of the root could be treated from the outside rather than through the root-canal.

Dr. Barrett said we would have to modify our view in regard to the pathology of alveolar abscess. He believed it to be thoroughly demonstrated that the pericementum furnishes all blood-supply to the growing tooth. He did

not believe anybody ever saw arteries and veins passing through the apical foramen. He believed there is something like Haversian canals that pass through the dentine and the cementum to the pericementum, and that pus will often be found about diseased teeth at the bifurcation of the roots, and this shows why the treatment through the roots will not succeed. He believes that thorough drying will make a tooth aseptic, but sometimes the point of infection will be found away off from the tooth that seems to be the cause of suffering to the patient. In these cases, of course, the treatment must be on the outside, and followed up till the point of infection is discovered and broken up and cleaned out.

THE ETIOLOGY OF LARYNGISMUS STRIDULUS.

Read in the Section of Laryngology and Otology, at the Forty-third Annual Meeting of the American Medical Association, held at Detroit, Mich., June, 1902.

BY JOHN O. ROE, M.D.,
ROCHESTER, N. Y.

Scarcely any affection has excited so much speculation in regard to its cause as laryngismus stridulus. The first definite theory regarding its etiology was put forth by Kopp in 1830, who asserted that it was caused by the enlargement of the thymus gland.¹ In 1836 Ley maintained that it was always due to "paralysis of the abductor muscles arising from the pressure of strumous, bronchial or cervical glands on the recurrent or pneumogastric nerves."² Marshall Hall ascribed laryngismus to a reflex cause, believing that it resulted from irritation in some other part of the body;³ and this theory was supported in 1849 by Reed, who observed that the spasm was frequently caused by retained meconium, faecal masses and worms.⁴

These opinions, however, were not universally accepted, for it was generally believed, as Mackenzie observes, that the weight of evidence pointed to the practical acceptance of molecular changes in the nerve centres as the essential cause of the phenomenon.⁵

In view of the fact that it occurs most often in rachitic children, Elsässer⁶ in 1843, and Lederer⁷ in 1852, maintained that it was caused by craniotabes and softening of the occipital bones, and that the attacks were excited by the pressure to which the brain was subjected when the child lay on its back.

From recent observations made from a physiological and neurological standpoint, Hughlings Jackson (than whom there is none more competent to speak on this subject) asserts that the relation of rickets to attacks of laryngismus stridulus in children is due to the abnormally soft ribs, that render the action of the diaphragm insufficient (the infant's breathing being almost wholly abdominal), and thus, especially during sleep, when the attacks commonly occur, there is an overstimulation of the respiratory centres by supervenous blood, and an excess of the natural stimulant, which result in convulsions.⁸ In a previous paper on this subject, Hughlings Jackson⁹ was at a loss to explain how this spasmodic effect was brought about by overstimulation of the

brain centre; but since Seamon and Horsley¹⁰ have found in their experiments that the adductors as well as the abductors of the vocal cords are controlled by nerves centering in the medulla, it is readily seen that stimulation of this centre may result in abductor disturbance. Hughlings Jackson also shows that similar results may be brought about by other methods, as for example in rabbits, by: 1. Cramping the trachea, thus producing insufficient oxygenation of the blood, and as a consequence, the overstimulating of the nerve centre; 2. By paralyzing with curare the motor nerves ending in the respiratory muscles, which results in convulsions of these muscles on account of the overstimulation of their nerve centres through the deficient aeration of the blood; 3. By dividing the phrenic nerve, thereby paralyzing the diaphragm (with which respiration in them is almost entirely carried on), which causes them to die of asphyxia, associated with convulsions; 4. By rapidly bleeding them to death through the opening of an artery, when convulsions are produced almost identical with those produced by compression of the trachea; 5. By tying the great arteries of the head, depriving the medulla of arterial blood and leaving the head saturated with venous blood, when convulsions are produced.

In explaining this phenomenon Hughlings Jackson does not claim that laryngismus stridulus is an asphyxia fit. Were this the case, he says, "this condition would certainly end in death in every instance; for as Dr. Gray says, 'supervenosis initiates the spasm, which increases the supervenosity, and laryngismus would consist of a single, and necessarily fatal, gigantic respiratory spasm.'" ¹¹ We know that in some instances the respiratory spasm ends fatally. That this does not more frequently occur is explained by the fact that when there is an enforced closure of the glottis by the overstimulation of the adductor centres, and the blood has become supervenous, it so acts upon the medulla as to bring the abductor centres into activity, and consequently to open the glottis and to re-establish respiration. This is the explanation of Jackson.

In analyzing, in the light of present knowledge, the various views relative to the causation of the affection, but one of these theories, that of peripheral irritation, put forth by Marshall Hall, is at all satisfactory. This irritation, in the production of central nervous diseases, has been amply illustrated by recent investigations of other nervous phenomena, such as asthma, hay fever, megrim and allied affections.

Other views relative to the causation of this disease, such as enlargement of the thymus gland, the softening of the occipital bones, thereby permitting pressure upon the brain, have been more or less fanciful, or the result of the investigation of cases in which this affection was simply coincident with these conditions.

The theory of the excitation of the central nervous disturbances by disturbed physiological conditions is, as we have seen, most ably explained by Hughlings Jackson. He, however, has studied the subject only from a physiological standpoint, and therefore fails to point out why it is that the nerve centre in the medulla controlling the abductor muscles of the larynx is more susceptible to irritation, or to its normal stimulus, than the nerve centre controlling

the adductor muscles of the larynx. This we believe can be readily explained by the fact that these nerve centres are rendered thus susceptible by irritation of the larynx itself, and that more or less continued irritation of the larynx has the effect to excite these nerve centres to undue activity, so that an irritation of the larynx that would at first have no appreciable effect on the nerve centres, would, when the nerve centres had become irritable and hyperæsthetic, have the effect to produce abnormal effects in the parts under their control.

In the study of the natural history of the disease we will readily see that influences and conditions that predispose to the causation of laryngeal irritation and laryngeal disease are exactly the conditions that predispose to the production of laryngismus stridulus.

Laryngismus stridulus is of most frequent occurrence in ill-nourished and rachitic children, and during the early part of the year when the system is depressed by long confinement indoors, and when the atmosphere is most irritating to local affections.

Heredity has been thought, in some instances, to play an important part in its production, as when both parents suffered from it during their infancy. In cases where the majority of the children in large families have suffered from laryngismus stridulus, heredity may have much to do with the production of this affection; only, however, to the extent that the children inherit physical conditions that predispose to laryngeal irritation and susceptibility to nervous disturbances. In the cases where many children in the same family have suffered from this affection, it may be accounted for by the fact that the children have all been subjected to the same influences that produce local irritation.

Children subject to snuffles, and those prone to frequent colds in the head and to sore throat, are especially liable to attacks of this affection. This, as we can readily see, is accounted for by the well known effect of nasal irritation and nasal obstruction, combined with oral respiration, in the production of laryngeal irritation. We also observe that the attacks of laryngismus stridulus usually occur during the night, at which time intra-nasal turgescence most readily takes place.

We also see that various subjective conditions which may have the effect to cause irritation of the larynx, are liable to cause attacks of laryngismus stridulus, as in the case of peevish and irritable children who indulge in much crying, thereby breathing largely through the mouth; also the forcible oral respiration consequent on laughing violently, and in fact, all those conditions that tend to cause irritation of the larynx will produce attacks of this affection. Thus we see that all conditions that produce more or less prolonged irritation of the larynx, tend to produce in children a marked susceptibility to this affection.

We therefore conclude that in the causation of laryngismus stridulus we must have the following conditions:

1. A chronic irritation of the larynx.
2. An abnormal activity of the laryngeal motor centres in the medulla, rendering them more susceptible to the normal blood stimulus and also more sensitive to irritation applied to the peripheral nerve filaments as a result of irritation of the larynx.
3. An unequal susceptibility of the adductor and

¹⁰ "On the Central Motor Innervation of the Larynx."

¹¹ Brit. Med. Jour., op. cit.

abductor muscles to local irritation and also to the normal blood stimulus.

The abductors of the larynx, situated on the outer portion of the laryngeal framework, are not so much subject to local irritation; their motor centre in the brain is less excited and less susceptible to normal stimulus, and thus, spasm of the abductor muscles is less frequent than spasm of the adductor muscles, and less persistent when it occurs.

THE TECHNIC OF CATHETERISM OF THE EUSTACHIAN TUBE, AND THE INDICATIONS FOR ITS USE.

A Clinical Lecture delivered at the Chicago Polyclinic, August 2, 1892

BY JOHN F. OAKS, M.D.

INSTRUCTOR IN LARYNGOLOGY, RHINOLOGY AND OTOTOLOGY, CHICAGO POLYCLINIC.

By catheterism of the Eustachian tube we understand the introduction of a properly curved tube into the tubal orifice, from 5 to 15 mm. according to the depth of the trumpet shaped opening of the pharyngeal orifice of the Eustachian tube.

Since our time is limited and you can readily find in your text books the historical details of this procedure, I will at once enter *in medias res*.

The necessary instruments for the proper performance of eustachian catheterization are, 1, the catheter; 2, the auscultation tube sometimes improperly called the otoscope and 3, the air bag.

Eustachian catheters are made of hard and soft rubber and of silver. Hard rubber catheters have the advantage of cheapness and lightness; they are not easily corroded. The aurist can supply himself with a number of all sizes and curves, so that each patient may have one to himself and thus escape the danger of possible infection. On the other hand the silver catheter if made of virgin silver, is much thinner than those made of hard rubber giving the important advantage of a larger calibre. Silver catheters are flexible, and any need to change the curve of the distal end is thus easily obtained in one instrument. It has the further advantage of being easily cleansed and sterilized by immersion in boiling hot water, or by holding in the flame of a gas burner (ausglühen.)

Again, they are not fragile like the hard rubber ones. It is very important to bear this in mind since it may happen that by a sudden motion or flinching or even the forcible grasping and extracting of the h. r. catheter by the patient the distal end may break off and remain imbedded in the tubal orifice, or serious traumatism to the naso-pharyngeal or nasal mucosa may be entailed. Not so with the silver catheter, on account of its great flexibility.

The soft rubber catheter I will dismiss in a few words. They are difficult of introduction on account of their being too flexible, unless they are made so thick as to be clumsy and too large in diameter for the average nasal fossa, and the small size of their calibre.

The silver catheter, see Fig. 1, is usually made in three sizes being respectively 2, 2.5 and 3, mm. in diameter. The whole length of the catheter should be about 16 cm. and the length of curve at distal end is from 2 to 3 cm. and varies from 140° to 150°. The beak, (see Fig. 1) is olive-shaped and has the advantage over the usual square end, of being less liable to produce a traumatism and the possible con-

sequent emphysema. The indicator ring at the proximal end serves the purpose of indicating the direction of the beak and is usually placed in the axis of the curve of the catheter.

The silver catheter as described is made by Sharp & Smith after the German model.

The air bag I here show you and which has been used in this clinic for several years is known as the Lucae double balloon (see Fig. 1). It is composed of a heavy rubber bulb with an automatic valve at b.; the second bulb is called the balloon, and is supplied with a similar valve at a. It is covered with webbing so as to prevent rupture by over filling. By means of this balloon, we not only get a continuous supply, but also an increased pressure of atmospheric air by compression of the balloon, which can be nicely graduated and regulated at will. The continuous atmospheric pressure obviates the necessity of disconnecting or removing the air bag from the catheter as must be done after each compression when using the Politzer bag. It also has the advantage over the Politzer in permitting of a more accurate observation of the auscultatory sounds, in consequence of the absence of the supplementary noises made during the acts of swallowing or phonation which are unavoidable in Politzerization.

Another advantage of the Lucae air bag is its simplicity and convenience. A short distance above the second bulb or balloon is a hook by which the air bag can be suspended from a button hole in the lapel of the coat (see Fig. 1 d.). At the distal end of the rubber tubing is a tip (see Fig. 1. "c.") which should be made to fit accurately into the funnel shaped end of the catheter.

The auscultation tube (also called the diagnostic tube) consists of rubber tubing made of pure gum. It should be about 120 cm. long and from 8 to 9 mm. outside diameter, that being the size that will fit into the average external meatus. The end pieces of different color usually recommended in the text-books are a disadvantage unless the calibre of these end pieces is nearly equal to that of the rubber tubing. Schwartze and other eminent aurists dispense entirely with the end pieces and prefer to mark the ends of the tubing for patient and operator by making the cut ends respectively oblique and straight.

One end of the auscultation tube is held snugly in the external meatus of the ear to be catheterized, while the other end is brought around and behind the neck, and over the shoulder into the corresponding ear of the examiner. This disposition of the latter end makes it less liable to slip out or being dragged out by gravitation and therefore makes it more secure.

Although Roosa (*loc. cit.* page 76) does not consider the auscultation tube a necessary adjunct to successful catheterism of the Eustachian tube, yet its importance will be conceded when we consider the following facts which our extensive clinical material has established beyond peradventure viz:

1. By means of the auscultation tube we are enabled to determine absolutely, whether the distal end of the catheter is properly engaged in the t. o.¹

2. To diagnosticate the perviousness or patency of the E. t.² which can be quite accurately determined by the pitch of the auscultatory sound or a stenosis

¹ t. o. stands for tubal orifice.

² E. t. stands for Eustachian tube.

of the E. t. by the amount of atmospheric pressure required to overcome the resistance.

3. Condition of the mucosa of the E. t. and middle ear cavity; whether moist or dry, or whether there is present much or little fluid. Moist râles indicate an excess of fluid caused by the admixture of air and fluid contents of c. t.³ If contents are serous, the râles are fine, if mucous they are more like vesicular breathing ("bruit de pluie," "Regensgerausch" from its resemblance to the falling of rain through the leaves of a tree). These râles must not be confounded with those produced at the t.o., when the beak of catheter is not properly engaged but lies near or in the lumen of the ostium.

4. When the sound is intermittent, with explosive noises during the act of swallowing it may indicate stenosis from swelling of the mucosa in cartilaginous portion of the E.t. or near the ostium tympanicum. Explosive sounds may also be due to sudden tension of m.t.⁴ or when there are adhesions between it and the inner wall of the c.t.

5. A whistling or hissing sound will indicate a perforation when it is small. Where the perforation involves all or a greater portion of the m.t. without any appreciable moisture in c.t. the auscultatory sound may simulate that of a normal and patent E.t.

6. If in the presence of a pervious E.t. (which can be determined by a bougie) there is an obscuration of the usual auscultatory bruit we may assume that the c.t. is occupied by some inflammatory product or the space compromised by swelling or proliferative thickening of the mucosa.

So much for the diagnostic use of catheterism. It also aids us in our prognosis in so far as we can determine absolutely or approximately the pathological conditions which obtain.

Let us now consider briefly the therapeutic indications for Eustachian catheterization.

1. One of the principle indications for its use and in the patient before us is a sense of fullness and pressure with tinnitus and deafness. These symptoms are usually due to disturbance of the equilibrium of atmospheric pressure in the middle and external ear from defective ventilation of the c.t. by way of the E.t., giving rise to diminished air tension and consequent hyperæmia *in vacuo* with more or less collapse of the m.t., and consequent involvement of the apparatus of hearing made manifest by impairment of the aerial conduction of sound.

2. In acute otitis of the middle ear, as soon as the acute pain has been relieved by the usual treatment, the air douche is indicated. Where the otitis is unilateral, catheterization is to be preferred to Politzerization. Catheterization secures perviousness of the E.t., establishes the equilibrium of atmospheric pressure, thereby relieving tension of the m.t., the tendon of the tensor tympani muscle, also chain of ossicles and undue pressure on the labyrinthine windows; it disperses and displaces intratympanic exudations *via* the E.t. into the pharynx, or in the presence of a spontaneous or artificial solution of continuity of the m.t. into the external meatus; it establishes normal intra-tympanic pressure with consequent reduction of hyperæmia *in vacuo*, absorption of exudation and by virtue of what might be appropriately called aural massage, viscid mucous

and plastic exudates are displaced and removed from the immediate vicinity of the oval and round windows and foot plate of the stapes which tend to more or less compromise the function of the apparatus of hearing. Plastic exudations are prevented from becoming organized and forming bands of adhesions between the m.t. and inner wall of the c.t. or immobilizing the maleo-incudal incudo-stapedial joints.

3. In chronic catarrhal otitis of the middle ear it forms the most important factor in the treatment. The rationale is the same as that mentioned in acute otitis. Perhaps the element of mechanical pressure (aural massage) is of greater moment in the treatment of the chronic forms of otitis media, especially where there is much swelling or proliferative thickening of the tympanæ mucosa. It prevents the fixation of the chain of ossicles and secondary tympanic membrane (the membrane covering the round window) by connective tissue proliferation; it also prevents stenosis of the ostium pharyngeum and ostium tympanicum of the E.t. as well as in its continuity.

4. In deafness and tinnitus caused by the above mentioned pathological conditions, it is the only treatment that will prove of any avail. If it does not cure the deafness and tinnitus it will most certainly in the majority of cases relieve them, and prevent rapid progressive impairment or entire loss of hearing.

5. In acute-suppurative otitis of the middle ear catheterization and careful inflation may induce dispersion and absorption of sero-purulent exudate without perforation. Where, however, there is a perforation, the purulent secretion is displaced into the external meatus from whence it is removed by irrigation with a $\frac{3}{4}$ per cent. solution of sodium chloride or a 2 to 3 per cent. solution of boric acid, or by pledgets of borated cotton, *secundum artem*. It furthermore establishes the desirable intratympanic conditions which favor subsidence of hyperæmia and stimulates absorption of abnormal exudations.

6. In chronic suppurative otitis the same indications obtain as in the acute form, the rationale being the same. In addition, catheterism also furnishes the means for irrigating the c.t. by way of the E.t., as recommended by Schwartz, *loc. cit.* 194.

You ask, how soon should inflation be repeated?

As a result of clinical experience we find that the improvement after the first few catheterizations (that is in otitis media chronica) usually lasts from a few to 24 hours and recedes again. It is therefore advisable to repeat the inflation, indeed before the benefits of the preceding one have entirely disappeared, otherwise your patient would remain in a condition of *statu quo* or the improvement would be at least very slow. It is advisable to inflate daily for five or six days, or until such time as the improvement is more or less permanent, when the interval can be prolonged according to the progress or exigencies of the case. Therefore, in the chronic forms of Otitis media catarrhalis and suppurativa you must continue in this line of treatment for a long time, or as long as the pathological conditions that obtain compromise the sense of hearing or the integrity of the temporal bone.

In this connection I wish to call your attention for a few moments, to the contra-indications of

³ C. t. stands for cavum tympani.

⁴ M. t. stands for membrana tympani.

Eustachian catheterizations, and will divide them for more convenient study, into absolute and relative.

Absolute.—1. When there is ulceration in the nose or naso-pharyngeal cavity with or without tendency to hemorrhage, on account of the danger of septic infection. 2. hyperpyrexia. 3. Acute otitis complicated by acute pharyngitis and severe otalgia. 4. Emphysema of pharynx or larynx.

Relative.—1. Early childhood. 2. Senility. 3. Neurotic conditions. 4. During convalescence where there is great nervous prostration.

As to the technic of the procedure you know, gentlemen, that the pharyngeal orifice of the E.t. is located on the lateral wall of the naso-pharynx, nearly on a line with the inferior meatus of the nose, and that between the posterior lip of the ostium (also called the salpingo-pharyngeal fold) and the posterior wall of the naso-pharynx is a depression called the fossa of Rosenmüller. If the distance from the anterior nares or the posterior wall of the pharynx to the t.o. was uniformly a fixed one (which, however, is not the case) there would be no difficulty in finding it by means of a fixed scale on the catheter. Therefore, we proceed after a method (of which there are a number) that establishes a fixed point or landmark as a point of departure for the *maitre de tour*.

The method that is taught in this clinic is known as the modified Kramer or Gruber method. The patient should be seated well back in a chair with body erect. It is desirable to have the patient blow the nose so as to cleanse nasal passage and to moisten the same.

The catheter having been scrupulously cleansed and sterilized, make sure that it is pervious by forcing air through it from the air bag (not by the mouth for that would not be aseptic) then adjust the auscultation tube as noted; place your left hand on the patient's forehead and with the thumb raise the tip of the nose; grasp the catheter delicately at its proximal end between thumb and index finger of the right hand holding it nearly perpendicularly, with the beak resting at the outer side of the floor of the vestibule, make an upward and forward motion carrying beak over the muco-cutaneous fold (the junction of the vestibule and nasal floor proper) at the same moment bringing the catheter to a horizontal, on a plane with the floor of the inferior meatus and continue the forward motion *with beak hugging the floor* until it reaches the naso-pharynx and you feel the resistance of the posterior pharyngeal wall; the catheter, with the indicator ring pointing directly downward and on a horizontal plane, is then drawn forward until the resistance of the soft palate is felt, when without hesitation it is turned outward and upward through the arc of a circle of about 135°, so that the indicator ring is on a line with the outer angle of the eye, or at an angle of 45°, when the beak of the catheter will usually glide into the t.o. The latter movement is aided somewhat by the contraction of the palatal muscles which, so to speak, lifts and rides the distal end of the catheter toward the t.o.; then, sliding left hand downward over forehead (not raising the hand from its support) grasp the catheter firmly between the thumb and index finger to prevent motion or rotation on its axis while making connection with the tip (see Fig. 1, c) on the Lucae air bag, at the same time keeping the tips of the remaining fingers fixed against the glabella as a

fulcrum. On compressing the bulb and filling the second balloon moderately with air the auscultation tube will at once determine the success or failure of the manœuvre.

Fig. 1.

I will in this connection, without comment, mention in brief some of the other methods of procedure.

In the Lowenburg method you proceed as in the one before mentioned, until the beak of the catheter meets the resistance of the posterior pharyngeal wall, when it is rotated inward through the arc of a circle of 90° and brought forward until the concavity of the curved distal end meets the resistance of the posterior margin of the septum nasi (which in this method is the landmark), it is then rotated downward, outward and a little upward, describing a little more than a semi-circle, with indicator ring at same angle as in the previous method.

In Kuh's method, the beak, after meeting with the resistance of the posterior pharyngeal wall, is turned outward into the fossa of Rosenmüller; it is then brought forward until the resistance of the posterior lip of the t.o. is felt, when it is drawn gently over the lip or fold into the t.o. By this manœuvre there is more or less danger of injury to the mucous membrane sufficient sometimes, to entail the serious consequence of emphysema, especially where this landmark is unusually developed. The following method of Bing is an improvement on the latter. You will proceed as in the previous method until the posterior lip is plainly felt, which can be more easily discerned, by carrying the proximal extremity of the catheter toward the septum, when it will be noticed that on slight traction, the beak being directed slightly downward, that it can be made to glide easily downward and around the posterior lip, and circumducted, so to speak, into the t.o. The greater the development of this land-

mark (the posterior lip) the easier and more certain is catheterization by the Bing method.

Gentlemen, you must not forget that familiarity with, and dexterity in these methods of procedure are absolutely essential to success; that that method is the most desirable, that accomplishes catheterism with ease and without pain, "tuto, cito et jucunde."

As you become expert in the manœuvre you will not confine yourself to any particular method, but will proceed more or less unconsciously and independent of any special landmarks, as after the method of Boyer or Gairal, in which the catheter is passed along the floor, being held somewhat obliquely so that the convexity of its distal extremity is upward and inward and the concavity downward and outward, until the distal end reaches the nasopharynx when it is turned outward and upward into the tubal orifice.

A knowledge therefore of the topography of the nose and naso-pharynx and a practical experience in the procedure are the only means that will insure success.

705 Venetian Building.

EYE TROUBLES WHICH CONSTITUTE A FREQUENT SOURCE OF HEADACHE, VERTIGO AND NAUSEA, AND OTHER NERVOUS DISORDERS.

Series of four lectures delivered at the Fourth Special Course of the Chicago Polyclinic.

BY F. C. HOTZ, M.D.,
PROFESSOR OF OPHTHALMOLOGY.

LECTURE II.—STRAIN OF THE OCULAR MUSCLES IN BINOCULAR VISION.

Second Group.—The ocular affections to which I wish to invite your attention to-day, create disturbances in the nervous system also by strained muscular action. But while a person with abnormal refraction may suffer from nervous symptoms whether he sees with one eye or with both, the group of affections now before us can trouble the person only when he uses both eyes together. *The nervous symptoms caused by this second group are due to unusual demands upon the ocular muscles to maintain binocular vision.*

Binocular vision is only possible if the visual line of each eye (i. e. the straight line drawn from the macula through the center of rotation of the eye) connects the macula with the object, or as it is usually expressed, both eyes must be turned directly towards the object. The slightest deviation of the one visual line from the object disturbs binocular vision by causing diplopia, as you may easily prove to yourselves by a very simple experiment. Place one finger very lightly on the upper lid of your left (or right) eye, and then make with this finger the faintest pressure upon the eyelid while you are looking steadily at one object. You will at once see the object double, because the pressure upon the lid is transmitted to the eyeball, causing a slight displacement which faint though it be is sufficient to change the direction of its visual line and thus to cause double vision. When the object is far away from the eyes, the direction of these visual lines is so slightly convergent that it is customary to speak of them as being parallel. The nearer the object approaches the eyes, the more convergent must be the visual

lines; and hence in looking around from one object to another, we are constantly changing the position of our visual lines. The movements the eye-balls have to make for these adjustments of the visual lines, are effected by the actions of the four straight and two oblique muscles. Under normal physiological conditions, these muscular forces are so well balanced that when the muscles are in a state of physiological relaxation the visual lines are practically parallel; if, therefore, we look at distant objects, these muscles are pretty well at rest, and they become active in proportion as the object gets nearer to the eyes. And as we frequently change looking from near to distant objects, the ocular muscles undergo so frequent changes of tension and relaxation that they can easily meet the demands imposed upon them in the interest of binocular vision.

Now in the affections which interest us to-day, this physiological equilibrium of the ocular muscles is slightly disturbed; the visual lines are not parallel when the muscles are in a state of perfect relaxation, but the visual line of the one eye is slightly turned upwards or downwards, convergent or divergent. But these departures of the visual lines from parallelism are so slight that they do not cause any manifest deviation (as in strabismus) and for the sake of binocular vision can be and are corrected, and the parallelism of the visual lines is restored by persistent special efforts of one or the other of the ocular muscles. For instance, if in the state of muscular rest my right eye was just a little convergent, my sight would be confused in a peculiar way in looking at a distant object, because its image would not be received exactly on identical points of the two retinae; in the left eye the image would be on the macula, but in my right eye it would be on the nasal side of the macula. And while the left eye would see the object in its true position, my right eye would see it slightly shifted to the right, according to the laws of projection; but the shifting would probably not be great enough to produce distinct double images; the two images would neither be distinctly separated nor exactly blended, they would overlap each other and make the object appear to me in very uncertain contours, like blotted type. To get rid of this very distressing state of vision I must bring the visual line of my right eye to bear directly on the object, and I should accomplish this by inducing the external rectus of my right eye to make a special effort to turn this eye just so much that the image of the object is thrown upon the macula. The visual lines of both eyes then connect the object with the macula, and binocular single vision is restored. But it is restored at the expense of the external rectus of my right eye which is obliged to keep up a certain degree of tension to oppose the natural tendency of the eye to turn in. And as this extra tension had to be kept up all day, it would not be surprising if sooner or later this strain upon the external rectus muscle would lead to similar nervous symptoms which, as you have learned in our first lecture, are so often caused by the strained efforts of the ciliary muscle. And so we find it in reality: headaches, neuralgia, vertigo, and the whole train of neuroses indicative of an unusual and excessive consumption of nerve force are frequent complaints of persons whose eyes show these peculiar disturbances of the muscular equilibrium.

Dr. G. T. Stevens¹ has introduced a series of new terms for these muscular anomalies; and since his terms have been adopted by other writers, and also by the ophthalmological Section of the American Medical Association, I will briefly explain them. The state of perfect muscular equilibrium is called *Orthophoria*, and all those disturbances of equilibrium which favor the deviation of the one visual line from the other, but in which this tendency is opposed and the actual deviation prevented by special muscular efforts, are grouped under the general term *Heterophoria*. According to the direction in which the deviating tendency may exist, heterophoria may be subdivided into:

1. *Esophoria*.—The visual line of the one eye has a tendency to turn inward (convergence).

2. *Exophoria*.—The visual line of the one eye has a tendency to turn outward (divergence).

3. *Hyperphoria*.—(Right or left)—The visual line of the one eye has a tendency to turn upward.

As these faulty tendencies are counteracted by muscle strain as long as binocular vision can be maintained, the existence of heterophoria in any given case can only be revealed if binocular vision is suspended by some artificial means. A very simple and inexpensive contrivance for this purpose is Dr. Maddox's glass rod, a small piece of a glass cylinder set in a slot of a round metal disc. If you place this glass rod before your right eye and look at a light, you will see a long streak of light, while with your left eye you will see the natural shape of the flame. If the glass rod stands vertically, the light streak is horizontal, and if the rod stands horizontally, the streak is perpendicular.

Now for binocular vision, both eyes must receive identical images on the macula; but a light streak and a flame are so different images that they cannot be united into one visual perception. Binocular vision, therefore, is suspended by the glass rod; but as soon as binocular vision is made impossible it matters not whether both visual lines are directed towards the light, or whether one visual line is turned in another direction. We therefore see that under the influence of this glass rod any special effort which may have been made in the interest of binocular vision to prevent the deviation of the visual line, is abandoned, and the deviation if the tendency therefore exists, is allowed to take place. In orthophoria the streak is seen to pass right through the middle of the light; but if heterophoria exists, streak and light are seen separated, and the position of the

FIG 4

streak (whether above or below, to the right or left of the light) will determine the kind of heterophoria.

Another way of suspending binocular vision is to induce diplopia by means of prisms. A prism deflects the rays of light towards its base. If you place a prism (*p*) with its base downward, before one eye, for instance, before the right eye, the rays from this candle light (*l*) are deflected so that its image is

cast upon the lower portion of the retina (below the macula) of the right eye; you will see two lights, and the one seen by the left eye will appear in its true place (at *l*) and the one seen by the right eye will appear above the other (at *k*). Binocular vision being suspended by the prism, any existing heterophoria will reveal itself by the relative position of the double images, as I shall show to you presently. For this prism test Dr. Stevens has devised this instrument called *phorometer* with which you can not only detect very quickly the existence of heterophoria, but also very accurately determine its kind and degree.

Let us now briefly consider the principal forms of heterophoria.

ESOPHORIA.

The visual line of one eye has a tendency for convergence.

Tests.—1. The vertical light streak produced by the glass rod is seen to the right of the light if the rod is before the right eye, and to the left of the light if the rod is before the left eye.

2. The double images (produced by the prism with its base down before one eye) are not in perpendicular line, but the upper image appears displaced to the right if it belongs to the right eye, or the left if it belongs to the left eye.

To get the images on a vertical line, or to make the light streak run straight down through the flame, you have to place a prism with its base towards the temple, before one eye. The number of the prism which brings both images in a perpendicular line indicates the degree of esophoria.

In esophoria, binocular vision is maintained by the constant tension of the external recti muscles. In moderate degrees relief may be obtained from the use of prismatic spectacles; in the higher degrees of esophoria, carefully graduated tenotomies of the internal recti muscles correct the deviating tendency.

Prominent among the nervous symptoms induced by esophoria, is severe pain in the back of the head. Sometimes this occipital headache comes after reading with such regularity that the patient naturally concludes there must be some relation between the eye work and headache. In many cases, however, the patient experiences no trouble in reading, etc., and has very good sight; but a visit to a picture gallery or a theatre, the attendance at a lecture-room or in church, is invariably productive of a severe headache.

Let me briefly relate to you two cases to show the different effect esophoria has on different people, and also the different means by which relief can be obtained.

Case 1.—P. O., 17 years of age, has been suffering from temporal and occipital headaches more or less for years, but since he has entered college the attacks have become so frequent and severe that he was often obliged to interrupt his studies; he had noticed if he read in the evening he would always wake up with a headache in the night, and if he studied for one hour in the afternoon, he would usually have to suffer for it in the evening. The headache was often preceded by a numb feeling in the fingers which gradually extended up the arms to the shoulders. At the age of 8 years he had been operated upon for convergent strabismus of the left eye. His vision was excellent ($\frac{20}{15}$) and the refraction emmetropic, with accommodation fully paralyzed. At first we found esophoria

¹ Functional Diseases, their causes and treatment. New York, 1887.

2° but in a few days it gradually increased to 10°. Graduated tenotomy of both internal recti produced orthophoria, and as he reported six months later, relieved him permanently of the headaches and other neurotic symptoms.

Case 2.—Mrs. F., 23 years old, has no trouble in reading except that her eyes begin to burn and smart; but has been troubled with violent sick headaches all her life; never went to the theatre but what toward the end of the play her head would ache.

Examination, Jan. 28; esophoria 7°; good vision ($\frac{20}{20}$); under cocaine and homatropine, hypermetropia 2 D, and esophoria 14° (!).

Feb. 1.—Had severe headache after examination with the homatropine. With H. corrected still Es. 7°. *Ord.* prism 3° for each eye.

Feb. 9.—Several evenings in theatre, and no headaches.

March 15.—Glasses continue to give perfect comfort.

EXOPHORIA.

The visual line of one eye has a tendency for divergence.

Test.—1. The glass rod shows the vertical light streak to the left of the flame if the rod is put before the right eye, and to the right of the flame, if the rod is put before the left eye.

2. The vertical double images produced by the prism, are so displaced that the higher image appears to the left if it belongs to the right eye, and to the right if it belongs to the left eye.

A prism placed with its base toward the nose before one eye can get the two images in a vertical line, and also make the light streak pass through the flame. The value of this prism represents the degree of exophoria.

The deviating tendency of the visual lines is opposed by the requisite constant tension of the internal recti muscles. Its relief requires either the appropriate prismatic spectacles, or carefully graduated tenotomies of the external recti muscles. Exophoria is preëminently embarrassing in near work, causing quick fatigue, and pain in the eyes and head, in fact that train of symptoms usually mentioned in the text books under the heading "Muscular Asthenopia."

A very good clinical illustration of exophoria is the following case: In August of last year, a physician 34 years old, from Iowa, came to get relief for these symptoms: A constant tight feeling across the forehead; when looking at any object he had a desire to close his eyes to rest them; could read but a few lines, and scarcely able to write prescriptions because "the letters chase each other." The examination revealed normal refraction; perfect vision ($\frac{20}{20}$) and 2 degrees of exophoria. A prism of 1° for each eye gave such instant relief that the doctor wished to go back home with them at once, promising to report, or to return if the glasses should fail to give permanent relief. But he is not likely to come back, for on Feb. 28 he wrote this: "I could not live without my glasses now, they give me perfect comfort; can't be without them. If I lay them aside for a moment my eyes and forehead begin to pain again. But when I wear them there is no pain whatever."

HYPERPHORIA.

The visual line of one eye has a tendency to turn upward.

Tests.—1. The horizontal light streak seen through the glass rod appears above or below the flame; and,

2. If diplopia is produced by a prism placed with its base toward the nose before the one eye, the two images do not appear on a horizontal line (as they would in orthophoria) but the right or the left image stands higher than its partner. The lower image always belongs to that eye whose visual line is directed above the visual line of the other eye; and a prism placed with its base down before that eye will bring the two images in a horizontal line (and also make the horizontal light streak pass directly through the middle of the flame.) This prism represents the degree of hyperphoria.

Hyperphoria is by all means the most interesting of all the heterophoric conditions, because even very slight deviating tendencies of the visual lines in the vertical direction are very embarrassing to binocular vision, and frequently induce very troublesome nervous symptoms. Preëminent among those is vertigo and a peculiar confusion or uncertainty of vision, which makes walking in a crowded street a very difficult and dreaded task for such people. Some patients compare this visual vertigo with the sensation experienced on board of an ocean steamer; others only notice a peculiar unsteadiness and haziness of the horizon when they look with both eyes, while it appears perfectly clear and sharp when viewed with either eye alone. Some have a more or less constant feeling of a tight band around the head; others are tortured by frequent attacks of violent occipital headache.

How embarrassing a slight degree of hyperphoria may be, I cannot illustrate any better than by relating to you the following observation: In September, 1889, H. K., 34 years old, an actor, consulted me at the suggestion of his physician. Since two years he had been annoyed by frequent attacks of vertigo, which were extremely embarrassing to him. When on the stage he felt as if his body was swaying from side to side, and when he had to make his exit in a certain direction, he had to fix his eyes right to the spot, strain every muscle to walk straight toward the place where he was to leave the stage. He was always afraid the audience would notice the uncertainty of his gait, and think he was intoxicated. He was a man of splendid physique, and a number of competent physicians who had examined him from head to foot, inside and outside, could find no flaw in his organization. His eyes showed normal refraction, and remarkably good vision, ($\frac{20}{20}$); but there was $\frac{1}{2}$ ° of hyperphoria of the L. E.; and when this was corrected by $\frac{1}{2}$ ° prism, he was quite amazed by the wonderful change of sensations it produced. Everything appeared so steady and clear; his head felt as if a heavy weight had been lifted from it, and every trace of vertigo had disappeared.

In dealing with these heterophoric conditions, we must not lose sight of the fact that a weak state of health, poor nutrition, nervous prostration by disease or overwork, may weaken the ocular muscles so that they are easily tired in the performance of their regular daily work. Their actions become unsteady, jerky and easily simulate heterophoria of one kind or another. But if you examine such eyes on different days (and in all these muscular affections, you should never make your diagnosis on one single examination) and find each examination shows a very different degree or even a different kind of hetero-

phoria: you will understand that this is not a case of true heterophoria. Another point we must not overlook, is the fact that apparent heterophoria is often associated with errors of refraction, and disappears when these errors are corrected by suitable glasses.

But after all these cases have been carefully sifted out, there still remains a certain number (like the cases reported in this lecture) in which the most searching examination can detect no other disturbance in the eye but heterophoria, and in which the correction of this muscular disturbance is promptly followed by the complete relief of existing disturbances in the nervous system. I wish to impress this fact upon your mind with particular emphasis, because some writers, utterly disregarding these clinical facts, are trying to make their readers believe that heterophoria has no bearing on asthenopia or nervous symptoms, but that these complaints are always caused by anomalies of refraction, and relieved by the correction of the refractive errors.

NOTES ON THE EUCALYPTUS.

BY W. C. TYNDALE,
OF CHICAGO, ILL.

The Eucalyptus tree is a native of Australia and Tasmania, where it forms large forests. There are about 140 species described, but they vary extremely, different kinds of leaves being produced on the same tree, thus presenting distinct specific characters, and varying also in the nature of their barks.

In Tasmania and Gippsland Victoria, they grow to an immense height, often exceeding 400 feet. Their naked and branchless stems of a dirty white color look like natural columns. These are often blackened by the fires of the natives or wrung by the settler's axe, when they afford a grand but dismal spectacle, as one speeds along in the train; in some districts square miles of country is passed in which the forests have been wrung preparatory to settlement, and in some cases for no obvious reason, as the land is unfit for occupation and there stand those former monarchs of the forest like giant skeletons, sapless, lifeless looking, dismal and forlorn in the midst oftentimes, of a luxuriant undergrowth.

The trees are named usually according to the nature of their bark, which they shed instead of their leaves, such as Stringy Bark (*E. Obliqua*), Iron Bark (*E. Sideranylon*), Blue Gum (*E. Globulus*), Peppermint tree (*E. Amygdalina*).

The wood of some is very hard and durable, and so heavy as to sink in water. Many yield a kind of resin or gum, such as *E. Resinifera* and *E. Amygdalina*. A volatile oil of wonderful medicinal qualities is also produced from the leaves of various kinds but more especially from that known as the *E. Amygdalina* which is the most productive, and yields nine-tenths of the oil of commerce, though not always placed in the market under its own name.

This arises from a certain amount of notoriety gained for the *E. Globulus* abroad owing to the fact that it is the easiest of the species to acclimatize. As a matter of fact, however, there is scarcely any *E. Globulus* distilled in Australia. *E. Maunifera* yields sweet secretions analagous to manna. *E. Gunnii* furnishes a liquid that ferments and forms a kind of beer. They all produce abundance of seed,

which vegetates freely and becomes naturalized in various countries.

THE GIANT EUCALYPTUS TREE.

The *E. Amygdalina* or Giant Eucalyptus, called "Waugara" by the natives, is also known as the Peppermint tree. This is one of the most remarkable and important of all the plants in the whole creation.

Viewed in its marvelous height when standing forth in its fullest development on the slopes or within the glens of mountain forests it represents probably the tallest of all the trees of the globe. Regarded as a hard wood tree of rapid growth it ranks foremost, and contemplated in respect to its yield of volatile oil from its copious foliage it is unsurpassed and perhaps unequalled by any tree in the world. These qualities have made it become generally known and much through the exertions of Baron Von Mueller, this tree is now being introduced abroad with good results in countries neither subject to severe frost or intense moist heat. It assumes under different climatic and geologic conditions, various forms. Thus, in the ravines of the cooler ranges it attains its greater height, combined with a perfect straightness of stem, while the bark strips so completely as to render the huge stem quite smooth and almost white.

In the more open country it is much smaller. Under these conditions it is called a "Peppermint Tree" in Victoria and Tasmania, and a "Messmate Tree" in New South Wales.

In Victoria this tree often exceeds 400 feet in height. Such trees are found on the Black Spur, Upper Yarra Yarra, and Upper Goulbourn. A fallen tree on the Dandenong Ranges measured 420 feet. The length of the stem up to the first branch was 295 feet. The diameter of the stem where it was broken 365 feet from the root was three feet.

A still thicker tree in the same locality measured 53 feet in circumference three feet from the ground.

A tree near Mount Wellington, Tasmania, has been found which measured 12 feet in diameter, 220 feet from the ground. Another tree was found 130 feet in circumference at the base. Within a square mile 100 trees could be counted with a circumference of at least 40 feet. At the foot of Mount Baw Baw, Victoria, is found the highest of the giant trees of Australia. This monster is 471 feet high, and another on the Cape Otway ranges is 415 feet in height. The final height is sometimes attained by a single branch pushing skyward.

It is a grand picture to see a mass of enormous tall trees of this kind with stems of mast-like straightness and clear whiteness so close together in the forest as to allow them space only towards the summit to send their scanty branches and sparse foliage to the free light.

The distillation of the oil was first initiated by Baron Von Mueller. *E. Amygdalina* yields more oil than any of the other varieties, and is therefore almost solely employed for the purposes of distillation. It is also one of the best for subduing malarious effluvia in fever regions, although it does not grow abroad quite so well or quickly as *E. Globulus*.

The respective hygienic value of various trees may to some extent be judged by the percentage of oil in their leaves as stated below.

	Per cent. of Oil.
<i>E. Amygdalina</i>	3.313
<i>E. Oleosa</i>	1.250

	Per cent. of Oil.
E. Leucoxylo	1.060
E. Goniocalyx914
E. Globulus719

The lesser quantity of oil in E. Globulus is compensated for by the vigor of its growth, and early copiousness of its foliage. It readily adapts itself to other climates and hence abroad nearly all varieties of the oil are known as Globulus. During the last twenty years the Blue Gum has come into high repute as a sanitary tree. A high authority states that the sewage system of large towns in warm climes would be simplified if each house had the ever green gum tree in the back yard. The disinfecting and deodorizing virtues of the tree are unquestionable.

Flesh of any kind is as well preserved by eucalyptus as by creosote, while beef sprinkled with it will dry hard without putrefaction. It is fatal to bacteria and other microorganisms. It may be injected into the veins and arteries of cadavers for purposes of preservation. It is also a good admixture in dressing gangrene.

SOCIETY PROCEEDINGS.

American Electro-Therapeutic Association.

Second Annual Meeting, held in New York, October 4, 5 and 6, 1892.

WILLIAM J. MORTON, M.D., PRES.

FIRST DAY, OCTOBER 4—MORNING SESSION.

(Continued from page 48.)

2. *Electrolysis.* By this term is meant not alone the products of chemical decomposition at the electrodes but also the action of the current in its intrapolar course. There can be no doubt that every current, however small, acts upon the tissue included between the electrodes. In the first place there would exist no current, no conduction, unless the electricity moved *with* the atoms of matter and not through and among them. This is the essential feature of electrolytic conduction as in the fluids and semi-fluids of the body. Therefore, the atoms move as long as a current passes.

Again, the phenomenon of internal polarization and counter electromotive force (as high as one-fifth of a volt) demonstrates the intrapolar activity of the continuous current. The effect of this action upon a tissue, for instance a muscle, is proven to be a great diminution of its excitability and a profound alteration in its structure, microscopically demonstrable.

3. *Cataphoresis.* The fluids of the human body, varying according to their electrical resistance, move with the flow of the current from the positive to the negative pole.

Electrolysis, chemically and cataphoresis mechanically alter the amounts and distribution of that very small percentage of salts essential to the nutrition and function of parts of the organism upon which they act and thus produce tissue changes, as in tumors and exudations.

4. *Vaso motor effects,* are too familiar to more than require mention.

Further objective evidence might be adduced such as the important action of electricity upon the pulse, upon the temperature and upon the secretion of urea and other end-products of metabolism.

Again, the evidence of clinical observation is of great weight.

But the time at my disposal and the limits of your

patience, forbid the further pursuit of this train of thought. The field is too broad a one for this brief treatment. I would like to have referred to the medical possibilities of electricity in its relations to microbes and microbe chemical products; to the recent attack upon electro-therapy as upon all therapy founded upon that recognized therapeutic measure known as "suggestion," but, as I have said, my time is too short and I will content myself with a mere reference to a line of work which lies before us.

Certain directions of investigation point to a field where electricity may play an important rôle in the cure of disease. To-day much attention is divided between an organization the most complex—the nervous system and one most simple—the animal cell. The former has long held sway as the great controller of those functional processes incident to the life and the activity of the organism, but the latter is found to possess distinctive capacities of its own which would suggest that in all that relates to the performance of vital functions it could act independently of the influence of the nerves. The capacity of an amœba to select nutrition appropriate to itself, of an intestinal epithelial cell to pick out fat globules to the exclusion of other material and of a leucocyte to attack and destroy a microbe are examples of this independent action. The natural history of animal cell life and the possibility of its modification by electricity is an inviting field for study. If the leucocytes in a living being may be anesthetized by chloral so that they are unable to do their work they may likewise be exhausted or revived by the electric stimulus. And what is true of the leucocyte is true of other animal cells, if not all, which go to constitute our several tissues. Who shall say that the primary impulse of a nervous centre is not initiated by a capacity in the nerve cell as individual as that exercised by the amœba, the epithelial cell or the leucocyte. Indeed, if this initiative capacity to perform certain work is not inherent to the cells of the nervous system we must retreat to an immaterial principle underlying the phenomena of nervous action and hypothecate a sort of metaphysical *nervi nervorum*. It is then to an effect upon the life history of the cells involved in a given morbid process that we may look to for well known remarkable effects of electricity upon nutrition and a consequent modification of the processes of disease.

It is not improbable that a final field of contest in the cure of disease is between the physical phenomena we term electric and the chemico-biological processes of metabolism exhibited by the animal cell—between electricity on the one hand, which in the human body, by electrolytic conduction, becomes a chemical process and the chemical processes on the other hand, which constitute life in the organism—chemistry against or in conjunction with chemistry. From this point of view, much of electro-therapy becomes cellular therapy, in which electricity is the active agency in producing results which in general we term nutritional; and the explanation of the cure of curable diseases is to be found in the tendency of palliation and cure to be measured by the degree of nutritive improvement effected. The electro-therapy of the future must include acute as well as chronic diseases. Paradoxically, we may put the statement, cure the patient's body and we cure his disease. It is upon this great and broad general principle and not solely upon specific local effects that I believe the future success and position of electricity in medicine must be based. May we not term this process electro-cellular therapy?

REPORT OF THE COMMITTEE ON STANDARD COILS.

As the Committee had been unable to formulate a report, the members were asked to express their individual opinions.

Dr. A. H. Goelet, of New York, said that the difficulties which they had to contend with were best understood by those who had endeavored to secure a perfect faradic apparatus for medical use. The manufacturers, with the exception of the Chloride of Silver Dry Cell Battery Co., of Baltimore, and the Galvano-Faradic Co., of New York, had evinced a disinclination to undertake the necessary experiments because of the expense which would be incurred. His own experiments however, had shown him that the suggestions made in his paper at the last meeting, were in the right direction. If such a coil were constructed and adopted, the results obtained by different investigators would be much more nearly uniform. The speaker proposed that the committee should report progress, and that they be continued for another year.

Dr. W. F. Hutchinson, of Providence, thought this proposition an excellent one. The members of the committee were receiving an astonishing number of inquiries from medical brethren showing a wide-spread ignorance of the subject of electricity, and matters are made still worse by the variability of the instruments at present at our disposal. The coils should be made of a definite length and resistance and the current operating it should have a definite strength.

The President suggested that the services of an electrical expert would facilitate the work of the committee, and added, that he thought it would be well to add the name of Mr. A. E. Kennelly to the committee. Suggestion approved.

Dr. G. Betton Massey, of Philadelphia, said that he had especially directed his attention to a consideration of the powers of the primary faradic current to contract muscle. In the course of his experiments, he had found that an Engelman faradic battery when tested on a very muscular myoma failed to produce the same amount of contraction which resulted when currents from other primary coils were tried. Four du Bois-Reymond coils in his possession act very differently, and these differences he thought were due to variations in the length of the primary wire, in the mass and length of the core, and in the character of the current interruptions.

The President said that there need be no surprise at the difficulty the committee found in pursuing their investigations, when one remembers that induction coils may be made varying from less than twenty vibrations per second, to one giving alternations of 20,000 per second, and producing a current, which, so far as is known, has no effect on the human system.

On motion of Dr. Hutchinson, the name of Mr. Kennelly was added to the committee.

Committee on Meters.

As none of the members were present, there was no report.

The Committee of Arrangements announced that the Association had received an invitation from the Electric Club to a reception given that evening in their honor, also an invitation to visit and inspect the Telephone Exchange.

THE USE AND ABUSE OF ELECTRICITY IN MEDICINE.

By A. D. Rockwell, A. M., M. D., of New York, formerly Professor of Electro-therapeutics in the New York Post-Graduate Medical School and Hospital, etc.

Anything that is used, can be abused. What we eat and drink and the air we breathe, are common and ever present examples of the folly and ignorance of man in the use of the good things of life, and in every direction the tendency is to abuse rather than to rightly use the gifts of nature. Activity without insight is the law that governs, and the result is that evolution of correct principles becomes handicapped in unnumbered ways. Now while this applies to many

departments of our art, as well as to other fields of investigation, it applies with especial force to the study and practice of electricity in medicine. Devolution or destruction accompanies and is a part of the general process of evolution, and it is a significant fact that this reverse process of devolution which should by this time have exhausted its ill directed energy is more active than at any previous time in degrading a field of research as fascinating and important as any in the whole range of medicine.

Now this clog or hindrance to the right appreciation and the right use of electricity does not emanate so much from self-confessed charlatans. With the advance of a better knowledge of the subject, the emoluments of their trade have been so curtailed, that with the advertising oculists and throat doctors of a quarter of a century ago, they form an insignificant and almost unrecognized factor in the line of this special work.

Neither do I allude to those members of the profession who, making no use of electricity themselves, honestly believe it to be of little practical value and discountenance its employment.

My remarks are suggested in remembrance of a far larger body—members of the regular profession who freely use electricity, and of a still larger number of the laity who either with or without advice make use of this agent as commonly and as confidently as they take their morning bath or daily friction.

I would here make one emphatic disclaimer, for when one advocates certain restrictions in the use of measures in which he himself is especially interested, he lays himself open to the charge of being a special pleader actuated by unworthy motives. I am far from believing that only those can use electricity with satisfaction to themselves or benefit their patients who have devoted years to its study and to the practical details of its application. I am sure that no physician is thoroughly equipped, who has not in his profession and always in perfect order, some form of electrical apparatus.

While engaged in the preparation of this paper I read in the daily press of a fatal case of opium poisoning. Four physicians gather at the house and recognize that the only hope of saving the patient, is the prompt and persistent application of electricity. Eager and prolonged search finally results in unearthing at a neighboring druggist's an old apparatus, which on trial proves inefficient, and the patient dies.

Possibly a life might have been saved had the proper appliance been at hand, with a knowledge of the necessary simple details of its application in such cases, for we all know that by the use of this powerful agent, artificial respiration can be continued for hours, until the paralyzing effects of the poison wears away.

Neither do I believe that in every case and on all occasions it is necessary that all applications be made by the physician, although I am confident that every medical man who has had experience in this direction, will agree that such self-treatment is usually unscientific and unsatisfactory and in many cases utterly impracticable.

The temptation on the part of the people to use electricity themselves, and on the part of the profession to allow them to do so, is very strong. The majority of physicians know little more of electro-therapeutics than their patients. Forgetting that it is not so much electricity that cures disease as the method of its employment, forgetting that there are various kinds of electricity in common use and many different methods of applications, every one of which is capable of various modification, forgetting that there are certain temperaments who do not bear electricity well, and upon whom the currents and methods employed must be stud-

ously varied during a course of treatment, in short, forgetting that electro-therapeutics considered as a science or an art is wonderfully complex and exacting, orders the patient to get a battery and try electricity. Now, to hold at this stage of its development such mean ideas of electro-therapeutic science is unworthy any intelligent mind and it should be the aim of the members of this Association to counteract such erroneous teachings. This is the more necessary because from its very nature electricity in its therapeutic relations is far more readily misunderstood than understood and abused than rightly used.

Any one can buy a battery of some sort, for the market is glutted with machines of the most inexpensive and worthless construction. Any one can readily learn to put it in action and apply the electrodes, and when this is done whether by physician or patient, it is too often with the understanding that what has been done is all there is to electricity. No matter how generally well equipped for his work every medical man acknowledges the necessity of preliminary training and an acquired experience before he can claim expertness in operative surgery, or in the various special departments of medicine, but in electro-therapeutics, not only the otherwise well educated physician but the veriest fool considers himself competent as soon as he has mastered the mechanical details of such ordinary induction coil or galvanic apparatus as may happen to be in his possession. Such assumption is the height of injustice both to the reputation and to the scientific development of the agent, and to the patient who has been deceived. The fault of the physician lies not in the use of electricity, even though he be no expert, but in the claim of a degree of knowledge and expertness that he does not possess. Precept should teach by example, and as a picture of genuine and frequent experience I have in mind two cases of infantile paralysis. In both of these cases there existed but the slightest evidence of muscular irritability, and the previous history and course of both were almost identical. The first of these cases was subjected to prolonged applications of the galvanic current with frequent interruptions, sufficiently strong to call forth the slight reactions that it was possible to obtain. The result was that muscular irritability became entirely extinguished, the limbs that might under judicious methods have regained a certain power of locomotion became hopelessly paralyzed. Here then we have evidence that sudden galvanic shocks, whatever useful purpose they may sometimes serve, are often dangerous in the extreme. Their effects are in the main undue stimulation, and in their relation to nutrition, destructive, rather than reconstructive.

The continuous passage of the current on the contrary, while in a certain sense stimulating in its effects, combines influences that are sedative and tonic, and preëminently reconstructive, and is alone equal to the task of resisting progressive degenerative changes in nerve and muscle.

The second case, treated patiently by the continuous action of the current, without any frequent attempt at first at muscular contractions pursued an entirely different course.

Very gradually, the muscular contractions became stronger and stronger the limbs warmer and larger, until finally the patient regained a considerable and permanent control over the paralyzed members. I here present to you a patient who is an excellent example, on the one hand, of misdirected energy, that activity without insight to which I have alluded—and on the other, of the benefit to be derived by a method which for the want of a better name I have termed, the cumulative effects of electricity. Last November he was caught by a slowly moving engine, dragged along the ties, and sustained fractures of the clavicle, hu-

merus and several ribs. Traumatic paralysis of the radial, median and ulnar nerve supervened, with complete motor and partial sensory paralysis of the right forearm and hand and in a less degree, of the arm and shoulder. He was for three months treated electrically by his attending physician who used the faradic current only, having the patient hold the electrodes in his hands. On one occasion he went away and forgot all about the patient and allowed a strong current to pass for nearly an hour. The paralysis failed to improve under such barbarous treatment, and when he fell under my observation in May last, there was such a profound atrophy and loss of muscular irritability, associated with degenerative reactions, that I gave a discouraging prognosis. You observe however, the very excellent results of the method adopted. He at once began to improve and improved rapidly, and is now able to engage in manual labor with almost as much efficiency as ever. The increased efficiency of the galvanic current when it is applied for some time along the course of a nerve without interruption as was done in this case is a most interest phenomenon. Energy is undoubtedly stored, possibly in the same sense, although not in the same demonstrable way that chemical action is stored in the ordinary storage batteries. The result is seen not only in increased power in deflecting the needle of the galvanometer, but in overcoming conditions of disease. One factor accounting for this increase as must be quite evident, is the better conductivity of the tissues gradually taking place at the seat of the recombination of the current—a result due to congestion of the skin and adjacent parts under the electrodes. That this explanation however of the increasing strength of the current when continuously passed through living tissue is but partial, can readily be demonstrated.

I apply the current from a given number of elements to the arm and forearm, and seven milliamperes are immediately registered. In two minutes there is an increase of one degree, in two minutes more an additional degree, and in eight minutes twelve milliamperes are registered. That this extraordinary increase in strength is not caused by improved conduction simply, I soon satisfy myself by applying vigorous friction to the other arm, and when the congestion is as intense as that produced by the electricity, the electrodes are applied. Instead of seven, the meter does indeed immediately register ten milliamperes, but it is not until several more minutes have elapsed that the additional two degrees are registered.

To analyze the molecular disturbances that evidently take place during the passage of the galvanic current is a labor of the greatest difficulty, and the phenomenon is not yet thoroughly understood.

Evidences, however, of the chemical action of electricity as it passes through the tissues are not wanting, and the sudden increase of strength is perhaps due to the electrolytic or polarizing action of the current, exciting a secondary current in the living body, similar to what is observed in a reservoir or secondary pile.

It would perhaps be too much to assert, that any intelligent physician using electricity is unacquainted with the fact that there are three main divisions of the subject, namely: the static, galvanic and faradic forms of electricity, although it is certainly true that the majority have very little appreciation of the wide difference in their physiological and therapeutical effects. How many, however, are aware that the induction coil itself is so differently and variously constructed as to yield qualities of current that for all practical purposes are as separate and distinct as are the galvanic, faradic or static forms of electricity?

And of the number who have knowledge of these facts of physics, how few there are who have given any adequate

consideration to the differential indications for their use.

To correctly differentiate between the various manifestations of electrical energy and then to decide upon the proper method of its administration, are questions of the highest importance and their solution beset with difficulties, and place electro-therapeutics in the front rank of scientific studies. Polar effects and current directions are again two factors in the production of therapeutic results that demand more careful investigation. No one would now assert that in gynecology or in electro-surgery it was a matter of indifference which pole was used, but it is not uncommon to hear the expressed opinion, that in medicine it makes but little difference which pole is used or which direction of the current. In the midst of the theories more or less fanciful that have accompanied the magnificent discoveries of Galvani and Volta, Mattenci was able to bring forward evidence of the chemical action of the current on organized tissue. His doctrine, though thoroughly scientific and based on experimental facts, had to make way for the classical yet confused hypothesis of the Germans—the theory of electro-tonos—a mere physiological theory having no relation to anatomy or histology. Two of the most celebrated disciples of Du Bois Reymond, the author of the classical physiological theory of electrotonos, Erb and Eulenbourg, had long experimented according to his ideas, in cities far apart.

Starting from identical principles, the result of their long years of study proved to be absolutely contradictory. This was rather embarrassing to the sanction of the theory. Looking for an intermediary capable of explaining the discord they referred the matter to Helmholtz, who explained the difference by showing that if you apply the negative pole at any point whatever there will result at this point an increase of excitability, but that for reasons of a purely physical order, there can be in the vicinity of the negative pole a positive point. If therefore you excite a nerve near its catelectrotonic point, you may chance to light on an anelectrotonic zone—a circumstance that fully explains how it became possible for two experimentors starting from the same premises to arrive at different results. It is quite certain that in indicating the formation of a zone with an opposite name around the excited point, Helmholtz, as did Mattenci, had in mind the chemical effects of the current, but in accepting his theory his countrymen have transformed a physiological action based upon electrolytic changes into phenomena the explanations for which were fanciful and unscientific.

I call attention to these old facts of history in order to emphasize the strong physiological and chemical basis for the study of differential polar effects in therapeutics. My own more recent investigations along this line greatly strengthen me in the belief that there are still richer veins to be worked in electro-therapeutics than have even yet engaged our attention. There can be no question as to the physiological significance of the complete elimination of one or the other pole in direct experimental tests, and clinical results, as I have had occasion to observe, are in more or less accord with the results of physiological experiment. Much fault is found with electricity, or rather with those who advocate its use, because so much is claimed for it. These claims are, however, based upon the demonstrated fact that it is a many-sided weapon. It acts efficiently in diametrically different conditions, and prejudice is often excited against its use because of the seemingly paradoxical claims of those who write about it. But the fact has been so thoroughly established that it is both a stimulant and a sedative, a tonic and depressor, or a violent irritant, according to the kind and quality of the current used and the method of its application, that those who oppose its use on

the ground of these paradoxical claims simply declare their own lack of practical experience.

In its relations to the arts and in its purely commercial application, electricity affords but little opportunity for the charlatan. In order to obtain an honorable recognition the electrical engineer must in reality be an expert. No incomplete and imperfect knowledge will serve his purpose. With the medical electrician, however, it is far different. He may be utterly ignorant of the simplest problems of physics and entirely at sea in regard to the important subject of current differentiation, and yet unblushingly palm himself off on a credulous public as an expert in electro-therapy. He may indeed be utterly ignorant of medicine itself and yet gravely call himself a medical electrician, while those upon whom he practices his crude and ill-digested art, and who in other things count themselves as wise, fail to see the incongruity between his equipments and pretensions.

Discussion.

In answer to a question from Dr. Massey, the author said that it was difficult to obtain any reaction whatever, although the reaction of degeneration was present, and the arm was greatly atrophied. One object of his paper was to demonstrate that electricity is capable of affecting degenerated fibres, and enough time had elapsed in this case before beginning the electrical treatment, for spontaneous regeneration to have occurred.

Dr. R. J. Nunn said it was absolutely impossible, in a sparsely populated district, for the medical practitioner to have all the most approved electrical appliances always at hand, and it was not so much his fault, as that of his surroundings. These country practitioners are the bone and sinew of the profession. Regarding the tolerance of patients to electricity, he said that he had sent a patient to Dr. Morton who developed albuminuria whenever a mild galvanic, faradic or static current was applied to him. The albuminuria was also produced by nervous excitement, over-fatigue or indigestion.

The President thought this peculiar effect of electricity was rather fortunate, as it gave objective evidence of the effect of this agent on metabolic processes going on in the human body. One should not lose sight of the very important point made in the paper concerning the chemical action of the current.

In answer to a question whether the *shock* of the treatment might not be responsible for the albuminuria, he said that as the patient was used to electrical applications, and the albuminuria followed the application of the quiet continuous current which should not cause any nervous excitement, it seemed evident that the occurrence of the albuminuria could only be explained by considering it a direct result of the irritating action of the current.

NEW CONTRIBUTIONS OF THE ELECTRICAL TREATMENT (BOTH FARADIC AND GALVANIC) TO THE DIAGNOSIS IN GYNECOLOGY.

In the absence of the author, the paper of G. Apostoli, M.D., was read by Dr. Hutchinson.

If the operative technique and surgery have almost arrived at their apogee in gynecology, having since the discovery of antiseptic methods, pursued a most brilliant and successful career, on the other hand it may be affirmed that the knowledge of the indications for operative interference based upon a diagnosis of the condition of the uterine appendages which is of predominating importance, is far from having made the same advance.

In consequence, uncertainty still reigns and a surprise is the rule in exploratory laparotomy.

It is unnecessary to insist upon the interest which attaches itself to a new method of exploration, destined by

its precision and the facility of its exploration to save many mistakes, to show the road, as it were, without the bistoury, thus avoiding irreparable if not fatal errors—destined, we may say, to disarm the surgeon or to counsel an advance after furnishing a sure and exact guide.

If conservative gynecology has indeed found its best and most precious auxiliary in electricity, surgery in its turn is rapidly destined to claim frequently its aid to light the way, to confirm or rectify a doubtful diagnosis, to impose or hasten an operation when at first sight it did not seem to be required or to proscribe it in others as being superfluous, useless or dangerous.

Two vital questions most difficult to solve present themselves every day in gynecology. Are the appendages diseased? If so, is there pus, or what is the degree of their inflammation.

It is to solve these questions that laparotomies called exploratory are made daily or castrations are done not authorized by the actual inflammatory condition, and it is for the solution of these problems that I propose to employ the aid of a *preliminary electrical treatment*.

Indeed exploratory laparotomies and mutilating operations practiced at the commencement for rebellious ovarian pain or for ovarian disease of a doubtful nature should be proscribed until the resources of *faradic sedation* and of the *intra-uterine galvanic reaction* have been exhausted in the diagnosis, I affirm that intra-uterine applications, faradic or galvanic, if questioned with sagacity and perseverance are destined with the greatest frequency to clear up the diagnosis in the following clinical conditions which may be condensed in these formula.

A.—Faradic Current. In 1883 I extended the road so largely opened by my friend and master, Dr. Tripier and demonstrated what might be gained in gynecology from the faradic current of high tension if administered *during a sufficiently long period*; I showed also that the faradic current of high tension (produced by a long fine wire) is a marvelous *sedative*, a calmer of pain in general and that it was of great utility in the treatment of the so called ovarian pains of *hysterical* origin which plays frequently so large a part in uterine pathology.

The therapeutic response given by the faradic current applied according to the rules which I formulated in 1883 are clear, precise and almost constant. It suppresses or at least diminishes or interrupts for a period varying from several hours to several weeks every hysterical ovarian pain, if it be hysterical only in its origin.

It acts sometimes so instantaneously that one might suppose it the result of a powerful and irresistible suggestion—it brings relief with such facility in the painful ovarian zone—with the more certainty if applied to the interior of the uterus than in the vagina—that armed with these facts I have utilized the method as a means of *diagnosis*. If every hysterical ovarian pain, most frequently unilateral, and without inflammatory lesion of the appendages is almost always appeased for a longer or shorter time by the faradic current and every failure of this medication must be attributed to a substratum of inflammation producing a more or less serious irritation of the appendages not amenable to the sedative influence of the induced current. Now, such is the exact clinical fact as an experience of more than ten years has made perfectly evident to me and I am enabled to-day to formulate in several general propositions the rules and practical conclusions which guide me.

Every ovarian pain of hysterical origin is amenable to the faradic current of high tension.

Every failure of this medication is due almost always to a concomitant inflammation of the appendages.

Given an ovarian pain of doubtful origin it is necessary

first to faradize the uterus, either the pain will disappear for the moment or it will not be influenced at all; in the first case it is of hysterical origin, and in the second, it is an unrecognized affection of the appendages which will require a complementary examination or a special procedure.

So if a woman consults us for an ovarian pain and a bimanual examination reveals no evident lesion of the appendages, it is necessary first, to faradize the uterus and if there is no relief it may be necessary perhaps, under chloroform, to make another examination.

If doubt remains the application of the galvanic current will render evident what the faradic only caused to be suspected.

En resumé. The faradic current of high tension instructs us as to the true nature of the ovarian pain, so called, of which it is the most rapid and efficacious calmer.

Ovarian pain is indeed most frequently amenable to the faradic current of high tension if the rules of procedure are followed as regards the number of applications, their duration, choice of coils and seat of application which I formulated in 1883.

If *hysterical, and hysterical only*, it is, if not cured, almost always relieved, while on the other hand if of inflammatory origin, notably if allied to an inflammation of the appendages, the application of the faradic current of high tension is unsuccessful in almost every case, so then if in a particular case the *successful cure* enlightens us as regards the diagnosis and imposes an abstraction from operative procedures, in another the failure shows that the pain is of deeper origin, which requires a supplementary galvanic treatment or an operation.

B.—Galvanic Current. Since I proposed in 1882 for divers gynecological affections (fibrous tumors, endometritis, peri-uterine inflammations, functional troubles, amenorrhœa, dysmenorrhœa, menorrhagia, metrorrhagia, etc.) a galvanic treatment uniform in appearance but differing essentially as regards intensity, duration, localization, number and interval of applications, choice of poles, etc., I have been struck with two facts of the greatest importance.

1. *The variable tolerance of the uterus in different subjects for the same dose of galvanic current.*

2. *The variation of this tolerance in the same uterus according to different peripheral anatomical condition.*

These facts at first empirical and confused in my mind only found their explanation when I placed the uterus in subjection to the innervation of the ovaries and tubes and when I had observed that the sensibility of the uterus was above all dependant upon that of the appendages.

The variations in sensibility in different subjects and in the same subject at different times according to the morbid or other condition of the appendages became perfectly clear. The law of salpingian and ovarian reflexes which controls this important problem was not long in receiving at my hands an experimental solution which was equal to a mathematical demonstration.

If it is really true that in a particular case, a woman suffers and is intolerant of the galvanic treatment because the appendages are inflamed, it is necessary only to suppress these organs to reestablish at once a condition of freedom from pain and to restore the equilibrium of uterine sensibility, in order to prove on the other hand that the uterine hyperæsthesia was indeed provoked by the morbid state of the appendages, it is sufficient to apply the electrical current under exactly the same operative circumstances after castration as it was applied before the operation.

The electrical tolerance should be acquired immediately by a uterus which before castration will not support it at

all or very badly. Such is the case and it constitutes the experimental proof of my clinical induction.

I have at present many examples of women whom I have vainly endeavored to treat by the intra-uterine galvanic current which powerless to produce the least benefit only served to indicate the necessity for castration.

This operation having been performed, immediately the excessive uterine sensibility has been appeased and I have been able, after this bilateral operation, after the abolition of the injurious reflexes, to bring to a successful termination an electrical treatment which before was not only intolerable but powerless and inefficacious. Thus the castration liberated the uterus from its galvanic hyperæsthesia and restored a tolerance almost identical with that conferred by the physiological integrity of the appendages.

I have thus been able at one stroke by the same therapeutical measure well directed, to clear up the diagnosis, legitimize a surgical intervention, and to complete later a symptomatic cure which the knife could not accomplish.

It is then perfectly true that the condition of the appendages regulates before everything else and almost entirely the question of intra-uterine galvanic tolerance and it is in this connection that I propose to paraphrase a well known proverb and say:

Tell me what the galvanic uterine reaction is with this or that woman and I will tell you the condition of her appendages.

This formula comprises in itself the new and important problem which I will briefly explain and develop. Since 1884, I have grouped under several heads the causes of this uterine intolerance.

1. *Hysteria.*
2. *Intestinal Inflammation.*

3. Peri-uterine phlegmasies (this word at first somewhat vague, expressing only a general formula, soon took a more concrete form and the expression, lesions, of the appendages, has been substituted.)

4. *Certain fibro cystic tumors of the uterus.*

In every intra-uterine galvanic application there are two points to note.

The Operative reaction which comprises the manner in which the current is supported and tolerated by the patient during the application.

The post-operative reaction (which is the most important of the two) comprising all the sensations experienced by the patient the same day and the following ones.

This reaction may be of a *painful character* or simply *nerveous* (a bending over, fatigue, colic, pains in the kidneys, etc., which may be prolonged one or several days perhaps obliging the patient to remain in bed.

This being said we will now examine the general clinical replies to our interrogations with the galvanic current.

a. Every intra-uterine galvanization of from 100 to 150 m. a. in a uterus simply hypertrophied or fibrous, with or without a concomitant endometritis, without an associated inflammatory lesion of the appendages or of the pelvis—every such galvanization I say, applied with all antiseptic precautions, is always absolutely harmless, almost always well supported and is never followed by a post-operative reaction febrile or very painful the next or the following days if care has been taken to respect the individual susceptibility or tolerance, although rarely however during the application there may be an intolerance which forbids and limits a dosage beyond the medium, but it is purely hysterical.

In this case if there is much pain during the application, it is rare that it does not cease at once when the séance is finished or does not rapidly subside.

In such a case I repeat the intolerance is of a purely hysterical character and the diagnosis becomes surer if we

observe an extremely painful reaction on one hand, and its rapid subsidence at the termination of the application on the other, without any consecutive febrile reaction.

In a word, the more a woman complains during the application, the more brusquely and out of proportion to the dose, the resulting reaction—the more generally the pain ceases when the current ceases to pass, the more precise the diagnosis of hysteria.

Having examined the first case we will now turn to the second.

b. On the contrary, in every case of peri-uterine phlegmasia the electrical intolerance during the application and above all the post-operative reaction begins, increases and is prolonged in proportion to the activity of the said inflammation of the appendages (ovaries or tubes). At this point I will stop to answer a perfectly natural objection to the procedure.

Is every intra-uterine galvanic application dangerous in the presence of an ovarian cyst or suppurating inflammation of the appendages?

Yes, if the application is too intense or badly administered.

No, if it is moderate and well conducted.

Yes, if the application is brutal, massive, particularly if the intra-uterine negative pole, and at the beginning of the treatment; no, if progressive, always tolerable, and if the positive pole is used at the commencement.

In conclusion, if when a question of pure hysteria the dose is not of great importance except that it is unnecessary to irritate the patient and turn her away from a salutary medication, in the other case, the greatest reserve is imposed as regards the dose, for it is the safeguard of its innocuity and of its efficacy.

The question must, however, be considered somewhat in detail:

Every cyst of the ovary pure and simple, that is to say without supuration and without concomitant lesion and inflammation of the tube or appendages opposite, can tolerate safely high intensities applied intra-uterine.

I have observed this quite a number of times in patients when I have applied the current through an error in diagnosis and no accident has resulted, not the shadow of a post-operative reaction of an inflammatory character.

These patients were operated upon afterwards with success and non-inflammatory ovarian cysts discovered with normal tubes.

These facts prove abundantly that to have exaggeration of the uterine reflexes above all there must be an *active* inflammatory process going on in the appendages for we find as a second clinical reply that:

Erysipellic suppuration, particularly acute inflammation of the appendages (ovaries or tubes) predispose to intense post-operative galvanic reactions.

Yes indeed, that the post-operative reaction which is proportioned to the *suppurating* inflammation of the appendages may cause accidents, it is necessary to have the courage to avow and to proclaim it openly in order to understand the reserve, the circumspection necessary to avoid accidents.

But is this any reason why we should disarm ourselves and renounce the employment of a remedy of incontestable utility?

Yes, if we have not the most certain means to defend ourselves, if we have not a true touch-stone to shield us from our possible ignorance.

No, if we have a sure and positive method of control, if mathematical precision, to shield us from the mistakes we are liable to commit.

This control is first of all *preventive* and inculcates in

doubtful cases the greatest moderation, feeling the way I should say, in the application and number of the first sances.

The general rules of conduct are the following:

a. *Begin every galvanic application with the positive pole in the uterus.*

b. *Never apply on the first occasion more than 50 ma. and never at the commencement go beyond the dose which will be supported by the uterus.*

c. *Make the first galvanization with the greatest circumspection and without brusqueness.*

d. *Interrupt the application as soon as there is manifest intolerance and renew it only after two or three days when all post-operative reaction has subsided.*

e. *Do not augment anteriorly the intensity and duration of the application except in proportion to the tolerance manifested upon the preceding occasions.*

These precepts are to be well comprehended and faithfully observed whether the remedy is tolerated or not.

If it is well tolerated, we have the signal which indicates that the road is open and we have to advance without fear or hesitation because the uterine periphery is healthy and the appendages in good condition, or at least they are not in a state of actual inflammation or suppuration.

If there has been previous inflammation (which is possible) it is for the moment extinguished which happens in those old exudations which are the posthumous witnesses of an anterior acute inflammation which has totally disappeared. In a word we find ourselves with a patient absolutely amenable to conservative treatment where we can and should try every means of saving the appendages with the chances greatly in our favor.

Every faculty of the practitioner should be employed to adapt to the case, the pole, the dose, and the number of applications. If on the other hand, the intra-uterine galvanic cauterization is not tolerated in spite of the precautions recommended, if in a word an intense post-operative reaction ensues although the sance was carefully conducted, we have in this fact if well interpreted a true *thread of Ariadne* which will serve to lead us to the true diagnosis.

Every circumstance becomes of importance and serves as a most precious means of control. The fever after—the pain which continues the next and the following days—the loss of appetite, the insomnia, principally the absence of all amelioration and the aggravation of the previous state serve as important guides.

If the post-operative reaction is intense and prolonged it is a cry of "halt!" a red disk which indicates that the way is barred and advance impossible.

So at times we may extract good out of evil; it is the danger avoided while suspected and foreseen which serves as a touch stone to clear up and fix the diagnosis saying plainly:

Here the appendages are suppurating; there they are not.

Here a catarrhal salpingitis which is curable; there a suppurating inflammation of the tubes and ovary. Here an operation is required at once; there it would be a crime to do it.

Here an ovaro-salpingitis amenable to patient, laborious and progressive conservative measures; there a serious inflammation to be treated only by castration or vaginal hysterectomy.

It can be seen then readily how, from the very fundamental principles of this intra-uterine therapeutic method, the surgeon can and will in the future find indications of the highest importance which will enable him to make in advance and *not a posteriori* a correct diagnosis, which will arm or disarm him accordingly.

How vast and important this problem is and how worthy to occupy the attention of surgeons, who are often obliged

to open the abdomen to make a diagnosis; who perform inconsiderate mutilations or operate for supposed fibroid tumors when really it is salpingitis or ovarian cysts, or *vice versa*.

To epitomize what I have said: The galvanic current applied to the interior of the uterus is destined to inform us respecting the state of the appendages—if healthy; if inflamed, the degree of inflammation; if pus exists; if the disease is curable or not; if there is an inflammatory process in course of evolution.

It is capable of saving us from many clinical and operative mistakes and of enabling us to avoid, for one example among many, the error of mistaking a *subperitoneal fibroid tumor* for a *salpingitis*, and *vice versa*.

Two facts of the greatest importance dominate all galvanic intra-uterine therapeutics:

First, the *absolute tolerance* (with the exceptions I have noted).

Secondly, the *intolerance* which increases with the acuteness of the inflammation of the appendages.

The *uterine sensibility* is then in perfect subordination and relation to that of the *appendages*, and the reply we get from the application of the current will enlighten us upon the absence, or degree of inflammation of the appendages.

Beyond this first, most frequent and most important source of intolerance, there are others of secondary importance between which it is usually easy to make a differential diagnosis.

a. First in importance comes frank *hysteria* with its sudden, intense reactions, and general appearance which cannot fail to strike the most unobservant.

b. *Fibro-cystic tumors* of the uterus, very probably of a malignant nature.

c. *Phlegmasias* of the pelvis comprising the *intestines*, which have a well-marked and characteristic history.

The clinical consequences which ensue from these premises, briefly stated, are the following:

1. A uterus tested by the galvanic current with a dose of from 100 to 150 ma. which gives no operative reaction, which not only tolerates this dose but results in a diminution of the dominant symptoms (such as pain and hemorrhage); a uterus, I repeat, thus tolerant has always its periphery healthy, or at least there is not actual inflammation of the appendages requiring surgical procedures, but the galvanic treatment, of which the dose is limited only by the clinical indications to be carried out.

Even if there be a coexistent *ovarian cyst* without inflammation of the tubes, the same electrical tolerance will be preserved.

2. A uterus which supports only 50 ma. or supports it badly, where the consequences are much pain and fever, has a *suspicious periphery* and should be tested with moderation and prudence.

3. A uterus whose intolerance diminishes with the number of applications and is accompanied with marked and increasing attenuation of the symptoms, is that of a hysterical subject, or there is an inflammatory process in the course of regression or arrest.

4. A uterus whose intolerance at the commencement is excessive (supporting only 20 or 30 ma.), and which increases with the number of applications and is accompanied by an elevation of temperature, is a uterus whose periphery is attacked by a lesion not amenable to conservative gynecology. In this case a suspension of the galvanic treatment is imperative when the diagnosis is thus elucidated, and it becomes necessary to employ surgical measures—most frequently it will be a castration justified by the presence of an ordinary suppurating ovaro-salpingitis.

Discussion.

Dr. Massey said this seemed to him the most important paper ever written by Apostoli, and he could, from his own experience, endorse the views expressed in it. The surgeons could find in this new aid to diagnosis an additional help in enabling them to avoid performing many useless operations. In his opinion, the author had drawn the line rather too sharply in regard to the avoidance of electricity where the use of this agent elicits certain painful responses, and in this connection he wished to say that the idea of thrusting a perfectly rigid instrument like Apostoli's electrode into the uterus under all circumstances, was to him simply horrible. He was convinced that moderate inflammation did not contra-indicate very careful applications to the interior of the uterus, but the presence of pus in a tube, without free exit, is a positive contra-indication, as is also the presence of any phlegmonous inflammation which has reached the stage of suppuration. Where the os is at all patulous, and it usually is when there is an inflammatory condition about the uterus, we should use a flexible electrode, with the point protected by a globule of shellac or hard rubber. It may be covered like an applicator with absorbent cotton, moistened with hot water or with a solution of cocaine. In cases of suspected inflammation of the appendages, and with undoubted enlargement and softening of the uterus, he had noticed that where this plan had been adopted, the treatment had been followed by less pain. He was convinced that all ovarian and salpingitic cases are originally uterine, and the question to determine is whether the case is more uterine than ovarian, and this will usually be settled by the treatment.

Dr. Goelet had utilized the faradic current in the vagina by the bi-polar method to facilitate diagnosis, but had hesitated to use it in the uterus in the manner described by Apostoli, because he had found that such cases were at first rather intolerant of intra-uterine interference because of the coexisting endometritis. Treatment of the endometritis, however, which in many instances is responsible for the continuance of the inflammation in the tubes, will so far relieve the undue sensitiveness as to admit of such treatment even in cases which were previously supposed not to be amenable to this treatment. He thought harm would surely result from an indiscriminate practice of this test for diagnostic purposes. The gynecologist is the best qualified to conduct this treatment. It must not be forgotten that what Apostoli might do with impunity, many others, even gynecologists, should hesitate to undertake, for Apostoli has reached a rare state of proficiency in manipulation. He did not approve of condemning every case of uterine intolerance to operative interference, nor did he think Apostoli intended to convey such an impression, for in another portion of the paper, he said that many of these cases can be better treated by electricity than by cutting operations. Endometritis is responsible for the uterine intolerance, and after relieving this, electrical treatment can be resumed with benefit. The so-called Apostoli bipolar intra-uterine electrode as ordinarily made in this country, is an abominable instrument, as it would in many instances require previous dilatation of the canal to allow its introduction, but Apostoli's original instrument is quite flexible and not much larger than an ordinary intra-uterine sound. The platinum electrode, though rigid, can be introduced as readily as the uterine sound if one possesses ordinary skill in manipulation.

Dr. Nunn thought that any high tension current, as for instance the static current, could be used as well as the faradic for the relief of pain. The difficulties in diagnosis in some of these cases are very great. He recalled one case which had been for three years under treatment by an accomplished surgeon for what was supposed to be an ovarian

tumor. There was certainly a tumor on the right side, but the faradic current showed the tumor to be entirely hysterical, and it eventually disappeared. The intolerance which she at first exhibited disappeared after considerable perseverance in the treatment. He might have been particularly fortunate, but he was bound to say that in his hands, inflammation had never followed from the introduction of an electrode. He had been much pleased with the tin electrodes suggested by Dr. Goelet. He preferred to select a small one, and cover it with absorbent cotton until it is of the desired size. Intolerance to electrical treatment had been considered to be dependent upon inflammatory conditions, but the speaker was inclined to attribute it more to idiosyncrasy, and he cited two cases to illustrate this point. One of these patients rarely could stand fifty milliamperes, while the other usually takes one hundred milliamperes without discomfort.

Dr. Roekwell said that before the practice of using high tension currents from very fine wire coils came into vogue, there had been no doubt in his mind as to the superiority of the galvanic current over the other forms, where it was desired to relieve pain, whether external or internal, but now he found it difficult and sometimes impossible to determine *a priori* which current is more suitable for a given case. He had been accustomed to use the current from a coil containing 2,000 feet of wire, made up of several coils of different sizes of wire, all connected into one continuous coil. The current from this coil had a remarkable analgesic effect, like that described in the paper, and it was therefore of value in relieving pain of a neurotic type, and in excluding organic trouble. A short time ago, a patient with all the symptoms of ulceration of the stomach was referred to him for treatment of an associated gastralgia. A current from a very long coil run by five or six Leclanche coils, relieved him promptly, and the speaker then felt justified in stating to the attending physician that he did not consider there was any organic disease present. The subsequent history of the case confirmed this opinion.

Dr. H. H. Hahn, of Youngstown, O., said that he had frequently noted a striking difference in the effects obtained with various electrodes, and in some cases, any stiff electrode, no matter how well made, will drag the neck of the uterus forward, and pull upon the attachments. Under these circumstances, the patient is often intolerant of the treatment, but this may be diminished by using a flexible electrode. He had devised one with a joint just external to the os, so that after the introduction of the instrument, the uterus will be allowed to resume its usual position before the current is turned on. He had in this way been able to use the current in cases in which Apostoli would not employ it, and by beginning with ten milliamperes, and after an extended course of treatment gradually increasing it up to 150 milliamperes, he had obtained very excellent results.

Dr. Charles R. Dickson, of Toronto, said that in some of the cases in which the stronger currents were contra-indicated, he had met with success from the use of exceedingly mild galvanic currents, starting with perhaps only five milliamperes for five minutes. He had had cases in which even with very mild currents, a rash was produced, but after a few weeks of cautious treatment, he had found that the current could be very materially increased. He was not accustomed to employ the ampère advocated by many.

(To be continued.)

A NEW gynecological operation has been devised by Dr. Duhrsen, of Berlin. Its object is the vaginal fixation of the uterus for the relief of retroversion.

THE
Journal of the American Medical Association
PUBLISHED WEEKLY.

SUBSCRIPTION PRICE, INCLUDING POSTAGE:
PER ANNUM, IN ADVANCE \$5.00
SINGLE COPIES 10 CENTS.

Subscriptions may begin at any time and be sent to

THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION,
No. 68 WABASH AVE., CHICAGO, ILLINOIS.

All members of the Association should send their Annual Dues to the Treasurer, RICHARD J. DUNGLISON, M.D., Lock Box 1274, Philadelphia, Pa.

MEMBERSHIP IN THE AMERICAN MEDICAL ASSOCIATION.

This is obtainable, at any time, by a member of any State or local Medical Society which is entitled to send delegates to the Association. All that is necessary is for the applicant to write to the Treasurer of the Association, Dr. Richard J. Dunglison, Lock Box 1274, Philadelphia, Pa., sending him a certificate or statement that he is in good standing in his own Society, signed by the President and Secretary of said Society, with five dollars for annual dues and subscription for THE JOURNAL. Attendance as a delegate at an annual meeting of the Association is not necessary to obtain membership. On receipt of the above amount the weekly JOURNAL of the Association will be forwarded regularly.

SATURDAY, JANUARY 21, 1893.

COLLATERAL ORGANIZATIONS.

The recent rapid increase in the number of physicians in this country, accompanied by a corresponding development and progress in our art, has of necessity caused the formation of special societies for the promotion of special lines of professional work. Some of these organizations are naturally collateral and coöperative in their purposes with the American Medical Association. Of these may be named the American Academy of Medicine. The American Medical College Association and the American Medical Temperance Association.

These Societies are each made more successful in their work and purposes by reason of their meetings being held either prior to or during the days of the sessions of the American Medical Association, and at the same place.

Some other Societies would very greatly enhance their own usefulness and prosperity by arranging their place of meeting to correspond with the same place, and either the week before, or after that of the American Medical Association.

In arranging to attend any of the National Society gatherings, everyone desires to obtain all the possible benefits there are to be had during a brief outing. That this may be most perfectly accomplished, a focalizing of societies is necessary. It is to the interest of several hundred physicians and surgeons to have the railway surgeons meet the week after and at the same place with the American Medical Association. At the same time and place the surgeons of the National Guard should hold their annual meeting. It is no exaggeration to say that nine-tenths of the members of these two organizations belong to the American Medical Association. Hence, it is easy to see how desirable it is to them that they may be able to save time and money by such a concentration of meetings as suggested.

The American Microscopical Association is largely composed of physicians, and would add very materially to its working membership by holding its annual session during the week preceding the meeting of the American Medical Association, and at the same place. While mentioning these particular organizations we might refer with equal propriety to others, which would be correspondingly benefitted by holding their meetings at the time and place designated.

In a unification of work and purposes will be found the greatest good to the greatest number.

THE ASSOCIATION OF SOUTHERN MEDICAL COLLEGES.

The editor of the *Southern Practitioner*, a journal edited at Nashville, Tenn., takes exception to our editorial criticism anent the organization of the above named Association. Knowing the history of the attitude of several of the Southern medical schools towards the Association of American Medical Colleges, knowing that twenty-six of these colleges were represented by one or more delegates at the time of the provisional organization of the National body at Nashville four years ago, knowing that a pronounced spirit was manifest by a few of these schools even from the initiative organization, to thwart the establishment of a high grade of requirements, knowing that this disposition was manifest upon the floor of the convention then in session, and that the strongest argument made against any progressive action emanated from a distinguished orator protesting against our attempt to scale the mountain's height by a single leap, knowing that this advanced position upon the part of the delegates was rendered doubtful by a body of delegates representing a few Southern schools immediately convening a caucus in a corner of the same room wherein the National body was holding its convention, knowing that a subsequent caucus was held at the Arlington Hotel, Washington, D. C., immediately antedating the second annual session of the National body in the above named city, knowing that only two of these colleges had severed their connection with the National body and that several were ignoring the provisions of this Association, knowing that the representatives of several of these schools were directly or indirectly trying to destroy the American Association, knowing that gross irregularity existed in regard to the enforcement of even a halfway respectable curricula, by conferring degrees after the study of medicine for a period of "eighteen months" together with attendance upon a few continuous weeks of lectures, or by conferring the degree of M.D. upon the scholarly drug clerk if he will only take "one course of lectures," knowing that the opposition to the adoption of a high standard by the

National Association came from a restricted portion of the South and that the larger portion of the colleges represented in the new Association were these same schools, knowing the above facts at the time of publication of the editorial in question, knowing that the broad-minded, unprejudiced representative of the poorest medical college in America could not conscientiously criticise the tone of the article—knowing these data, we saw fit to manifest the courage of our unbiased convictions by the publication of the editorial in question.

Permit us to suggest parenthetically, that we question the ability of any one journal to prejudice any body of practitioners against the National Association unless it is directly to their interests to manifest such spirit. We are of the opinion that the great mass of practitioners of medicine in Kentucky and Tennessee are as desirous of high grade college instruction as the practitioners of Illinois, Minnesota or New York. If the practitioners of Kentucky and Tennessee were to follow the example of their more outspoken brethren in Virginia, North Carolina, Alabama, Minnesota, New York, New Jersey, and several other States they would shortly be equipped against the dangerous product of several low grade colleges in their immediate vicinity. The experience of a large number of States possessing adequate medical legislation reveals the well known fact that a large portion of the alumni of the medical colleges of America, that are conducted "for revenue only" are unfit to be entrusted with the lives of the people. Even though their examinations are far from rigorous over 25 per cent. of their alumni fail to secure a license. Careful statistics gathered by the secretaries of these boards reveal the fact that these men shortly drift out of the profession or locate in States not possessing efficient medical legislation.

Many of these men when too late to retrieve their great loss openly damn their alma mater.

The columns of this journal in the past have been greatly given over to scientific papers and will probably continue to be in the future. Questions of medical sociology have been greatly neglected notwithstanding we are the legitimate organ of nearly one hundred thousand practitioners of medicine in the United States. In view of the repeated and outspoken voice of the American Medical Association in behalf of better medical education we feel justified in assuming the position we do in discussing this question.

It is stated that both the Rush Medical College and the College of Physicians and Surgeons of Chicago, have offered to give up their entire property to the Chicago University, and the faculties to resign unconditionally in order that a medical department may be organized on a level with other schools in this already wonderfully well organized institution. It is stated that \$1,000,000 is in sight for the endowment of such a medical department.

NATIONAL QUARANTINE LAWS.

We are much surprised at the recent querulous debates in Congress pertaining to the utility, extent and provisions of quarantine laws that are required for the protection of our Nation from such infectious diseases as may be prevalent in other countries.

There has been a unanimous expression of opinion by the medical profession as voiced in the medical press, as to the pertinence and necessity of the National Government assuming absolute control of quarantine measures along the Nation's boundary lines.

This is essential because the questions of control of immigration and imports are wholly within the province of Congress and not of State legislatures. The peculiar rights of the several States are always subservient to measures taken which have a purpose of the greatest good to the people of the whole Union.

The captious disagreements of members of Congress in regard to the formulation of needed laws is a bold illustration of the usefulness to the government of a Cabinet Officer of Public Health.

This official would be the legitimate advisor of the President and of Congress, when all such questions arise for action.

It is quite inappropriate and preposterous to place quarantine measures in the hands of the Secretary of the Treasury, an official whose functions are those of the Nation's banker and credit man. Nor would it be more proper to pass sanitary affairs over to any of the other secretaries for their control.

The men who are familiar with the laws of disease, their prevention and treatment, are the Nation's conservators of health. What do Senators CHANDLER, HARRIS, or SHERMAN, or any other of the members of that august and honorable body—the United States Senate, know of the laws of contagious diseases. What do the Secretaries of the Treasury, the Navy or the Attorney General know of the science of bacteriology and its relation to epidemic diseases? Echo answers—nothing. Nor are they supposed to be versed in such a knowledge. Hence, their action, whatever it may be, must either be of the flaring shotgun order, or depend upon the advice of members of the medical profession.

More eminent sanitarians than those selected by the New York Chamber of Commerce to advise upon the enactment of National Sanitary laws, do not live, move and have their being on our planet, and yet we see Congress paying little or no heed whatever to their recommendations.

A year and a half ago the American Medical Association, the largest representative body of physicians in this country, unanimously passed a resolution requesting Congress to enact a law creating a Cabinet Officer of Public Health, and appointed a committee to formally present, and represent the purpose of

the resolution to Congress. This action of the American Medical Association was endorsed by nearly every State Medical Society from California to Maine.

We regret to say that Congress has been heedless of the resolution.

Never before were such vast health and financial interests at stake, and we see them faced by our Nation's legislators in a way that is puerile in the extreme.

It is not the function or the province of the medical profession to volunteer an expression of opinion in regard to the armament of the Nation's forts or ships, the construction of Government buildings, the disposal of public lands, the enforcement of the Monroe doctrine, the legality of the Inter-State commerce laws, the distribution of seeds, or regulate rates of postage, but because of their special knowledge and information pertaining to conditions of health, of disease and its consequences, they are the accepted and only reliable advisors of the people and their representative law-makers on all quarantine, sanitary and hygienic subjects.

A refusal to recognize the value of such advice, is an indication of egotistic ignorance that is likely to result most disastrously to the welfare of the whole Nation, and at a time when we are most desirous of placing our best foot foremost in the eyes of the Nations of the earth.

It may be that the ignoring of the reasonable suggestions of the medical profession, had a little something to do with the change of political power brought about and determined upon by the people at the recent election. The votes of one hundred thousand educated physicians, evenly distributed throughout the States, besides those influenced by them, is a factor that the most astute politician may not hereafter ignore with sublime indifference.

We are inclined to believe that the recent change of Governors in this great State would not have been effected but for the solid vote of the medical profession.

A study of political economy is in no way antagonistic to that of pathology and therapeutics.

EXAMINATIONS FOR THE MEDICAL DEPARTMENT OF THE U. S. ARMY.—We learn from reliable authority that the statement that has appeared in several recent papers and journals, including this, in regard to the examinations in October last in New York City, was incorrect. Twenty-two was the number who received invitations, but eighteen only presented themselves. This number was reduced to fifteen by failures to reach the physical standard, so that but fifteen were actually examined professionally. The number of successful candidates, four, was correctly reported.

THE CINCINNATI COLLEGE OF MEDICINE AND SURGERY.—Dr. J. Trush has resigned the Chair of Theory and Prac-

tice of Medicine in consequence of ill health and the vacancy thus created has been filled by the transfer of Dr. E. W. Mitchell from the Chair of Materia Medica and Therapeutics. Dr. G. A. Fackler, Professor of Materia Medica and Therapeutics at the Woman's Medical College of Cincinnati, has accepted the appointment to the vacancy created by the transfer of Dr. Mitchell.

THE SOUTHERN MEDICAL COLLEGE ASSOCIATION VERSUS THE AMERICAN MEDICAL COLLEGE ASSOCIATION.—There have been several medical college associations, all having exerted more or less influence for good upon the medical education of the United States. Last year after due consultation, a new American Medical College Association held its first regular meeting in Detroit. The feature most noticeable concerning this was that its membership included but one Southern medical school, viz., the Hospital College of Medicine of Louisville, Ky. The Northern medical colleges were mostly represented. The minimum standard of a medical college was laid down. Most intelligent physicians unite in affirming that this standard was not higher than necessary for the proper training of medical men of the present time. Still the Southern medical colleges, with the exception mentioned, kept aloof. The object at this is now apparent.

At the late meeting of the Southern Surgical and Gynecological Association, the Southern medical colleges formed a Southern Medical College Association, upon a plane distinctly lower than that of the American Medical College Association. The members of this Association would not join the older one, because its requirements were too high. Elsewhere we publish the full text of its rules and regulations. Doubtless some good may be accomplished by this movement, but we fail to see in what direction it is to be sought. It advertises Southern medical schools as low-grade institutions, unable or unwilling to furnish medical students the means for acquiring a first-class medical training. It may be that financial prosperity will follow such a course, but we fail to see that professional advancement lies along this route. Certainly the best grade of Southern medical students will be repelled by it, and desert Southern low-grade medical schools for the halls of such institutions as dare to support their convictions respecting medical training by their practical requirements.

It was a short-sighted policy that inaugurated this movement. The South, as much as the North, needs the best medical training for its medical students; and it must be a matter of regret that by this new organization the Southern medical schools have said to their brightest minds; "If you want the best medical training, you must go to the Hospital College of Medicine at Louisville or to some one of the Northern medical colleges, for the Southern medical schools have agreed to arrange their system of teaching to meet the needs of an inferior demand."

It is a matter of regret to every lover of medical progress that these Southern schools had not ranked themselves with the best in the land, and joined with them in advancing the requirements for the degree of Doctor of Medicine. We still hope that on second thought they will change their minds and join the foremost procession.—*American Lancet.*

DR. RALPH BUTTERFIELD, of Kansas City, a graduate of Dartmouth College in 1839, has bequeathed \$180,000 to the College for the purpose of founding a professorship in archeology and kindred subjects and for the erection of a suitable building. The donor acquired his property in business and not by the practice of medicine, and was supposed to be poor and needy until his death.

DOMESTIC CORRESPONDENCE.

Revision of the Code.

To the Editor of the JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION:

Sir:—The reply of "A Conservative Member" to my inquiry as to his opinion of the editorial in the *Medical News* of September 17, on revision of the "Code," is very instructive. It was to be expected that an original member of the Association would dwell with affectionate sympathy upon the origin of the Code, and the high character of its model—the famous letter of Dr. Percival. To many of the younger members this information will prove very useful, and I am sure that the sage reflections of your correspondent will greatly instruct and benefit all of your readers. It is undoubtedly true that the "Code" is the expression of the most exalted moral sentiments found in any literature, if we except the Holy Scriptures. But the question at issue is not as to the matter of the "Code," but as to the form and method employed in giving expression to the precepts which it inculcates. The editorial in the *Medical News* referred to contains a series of "tentative" propositions designed to suggest to the revisers of the "Code" the direction in which they could advantageously improve its construction. My purpose was to elicit from so able a defender of the "Code" a criticism of those "tentative" suggestions, for they seem to me very reasonable. If I do not intrude too much upon your space, I would still call the attention of "Conservative Member" to this portion of the editorial in question.

INQUIRER.

NECROLOGY.

Dr. George W. Sargent.

January 1, 1893, Dr. George W. Sargent, one of the best beloved of the physicians of Lawrence, Mass., died, aged fifty-eight years, having been born in Concord, Vt. on the 9th of April, 1834. He was the son of Dr. Seneca and Mary Wilder Sargent, his own full name being George Wilder Sargent. Soon after the birth of George, his parents moved to Pittsfield, N. H., and when he was about twelve, they moved to Lawrence, where he has resided almost continuously ever since. George graduated from the Lawrence High school and then went into the office of his father to study medicine and surgery. He graduated from the Albany Medical College in 1857 and received an appointment as physician and surgeon on a New York vessel, the *New World*, which ran between New York and England. He made two voyages on this vessel and then located in Lawrence. During the war he was a surgeon in the sixth regiment. On the death of his father, he succeeded to his practice. For over thirty years he had been an attending physician and surgeon at the jail; he had been one of the corps of consulting physicians at the general hospital since its foundation and was also treasurer of the United States Pension Examining Board. The only public office he ever held was that of city physician, which position he occupied for several years.

He was a member of Tuscon Lodge of Masons, of Monadnock Lodge of Odd Fellows, of Needham Post, G. A. R., of the American Medical Association, the Massachusetts Medical Society, the Essex County and Lawrence Medical clubs and the Monday night club.

He leaves a wife and two children. George B. is now at the Harvard Medical school, and Irving W. is at Phillips Academy, Andover.

Dr. B. A. Watson.

This well known and justly distinguished physician died at his home in Jersey City, December 22, aged fifty-six years. Dr. Watson was a surgeon of prominence in the army during the war. Since then he has attained distinction in the profession by his medical works. Dr. Watson had not long ago made a valuable series of observations on concussion of the spine. He also contributed to the subject of hydrophobia.

MISCELLANY.

OFFICIAL LIST OF CHANGES in the Stations and Duties of Officers Serving in the Medical Department, U. S. Army, from January 7, 1893, to January 13, 1893.

Major Robert M. O'Reilly, Surgeon U. S. A., the order directing him to proceed to Washington, D. C., and report for duty as attending surgeon, is suspended until further orders.

Lieut.-Col. Chas. R. Greenleaf, Deputy Surgeon-General U. S. A., is detailed as a delegate to the Eleventh International Medical Congress, to convene at Rome, Italy, on September 24, 1893, and will at the proper time proceed to the place designated. While abroad in pursuance of this order he will visit such points in Great Britain, France, Germany, Russia, Austria, Italy and elsewhere, as may be deemed necessary by the Surgeon-General of the Army, on official business, and on completion of the duty contemplated will return to his station, Washington, D. C.

First Lieut. J. D. Glennan, Asst. Surgeon U. S. A., having reported at Hdqrs. Dept. of Texas, will proceed to Carrizo, Tex., and report to the commanding officer of the Seventh Cavalry squadron at that place for duty.

Capt. J. L. Powell, Asst. Surgeon U. S. A., is hereby granted leave of absence for one month, with permission to apply for an extension of one month.

First Lieut. B. L. Ten Eyck, Asst. Surgeon U. S. A., having reported for duty at Hdqrs. Dept. Texas, will proceed to Laredo, Tex., for service in the field, to relieve Capt. W. B. Davis, Asst. Surgeon, who upon being thus relieved will return to his station (Ft. Sam Houston, Tex.).

First Lieut. Frank R. Keefer, Asst. Surgeon U. S. A., is relieved from duty at Ft. Riley, Kan., and will report in person to the commanding officer, Ft. Stanton, N. M., for duty at that post, relieving Capt. John M. Banister, Asst. Surgeon. Capt. Banister, upon being relieved by First Lieut. Keefer, will report in person to the commanding officer, Ft. Leavenworth, Kan., for duty at that post.

OFFICIAL LIST OF CHANGES of Stations and Duties of Medical Officers of the U. S. Marine-Hospital Service, for the four weeks ended January 7, 1893.

Surgeon George Purviance, detailed as chairman of board for physical examination of P. A. Surgeon S. C. Devan, December 21, 1892.

Surgeon J. M. Gassaway, to proceed to Gulf Quarantine on special duty, January 4, 1893.

P. A. Surgeon S. C. Devan, to report for physical examination, December 21, 1892. Detailed for special duty at Philadelphia, Pa., December 28, 1892. Granted leave of absence for two months on surgeon's certificate of disability, January 7, 1893.

P. A. Surgeon P. C. Kalloch, to assume command of the Service at Cincinnati, O., when relieved at Boston, Mass., December 21, 1892.

P. A. Surgeon A. H. Glennan, leave of absence extended sixteen days on account of sickness, December 13, 1892. To proceed to New York City for special temporary duty, January 3, 1893.

P. A. Surgeon L. L. Williams, to proceed to Helena, Ark., on special duty, January 3, 1893.

P. A. Surgeon W. P. McIntosh, when relieved, to proceed to Boston, Mass., for duty, December 21, 1892.

P. A. Surgeon G. A. Magruder, when relieved, to proceed to San Diego, Cal., on special duty, thence to New Orleans, La., for duty, December 16, 1892.

P. A. Surgeon J. O. Cobb, upon expiration of leave of absence, to proceed to Port Townsend, Wash., for duty, December 21, 1892.

Asst. Surgeon W. G. Stimpson, to proceed to Detroit, Mich., for duty, December 20, 1892.

Asst. Surgeon B. W. Brown, to proceed to Port Townsend, Wash., for temporary duty, December 16, 1892.

ORIGINAL ARTICLES.

ON THE ABSENCE OF COW'S MILK FROM JAPAN: ITS BENEFICIAL CONSEQUENCES.

Read in the Section of Diseases of Children, at the Forty-third Annual Meeting of the American Medical Association, held in Detroit, Mich., June, 1892.

BY ALBERT S. ASHMEAD, M.D.,
OF NEW YORK.

One of the most striking features of that most curious of countries, Japan, is the singular scarcity of domestic animals. There you will never find the fields dotted with oxen or horses drawing the plough, for the Japanese are hardly acquainted with that time-honored tool and symbol of agriculture. Even to serve under the saddle does not come natural somehow to the Japanese horse—"a grudging, ungenerous animal, trying to human patience, with three movements (not by any means to be confounded with paces), a drag, a roll and a scramble."¹ Horses and cows are only seen in cities and on the roads, as pack animals; there are no pastures sweet. Silence is here really a striking, magnificent feature of the *rus beatum*. The cone-shaped Mystic Fusiyama rises, dimly seen, in the midst of an awful quietness. No lowing herds wind o'er the lea; the barnyard fowl's is almost a voice *clamantis in deserto*; he reminds the farmer, but only in the morning, that even under these stagnant circumstances, time flies. Here and there, however, a dog howls; that is all. The animal life of the land is set apart, concentrated and taken care of, as in a kind of common preserve, general park or reservation in the interior of the land, where it browses and prances and bellows and reproduces itself, contaminating as little as possible that high type of Eastern humanity which is now making ready for the baptism of Western civilization. But let it be said in passing, what the European in Japanese fields misses, I believe, more than anything else, is

"The music of those silver bells,
Falling at intervals upon the ear,
With cadence sweet."

I intend here only to speak of one of the consequences of this quaint absence of animal features, of something not poetical at all, but practical in the highest degree. The cow in Japan is not wanted for her milk; otherwise she would lift her voice more loudly in the landscape. Milk being an animal product, falls under the general condemnation which excludes everything that has pertained to a living body from the alimentation of man. Now, it is true, this latter rule has a strange exception, for the animals of the chase are eaten. Let us not shrug our shoulders at the apparent inconsistency; the Oriental mind understands itself. Thus it happens that, as

Japan may not use cow's milk, the Japanese mothers are compelled by stress of circumstances to suckle their babes themselves—and these delicate dwarfs have become the most perfect, the most successful *Alma Maters* of the world. Artificial lactation is altogether unknown. The children are suckled until the sixth year, and you may hear them ask for the breast in a language as correct as that of adults. But it must be said that the mother's milk is not the only food of the little Japanese. River fish enter for a large part into their diet; after the first year, some other elements of general alimentation are added to their bill of fare. But the mother's milk always remains the *plat de résistance*.

Nature and society have endowed this notable mother with some great and peculiar advantages. Here menstruation returns only a year and a half after birth. Moreover, rules dating back to time out of mind insure the young mother a long period of especial attention on the part of the husband and the whole household. The existence of the concubinate is also, strange as it may appear, a considerable relief to the Japanese matrons. All that must tell favorably on the health of the children. Even the infantile minds find themselves in a wholesome, pleasant medium. Nowhere are children so constantly, so lovingly taken care of. Japan, it has been said, is the very paradise of childhood. Nowhere are the adults so well qualified to enter into the nascent ideas of the infant, to play with him—for the nature of the Japanese contains an extraordinary proportion of simplicity and childishness. The principal food of the mothers is, besides the everlasting rice; fish, shells, seaweeds and other products of the sea. No wine or beer enters into the diet of a lactating woman.

The great reward which Japan reaps from this meritorious care of motherhood and childhood, is the absence of rachitism. All observers have referred to the fact, and to the absence of rachitic pelves which is the consequence of it; hardly any difficult confinement, and a very small percentage of deaths in childbirth. Now I think I am not wrong in affirming that the chief and central source of these great sanitary blessings is the absence of cow's milk.

It is a remarkable fact that Japan, which according to Dr. Brush ought to be exempt from tuberculosis, is very far from being so. It is probably well known to you that, according to this observer, tuberculosis passes from the cattle into the human organism. In Japan, this disease exists mainly in the upper classes, where evidently cow's milk has nothing to do with it, and where it is easily explained by a systematic custom of close intermarriage, a system of, according to our ideas, incestuous inbreeding, which has endured for many centuries. This is the same process by which the disease is developed in cattle, according to Dr. Brush. It seems therefore, that there is no

¹ Miss Bird, Unbeaten Tracks in Japan.

necessity of transmission, and that the human organism worked upon by the same causes, will show the same effects. Strange to say the mountaineers, who have the most intimate relation with the isolated Japanese cattle, on their breeding-ground, are practically free from tuberculosis. There is also an historic fact which goes much against Dr. Brush's theory. The cattle were introduced into Japan from China, in the third century, and tuberculosis is known to have existed there, in that same high bred class, from times immemorial. The aristocratic disease, tuberculosis, was certainly communicated to the common people through a very extensive concubinate. And I am equally convinced that it was the milk of the mothers that preserved the lower orders from destruction.

Thus it would appear that the absence of cow's milk, though not a blessing in the sense of Dr. Brush, has had, in another way, an exceedingly beneficial influence on the general health of the race.

Racial immunities or the natural resistance of a race to certain diseases, are, at least partly, transmitted by the mother's milk. It is thus, as I said, that this race is free from rachimism. And there is another privilege of the same kind transmitted through the milk to the suckling. The iodized sea-foods, more especially sea-weeds, and the fats and oils of fishes, which have for so many centuries formed a considerable proportion of the diet of nursing mothers, have, without doubt, helped to build up the racial resistance to their national inheritance, syphilis and tuberculosis. In the case of tuberculosis this resistance is so efficient that even the child of a tuberculous mother, fed on what might be supposed to be tuberculous milk until the sixth year, in the majority of cases remains unaffected. Now, if a tuberculous cow's milk transmits the disease to the human organism, why should not this tuberculous mother's milk transmit it? Even we do not object to the suckling done by our own tuberculous women, which indeed extends generally over but one year; yet their offspring, for the most part, are unaffected by the disease, at least in childhood. Now it is more than likely that if there were a contagion through milk, its effects would be apparent in the children.

All these benefits would, of course, be cut off by the substitution of a foreign element for the natural means of transmission.

I have, while I was in Japan, conceived an idea, quite satisfactory at least to my own mind, of the manner in which the iodized food renders its great service to the Japanese race. It is generally supposed that the contagium of tuberculosis is communicated by the inhalation of particles of dried sputum, disseminated in the air. It is my firm conviction that this is not so. I believe that these germs of disease are swallowed with the saliva, and alter the nutrition through the chyle and mesenteric glands. In an organism fed directly or indirectly by iodized substances, the poison meets and is neutralized by its own antidote. The Japanese mother, as by an instinct, never kisses her child on the lips. Indeed, the whole institution of kissing is practically unknown in Japan (except in the sexual act). It is even formally condemned, because the Japanese *know* that the kiss is the carrier of tuberculosis and syphilis. I have no doubt but that the caresses of the sick have added enormously to our own statistics of tuberculosis, and have caused much of the mischief which Dr. Brush would attribute to cow's milk.

I do not know whether the following has struck any other observer, or if I am the first to call attention to it. There is another, an occult and insidious danger which Japan escapes by letting cow's milk alone. If they drank it, as we do, it is very probable that they would drink it as we do, *volentes volentes*, mixed with a nobler fluid. Now, thanks to the rice plantations, the water of Japan is by no means *the best of things*; it is even the worst, for it is pregnant with typhoid germs, being continually polluted with human excrements, and swarming with the brood of the distoma. Total abstinence from cold water—an inverted tea-totalism—has been the salvation of Japan. Water is only drunk boiled with tea; the boiling kills the typhoid germs and the eggs of the distoma.

4 King St., New York.

A CASE OF TUBERCULAR SYPHILIS.

From the Clinic of

JOHN V. SHOEMAKER, A.M., M.D.,

PROFESSOR OF SKIN AND VENEREAL DISEASES, IN THE MEDICO-CHIRURGICAL COLLEGE OF PHILADELPHIA.

[REPORTED BY DR. GEO. HEWITT.]

Gentlemen:—Mr. S., 35 years of age, a stonemason by trade, was admitted to the Medico-Chirurgical Hospital, Dec. 15, 1892. In the year 1878, the patient contracted gonorrhœa. Being at that time of wild and reckless habits, addicted to drink, he was careless as regards treatment. As a consequence the disease was not readily cured and he suffered from it for at least four months. During this period he was not aware of any chancre upon the penis or elsewhere, nor does he remember any enlargement of the inguinal glands. He at length recovered from the gonorrhœa and remained in good health for ten years. For the last six years he has been strictly temperate. During the interval he never had any eruption upon his body except small papules which came out upon the face especially after he had been drinking. He does not know that he ever had any general eruption. He has been subject from boyhood to occasional attacks of sore throat. With this exception he has not experienced any difficulty in the mouth or throat. In November, 1888, he had a bad fall from a railroad car; he struck heavily upon the right hip and was rendered almost insensible. In the early autumn of 1889 he noticed a swelling over the tuberosity of the right ischium. At first it was very small, it enlarged very slowly, but finally attained the size of a pigeon's egg. Painless in the beginning, it ultimately caused him a great deal of suffering, particularly at night. On September 23, 1890, the swelling spontaneously opened, and gave exit to a considerable discharge. He was then confined to the house for twelve days and his attending physician trimmed away undermined or sloughing edges, and dusted the surface with iodoform. The ulcer, however, did not heal. A similar, though smaller, lesion had made its appearance upon the right buttock and had pursued the same course. On Feb. 7, 1891, the ulcerated areas upon both buttocks were excised and the edges of the wound drawn together by stiches. It was about five weeks after this operation before he was able to resume his work. He had not been at work more than three weeks before a third tumor made its appearance a little below the left clavicle near the costo-sternal articulation. Like the preceding swell-

ing, it was at first small and painless, grew slowly at length became the seat of throbbing pain, and in August, 1891, spontaneously ruptured. About two weeks after it opened this lesion was also removed by the knife. Before he had completely recovered from the operation a patch of inflammation developed behind the left shoulder joint. The skin, in this instance, was not, in the beginning, elevated. Subsequently two distinct points of swelling appeared and followed the same course as those already described. This last lesion began about six months ago. The skin has now been broken for about a month.

In the summer of 1885 a barber, when cutting his hair, noticed a bald spot about the size of a dime, situated upon the right side of the head above the ear. He made applications of crude petroleum to this patch and new hair soon grew. But eighteen months ago his wife observed that his hair was again thinning in the same situation. As, however, he was then suffering from the cutaneous lesions, he paid no attention to the spot of baldness, which has continually increased, until it now extends from the ear to the parietal eminence. It is about two inches in diameter and of a roundish form. Upon the vertex, also, the hair is becoming quite thin.

The patient's voice has been husky for three weeks past, and he has had, during that period, a dry feeling in his throat. He has no pain in swallowing. He has never had any inflammatory trouble with his eyes.

During the progress of this malady he lost a good deal of flesh, and became quite weak. Except when he was detained in the house after the operations, he was able to work but came home so fatigued that he was obliged to go to bed at once. His appetite was not good for breakfast, but he generally ate a good supper. His appetite is now good and he has no marked indigestion. His bowels are regular. He has regained flesh and sleeps well.

Upon inspection I found a large depressed cicatrix above and just below the tuberosity of the right ischium. The two are connected by a linear scar, which begins about one inch above the upper cicatrix. At a nearly corresponding point on the left buttock is a large crucial shaped scar. On the front of the chest, extending from the sterno-clavicular articulation about one and one-half inch outward and about two inches inward, is an irregularly oval scar about one and one-half inch in extreme width. At the inner extremity of this lesion an induration, resembling keloid may be detected. This spot is somewhat painful when pressed. The surface of the scar in general is not abnormally sensitive but he is conscious of a sensation of weakness at that spot when he makes unusual exertion, as, *e.g.*, in lifting a heavy weight. On the back of the right arm, just above the axillary fold, is a deep ulcer about the size of a three cent piece. The edges are overhanging and of a dull red color. A little behind and below the ulcer is a medium sized patch of redness, which exhibits here and there a little crusting, and at its lower border a slight maceration of the epiderm, leaving the derma exposed.

Though the origin of this case seems for a long time to have been attributed to traumatism, yet it is doubtless of a syphilitic character. The history of the case, it is true, gives no direct information as regards primary infection but the slow progress of the lesions, their destructive course and their appearance testify to the nature of the affection.

Many patients are met with who freely admit the existence of a gonorrhœa, but are entirely ignorant of ever having had a chancre. It seems strange that a sore of such significance should be overlooked but we must remember the careless habits of many men, the apparently trifling character which the initial lesion often presents. Frequent intoxication, or semi-intoxication lends, as in this case, an element of uncertainty to the history. The man who brutalizes himself with drink is not very observant as regards his person. Large, freely suppurating, and multiple chancroids with a huge, inflammatory and painful bubo cannot be disregarded by the most careless. A gonorrhœa, by reason of the painful micturition which it entails in the acute stage, cannot fail to be recognized. A large ulcerated Hunterian chancre will, we may suppose, always be discovered. There are, however, cases of true infecting chancre which may be overlooked if careful observation be not made. What is known as the "superficial erosion" is of very harmless appearance to one ignorant of its nature. It is small, it does not furnish much secretion and it involves no great depth. It is characterized by parchment induration of the base when pinched up between the fingers, but this is a feature of which the patient is ignorant and which, in a hasty examination by the medical attendant, may readily pass unnoticed. Another form of chancre is still less likely to attract attention. I refer to the dry papule in which induration is present, but nothing more; the skin is intact and even the epiderm may be unaffected; in some cases a little superficial scaling takes place. To mere inspection nothing abnormal may appear. If, however, the lesion be grasped between the fingers, it is found to be of very firm consistence, and feels like a shot or split pea imbedded beneath the skin. I have on several occasions had the opportunity of demonstrating this variety of chancre in a patient who was totally unaware of its existence, but who was at the time suffering from sore throat and one of the earlier secondary rashes. The induration may remain for months before it subsides. A chancre located within the urethra may give rise to some discharge, which might be mistaken for gonorrhœa. Finally, the ganglionic enlargement which accompanies chancre may consist only of a chain of moderately enlarged, painless, or almost painless glands, which might escape careless examination.

For these reasons a patient may easily be misled and declare at a subsequent stage, with perfect truth, that he has never had a chancre. The physician, however, should not be so readily deceived. He should search intelligently for hidden sources of infection. It is equally reprehensible to content oneself with a cursory inspection of the penis, overlooking everything but an open lesion, or to go to the other extreme and carelessly denominate every open sore a chancre. In the one case a grave specific poison is permitted to lurk unsuspected within the organism; in the other a patient is needlessly drugged with mercurials to no avail, or rather to his positive detriment. Everyone should now be acquainted with the broad and fundamental distinction between simple and specific venereal disease, between chancre and chancre, between a local and an infecting sore, between an acute and severe local process which goes no farther, and between the slow and comparatively insignificant initial lesion, which is

only the first expression of constitutional contamination. Chancroids are generally multiple, chancres are generally single; chancroids suppurate abundantly, chancres are comparatively dry, the chancroidal bubo suppurates, the syphilitic bubo is generally unattended by suppuration. Herpes of the genitals ought never to be confounded with chancre or even chancroid. Herpes is of frequent occurrence in the same individual, it comes on without reference to sexual congress, the lesions are evanescent and never produce any enlargement of the inguinal glands. There is, indeed, one form of the initial lesion of syphilis which might be pardonably mistaken for herpes progenitalis. It has been described under the form of "multiple herpetiform syphilitic chancre." This manifestation is, however, extremely rare. It may be distinguished from simple herpes by the absence of itching or burning, their deeper color and their chronicity.

The same inattention which leads a man to overlook the occurrence of a chancre renders it possible that secondary eruptions will escape his notice. The erythematous or the small papular syphiloderm are not infrequently detected by the physician in examining a patient unaware of their existence. Thus, it is by no means uncommon for cases to pursue a comparatively mild course for a number of years when some of the destructive lesions of late secondary or tertiary syphilis develop, to the amazement of the patient, when informed of their true nature. I can recall to mind numerous instances of sarcocele, caries, gummata and visceral syphilis totally devoid of any history of infection.

The only secondary manifestation of which I obtain any decided trace is the circumscribed patch of alopecia. The patient appears to be a man of ordinary intelligence and education, yet, in accordance with his habitual negligence it was only through the discovery of a barber that he became aware that his hair was falling out in a circumscribed patch. A limited area of baldness upon the side of the head would seem far more likely to attract a man's attention than the ordinary and slowly developing baldness of the vertex. Syphilitic alopecia is generally an early constitutional manifestation but, like other symptoms of the disease, it may be postponed. Although in the vast majority of cases we witness a regular evolution of symptoms in relation to form and time, yet in exceptional cases the manifestations distinctive of the secondary period may be postponed or may recur for years. On the other hand, the lesions of tertiary syphilis may appear prematurely during the secondary stage. No soreness of the scalp had, in the present case, preceded the loss of hair. The patient could not remember that he had been particularly subject to dandruff. This is the history of syphilitic alopecia, which is not, as a rule, dependent upon the presence of a syphilide of the scalp, but is due to insufficient nutrition of the hair-bulbs. The patient applied crude petroleum to the affected spot and after a time a new growth occurred. The stimulant affect of the fluid may have had an influence in promoting local nutrition, but syphilitic alopecia is seldom permanent, and the hair begins to grow again at the expiration of five or six months, even in the absence of any treatment. At a later period, when the general condition was seriously depressed, the baldness returned, and the denuded patch has attained a considerable dimension.

Traumatism undoubtedly has an effect in determining the localization of infectious processes. Depressed nutrition due to injury renders a part more amenable to the action of any toxic principles which may exist in the system. Schüller has clearly demonstrated in a series of careful experiments, the influence of traumatism on the localization of tuberculosis. Professor Verneuil has shown that a contusion occurring to a subject in whom syphilis is latent may be followed by indolent ulcerations which partake of all the characteristics of a syphilitic lesion. He has shown, moreover, that though these manifestations may first occur at the site of injury, they may subsequently develop in parts of the body more or less remote. In other words, any local injury may excite or precipitate an outbreak of syphilis in an individual in whom the disease was latent and perhaps unsuspected. The lesion may first occur at the point of injury, but may afterwards involve distant regions. This mode of manifestation corresponds to the history of the present case.

Upon two occasions an extensive area of ulceration was removed. Cicatrization took place but slowly, and the cicatrices are large, rough, thick, with a tendency to the production of a keloid condition. Observation has convinced me that the less the knife is used in this stage of syphilis the less is the destruction of tissue and the less extensive and disfiguring the scar which results. When the diagnosis is plain, surgical interference is seldom attempted, except in the first and last stage. Notwithstanding the advocacy of certain eminent authorities, excision of the chancre cannot be entirely relied upon as a method of preventing the evolution of constitutional phenomena. It is decidedly inadvisable to open gummata unless degeneration has taken place, their contents have become softened, fluctuation is marked and the overlying skin is reddened. In that event the contents may be evacuated by a small incision made at the most dependent part of the tumor. At an earlier stage constitutional treatment will cause absorption of the pathological material.

I arrived at a diagnosis of syphilis in this case by a process of exclusion. With what other diseases could it be confounded? What other constitutional affections give rise to such extensive ulcerations? Leprosy does this, but leprosy scarcely enters into our conception of any case developing in this region of country in an individual who has never resided in a country where leprosy prevails. Tuberculosis may invade the skin, but is not common in that tissue. Tubercular ulcers generally occur around mucocutaneous orifices they manifest no disposition to heal, generally coexist with pulmonary tuberculosis or occur in those persons whose work bring them in contact with animals or cadavers. Lupus vulgaris gives rise to ulcers which might confuse the diagnosis, but lupus usually develops during early life, the tubercles of lupus are smaller than those of syphilis and pursue a more chronic course. The ulcers of lupus are more superficial and the discharge which they produce is more scanty than in tubercular syphilis. In epithelioma there is almost invariably but a single lesion, the ulcer bleeds at the slightest touch, its base is red and fungous and covered with a thin, sanguinolent or sero-purulent secretion. Epithelioma occurs in people of advancing years, it is painful almost from the beginning, and it manifests no disposition to recovery. Sarcoma of the

skin is usually a solitary growth, increases rapidly in size, generally recurs after extirpation. Ulcerated epithelioma usually proves fatal within a year or two, sarcoma within three or four years.

Having determined that the lesions are of a syphilitic nature the question next arises, what particular form of the disease do they represent? The history of the case, the appearance and situation of the lesions leave but little doubt as to this point. The earlier manifestations do not enter into the consideration of the case. The size and course of the lesions, together with the date of their appearance, narrows the distinction down to the syphilitic tubercle or gumma. Both these specific neoplasms begin as small, roundish, painless nodules, increase slowly in size and terminate either by absorption or ulceration. A cutaneous gumma usually attains a larger growth than the tubercle and is generally single. Tubercles are not numerous but are generally multiple. It is not unusual for several tubercles to form in the same neighborhood, and as they undergo their phases of development and retrograde metamorphosis they are apt to coalesce and form an ulcer of irregular and serpiginous outline. The ulcer produced by degeneration of a single tubercle is smaller than that caused by the breaking down of a gumma, but the coalescence of neighboring nodules may result in the formation of more extensive ulcers than a single gummatous ulcer. We cannot, consequently, depend entirely upon the size or the number of the ulcers, but evidence of this kind must be compared with the history of the case. This patient states that the swellings were, in the beginning, very small, that they enlarged slowly, that they were multiple. In examining his body the scars bear witness to the essential truth of his declarations. Not only so, but in the last developed lesion, namely, that upon the shoulder, the ulcer is one of moderate size and I detect several points in the vicinity at which syphilitic deposits have previously undergone degeneration. For these reasons I look upon the case as one of tubercular syphilis.

The distinction between the tubercle and superficial gumma is not very pronounced. Both are late lesions and may not make their appearance, as in this case, until ten years after primary infection. They are both situated in or beneath the skin, they both consist of an aggregation of round cells which eventually by compressing the capillaries of the part in which they are situated give rise to degeneration of themselves and the tissues by which they are surrounded. Cellular proliferation is an essential feature of the pathology of syphilis in all its stages. This fact negatives the ingenious theory of Mr. Jonathan Hutchinson, who likens the progress of syphilis to that of an exanthematic fever and the manifestations of the tertiary stage to the sequelæ which follow those affections. The coëxistence of secondary and tertiary symptoms, the tardy development of secondary lesions and the precocious appearance of tertiary phenomena are also arguments against this theory.

The treatment since admission has consisted in the administration of two fluidrachms of the syrup of hydriodic acid three times a day. He had previously been for some time upon the ordinary mixed treatment, which had not, however, seemed able to hold the disease in check. I, therefore, was not disposed to continue a course which had not been at-

tended with marked success, and prescribed hydriodic acid which is an excellent means of introducing iodine into the system. The iodine is liberated within the organism, and is particularly energetic in the nascent form. Externally the infiltrated patch upon the shoulder has been anointed with a preparation of:

R. Ungt. aq. rosæ
Ungt. zinc oxid ʒʒss.
Aristol ʒi.
ʒʒ. ft. Ungt.

A starch poultice has been applied every two or three days to the ulcer, which, in the meantime is kept packed with aristol. The aristol is retained in place by means of a piece of gauze, which is secured by a layer of styptic collodion.

Under this treatment a noticeable alteration has been already effected. The redness has lessened, the infiltration is disappearing, the surface of the ulcer manifests a more healthy appearance and has taken on reparative action.

NATIVE AFRICAN CHILD-MARRIAGE: ITS RELATION TO UTERINE DISEASE AND DIFFICULT PARTURITION.

BY ROBERT H. NASSAU, M.D., D.D.

UNIVERSITY OF PENNSYLVANIA, MISSIONARY OF THE AMERICAN BOARD, ETC.

The common impression that maternity is easy among nations uncivilized and consequently untrammelled by the restrictions of fashion and conventionality, is incorrect—certainly as to the tribes of Western Equatorial Africa. An acquaintance, based on a residence there of over thirty years, with native African customs and habits, has made it apparent to me that the sexual life of the native women is thereby marred, maternity made painful and often fatal, and diseases entailed that make their lives a burden. I have observed the following facts, which are fruitful sources of uterine disease and difficult parturition.

1. Women are taken in marriage at too early an age. Sexual connection is commonly had before the age of puberty.

Under the polygamous customs of the country, little girls, even in infancy, are bargained for with their parents by suitors, each running a race, trying who shall first complete the sum of money demanded by the parents as "dowry." That sum given, the successful suitor has a right at once to take the child to his own village, and add her as "little wife" to his harem. There she is the servant of the older wives. In her plays she sees lads of her own age whose lascivious advances please her more than the thought of sexual relations with the adult or perhaps aged man who has paid for her. Through the amorous plays of young people, few girls reach womanhood with their virginity unbroken. The polygamist owner of the child, aware of this, jealously decides that if the unripe fruit is to be plucked by any body, he will claim the first right. And he does. As all little boys and girls run almost perfectly nude, his quick, jealous eye observes the very first growth of hair in the axilla, and promptly assumes that there is an equal growth on the external genitals. That is, to the native, a diagnostic sign of fitness for sexual intercourse.

Should a betrothed girl have been allowed by her

polygamist owner, or even by a Christian monogamist, to remain a virgin till puberty, the first eruption of the menses is regarded, not as Nature's official proclamation of womanhood, and of her fitness for sexual access, but as a proof of unfaithfulness—as a sign that access had already been allowed to some lover; and her indignant owner demands that she at once take her place as his married wife.

2. There is no compatibility of age or temper. The girl's consent was not asked while the money negotiations were being carried on for her—a child in her mother's arms. There is no tender courtship, no gentle deference of a lover. Her owner's rôle is that of teacher or master, whose eye is always that of a jealous inspector. And the child responds with the trickery of a pupil, and the subterfuges of a slave. It is impossible that there should be conjugal affection or connubial happiness. Her own wishes and preferences are elsewhere. She clandestinely gratifies them. Her sexual life therefore really goes on under polyandry: the combined (enforced) association with her owner, the (preferred) association with her chosen secret lover, and the (required) connection with her owner's guests. This latter is a part of native African hospitality. The chief furnishes his guests (black and white) with food by day, and a bed and female companion at night. It is the custom of the country. The chief gets his return from his black friends when his turn comes to visit among them; and from white trader guests, by their liberal pay of cloth, beads, etc. The woman has no share in these, but she makes her own plea, and receives from the white man's generosity her own additional gifts. While prostitution is not known, in the form of women as street-walkers openly soliciting men, the house of the polygamist thus becomes, practically a brothel. He is willing to hire the honor of his women to any stranger for a night, or for a longer time to wife-less young men attached to his retinue, only so that the bargain is made with *himself*—the pay placed in *his* hands. He sets up the cry of injured husband only when he discovers some clandestine amour of any one of his women with some man of her own choice. This almost promiscuous intercourse breeds syphilitic disorder; a disease, however, which natives assert is not as virulent among themselves as it is when white depravity is superadded to their own.

A result of the early and promiscuous intercourse, as above described, is the common sterility among women, and impotence among men. Polygamy, arising originally from a desire for progeny, thus defeats itself.

3. Even when the young wife has become pregnant, the chances are against her babe's safe delivery. The probabilities are large that there will be miscarriage.

The physical works of the women are numerous and severe. On them fall not only the ordinary and proper cares of cooking, weaving mats, etc., etc.; but they are also the laborers in the plantations of cassava, plantains, maize, yams, etc. The men recognize as their own share of plantation work, only the felling of the trees, in making the clearings in the forest. All works subsequent to that, the planting, weeding, watching at night against depredations of elephants, hippopotami, wild oxen, wild hogs, monkeys, etc., etc., are regarded as tasks of the women, who may be seen daily, trudging each morning to the plantation

with empty baskets, and returning in the evening laden with burdens of plantain, cassava tubers, etc., a log of fire-wood, and a jug of spring-water. Pregnancy is not accepted as excuse from such labor; the strain of which coming on the muscles of the loins and sacrum, very frequently causes miscarriage, with its usual dangers of habitual abortion, uterine displacements, or entire sterility.

4. The prospect of maternity is welcomed by the young wives: for the women all cherish their babes affectionately (that is the only lasting affection that enters their lives): and they are given by their owners better position, in recognition of their having increased his importance as a father. The prospect is welcomed also by the woman's female relatives: for they also are to share in the increased honor of the family.

But their preparations for the event are wearying, harassing, and often injurious. The young, expectant mother is vexed with innumerable superstitions and prohibitions of what she must not do or eat; she must not look on a corpse, or a butchered animal, or indeed on any sight of blood: she must not eat certain meats, or certain parts of the animal: must not tie a knot, or drive a nail, etc., etc., lest all these cause her hard labor or close her womb. She must be dosed with decoctions, for months in advance, to insure an easy labor. Between prohibitions and requisitions and warnings, her mind is terrified at the possibilities before her, and she approaches her hour of trial weakened in body and spirit, and the hopeful morale for the struggle gone.

5. When parturition does begin, it is met with unskillful treatment. (*a*) The patient's hut is crowded with officious and curious female relatives, of old and young. All are volubly discussing probabilities, offering advice, and shouting directions. They know of the proper number of months to be counted for pregnancy, but they often mistake the probable day, and seize at once on even "false pains." (*b*) The three stages of labor are not recognized. The patient is urged and even objurgated, during her cries of pain in the initial stage, and bidden to force down; her position for that purpose being changed from a recumbent to a sitting posture. (*c*) Nature is interfered with by the pouring of hot, even scalding, water on the sacrum, under the idea that the convulsive recoil of the muscles will hasten the expulsive efforts of the womb. (*d*) Severer treatment is resorted to, when the labor is long, by the rubbing into the back, and introduction into the vagina, of cayenne pepper. Even forcible enlargement of the vagina by the hand of a female (sometimes a male) doctor, is performed in a protracted labor, resulting in rupture of the perineum, or lateral rupture of the external genitals. (*e*) When, finally, the babe is born, the mother is allowed no interval of rest. All the anxiety of the attendants is for the expulsion of the placenta. They properly recognize the importance of its expulsion, but give the patient no time to recover strength for the second struggle. The cutting of the cord is often delayed until the appearance of the placenta, the infant's feeble life dying out sometimes in the interval. (*f*) An expedient of our civilization to aid in the extrusion of the placenta, *i.e.*, the placing of the new-born babe to its mother's breast, is not allowed. They have gotten hold of the half of two truths, and wrest them both to the injury of mother and child. They are

aware of the desirability of the babe's *pruving* away its meconium: they are aware also that the colostrum of the mother's breast is not *food*. They therefore give the child purgative medicines, and refuse it its mother's breast for three days, while the colostrum is being artificially squeezed out, the child meanwhile being fed on raw sugar-cane juice, or suckled on the watery milk of some aunt or grandmother. Many of the native women never "go dry." Fevered and "caked" breasts are a common result, with frightful mammary abscesses. My patience has often been tried when I have said to some of the old hags:—"Yes, I too know that colostrum is not *food*, but it *is* medicine—the very medicine the child needs as a purge, and which God has put in the mother's breast for that express purpose—which should promptly be extracted from her breast, and which can best be extracted by her child's lips. *g.* Native women are not bandaged for the support of the abdomen's post-natal, flaccid walls. They are expected to arise, perhaps, the very day of parturition, and resume their usual labors. Very common are uterine displacements, and subsequent sterility, which the polygamous father resents. He does not see why the woman who has born him one child should not bear him more. Her inability to do so, he punishes with neglect, unkindness, or severity.

h. An argument given by polygamists for the system is their assumed necessity for having additional women with whom to cohabit, while the one who has just become a mother is nursing her child. Children are not weaned till they are three or four, or even more, years of age. During this time the mother avoids sexual congress, on the plea that her milk may be "spoiled" for her babe, on whom she now lavishes her affection, having had none for the father. Yet that milk, in due time, becomes, thin, watery, and void of sufficient nutriment for the child that has developed most of its first set of teeth. The child loses its infantile chubbiness: becomes thin; and breaks out with eczema and other sores; and its joints become abnormally large.

Among the most common results of African child-marriage, I observed: 1. Rupture in the genital region, either from the little mother's bodily structures being not fully developed, or from outside force used in aid of parturition. 2. Displacements of the uterus. 3. Sterility. 4. Ovarian tumors. 5. Uterine ulcers. 6. Dysmenorrhœa and menorrhagia. 7. Premature loss of good looks, and early appearance of haggard old age.

THE QUALITY OF COMPRESSED AIR FOR SPRAYS AND INHALATIONS.

BY D. LICHTY, M.D.,
OF ROCKFORD, ILL.

Asepsis is now in the zenith of its usefulness and has demonstrated beyond controversy its beneficence to all unfortunates who have to experience the surgeon's dextrous touch or feel his keener blade; every newly made wound is carefully guarded against the ingress of air, of any kind, and quickly sealed against it; the surgeon, gynecologist or accoucheur goes about his work now, with a comfortable assurance that the painstaking physician must envy in conscious helplessness when he recognizes the environment in which he must combat disease.

There is an avenue however, which for the introduction of disease and death growing germs has no parallel and no excuse for its existence, other than that it is here, and no one has protested against it.

The allusion made, is in regard to the *quality* of air usually used in the compressed air receivers of those who treat diseases of the nose, throat and lungs by this means: all the air pumps I have observed offered for sale or in physicians' offices—and I have taken special pains to see as many of them as possible, are situated on the floor of the doctor's office, in not an overclean corner from which the air is drawn into the pump and thence stored in the reservoir to be afterwards projected with a pressure of from fifteen to twenty pounds into the diseased larynx or pharynx of the innocent patron whose inflamed crypts are deep and open wells for the speedy reception, and successful propagation of any of the germ diseases; with just the right factors of moisture and heat to develop them all; or, if drawn into the deeper structure of the lungs to mingle with, or become a portion of the residuary air, a sufficient period would ensue before again exhaled, for the successful incubation of almost any germ, and a nidus for dangerous disease be formed.

To ease my conscience of this offense against my patients I had a mechanic of the Air Brush Co., of this city, at my suggestion, construct for me a small oscillating pump which is run by a one-eighth horse power electric motor, that draws the air from out of doors; first through a five inch funnel shaped chamber, whose open end is covered with wire gauze and its inside loosely packed with asbestos wool to make a complete filter: this filter chamber is fastened to the outside top of a window sash of an upstairs office, and is connected by a rubber tube, larger than would seem necessary—to reduce resistance to a minimum—to the inlet valve of the pump, and is thence, at the return of the piston, forced into the air receiver for future use; by this means all the air comes from outside, is filtered, and it is claimed, that cleaner air is obtained than by the pumps generally located on doctors' dusty office floors.

The mechanical difficulties necessary to adjust any air pump to a similar filter system are not great, or expensive; and it is hoped that the physician will be enabled to use as aseptic air to inhale, or to spray diseased throats as the surgeon does to douche his patients' wounds.

A STUDY OF THE CHEYNE-STOKES RESPIRATION.

BY SAMUEL WOLFE, M.D.,
OF PHILADELPHIA, PENN.

The patient, aged 65, an employee of the City Gas Department had for many years, when exposed to breathing illuminating gas, in the pursuit of his occupation been subject to attacks during which he lost consciousness, but after a short period of half an hour or an hour recovered and was able to resume his work. About three weeks prior to the time when the present observation was made he had suffered from one of these attacks, of more than usual severity and duration, and immediately thereafter was confined to his room for four or five days, with urgent dyspnoea and severe bronchial symptoms. Later on there was continued cough, and great rest-

lessness, and threatened cardiac failure. After partial recovery he again relapsed with great dyspnoea, and gradually became delirious, and during a portion of the time apathetic and lethargic. The Cheyne-Stokes respiration then appeared accompanied by a pulse of 112, the temperature being normal. A cycle of respirations occupied 55 seconds there being 27 respirations. The period occupied by the rising respirations was 25 to 30 seconds by the declining respirations 15 seconds. The number in each of these phases was about the same—14, making the succession during the declining period nearly twice as rapid as during the rising period. The pause lasted from 10 to 15 seconds. In this phase there was no perceptible alteration in the rate or character of the cardiac action, and no alteration in the pupils. Coughing during the cycle, did not influence its duration, nor any of its intrinsic characters. When aroused from his somnolence, which could be easily effected, there was no change in the cycle, except that the phase of decline was lengthened by a few additional respirations, during which there were no chest movements, but air could be heard to enter the extreme lower parts of the lung in jerky momentary pumps. The pause was of course correspondingly shortened. Otherwise the pause was a period of absolute stillness, so far as respiratory sounds were concerned, but as already remarked the cardiac sounds were in no respect altered. The patient died ten days later. The breathing during the whole period was closely allied to the Cheyne-Stokes type, but at no time was it found as typical subsequent to the above observation, as at that time.

CAFFEINE AND THE QUESTION OF ITS ISOMERISM.

Read in the Section of Materia Medica and Pharmacy, at the Forty-third Annual Meeting of the American Medical Association, held at Detroit, Mich., June, 1892.

BY ALBERT B. PRESCOTT, M.D.,
OF ANN ARBOR, MICH.

In chemistry, caffeine is a body of distinctive molecular character, the subject of active research within the past ten years. In physiology it is bound to be of increasing interest that caffeine, the chosen adjunct of food, holds a remarkable relation to uric acid, an excretory carrier of nitrogen. In dietetics it is of wide import that the beverage plants of the world owe their effects in great measure to caffeine. In pharmacognosy it is worthy of attention that uncertain combinations of caffeine are in medicinal use. In these several studies it is desirable to settle the chemical question, whether caffeine be capable of isomerism or not.

This is not a question that has been raised by chemists; nor is there at present any chemical evidence, that I am aware of, for so much as a suggestion of the isomerism of caffeine. Pharmacologists have virtually raised this question, though they have not defined it as one of isomerism. And there is a great extent of medical opinion and lay opinion that, whatever chemists may say, the alkaloid of coffee does not produce the same effect upon the nervous system that is produced by the alkaloid of tea. If this somewhat widespread opinion, though not well defined, be well grounded, the chemist ought to be able to account for it. On one point the chemist is clear, if there be a caffeine in tea in itself not of the

same physiological effect as the caffeine in coffee, then these bodies are not chemically identical. Then, both being caffeine, that is, trimethyl xanthines, it follows that the one must be isomeric with the other. Before this point is reached, however, there is a great deal for chemical analysis to do, and something for pharmacology to do.

There are five beverage plants, growing in different quarters of the earth, all largely adopted into use by uneducated man, as a restorative from fatigue and a stimulant with food, and each of these plants contains an abundance of the body named caffeine. The body has been found as a slight or inconstant constituent of a few other plants, all of them adjuncts of food.¹ It was found in coffee in 1821; in tea in 1827; in guarana in 1840; in the maté of Paraguay in 1843; and in the kola of South Africa in 1865. In 1838 Jobst and Mülder declared theine to be identical with caffeine. As soon as an alkaloid was found in guarana, in maté and in kola, in each instance the body was reported to be caffeine, and there have been no chemical reports to the contrary. The names, theine and guaranine, have fallen into disuse, and no other name than caffeine has been given to the body derived from maté or kola.

This one body, from five vegetable sources, is one of strongly marked chemical character. It is clearly determinate in character, more so than the most of the alkaloids are, and a body built altogether unlike them. Indeed, it is well within the control of synthetic chemistry. It is liable to be put upon the market as an artificial product. As an artificial body, if properly purified, it should be not an imitation but a veritable reproduction of the natural article. It is becoming probable, however, that this body, the chief alkaloid of five plants, is not the only one existing in them. Traces, at least, of two or more homologues of caffeine have been found in certain teas. There is need of analysis for these homologues, as lesser constituents. The presence of alkaloids accompanying caffeine, as codeine accompanies morphine, is to be put out of the way. Then there will be a clear field for the question of isomerism between the chief alkaloid of one beverage plant and the chief alkaloid of another, such as the difference between atropine and hyoscyamine.

As to the isomerism of caffeine, its probability can be denied only by full study of all research hitherto done on the molecular constitution of this group of bodies. The possibilities of isomerism are coming in greater number into view, as science advances. When the chemist believed himself able to find the arrangement of atoms within the molecule as truly as the order of the fingers upon his hand he seemed to have reached a limit of isomerism. Then it appeared that nature had not stopped at this limit. Whereupon the chemist bethought himself that the order of five fingers as they face on the one hand is

¹ Caffeine occurs in small amount in cacao beans, according to Schmidt (1883), theobromine being, as is well known, the principal alkaloid. The U. S. Department of Agriculture, in Division of Botany, has lately published (Bulletin No. 14, 1891) descriptions of the flex cassine, growing from Virginia to Texas, and used by the aborigines as a beverage on festal occasions. Prof. E. P. Venable found it to contain caffeine 0.27 per cent.; tannins, 7.39 per cent.; total nitrogen, 0.73 per cent. This plant is another species of the maté, *Ilex paraguensis* (Am. Jour. Pharm., 57, 389). The South African "bush tea," used for a beverage, consists of species of *Cyclopodia*. Three of these species were examined by Greenish in 1881 (Phar. Jour. Trans., [3] 10, 217-221) for caffeine, and none was found. Another species was examined for caffeine by Church in 1870 (Chem. News, 22, 2), and none was found. A few months ago a small sample of a leaf stated to be a species of *Cyclopodia*, and a "bush tea" from South Africa, strayed to my laboratory. Analyzed by Mr. Gombert it was found to contain caffeine. A further sample has been sent for.

not the order of the five as they face on the other hand, and lo! these were just some of the additional possibilities that nature had filled out. Moreover, the most recent biological chemistry is full of suggestions of isomerism as yet not traced out at all. But caffeine is a body so well controlled in its structure, that the limits of variable order in its molecular parts are not out of the reach of chemical studies.

A difference of physiological effect, once well established for a pure body, a body that is one in all its laboratory reactions, chemical and physical, is a difference to be accepted as proof of isomerism. This might be termed physiological isomerism, but it must be a chemical fact none the less. It must be due to the manner of chemical union. Matter is made up of molecules, and a molecule is always a product of chemical action, whether such action can be traced out or not. If a function of life can serve as a qualitative reaction for any chemical body, a reaction to which chemical union is more sensitive than it is to light or heat or laboratory reagents, it belongs to the chemist to measure the results as well as he can.

But it were well first to avail ourselves of existing evidence as to the relative effects of tea as a whole and coffee as a whole. Such evidence, whether taken from certain functions of the body or from the sum of all the functions, is conclusive to many persons. If not conclusive to the pharmacologist, who would measure effects of each constituent upon each function taken separately, still the evidence drawn from the action of the whole of tea or coffee is not without bearing upon our estimate of the value of caffeine. We have a right to ask what there is in tea, and in coffee, beside alkaloids, to which the observer can ascribe the effects of these articles as beverages. Some answer to this question ought to be afforded by chemical analysis, as I have urged from time to time since 1876. The question, like others of the same sort, is not so simple as it is apt to be supposed; and much careful analytical work is wanted upon it.

What is wanted is a full analysis of the entire content of the ordinary beverage infusion of tea and of coffee. If we go to the common analyses of the books, we fail to find out what and how much, out of tea or coffee, goes into solution and into the stomach and into the blood, for dynamic registration by the brain, the heart, the vascular system, etc. Such account of the actual content of the beverage infusions as I have been able to collect, I have grouped together in the accompanying table. Some of the earlier data were obtained in my laboratory, a former student of mine has independently furnished the fullest data, other quite comprehensive results are from sources remote from my personal knowledge, and to fill up a few gaps I have resorted to factors of comparison. The citations specify the several sources of the figures presented.

The following conclusions are evident:

1. The alkaloid counted as caffeine is mostly dissolved by ordinary hot infusions and by decoctions of tea and coffee, even if brief in maceration. Of the two beverages, coffee is apt to be a little the richer in alkaloid, but this difference is not distinctive. Three grains per pint is a common proportion.

2. Tea beverage is very rich in tannins, which are nearly absent from coffee beverage. Tannins are very slowly drawn into infusion, so that the time and temperature of infusion govern its astringency. A cup

of tea may have from two to six times as much of tannin as it has of alkaloid.

Note A.—J. F. Geisler, chemist to the New York Mercantile Exchange, American Grocer, October 23, 1881; Prescott's Organic Analysis, 1887. The thirty grades embrace six "Indian teas," with an average of 15.8 per cent. tannins; thirteen Oolong, 16.4 per cent. tannins; and eleven Congou, 12.6 per cent. tannins. The teas were obtained of importers, as selected representative grades. Percentages are given on the tea dried at 100 C.

Note B.—"Werthbestimmung," p. 60. Recalculated to give percentages on the tea dried at 100 C. From twenty-three grades and varieties of tea; the tannins from only four varieties. From twenty-five varieties of coffee; the potassa from only seven of these. The analyses of teas are credited to Prof. Dragendorff and Mr. Weyrich.

Note C.—Univ. Mich., 1876; Am. Chemist, 7, 44. In use of a method of volumetric analysis with cinchonine, titrating the excess with iodomercurate, as adapted for analysis of tea in the work reported upon.

Note D.—The contribution cited in Note A. Average of results from sixteen varieties. These results are separately given in the report, as are those of I, 1. The infusions were made by 100 parts of distilled water, poured on boiling, and standing ten minutes. The percentages are given on the air-dry tea. (The thirty teas of I, 1 average 6.6 per cent. of moisture.)

Note E.—Chem. Lab. Univ. Mich., 1880; Physician and Surgeon, 2, 342. From eleven varieties of tea and six of coffee. Infusions in 50 parts of distilled water at about 90 C.; the estimations by the same method designated in Note C. In some way, perhaps in not accounting for retained liquid (out of the 50 parts of solvent) the results are probably too low, but they are of value in comparison with each other, showing the effect of prolonging the period of infusion, and the difference between coffee and tea in parallel conditions.

Note F.—Laboratory of Internal Revenue Department, Ottawa, Canada, 1891, Bulletins No. 24 (tea) and 29 (coffee). The infusions were made under the conditions adopted by Geisler, Note D, namely: ten minutes action of 100 parts of water, taken boiling. The percentages are given upon air-dry tea; the moisture being 6.5 per cent. for the black, and 4.0 per cent. for the Japan varieties.

Note G.—In these calculations a certain "strength" of each beverage must be assumed. The standard of common strength which the writer arrived at, from various data, in 1880, is here adopted. The data are given by the present writer, in Physician and Surgeon, 2, 342, and the standards are as follows: For tea, 73 parts of water, 1 pint from 100 grs.; for coffee, 23 parts of water, 1 pint from 317 grs. This gives 224 five-ounce cups from one pound of tea, and forty-five eight-ounce cups from one pound of coffee. To this strength the results of Geisler and of Kenrick are reduced. Of course Geisler's infusions, more dilute, would dissolve somewhat more than an infusion of this domestic average. The greater concentration of coffee beverage should bring down these figures, and infusion for over ten minutes would raise them.

Note H.—Calculated to the assumed average strength of beverage stated in Note G.

3. Coffee beverage carries quite constant potassium salts amounting to four times the quantity in tea beverage. A cup of coffee contains potassium salts about twice the quantity of its alkaloid. Some of the potassium is in phosphate.

4. The nutrient and other remaining solids in coffee infusions amount to four times the quantity of the corresponding solids in the infusions of tea. A pint of coffee contains an average of 50 to 60 grains of solids beside alkaloid, ash, and tannin. The

pharmacology of some of these bodies ought to be studied.

5. There follows to be determined the homologues of caffeine (theophylline, theobromine, and xanthine), their presence, quantity, and effect. Then remains, if found at all, any evidence as to isomeric caffees. For these inquiries it is needful to discuss the known constitution of caffeine itself.

Caffeine stands apart from vegetable alkaloids as a class. It is not a derivative of pyridine. It does not give evidence of a closed chain of carbon atoms in the same state of saturation found in pyridine derivatives. It does not contain any part of the fruitful benzene molecule. When it is broken up in any way, aromatic compounds are not formed out of it. In all these related particulars caffeine is unlike the numerous alkaloids of cinchona, or opium, or hydrastis, or coca, or pepper, or conium, or henbane, or tobacco. It stands apart, also, in the great content of nitrogen it carries, namely 28.8 per cent. Proteids have 16 per cent.; quinine has 8.6 per cent.; strychnine, 9.0 per cent. of the same element.

Caffeine is a thrice methylated xanthine as clearly as chloroform is a thrice chlorinated methane. As trimethyl-xanthine its chemical possibilities in general are those of xanthine, itself. As a tri-derivative of xanthine, it is methyl-saturated, and does not have the obvious theoretical possibilities of isomerism that di-derivatives and mono-derivatives possess. These have been readily realized in synthesis.

Of the four atoms of hydrogen in xanthine, $C_5H_4N_4O_3$, only three are linked to nitrogen, and only these three are replaceable by methyl. The fourth atom of nitrogen in xanthine is linked to carbon only, in the manner of a tertiary base. Probably this is the point of unyielding difference between uric acid structure and xanthine structure, preventing the conversion of the one ($C_5H_4N_4O_3$) into the other ($C_5H_4N_4O_2$). The resistance to such conversion was shown by E. Fischer in 1884.²

Four methyl groups can be introduced into uric acid; only three into xanthine.³ In every case the introduction is a substitution for hydrogen, and a linking to nitrogen. In every case, when the methylated compound is broken up, the methyl groups remain linked to the nitrogen, either in methylated urea or in methylated ammonia.

Xanthine and uric acid agree in this, that they contain two molecules of urea united to an unsaturated chain of three carbon atoms. The carbon chain holds the fourth hydrogen atom of xanthine, and the third oxygen atom of uric acid. Each urea group contains two ammonia groups. When an ammonia group is broken off, it is capable of neutralizing one valence of an acid, forming a strong salt. Were the four nitrogen groups of xanthine, or caffeine, sufficiently positive in their polarity, then they would hold four valencies of an acid. Then caffeine would be a quadrivalent base. But it lacks the positive polarity to be a decided base at all. Urea is almost as near an acid as a base, such is the negative power of its carbonyl group. The three-carbon chain of

xanthine, and of uric acid, introduces such a negative preponderance that they are acidulous rather than basal. The mono-methyl, and di-methyl derivatives of xanthine are less basal than caffeine. When three methyl groups are introduced their polarity as positive groups appears to create a slight balance of electro-positive quality to the molecule. As a result caffeine is capable of serving as a base, but not to the extent of more than one valence. So urea can at most hardly neutralize more than one acid valence. When an acid valence is united either to caffeine or to urea, its negative polarity so far preponderates in the entire molecule that the remaining nitrogen groups are powerless to unite with acids. The case is like that of acetamide. That caffeine unites with strong acids, slowly but in final proportions quite true for monovalent base, was demonstrated last year in the admirable paper of Mr. H. W. Snow.⁴ The acetate, however, was found by Biedermann⁵ to be divalent.

In the halogen derivatives, however, such as bromo-caffeine, chloro-caffeine, etc., the halogens are received as they are by a hydrocarbon. One halogen atom can be united by substitution for the fourth atom of hydrogen. Also two halogen atoms can be united by a saturation of the unsaturated couple in the carbon chain. Union of hydroxyl, the amido group, an ethoxy group, etc., in this way, are unions independent of the nitrogen groups, or of any basal properties whatever.

The introduction of a methyl group in connection with the carbon chain of caffeine has not been accomplished. To do this would be to make an interesting homologue of caffeine. To make the same introduction in theobromine would give us a clearly distinct chemical isomer of caffeine. An attempt to make this isomer by different well-known methods for such substitution, has been faithfully made in my laboratory, this season, by Mr. M. Gomberg, as a part of investigations, not yet published, upon the question of isomerism of caffeine.* Various conditions of reaction were employed. This much is evident, the carbon chain does not readily attach either methyl or ethyl. On the other hand, the impossibility of such methyl introduction has not been established. Mr. Gomberg has introduced other groups, not heretofore brought into union with the carbon chain, and will proceed upon the line of work in which he is engaged.

As to the possibility of a plural of trimethyl-xanthine, some things are obvious. Assuredly its isomerism, in the more common ways, is not pointed out to us by the chemistry of the xanthine group. The fourth atom of nitrogen in this body does not receive methyl, except by bivalent addition, a sort of over-saturation. No asymmetric carbon atom appears in the body. And whether from coffee or from tea, the alkaloid is inactive to polarized light.⁶ But it would be rash to assert the impossibility of isomerism of any sort. For example it is open to ask whether the atom of hydrogen not methyl cannot link to the intermediate carbon of the mesoxalic chain, doing

² Ber. d. chem. Ges. 17, 328. The report of Strecker, from the work of Rheineck, in 1874 (Ann. Chem. Phar. 131, 121) that uric acid is deoxidized to xanthine by sodium amalgam, was a singular instance of error lingering long in literature. It was disproved by E. Fischer in 1884 (Ber. d. chem. Ges. 17, 1776.)

³ This is true of the substitution compounds. The addition of methyl iodide to caffeine, obtained by Tild n (1865; Jour. prakt. Chem., 94, 374) and examined by Schmitt (1883; Ann. Chem. Phar. 217, 270) (1885; *ibid* 141) furnishes an apparent approach to a xanthine derivative. This addition compound is, however, a sort of super-saturated body.

⁵ 1883; Archiv. Phar. [3] 21, 175; Jour. Chem., Soc., 46, 185.

* Read in Am. Assoc. Advancement of Science in August, 1892, "Trimethyl Xanthine and some of its Derivatives," by Moses Gomberg, M.S.; Am. Chem. Jour., 14, 611. (Reprints.) Mr. Gomberg continues this investigation, working in the laboratory of the writer.

⁶ This was determined in the writer's laboratory in 1887. Other physical differences were sought for and not found. (Unpublished records.)

this in exchange with the valence of nitrogen of the third position.

With some outline of caffeine structure before us, it will be easier to see its relation to certain of its homologues, some of which, as already intimated, have been found in tea. There is a lack of thoroughgoing analysis to this end. The reports, so far as I have found them, are as follows:

Theobromine, or dimethyl xanthine, the alkaloid of chocolate, was found in Himalaya tea by Zöller in 1871.⁷ Its solubilities in water and in ether are not so large as those of caffeine, but in smaller quantities it will not be excluded in customary preparations of caffeine. Neither will it be detected by ordinary tests. Xanthine itself, and hypoxanthine, were found in several samples of tea by Baginski, in 1885.⁸ It has not been much searched for. Its very slight solubility in water would, apparently, reduce its proportion in infusions to very narrow limits, even if present in tea leaf, but as it is exceedingly soluble in alkalis it may be affected in solubility by the presence of the alkali salts of tea.

A dimethyl xanthine, isomeric with theobromine, was announced as a discovery in Himalaya tea, by Kossel, in 1888,⁹ who named this new vegetable body, theophylline. Like theobromine it unites with alkalis as well as with acids. Its methyl derivative was found identical with caffeine. Broken up, its alloxan is a dimethyl compound, its urea is not methylized; so its methyl groups are in positions 1 and 2. This explains its difference from theobromine, in which a methyl group occupies position 3.¹⁰ Theophylline was found much more soluble in water than theobromine. Therefore, if in tea leaf, it will be in the infusions. As described, its presence in caffeine would probably be overlooked.

The existence and occurrence of theophylline has not been verified or followed up. Kossel had been known in chemical literature for his frequent contributions analytic and synthetic upon xanthine and allied bodies, for eight or nine years prior to the announcement in question. The year after, Messrs. Paul and Cownley¹¹ examined the extract of 200 grams of tea of Himalaya, and found an alkaloid not fully determined. They have since¹² reported a series of estimations of "theine" in tea, without, so far as I have seen, any account of residual alkaloids. Coffee does not appear to have been carefully examined for alkaloids homologous to caffeine, that is, trimethyl xanthine, and the same is true of guarana, maté and kola.

It has been usually assumed that pure "theine" is the alkaloid of tea completely freed from matters not alkaloids. "Caffeine" and guaranin" have been defined in the same way. There is now a degree of uncertainty as to the chemical purity of the several articles under these names, an uncertainty which it belongs to the chemist to clear up. Let us see what stipulations of purity have been made for these articles when they have been taken for physiological trial.

Shortly after Emil Fischer's researches on the xanthine group, showing how little relation xanthine

has to uric acid, and how clear is the homology of caffeine and theobromine to xanthine, Wilhelm Filehne made a pharmacological investigation of these four bodies. This was in 1886.¹³ Happily, Fischer supplied Filehne with the articles, xanthine, caffeine, theobromine. No mention is published of any precautions against xanthine as an impurity in caffeine, nor any statement as to the source of the caffeine, whether from tea or coffee or synthetic work. The object was a physiological comparison of xanthine, dimethyl-xanthine, and trimethyl-xanthine. Filehne found the three bodies to differ in degree rather than in kind of action, and that the effect of xanthine was the most intense, that of trimethyl-xanthine the least intense of the three. He found, as others have, that uric acid does not possess the power of xanthine at all. Ethoxy-caffeine was found by Filehne, as also by Baumetz,¹⁴ to have a distinctly different, somewhat stronger action.

Dr. Thomas J. Mays, in 1886,¹⁵ made a full and careful comparative trial of caffeine and theine. He had the alkaloids prepared for him by designated makers, to ensure that the one came wholly from coffee and the other from tea, but no mention is made of other precautions as to purity. In his conclusions the two are not identical.

In 1887 Dr. T. Lauder Brunton put caffeine and theine upon pharmacological trial.¹⁶ His precautions as to true samples are mentioned as follows: He obtained the caffeine from Schuchardt. The theine was a pure specimen from Messrs. Hopkins and Williams. In referring to the "discrepancies" between Dr. Mays results and his own, Dr. Brunton says they may be "due to difference in the animals employed or to variations in the theine," "for it is just possible that there can be differences in the active principles obtained from different kinds of tea, or even from the same kind by different methods of treatment." Dr. Brunton did not find his "theine" and his "caffeine" to have the same action, nor did he find the difference between the two to be the same recorded by Dr. Mays.

In the present state of evidence, then, we reach certain conclusions as follows:

1. The five beverage plants owe some of the differences in their effects to their different yields of bodies not classed as active principles.
2. The total active principle of a beverage plant, the "theine," "caffeine," etc., as obtained, is perhaps liable to contain small quantities of xanthine and other homologous bodies of physiological effect.
3. The main active principle in each of the five beverage plants is, unquestionably, a trimethyl-xanthine. Chemical studies indicate, as yet, only one trimethyl derivative of xanthine. If, however, strictly pure trimethyl-xanthine, known as caffeine, from one plant clearly differs in physiological effect from the same body taken in strict purity from another plant, then the chemist will recognize a proof of isomerism, and await its explanation by later chemical researches.

University of Michigan.

Discussion.

Prof. Remington called attention to the scientific foundation for the custom of simply making an infusion of tea, by

which the flavoring substances and caffeine are extracted, leaving the insoluble tannin behind.

The chairman stated that if the statement is to be accepted that theine is different from caffeine, it will be necessary to write "thea" after caffeine, since much of the supply of caffeine is obtained from damaged tea. Dr. Edward R. Squibb, in a letter some years ago, declared that there was no difference between theine and commercial caffeine, and threw some doubt upon the existence of caffeine, as such in the living plant. A practical point, showing that tea is prized for something more than its alkaloidal content, lies in the fact that some cheaper grades of tea are richer in caffeine than the higher-priced teas. As regards the difference alleged to exist between the alkaloid derived from tea and that from coffee, it is possible that some of the volatile substances of the tea are not fully separated from the caffeine, and modify its physiologic action; just as piperine may owe much of its stimulating qualities to volatile substances usually associated with it.

In practical medicine, the insolubility of tannin should be remembered, and in making infusions for the astringent effects, as in antimonial poisoning, or for their action on mucous membranes, the tea or coffee should be boiled. On the other hand, when the stimulating effects alone are desired, a rapid infusion is all that is needed.

In closing the discussion, Dr. Prescott said that, During the discussion which followed the reading of this paper, the question had been asked, what extent of the effect of tea and of coffee is due to their essential oils; also to what extent caffeine or theine is changed by methods of extraction. To this he replied that, undoubtedly the essential oils in question are of decided influence. Many volatile oils are of active physiological effect. However, these oils have not been separated and examined. That of coffee is developed by roasting; that of tea, not improbably, is developed by the curing process, with its stage of fermentation, and of firing. As to the alteration due to modes of extraction, he believed they could hardly extend much beyond the liberation of the alkaloid from certain combinations of the same.

COLLABORATION IN MATERIA MEDICA AND PHARMACY.

Read in the Section of Materia Medica and Pharmacy, at the Forty third Annual Meeting of the American Medical Association, held in Detroit, Mich., June, 1892.

BY CHARLES RICE, PH.D.,
OF NEW YORK.

The new movement of establishing closer and official relations between the two professions of medicine and pharmacy was inaugurated at a time when its desirability, or rather necessity, had become generally recognized. Both professions have many interests in common, and both have to supplement each other by their special knowledge and attainments. Many are the topics—ethical, legal, historical, hygienic, statistical, educational, social, and particularly scientific—which can and will be profitably discussed at joint meetings of representatives of the two professions; and some of these topics may even be said to form burning questions which have hitherto been treated by the medical and pharmaceutical press mostly in an *ex parte* manner. It is hoped that these may, hereafter, be brought to a solution satisfactory to all.

But the discussion of professional topics, or the reading of papers thereon, at the joint annual meetings, does not seem to be sufficient to infuse life into a copartnership such as it is proposed to establish and maintain between the two professions. Something else, of a more lasting and permanent interest, something of tangible utility, so to say, seems to be wanted to serve as a firmer bond. In the judgment of the writer, such a bond can be established—and indeed its want has long been felt—by the official interchange of, and decision on professional or scien-

tific problems between the two professions. The physician as well as the pharmacist, each possesses, if properly trained, a fund of special knowledge, often laboriously acquired and constantly augmented by daily practice and experience, which, in these days of rapid progress, can no longer be expected to be met with combined in one and the same person, but which has to be gathered and studied by specialists for the benefit of the other members of their own or a kindred profession. Yet it is an indisputable fact that many important facts which have long been known to or recognized by *one* profession, and which yet vitally concern the *other*, remain often entirely unknown, or only imperfectly known to the latter for a long time. If there were an official channel through which such useful information could be conveyed, at regular intervals, from one profession to the other, much would thereby be gained. It may be well to mention an example by way of illustration. Many physicians are in the habit of prescribing *aconitine* without specifying what kind they intend. They are not aware that there are *four* or *five* different kinds in the market, each of them in vogue or preferred in some particular country or locality—one being the pure, crystallized alkaloid of great power; another an amorphous substance of comparatively feeble strength; another one made by a different process, or perhaps from a different kind of aconite, being of an intermediate strength, etc.—and that they are liable to have the most powerful dispensed when they perhaps intended the weakest, or *vice versa*. Would it not be useful to present to the medical profession, once a year at least, a concise summary of important matters of this kind, which would suggest themselves from time to time? As a rule, physicians do not read pharmaceutical journals, or circulars issued by chemical houses, hence information regarding subjects like that above mentioned often reaches them only when some serious accident has happened. If there were a source of information on topics of this kind, prepared by pharmacists specially for the benefit of physicians, much good would result. On the other hand, physicians often observe objectionable features connected with the form or efficacy of pharmaceutical or galenic preparations—as for instance deficiency of therapeutic action due to improper vehicles, improper coating, etc. The same medium of communication could be used for drawing the attention of the pharmacists to these matters.

If it is conceded that such a mutual exchange of information or of problems is desirable, it will not be difficult to devise a plan by which it may be carried out. The writer suggests the following, at least as a basis upon which something better may perhaps be erected:

1. The American Medical Association, through its proper Section (or in any other way that may be determined on), may annually appoint *seven* (or any other number) members, who, together with a like number of pharmacists, who may be appointed by the American Pharmaceutical Association, shall constitute the "Committee on Therapeutics and Pharmacy" (or whatever other name may be given to this).
2. This committee shall elect a chairman and vice-chairman, only one of whom shall be chosen from the same profession. These two officers shall also be the chairmen of their respective sections (medical and pharmaceutical) in the committee.

3. The committee may either hold joint sessions at such times as may be agreed upon, or it may transact its business by correspondence.

4. Either section of the committee shall be authorized and instructed to consider any professional questions or problems which may be submitted to it by the other, and after deliberation, to give such an opinion or such a decision as the subject may warrant, from the standpoint of the profession rendering the opinion or decision.

5. The section of the committee making the request or appeal shall bring the reply or decision of the other to the knowledge of the whole of its own profession, or, when this is unnecessary or inadvisable, at least to the notice of those to whom it more particularly applies.

6. The committee, or, if so determined by it, either or both of its sections separately, shall annually report at the joint meeting of the two professions (or say to the Section on Materia Medica and Pharmacy of the American Medical Association?) the nature of the questions and problems mutually submitted, if any, and the respective opinions or decisions rendered. These decisions shall be subject to a revision, if one is called for, at this meeting.

7. Each section of the committee shall annually present a report upon professional topics which it may be thought particularly necessary to bring to the attention of the other profession. Thus, the section on pharmacy may present, for instance, a report on new remedies, accompanied by practical suggestions as to their best mode of administration, as to precautions to be observed in prescribing them, as to incompatibilities to be avoided, and similar topics. And it may submit questions or problems involving *therapeutics as it affects pharmacy* to the other section, with a view of having them answered or decided. The section on therapeutics may, in its turn, present problems or questions involving *pharmacy as it affects therapeutics* to the other section for solution or answer.

In presenting this plan, the writer had in view scientific professional topics rather than ethical ones. There is no doubt that the latter would also form an abundant source of discussion and that this would, if properly conducted, bring the two professions still closer together; but it will under most circumstances be preferable to relegate such topics to the general annual meeting, there to be fully discussed and decided, rather than to have them passed upon by a small committee, the action of which may after all not be finally endorsed by the Association. On the other hand, a reversal of any decision by the committee on *scientific* topics, rendered after proper study and discussion, is scarcely to be apprehended.

The practical benefit which may be expected to be derived from an active coöperation of the two professions in the manner above outlined, provided the plan is fairly tried in practice, are believed to be such that the annual reports of the joint committee would be looked forward to with eagerness and interest.

New York, May 20, 1892.

MR. JOHN L. WOODS, of Cleveland, Ohio, made a Christmas gift of \$125,000 to the Medical Department of the Western Reserve University.

SECTION ON MATERIA MEDICA AND PHARMACY.

The sessions were held in the building of the Detroit Young Men's Christian Association, on the afternoons of June 7, 8 and 9. Dr. Frank Woodbury, of Philadelphia, Chairman of the Section, occupied the chair. On account of the absence of Dr. Whelpley, of St. Louis, Dr. F. E. Stewart, of Wilmington, Del., kindly accepted the position of Secretary *pro tem*. A delegation from the American Pharmaceutical Association was present and contributed largely to the proceedings. Among those present were Joseph Remington, Professor of Pharmacy in Philadelphia College of Pharmacy; Dr. A. B. Prescott, of the University of Michigan; Dr. H. A. Hare, of Jefferson Medical College; Professor P. W. Bedford, New York; E. H. Squibb, M.D., Brooklyn, N. Y.; H. W. Snow, Omaha, Neb.; Lewis C. Hopp, Cleveland, O.; J. E. Clarke, M.D.; H. W. Snow; A. S. Parker; J. W. Rabe; F. W. Jackson; F. A. Thompson; Prof. Eli H. Long, Detroit Medical College, and others.

The Chairman, in opening the deliberations of the session, directed attention to the evident disposition of the Association to devote more time to scientific work, and thus greatly increase the usefulness of the Sections. A peculiar feature of the Section on Materia Medica and Pharmacy, is that the Association has formally invited the American Pharmaceutical Association to be represented by delegates who shall participate in its scientific work. This recognition of the high standing of representative pharmacists is a just tribute to their professional attainments, and establishes pharmacy as a department of medical science. This is a consummation of immense value to both medicine and pharmacy; and that we have been able in any way to assist in bringing it about, should be a subject of congratulation. Its consequences upon the development of pharmacy in this country must be great and far-reaching. Biological chemistry and practical pharmacy are closely related and should be studied together. The present aspect of medicine, speaking from the therapeutic standpoint, is largely chemical, and is mainly based upon chemical ideas. Nutrition is largely a chemical problem. Indeed, we might almost represent health by a very complex chemical formula, graphically written, so as to express exact molecular composition. Various modifications and substitutions may take place, representing departures from the normal, more or less marked and corresponding with certain diseases or diatheses. While the researches of bacteriologists have revealed specific microorganisms characteristic of different infectious diseases, later observations serve to establish the fact that these so-called disease germs do not so much cause disease directly by their numbers as they do so indirectly by their chemical products, which enter the blood and act as toxic agents. The important relation of pharmacy to medical practice is, that it supplies chemical substances capable of acting as antidotes to the poisonous action of these agents. As illustrations we have quinine and arsenic against malaria; Koch's tuberculin against phthisis; acids against cholera, etc. It may be regarded as demonstrated that phagocytosis is influenced materially by chemical substances.

The first paper was one by Dr. Albert B. Prescott, of the University of Michigan, entitled "Caffeine and the Question of Its Isomerism."

In the absence of Dr. E. L. Patch, of Boston, his paper on "Examination of Market Fluid Extracts" was read by title.

A paper on "Pharmacy at Health Resorts," by Dr. F. E. Stewart, was also read by title.

Prof. Joseph Remington, of Philadelphia, read a paper entitled "Prescription Exigencies."

SECOND DAY—JUNE 8.

The discussion on the Revision of the United States Pharmacopœia was opened by Prof. Joseph Remington, of Philadelphia, a member of the Committee on Revision. He stated that the Pharmacopœia is rapidly approaching completion and that much of it is already in type. It is believed that the work will appear before the end of this year. Some important changes have been made, the most notable being the adoption of the metric system in the formulæ. The hope was expressed that this change would be approved and supported by the members of this Section.

The following resolution offered by Dr. Prescott was unanimously adopted:

Resolved, That we desire to urge upon the medical profession the desirability of the direct use of the Pharmacopœia of the United States by the physician himself, as a handbook of reference in materia medica.

That we urge upon teachers of materia medica such a direct use of the Pharmacopœia, by classes of students of medicine, as will ensure their habitual familiarity with the work itself.

Dr. Prescott said he desired to testify to the large labor undertaken and carried out by the Committee of Revision. As a member of the revision committee of 1880, he has full realization of the work involved. The committee of that revision expended the residue of the receipts from copyright in publishing a digest of published criticisms upon their work. A great deal of time has been expended by this committee in consulting these published criticisms. Also a great deal of experimental labor has been devoted to their work, as he said he knew from a reading of portions of the circular correspondence of the committee which had been kindly placed in his hands.

The Chairman opened the discussion on "An International Pharmacopœia." He stated that the adoption of an International Pharmacopœia has been under consideration for a number of years. The present seems a particularly propitious time for renewing the agitation. Americans read English and Continental medical journals and books, and extracts from these, containing formulae, are constantly reappearing in American journals and text-books. As there are marked differences in strength among many products bearing the same name (such as tincture of belladonna), and as even the ounce of water is not the same in the British and United States Pharmacopœias, an International comparative commentary upon the different pharmacopœias, containing the principal drugs in use by civilized nations, with their preparation, seems necessary. Such a work would be most convenient for reference, both for physician and pharmacist.

On the matter of an International Pharmacopœia Dr. Prescott said that he believed there was a proper field for this work, as a brief work, for the coordination of the several National Pharmacopœias, with definition of only the most important and frequently used articles. He hoped it would not be misapprehended, as a work designed at all to supersede the pharmacopœias of the several countries.

A series of resolutions was offered thanking the Committee on Revision for their valuable labors upon the Pharmacopœia, and requesting that in all doubtful questions coming up for decision preference would be given to those that would facilitate the creation of an International Pharmacopœia. The resolutions were unanimously adopted.

THIRD DAY—JUNE 9.

A communication by Dr. Charles Rice, of New York, on "Collaboration in Materia Medica and Pharmacy," was read and discussed.

The suggestions contained in Dr. Rice's paper were referred to a committee of conference to report at the next annual meeting.

The following papers were read by title: "Europhen," by Dr. J. V. Shoemaker, of Philadelphia; "Tablet Triturates and Dosimetric Granules," by Dr. Wm. F. Waugh, of Philadelphia; and "Notes on Therapeutic Novelties," by Dr. I. N. Love, of St. Louis.

The Business Committee of the Section was elected as follows: Dr. Horatio C. Wood, of Philadelphia; Dr. F. E. Stewart, of Wilmington, Del.; and the Chairman of the Section.

The election for officers resulted in the reelection of Dr. Frank Woodbury as Chairman, and the election of Dr. F. E. Stewart as Secretary.

PRESCRIPTION EXIGENCIES.

Read before Section on Materia Medica and Pharmacy, at the Forty-third Annual Meeting of the American Medical Association, held at Detroit, Mich., June, 1892.

BY PROF. JOSEPH P. REMINGTON, Ph.M.,
OF PHILADELPHIA, PA.

"Every pilot
Can steer the ship in calms; but he performs
The skillful part, can manage it in storms."

—Sir J. Denham.

The prescription is justly regarded by both professions as the most important link in the chain which binds them together. Upon the insignificant scraps of paper are traced the characters which represent the conclusions reached by the practitioner after most serious consideration of the patient's case and to the earnest physician the writing of the prescrip-

tion is his most responsible duty. Notwithstanding the exceptions to the rule that are constantly forced to the attention of the pharmacist, safe ground can only be held by assuming that the physician always means what he writes and writes for exactly what he means. But, exigencies arise, we are all fallible, and "errare est humanum" must never be forgotten. Constant vigilance must then be the rule for the apothecary. Yet it must be admitted by all that when the vast number of prescriptions that are written every day are considered, that very few serious errors occur it must also be noted that with the great development of modern pharmaceutical methods, systematic habits and checks are now used, which reduce the danger arising from ignorance, carelessness or lapses, to a minimum.

It has occurred to the writer that it might prove of some service to call attention to a few of the more common exigencies, many of which require skill, tact and judgement to successfully master. At the present time, every careful pharmacist uses what is known as the checking system. By this is meant the calling off by the compounder to a second person the various ingredients with the weights or measures used of the prescription. Before this method came into general use, many instances are on record of mistakes occurring from the use of the wrong ingredient, from the omission of something, or from an error in writing the label.

In one recorded instance, a prescription was compounded by the proprietor in which one of the principal ingredients was omitted. The bottle containing the medicine was handed to the boy of the family who started to take it home. When the pharmacist returned to his desk, he realized that the principal ingredient had been left out. He quickly explained the situation to a bright-witted boy, who managed to reach the messenger carrying the bottle before the latter had arrived at his destination. It was but the work of a moment for the embryo pharmacist to stumble and fall in such a manner against the bottle that it fell to the ground. Of course the usual pleasantries (?) were exchanged but it ended in the apothecary's boy reluctantly promising to have the prescription compounded without expense and delivered at once.

Nearly every pharmacist can recall instances of a persistence in adhering to an erroneous name or quantity by a physician in writing a prescription. Notwithstanding the fact that the compounder is positively certain that the physician does not want what he has written for and the true state of the case has been set before him, so firmly has the error become wedged in his inner consciousness, that he indignantly persists in having the prescription compounded exactly as he has written it.

An amusing instance of this occurred in the writer's personal experience. One of the most celebrated practitioners in Philadelphia wrote a prescription which was sent to be compounded. It was as follows:

R. Troch. chloroformi No. xii.
(Gr. v.)

Sig. Take one every two hours until relieved.

Suspecting that this was an instance of persistent adherence to a wrong impression, a messenger was sent with a note to the prescriber calling attention to the fact that there must be some error, as there would be no certainty that the patient would get any

chloroform, owing to its volatility, even in the first lozenge. The messenger was told very promptly (and evidences of wrath accompanied the communication), that Mr. — better compound his prescriptions just as they were written and that he was too busy to be bothered by such trivial interruptions. The assistant quickly returned with the tart reply and Mr. —, dutifully (and let us hope humbly) proceeded to prepare the chloroform lozenges, when suddenly the front door was thrown open and a flashing vision crossed the threshold; the next moment, a beaming face, adorned by the traditional gold spectacles of the wearer, was thrust around the prescription counter. "I beg your pardon, Mr. —, but I did not want chloroform but chloral lozenges." It is hardly necessary to say that the incident closed without prejudice to the patient.

Faulty abbreviations are constant sources of perplexity to the pharmacist. It would be far beyond the scope of this paper to enumerate even the more important of this class and it is only the cautious, intelligent pharmacist who has not only the knowledge, but more than this the intuition with which to select the substance intended by the physician and send it on its mission of healing. In this connection, I trust that I may be pardoned for alluding to an annoyance which has become widespread in this country. It is the writing in the place of the time-honored "Signa," the words, "As directed," often abbreviated "As dir." It has been urged in extenuation and in justification of this habit that the patient was intelligent and had no difficulty in understanding the verbal directions and that they were too long to write upon a label, etc., etc.: my brethren in the pharmaceutical profession will bear me out in saying that very often the patient will say when the finished prescription is handed to him, "How am I to take this?" "Well the doctor has given you the directions, has he not?" Yes he did but I have forgotten them." "Had you not better ask him?" "Oh, no, that will never do. That means two dollars more." So rather than pay the physician another visit, the patient takes his chance and probably makes a mistake. When a faulty abbreviation occurs with an "As directed" for a "Signa," the combination becomes very puzzling.

R. Hyd. chlor. grs. x.
Sig. As dir.

A natural delicacy which can be well understood prevents the apothecary from asking any questions of the patient regarding the prescription, for fear of throwing an element of doubt or suspicion around it. Thus we have presented another "Prescription Exigency." Most pharmacists would probably ask the patient how he was told to use the medicine and thus a clue would be offered which might or might not lead to satisfactory results. Unless the answer was unmistakable, it would be unsafe to proceed. Then the statement could be made that this prescription would have to be sent by messenger as it would take "considerable time to compound it." It is needless to say that no statement need be volunteered that the greatest share of this time will be spent in hunting the physician who wrote it.

The development which is ever going on in matters pharmaceutical has educated the public to expect bright transparent liquids for their medicines; and, when such are not dispensed, critical remarks are sometimes forthcoming. The thoroughly educa-

ted members of both professions know very well that the transparency of a liquid sometimes means that the greater part of the active principle of the prescription has been left upon the filter; and, the question which is presented to the pharmacist nearly every day of his professional life is, "Should or should not this prescription be filtered before dispensing?"

The behavior of solvents towards certain chemical substances, the extent, character and condition of the precipitate formed, the effects of temperature, are all factors which must be carefully weighed in the balance; and, it will be easily seen that a large fund of knowledge is required not only of the reactions of the official substances, but also of the physical and chemical properties of the immense number of the new synthetical products, which are crowding the shelves of the apothecaries and filling the coffers of the jubilant foreign manufacturers.

A frequent cause of friction arises between physician and pharmacist because of a difference of opinion or practice among pharmacists in the matter of filtration. A physician writes a prescription which is slightly incompatible; a precipitate (trifling possibly) ensues. The pharmacist, Mr. A., who compounds it concludes that it is unimportant, filters it out and dispenses the prescription in a transparent condition. The doctor sees the prescription at the patient's house, notices it, is pleased with the results and prescribes it in another case. This time the prescription goes to a different apothecary, Mr. B., who thinks that the precipitate may contain some activity and therefore it better not be filtered. The physician sees this prescription at the house of the patient and may say to him, "Why don't you get your prescriptions of Mr. A.? This muddy mixture is not right." The patient of course does not wish to pay for a prescription which has been improperly compounded, enters complaint, and there is very apt to be some hard feeling. The apothecary retaliating probably by showing the patient that the fault lies with the doctor who wrote the prescription, because he did not know that precipitation would take place. Due consideration and a proper spirit of professional etiquette should inspire the members of both professions and under no circumstances should the patient be a witness to differences of opinion.

The question of the use of cautionary or poison labels upon prescriptions has been fortunately settled legally in a satisfactory way and knowledge of this should be spread as far as possible. An apothecary of excellent reputation on one of the principal streets of Philadelphia, a few years ago, received a prescription from a well-known physician which ordered tincture of nux vomica to be taken in five drop doses. It happened to be compounded by a very conscientious and as it proved an over careful assistant, who reflecting that the bottle might be placed within the reach of children (and thus become dangerous) pasted upon the bottle a poison label. It happened that this particular prescription was for an old and hypochondriacal lady, who took fright immediately on seeing the poison label, sent for the doctor and peremptorily discharged him for daring to prescribe poison for her. He naturally sought the apothecary and what took place at the interview can well be imagined. The order went forth, however, from the apothecary that thereafter no prescription should be labelled "poison" except when so ordered by the physician.

Very remarkably not long after this occurrence, a family having vacated rooms in a tenement house were succeeded by a new tenant. As is customary in such cases, some of the friends of the incoming family aided in the moving. One of the inquisitive helpers found a bottle of sugar-coated granules, in one of the closets; and having seen some candies which resembled the granules, distributed them among the rest of his friends and they were eaten with apparent satisfaction. Violent convulsions ensued, medical assistance was summoned but one of the helpers lost her life. Investigation showed that the bottle contained granules of strychnine; that the label showed that they came from the same drug-store in which the conscientious assistant was employed and that this time the rule—not to put a poison label on a bottle unless ordered by the physician—had resulted in a death and the apothecary appeared to be empaled on both horns of the dilemma. The next friend of the unfortunate girl entered suit against the apothecary for negligence in not labelling the bottle "poison." But the case was thrown out of court without much difficulty, the ruling being that no blame could be attached to the apothecary as he had strictly followed the directions of the physician. The case excited a great deal of interest; many physicians going on record, that it was a vital necessity in many cases that the character of the medicine should not be known by the patient. This rule can then be formulated—poison labels are not to be placed on prescriptions unless ordered by the physician.

In connection with the subject of labels, it may often occur to the mind of the physician that he sees now frequently what are known as "Shake well" labels on liquids, that appear to be perfectly transparent. This is probably due to the fact that several dangerous poisonous cases have occurred through the precipitation of scanty, colorless precipitates. The mixture of bromide of potassium with sulphate of strychnine was one of these. Insoluble bromide of strychnine was produced which settled at the bottom of the liquid. The whole quantity of strychnine in the four ounce mixture was taken at one dose. It is an unfortunate peculiarity of this class of mixtures that the alkaloidal precipitates are not visible at the time the prescription is compounded, but they slowly settle out in the course of a few hours. This would be very likely to escape the notice of any one and on this account the careful pharmacist places a "Shake well" label upon the bottle, so that in case of precipitation, the patient will by shaking the mixture be sure to get the due proportion of alkaloid in each dose.

The writer regrets that space will not permit him to mention many other "exigencies" in prescription practice; but it is a source of gratification that probably at no time in the history of the world have pharmacists been so thoroughly trusted by physicians as at the present. The true pharmacist is always sensitive upon the question of additions or alterations in a prescription and he will never deviate from the rule, to permit no addition or alteration, which will interfere with the obvious intention of the prescriber. But no true physician will object to such alteration or addition if strictly within this rule. It is absolutely impossible for the busy practitioner to retain in his memory the varying degrees of solubilities of the great mass of chemical sub-

stances that are used to-day in the treatment of disease. Separation, precipitation, dissociation are almost always the rule. If by the addition of a little acacia, the active resinous ingredient of a tincture is prevented from adhering to the sides of a bottle and made to form a part of a homogeneous mixture; or if through the neutralization of the spirit of nitrous ether, the sodium salicylate in the mixture is held up; or if through the heating of one of the liquids, perfect solution is effected; and if the rule above quoted is never deviated from, then does the pharmacist truly fulfill his mission and become a most efficient co-worker.

Self-interest, lack of sufficient inducement, and liability of discovery are all powerful incentives in keeping the pharmacist who is not amenable to higher motives, from what is called tampering with the physicians' prescriptions. Wherever a deviation from the strict interpretation is demanded, it is the pharmacist's duty to render at once to the prescriber an explanation of the reasons for making any addition or change. As no pharmacist cares to risk the chances of an encounter with the physician, which is often times accompanied by at least unpleasant remarks, it follows that in the vast majority of cases additions and alterations are not only not made, but never suggested, thus it is that many prescriptions are sent out showing evidences of incompatibility, crudeness, and in some cases utter failure in accomplishing the objects of the prescriber.

The policy of "*vis inertia*" is, to most compounders the easiest and the simplest to adopt in order to avoid criticism and a possible contest with the physician. If a patient should complain of the unsightliness or inefficiency of a mixture, the reply usually is, "Well, you must not blame me for that. The prescription is compounded exactly as your doctor wrote it." But, brethren of both professions should these things be? Thousands of workers throughout the world are busily employed in wresting the secrets from Mother Nature in the search for some new substance to combat disease. Millions of capital are invested by shrewd earnest men in developing to the utmost the latest discoveries of science, for the use and benefit of the sick and helpless. The members of the medical profession know what sacrifices they have endured, what privations they have suffered, what years of labor it has cost to fit them to practice their profession. On the other hand has not the pharmacist toiled unceasingly, studied unremittingly, and suffered in a similar way from privation and sacrifice to fit him for his profession? Shall all this go for naught? Have not all of these earnest laborers had but one goal—the preparation of remedies for the cure of disease?

What matters it, if millions have been spent in the manufacture of a remedy, if when the supreme object of its existence is reached it falls short or fails of its mission, through the lack of co-operation or of a proper state of feeling between the doctor and the druggist. The educated, hard working pharmacist who faithfully labors to perform all of his duties, is worthy of the support of every physician in his neighborhood; confidence begets confidence and if this is once thoroughly established, the settlement of a "prescription exigency" when it arises becomes a simple problem.

EYE TROUBLES WHICH CONSTITUTE A FRE-
QUENT SOURCE OF HEADACHE, VER-
TIGO AND NAUSEA. AND OTHER
NERVOUS DISORDERS.

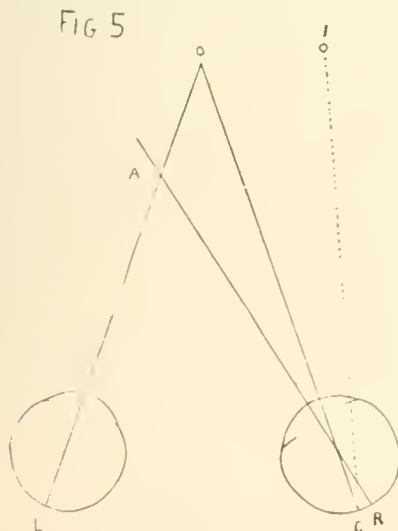

Series of four lectures delivered at the Fourth Special Course of the
Chicago Polyclinic.

BY F. C. HOTZ, M.D.,
PROFESSOR OF OPHTHALMOLOGY.

LECTURE III.—PARALYSIS AND PARESIS OF THE OCULAR
MUSCLES.

In the *third group* of eye troubles which are known to influence the nervous system, we again find the seat of disturbance in the ocular muscles. But the muscular disturbance is of a very different kind from that of the second group. There we found muscular over-activity; here we have to deal with defective muscular action, *paresis and paralysis of the muscles*: there we saw binocular vision maintained, here binocular vision is abolished. The affections of the second group are a particularly frequent source of pain in the head and other neuralgic symptoms: the paralytic affections induce vertigo, confused vision, and nausea, but never any headache or any other neuralgia.

In executing the movements of the eyeballs for the purpose of adjusting the visual lines in the acts of binocular vision the muscles of both eyes act together in sets; and the easy and accurate adjustment of the visual lines require that the same nerve impulse brings forth the same degree of action in the cooperating muscles of either eye. Any loss of action in one muscle results in a limitation of motion of the eye in that direction for which the cooperation of the weakened muscle is chiefly demanded. This limitation of motion causes all the symptoms (both local and general) which characterize the paralytic affection of the eye muscles, and which I will now point out to you in the case before you. It is a case of paralysis of the externus of the right eye; and the first thing which attracts your attention is the convergent squint of the right eye. When the patient wishes to look at an object (*o*) 10 or 15 feet

or further away, the weak externus is unable to turn the right eye sufficiently to connect its visual line with the object. The visual line of the right eye (*ra*) meets that of the left eye at a point (*a*) which is nearer than the object (*o*); or, as we say, the right

eye is converging. You therefore see: 1. *The limited motion results in a false position of the visual line, or in strabismus.* This strabismus becomes more marked (that is, the right eye becomes more convergent) when I make the patient turn his eyes to the right, because the paralyzed externus cannot turn the right eye in that direction. But when the patient turns his eyes to the left, the convergent strabismus quickly disappears, the eyes are straight: for the externus of the right eye has to be perfectly relaxed when this eye turns to the left; and therefore, whether paralyzed or not, the externus has no influence upon the position of the visual lines in this direction. This change of the degree of strabismus according to the position of the object (to the right or to the left) is peculiar to squint caused by the paralysis of a muscle (paralytic squint), and distinguishes it from the ordinary form of convergent strabismus where the degree of convergence is the same, whether the eyes are turned right or left or straight ahead.

2. *The false position of the visual line causes diplopia.*—Let this patient look at a light some little distance away, and he will see two lights side by side. Why? Because the right eye being convergent, the image of the light (*o*) is formed on the retina at a point (*c*) lying to the inner or nasal side of the macula (*r*), while the left eye receives the image of the light directly on its macula (*l*). But we see an object as a single object only when its image is produced upon identical points of both retinae, and this condition not being fulfilled in the case before us, our patient sees the light in its true place (at *o*) with his left eye, and a second light (*δ*) to the right of the other with his right eye: for we are accustomed to refer retinal impressions located to the left side of the macula to objects in space located to the right side of the object we are looking at; or in other words, an image produced on the nasal half of the retina of the right eye (or the temporal half of the retina of the left eye) is projected into space as an object situated at our right side; and *vice versa*, retinal images located to the right of the macula (on the temporal side in the right eye, or on the nasal side in the left eye) are projected back into space as objects situated at our left side.

Diplopia is the most important symptom of paralysis of ocular muscles, because its presence enables us to detect paralytic disturbances even when the resulting deflection of the visual axis (the strabismus) is almost imperceptible to our eye; and because the double images tell us at once which muscle is at fault.

For the paralysis of every one of the ocular muscles shows the double images in a peculiar configuration different and distinct from their relative positions observed in the paralysis of every other ocular muscle. We, therefore, have as many different configurations of double images as there are ocular muscles; their number is bewildering to the medical student, and the unsystematic way in which they are discussed and treated in the text-books, greatly adds to his confusion. It is no wonder that when he has finished the chapter on ocular paralysis he feels very much like the student in Goethe's Faust,

"So stupid from all he has read

As if a mill-wheel whirled in his head;"

and imagines the diagnosis of ocular paralysis one of the most difficult problems to solve.

And yet I say—and I am going to demonstrate it you—the correct interpretation of the diplopia tests is a comparatively easy task, if we only get a little system into our work and have a clear conception of the physiological function of each ocular muscle. In the first place it is, of course, necessary to know at once which of the double images belongs to the right and which to the left eye. For this reason we put a red glass before one eye because the images can then be distinguished by their different colors. Now, if you make it a rule to put the red glass always before the same eye (the right eye), for instance, of the patient, you will soon get so thoroughly accustomed to identify the red light with the right eye, that the relation of the images to the eyes and the question of homonymous or crossed images is decided by you without hesitancy and without any mental effort. We speak of *homonymous images*, if the patient (having the red glass before his right eye) sees the red light to the right of the other, because the image stands on the side of the eye it belongs to; but when the image has crossed over to the other side, when the red light appears to the left of the other, we speak of *crossed images*.

The principal rotations our eyeballs make in the act of seeing are of three kinds: looking sideways, upwards or downwards. Each of these movements is under the control of a different pair of muscles; the lateral movements are controlled by the internus and externus; the upward movements by the superior rectus and inferior oblique; the downward movements by the inferior rectus and superior oblique. Now, any paralytic disturbance of the harmonious coöperation of the muscles in any one set causes diplopia and the images will appear displaced in the line of rotation which this set of muscles controls. If the disturbance affects the lateral movements of eyes, the images appear side by side, and we will call it *lateral diplopia*; if the disturbance occurs in the vertical movements, the images are displaced more or less on a vertical line, and we will call it *vertical diplopia*. This vertical diplopia may occur only when the patient is looking up (vertical diplopia in the upper visual field), or when he is looking down (vertical diplopia in the lower field).

This simple classification of the diplopia tests enables us quickly to trace the paralytic disturbance to one of the three sets of ocular muscles; for lateral diplopia points to the first set (internus and externus); vertical diplopia in the upper field points to the second pair (superior rectus and inferior oblique), and vertical diplopia in the lower field points to the third pair (inferior rectus and superior oblique).

Now, having narrowed down our investigation to one pair of muscles, can we learn also from the diplopia test which muscle of the pair is at fault? Nothing is easier than this; for in each pair the paralysis of the one muscle causes more or less abnormal convergence, while the paralysis of the other muscle causes more or less divergence of the affected eye, and if you bear in mind that paralytic convergence is *always* associated with homonymous diplopia and paralytic divergence *always* with crossed diplopia, you have the unerring evidence to determine which muscle in the pair is affected. And upon these facts we can prepare the following schedule of the diplopia tests for a quick diagnosis of the paralytic affections of the ocular muscles:

1. *Lateral Diplopia.*
 - a. Homonymous images—paralysis of externus.
 - b. Crossed images—paralysis of internus.
2. *Vertical Diplopia in Upper Field.*
 - a. Homonymous images—paralysis of inferior oblique.
 - b. Crossed images—paralysis of superior rectus.
3. *Vertical Diplopia in Lower Field.*
 - a. Homonymous images—paralysis of superior oblique.
 - b. Crossed images—paralysis of inferior rectus.

Gentlemen, you see this schedule covers all the six ocular muscles, and leads clearly to the muscle which is at fault; the only thing left for completing the diagnosis, is to decide to which eye the faulty muscle belongs. To settle this point we move the light to the right and to left, upwards and downwards and note the changes in the relative position of the images. Let me illustrate this experiment in the case before us. Our patient says he sees two lights on a level and the red light on the right side; according to our schedule, lateral diplopia with homonymous images indicates paralysis of the externus. Now, to find out whether the externus of the right or left eye is at fault, I move the light to the left and the patient declares the images are coming together; he sees only one light; and now I move the light toward the right, and the patient says the two images are getting further away from each other. This experiment shows that the limitation of motion (which causes the false position of the visual line and thereby the diplopia) is manifested when the eyes turn toward the right; and as this rotation is executed by the coöperation of the externus of the right eye and the internus of the left eye, and we know our case is a paralysis of the externus, we now come to the conclusion that the externus of the right eye is the faulty muscle.

3. *The limitation of motion perverts the patient's judgment as to the true position of objects in space.* I will hold this lead pencil pointing to the right in front of the patient and bid him, with his left eye closed, quickly to strike with his right hand the end of the lead pencil. What do you see? He misses the pencil, every time striking too far to the right. And he does it because he believes the pencil to be right there where he strikes down. For we are accustomed to determine the location of an object chiefly by the muscular action required to turn the eye toward the object. The further, for instance, an object is to our right side, the greater is the effort the externus of the right eye has to make to bring its visual line to bear upon the object. The paralyzed externus of our patient expends all energy it has left in the attempt to turn the right eye just a few degrees to the right; but the patient receives the feeling that the externus is making a great effort, and guided by this impression he judges that the eyeball is making a great rotation toward the right, and accordingly concludes the lead pencil must be situated a good way to the right. And if he could not turn the right eye outward at all, the retinal image of the lead pencil would not be received on the macula, but to the nasal side of it, and, by the law of projection the patient would locate it further to the right than it actually is.

4. This perversion in judging the true position of objects, and the diplopia cause the greatest confusion of vision, making it often very difficult for peo-

ple to walk straight and to get along well on a crowded street. They are the causes of the vertigo, (therefore called *visual vertigo*) and all the other nervous symptoms. And as the visual embarrassment is removed as soon as the affected eye is closed, patients are usually very quick in finding this out and relieve themselves of the embarrassing diplopia by wearing a little shade over the faulty eye.

Or they will overcome the difficulty in another peculiar way. You will notice that when this patient is looking at you, his face is not turned squarely toward you, but to his right side. He has found out that when he turns his eyes to the left, the diplopia disappears, and he utilizes this fact to avoid the double images. He turns his face to the right so that the eyes are practically turned to the left, which is looking straight ahead. These peculiar attitudes of the head are very characteristic for the different forms of paralysis.

All the symptoms I have pointed out are well marked only while the paralysis or paresis is recent. After lasting many months the case loses more or less of its typical features. The patient, for instance, learns to suppress the second image, and also learns to correct the error of projection; and hence, he is no longer troubled by visual vertigo and its associated symptoms.

I must not omit, however, to state that I am speaking only of those cases of ocular paralysis caused by extra cranial lesions, and by such intra cranial lesions which have no disturbing influence on the nerve centres. For in a great many instances the ocular paralysis is due to some grave cerebral disease which itself produces vertigo, and the other nervous disturbances I have mentioned as resulting from paralytic affections of the eye muscles. In these cases, of course, the ocular affection is not to be treated as the cause of the nervous symptoms, but must be regarded as a collateral phenomenon.

In conclusion, I wish to state that paralysis attacks some of the eye muscles far oftener than others. In 1871 Professor Graefe collected 328 cases of paralytic affections of the ocular muscles; in 145 cases more than one muscle was affected; in 183 cases the paralysis was limited to one muscle, as follows:

Paralysis of the Externus	105

SOCIETY PROCEEDINGS.

American Electro-Therapeutic Association.

Second Annual Meeting, held in New York, October 4, 5 and 6, 1892.

WILLIAM J. MORTON, M.D., PREST.

FIRST DAY, OCTOBER 4—MORNING SESSION.

(Continued from page 78.)

Dr. Walker was glad that all did not share Dr. Massey's unfavorable opinion of Apostoli's electrode, for while watching Apostoli at his clinic, he had been pleased with all the instruments in use there. The speaker then referred to a case of a lady who had been referred to him for the removal of the uterine appendages for severe neuralgia. Thinking

that her condition did not justify such an operation, he advised electricity, but the patient would not consent to this, and another surgeon performed laparotomy upon her. When the abdomen was opened, no abnormality could be found, and the wound was therefore closed. The moral effect of this operation was to relieve her pain for several months. She then returned to the speaker, and submitted to Apostoli's treatment, and after a few weeks the pain entirely disappeared, and has remained away since then—a period of eighteen months. In connection with the paper just presented, it is particularly interesting to note that the pain in her case was *instantaneously* relieved by the faradic current.

Dr. Canaday remarked that he did not see that Apostoli's electrode differed very much from those commonly made in this country.

Dr. Margaret Cleaves, of New York, said her experience corroborated the statements made by Apostoli concerning the diagnostic value of the galvanic and faradic currents. Apostoli was one of the first to take the position that certain conditions could not be safely treated by the different forms of electricity, and if we all shared this view, there would be less reason for the prejudice which many gynecologists exhibit for electro-therapeutists. In her own practice, she always regarded uterine pain as indicating the necessity for an unusual degree of care in conducting any method of treatment.

Dr. W. F. Hutchinson said that although he had been using high tension currents for the past ten or twelve years for the relief of uterine and ovarian pain, he had not felt that he had accomplished much until quite recently, when he had constructed for him an apparatus capable of giving smooth and very rapid interruptions. By means of tuning forks he had been able to measure the number of vibrations, and had found that they were as high as 30,000 per minute, whereas in the ordinary induction apparatus, the number of vibrations was usually only seven or eight hundred per minute. Now, if the pain is destroyed by a certain faradic current of high tension and rapid vibration, and not destroyed by a smoothly flowing galvanic current, the conclusion is irresistible that the pain is due not an inflammatory process involving metabolic changes, but rather to a misplacement of the polarity of the cells of the body. He had long believed that the human body is made up of cells arranged in sections according to the poles of these sections, and that the passage of a current of sufficient strength reverses these poles, or throws them out of circuit. The theory is a new one, but as the whole subject is so little understood, every theory has its place and some value. The speaker also believed that each current has a distinctly diagnostic value.

The President said that he could not say from personal experience whether or not the fact that an electrical application caused undue pain, indicated the existence of pus in the adjacent tissues, yet he always looked upon this intolerance as a danger signal. Whatever be the cause of these pains, they are relieved by induction currents from coils having very fine windings, and by high oscillations of the static current, when administered either by sparks, or by the induced current from the Leyden jar coatings.

FIRST DAY, OCT. 4.—AFTERNOON SESSION.

G. Betton Massey, M.D., read a paper entitled

A NEW TREATMENT OF PROSTATIC HYPERTROPHY.

A proper presentation of the subject of the electrical treatment of prostatic inflammation and hypertrophy is divisible into several general propositions and statements. The first and most important statement that I wish to impress upon you is that the methods about to be advocated may be relied upon as a successful mode of dealing with

most cases of this troublesome affection. No method is worth the words to describe it unless this is more or less true, yet in this instance the claim of efficiency is specially noteworthy as the affection under consideration is generally regarded as incurable, and condemning its victims to merely mitigated misery for the balance of their days.

The second proposition may be put in the form of the question: Why and how does electricity cure these cases when properly applied? To answer this we must consider the nature of the morbid process and the character of the tissues involved, and apply to these facts the therapeutic deductions derived from the action of electricity in other analogous structures and affections. The prostate gland is a musculo-glandular body, the glandular tissue forming the bulk of its stroma, through which a multitude of muscular fibrils lace and interlace. The glandular tissue is in direct communication by continuity of structure with the glandular lining of the prostatic urethra. The affection under consideration: acute prostatitis and its sequelæ, does not differ essentially from such catarrhal affections as endometritis, rhinitis and other subacute inflammations of glandular mucous membranes; and most probably is caused or accompanied by the same microbic manifestations as those affections. The utility of the direct application of the galvanic current in combating the disease would therefore suggest itself to any one who had observed its value in endometritis. Of the suggestions to be derived from a parallel treatment of rhinitis I shall not now speak beyond mention of a series of experiments now being conducted by the speaker which already prove that nasal catarrh is a field of vast importance to the electro-therapist. Mildly cauterant of morbid surfaces and stimulant to the tissue changes of the whole organ, the direct application of the galvanic current to the prostatic urethra is quickly beneficial in changing the character of the morbid process in the glandular tissue. In addition to this resolvent action, another element of remedial power lies in the contractile effect of swelling currents on the muscular fibres so liberally supplied to the organ. It is the development of this constricting power of electric currents in the hypertrophied gland that forms the chief feature of my method, and as it is a most important feature in certain cases I have felt amply justified in designating the method a new treatment, without detriment to the credit due among others, to one of the fellows of this society, Dr. Robert Newman, who has done so much to attract attention to the value of electricity in prostatic disorders. I have seen little or no mention of the prostate as a muscular organ, and a recognition of this important fact is, in my opinion, the keynote to the most successful management of prostatic hypertrophy.

This catarrhal inflammation and hypertrophy are manifested in an organ closely analogous to the uterus, and in its several varieties and consequences, such as hyperplasia proper, true fibrosis, and myo-libromatous neoplasms, we have almost exactly analogous affections with those occurring in that organ. This being so, it merely follows that the curative treatment must be also analogous. Currents of five and eight milliampères, while useful in combating the more superficial prostatitis, will not cure the hypertrophies. As in fibroids of the uterus, we must bring the hypertrophied and degenerated organ under the influence of from 20 to 70 ma. This I have done frequently, the active pole, negative, being within the prostatic urethra, and the indifferent pad on the back. The only precautions used, in addition to scrupulous cleanliness of the electrode and gentleness of its insertion, being that the current was not permitted to remain at its strongest figure more than a few seconds as it was turned on and off at the controller to get the greatest constricting action with the least electrolytic irri-

tation. If this be repeated not oftener than five days no irritation will result, but rather a feeling of relief. In the intervals the same current strength is applied daily in the same manner through the rectal wall, the active electrode being an olive of proper size inserted into the rectum and pressed against the prostate, while the indifferent pad is on the abdomen. The primary faradic current should be used after the same method at each sitting, and I am inclined to look on it as an important adjuvant.

Under this treatment the shrinkage of the organ as a whole is soon manifest to the rectal touch, and as soon as a sufficient absorption of morbid products has occurred, with regression of interfering nodules and collars, the power and freedom of micturition will return.

During the progress of the curative treatment the catheter is passed as often as required, the instrument used for treatment serving the purpose of a catheter also at that sitting. Antiseptic flushing of the bladder is also not neglected at such intervals as the condition of the bladder demands.

A point of additional importance in the use of swelling currents of both varieties in prostatic disease is the fact that the expulsive power of the bladder is always below par in these troubles, sometimes overshadowing the condition of the gland itself, and for this condition the treatment described is of great value.

The effect of this treatment is greatest in the symmetrical enlargements of the gland, as it is in this variety that the muscular substance is capable of greatest response. In fibroid nodules in one lobe of the prostate the older method of continuous application is possibly the best, or we may resort to electro-puncture, though this last resort is undesirable on account of the difficulty of maintaining asepsis.

The instrument shown you is made from a silver catheter with large curve, which has been insulated everywhere with fused hard rubber except a bare surface about two centimeters long just back of the eye. Besides having the advantage of serving as a catheter, and thus saving double instrumentation, the eye at the end serves to notify us of the exact position of the bare spot previous to turning the current on. One of the chief advantages of this form of electrode is the ease with which it may be asepticated by heating in the flame of an alcohol lamp, the same heating permitting us also to repair any breaks that may have occurred in the thin hard-rubber coating of the instrument.

Discussion.

Dr. Rockwell was pleased to hear that the author had obtained such excellent results in the treatment of hypertrophy of the prostate by what must be termed an *ordinary* application of the current, for personally he had never been able to accomplish much by this method, although he had tried various plans of treatment and all sorts of instruments. In connection with this subject, he desired to refer to a unique case which had afforded him an exceptionally good opportunity for observation, from the fact that the patient had had suprapubic cystotomy performed on him. The prostate was enormously enlarged. By means of an insulated needle passed through the abdominal opening, the prostate was pierced to the depth of about $1\frac{1}{4}$ inch, and the gland subjected to a current of from fifteen to thirty milliampères. After several such treatments, the strength of the current was increased to fifty milliampères, and this caused a development of a swollen and very painful testicle, which necessitated a discontinuance of the treatment. Examination after the subsidence of this inflammation showed a positive decrease in the size of the prostate gland, sufficient to allow the patient to pass his urine freely. Subsequently the treatment was resumed, but this time the needle was introduced into the prostate through the rectum.

Dr. Massey, in closing the discussion, said that his experience had been limited to two cases. The first patient was seventy-three years old, and had been unable to micturate for some time. After the treatment this power was regained, and a year or more later, there was still no relapse. In the second case, the current was pushed up to seventy milliamperes, and after this treatment, rectal touch showed a decided diminution in the size of the gland.

OPENING OF DISCUSSION ON ELECTRIC CATAPHORESIS.

By Frederick Peterson, M.D., New York.

No definite scientific experiments had been made with electric cataphoresis in its medical aspects, I believe, up to the winter of 1888-1889, when I became interested in the subject while treating some cases of severe trigeminal neuralgia with galvanism. The references to the subject in text-books on medical electricity were meagre and unsatisfactory. Richardson, who in 1859 first called attention to what he termed voltaic narcotism, had subsequently retracted his opinions concerning it and abandoned its use. Adamkiewicz had written much more recently (1886) upon the diffusion of chloroform through the skin by electricity, but his methods had been so criticised and his results so disputed by men of eminence, that the very fact of the existence of such a force as cataphoresis seemed as undecided as ever. My first experiments were very carefully undertaken upon myself to establish to my own satisfaction in a scientific manner the fact or fallacy of anodal diffusion. Experiments and counter-experiments were made, with substances applied to the skin alone, with electricity alone, with drugs upon the cathode, and with drugs upon the anode, and all the details as to the kind of cells, number of cells, duration of application, quantity of electricity, size and character of the electrodes, were carefully recorded in order that there should be no mistake as to the results obtained. Then in order to exclude any error from personal equation, I verified these results upon medical friends and upon patients. The details of many of these experiments I published in my first paper,¹ so that any one who desired could repeat them and satisfy himself as to the truth of the statements I then made. Since then I have verified them over and over, and frequently demonstrated the process with various drugs to students at both the Polyclinic and Vanderbilt clinic, and all of the facts in my first paper and the several other papers I published later² have been confirmed and corroborated by many observers who have since taken up the matter of the anodal diffusion of various drugs through the skin or mucous membranes into the tissues. These facts may be briefly stated as follows:

There is, to use a gross figure of speech, a streaming movement of the electric current from the positive to the negative pole, in one direction, sufficiently powerful to carry with it particles of substances in solution through the skin or mucosa.

This property of the current, which we call cataphoresis, is purely physical and is not in any sense electrolytic.

There is no such thing as cataphoresis of a substance placed upon the cathode. The solution of the drug must be placed upon the anode, and the anode only. The process is in every sense an anodal diffusion.

The greater the resistance of the solution to be transfused the more powerful is the cataphoretic effect of the current.

By means of cataphoresis, medicaments may be applied locally to reach certain morbid tissues, to produce absorption, to act as an alterative, to bring about local anæsthesia, to relieve pain in superficial nerves.

For these various purposes many drugs have been em-

ployed, such as iodol, iodine, iodide of potash, corrosive sublimate, succinimide of mercury, strychnia, the citrate, benzoate and chloride of lithium, cocaine, chloroform, aconitia, menthol, onabain, strophanthin, carbolic acid, helleborin, atropia and curarin. The details concerning these will be found in previous papers of mine already referred to.

As to methods of administering remedies by means of the anode, there are three: one the bath with the alterative or other agent dissolved in the water of the bath; one the use of a solution of a drug on any ordinary sponge electrode; and finally for exact dosage the use of the cataphoric electrode made for me by Messrs. Waite and Bartlett. This is merely a metal disc, upon which a disc of tissue paper is laid, and a drop or two of any solution let fall upon the paper. Thus when closely applied to the body there is only a thin film of a known quantity of the medicament between the metal surface and the skin, a fact which greatly accelerates the diffusion. The number of cells or milliamperes to be used depends solely upon the sensitiveness of the patient and of the particular part to which the anode is applied. The feebler the current the longer must be the application. The stronger the current the better for rapidity of electrical endosmosis.

This discussion has been arranged for the purpose of bringing the clinical results together of its use in various lines of practice, but very great interest centres also in the nature of the physical process by which substances are thus diffused, and I have invited two eminent electro-physicists, Mr. A. E. Kennelly and Prof. Houston, to deal with this question, that more light may be thrown upon its apparent obscurity and mystery.

ON THE PHYSICS OF CATAPHORESIS.

By A. E. Kennelly, Chief Electrician, Edison Laboratory.

The cataphoric action of electric currents, sometimes named electrical endosmose, whereby a liquid is electrically transfused through a porous septum, was discovered by Reuss in 1807. The history of this phenomenon, with its anomalies and complexities, that for many years baffled analysis and exhausted conjecture, but finally yielded before persistent research, is a grand epic, and an interesting episode of the nineteenth century. It was the measurements of Wiedemann, published in 1852, which evinced the principal laws controlling the action, and which were corroborated later by Freund and others. Quinek appears in 1861, to have first given that theory of the subject which was extended and more fully developed by Helmholtz in 1879, and which remains in vogue to the present time. The best description and account of cataphoresis is probably to be found in "Die Lehre von der Electricität" Vol. II. Chap. IV (Brunswick 1883), by G. Wiedemann, whose above mentioned researches have had so important a share in the development of the subject.

When two liquids, similar or diverse, are brought into communication through a narrow channel of insulating material—such as a capillary tube of glass, or by a combination of narrow channels in non-conducting material, (such as exist in a porous diaphragm of earthenware, wood, porcelain, parchment, membrane, etc.) and an electric current is passed from one vessel of liquid to the other, through the tube or diaphragm, a flow of liquid generally accompanies the flow of electricity, and in the same direction; that is, from the vessel whose electrical condition is conventionally described as positive, to that which is negative, and the liquid accumulates round the cathode. If the two liquids are dissimilar, there would be a movement in the channel across the common boundary, before the current passes, and due to that diffusion which, as we know, is a property of dissimilar fluids at confluence. Also if in virtue of any

¹ N. Y. Med. Journal, August 27, 1889.

difference of level in the vessels, the liquids were not in equilibrium of pressure at the point of communication, there would be a motion in the tube, or a tendency to restore equilibrium in the ordinary way; but on passing the electric current, it is assumed from experimental results, that the flow due to electrical endosmose is simply superposed upon such diffusional or gravitational currents as may happen to exist. In measurements of electrical transfusion, it is therefore essential that these extraneous influences should be either entirely eliminated, or duly taken into account.

Rare cases have been observed in which the electrical transfusion either opposed the electrical current in direction, passing from the negative to the positive liquid, or assumed the intermediate condition of failing altogether in appearance.

Given a definite porous septum, and liquid in its pores, the total quantity of liquid electrically transferred, depends only on the total quantity of electricity transferred, and at any instant the liquid current is directly proportional to the current of electricity, so that to effect a certain transfer of liquid, a weaker electric current must be sustained for a correspondingly greater time. Wiedemann also showed that the surface of the porous septum, the extent of active surface over which transfusion takes place, does not affect the results, and a current of one ampère will apparently transfer as much liquid cataphorically through one square inch as through twenty square inches of diaphragm in the same time. Similarly, the thickness of the diaphragm does not come into consideration, and one ampère will carry liquid at the same rate through a plug of plaster of Paris, whether this be five centimetres or five millimetres thick. For any given electrical transfer, however, the liquid transferred depends upon the substance of the diaphragm, the size and number of its pores or channels, the nature of the solution, and particularly upon the solution's resistance. With mercury, the effect has not been observed, and with readily conducting liquids the effect is very much reduced. The following cases will exemplify the great difference between the transfusible powers of different liquids under otherwise similar conditions. Two small porous earthenware cells, such as are used in batteries, were partly filled by the writer with a solution of pure zinc sulphate in distilled water to a density of 1.054 at 15° C. Immersed in more of this solution to the same level, outside and in, with zinc plate electrodes, the mean electrical transfusion into and out of the porous cells in four trials was 8.658 c.e., or 9.125 grammes per ampère-hour, or since an ampère is an electrical transfer of one coulomb per second, a transfusion of 2.535 milligrammes of liquid accompanying each coulomb, so that one milliampère would require 109½ hours to transfer one gramme at this rate. The solution's resistivity was approximately 22 ohms at the observed temperature of 20° C., or in other words 22 ohms would be the resistance between parallel faces of one centimetre cube of the solution. With similar porous cells, but employing in place of zinc sulphate solution, distilled water, whose resistivity was found to be 194,000 ohms at nearly the same temperature, the mean observed transfer was at the rate of 5.440 grammes per ampère-hour, or 1.511 grammes to the coulomb, a transfer voluminally 628 times greater than in the previous case. These results are of course relative only, depending upon the particular quality and substance of the porous cells employed.

Wiedemann found the rate of transfusion to be approximately proportional to the resistivity of the aqueous solution of any given salt.

The accepted explanation for cataphoresis is based upon the same electrostatic force and motion by which Thales

first discovered, and placed electricity upon record, and by which light particles, pith-balls, gold leaves, etc., are made vehicles of energy, when electrified and brought into the vicinity of electrical charges. It is now a familiar fact that a charge of electricity at rest upon the surface of an insulated body, forms or is associated with an electrostatic circuit. Any other charge of electricity, say a pith ball charge, introduced into the circuit, will be acted upon by an electrostatic force. If the pith ball charge so introduced is relatively so small as not to sensibly disturb the circuit of the original electrification, the force with which the pith ball will be urged along the circuit will at any point be the product of the amount of the pithball charge, (the quantity of electricity it holds,) and the gradient of electrostatic potential at that point. If we imagine that the pith ball holds just one static unit of electricity, the electric force, measured in dynes, urging the ball along the circuitual path, is simply the local gradient of potential measured in static units. The geometrical disposition of electrostatic circuits are of course usually complex, as also the distribution of their potentials, so that this force is correspondingly variable from point to point; but we can take an electrostatic circuit of simple geometrical type, one which can also be practically realised with any reasonable degree of accuracy, and here study this action in its native simplicity, when released from the trammels of geometrical complication. Let us take two large plates of metal with plane surfaces, for example two large sheets of glass coated with tinfoil. Let these two plates be clamped by insulators parallel and opposite to one another, at a distance of say five centimetres apart. The geometrical condition of this system of conductors, forming in fact an air condenser, will be uniformly simple at all points between the plates, remote from their edges. Let one plate, A, be electrified to a pressure of say 3,000 volts, while the other, B, is connected to the ground. Then the difference of potential between A and B is 3,000 volts, and if we start from B, where the potential is zero, and move along the perpendicular towards A, the potential will steadily increase as we proceed, at the rate of 600 volts per centimetre, this being the uniform gradient at all points far from the plate edges. Half way across, the potential in the air would be 1,500 volts; and we might graphically depict the system by mapping out 3,000 equidistant, successive, equipotential plane surfaces, between A and B, each differing by one volt and 1-600th, of a centimetre. The electrostatic unit of potential happens to be almost exactly 300 volts, so that in these units, the total difference of potential between the plates is ten, and the rate of fall of potential from A to B, uniformly 2 units per centimetre. If now a unit positive static charge on a small pith ball were introduced between the plates, an electric force of two dynes would be exerted upon it at any point between A and B, distant from the edges, and since a dyne is a force slightly in excess of the earth's gravitational pull upon one milligramme of matter, the electric force on the pith ball would be about 2 milligrammes weight. Similarly if the charge on the pith ball had been eight units, the electrostatic force urging it along the straight line representing the path in the circuit, at the point it then occupies, would be 16 dynes or about 16 milligramme's weight.

A gradient of potential in air to the amount of one volt per centimetre, thus implies an electric force of 1-300th, of a dyne upon each static unit of electricity there introduced.

(To be continued.)

THE physicians of London average one to each one thousand persons.

THE
Journal of the American Medical Association
PUBLISHED WEEKLY.

SUBSCRIPTION PRICE, INCLUDING POSTAGE:
PER ANNUM, IN ADVANCE \$5.00
SINGLE COPIES 10 CENTS.

Subscriptions may begin at any time and be sent to

THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION,
NO. 68 WABASH AVE., CHICAGO, ILLINOIS.

All members of the Association should send their Annual Dues to the Treasurer, RICHARD J. DUNGLISON, M.D., Lock Box 1274, Philadelphia, Pa.

MEMBERSHIP IN THE AMERICAN MEDICAL ASSOCIATION.

This is obtainable, at any time, by a member of any State or local Medical Society which is entitled to send delegates to the Association. All that is necessary is for the applicant to write to the Treasurer of the Association, Dr. Richard J. Dunglison, Lock Box 1274, Philadelphia, Pa., sending him a certificate or statement that he is in good standing in his own Society, signed by the President and Secretary of said Society, with five dollars for annual dues and subscription for THE JOURNAL. Attendance as a delegate at an annual meeting of the Association is not necessary to obtain membership. On receipt of the above amount the weekly JOURNAL of the Association will be forwarded regularly.

SATURDAY, JANUARY 28, 1893.

MEDICAL LEGISLATION.

With a majority of the legislatures in session, medical legislation in different States is assuming renewed activity. About fifteen States remain that are substantially without any legislation whatever. A few others have very inefficient statutes, while the people of about one-half of the whole number of States are protected by very efficient legislation. In casting about for new laws for the regulation of medical practice we desire to suggest the propriety of exercising discretion in the selection of the legislation for submission to the different legislative bodies. It is quite universally conceded that the principles governing ideal legislation are three in number. They are as follows: *First*. All parties wishing to commence the practice of medicine in the various commonwealths should invariably be required to undergo an examination upon all the fundamental branches of medicine. *Second*. Boards should be granted the privilege of refusing and revoking licenses for gross unprofessional or dishonorable conduct. *Third*. There should be defined a minimum of the time to be spent in professional study, including time actually spent at lectures, to entitle the applicant to the privilege of entering upon the examination. Of course, it is understood that the board is to be composed of medical men and granted the same powers that other quite similar State boards possess. In regard to the first principle above mentioned, the rule of individual examination of applicants is the universal practice in every civilized country known to the writer. Individual examination is required in England, Ireland and Scotland, in Germany, France and all the countries of Continental Europe, likewise in Canada and Australia. There are fifteen States of this country that have statutes requiring an individual examination of all applicants. A few State laws permit the recognition of diplomas from

colleges in good standing, as entitling the parties to a license to practice. It is an embarrassment to a board to be granted this privilege. The first act regulating practice in Minnesota gave the board this privilege. It was repealed six years ago and a new statute adopted requiring all parties to undergo an examination. The present act in Minnesota is probably the most efficient act regulating medical practice, of any State in the U. S. Ten years' efficient legislation in Minnesota has reduced the proportion of physicians to the population as follows: In 1882 there was one physician to every seven hundred people, while in 1892 there was one to every thirteen hundred. St. Paul has the lowest proportion of physicians to the population of any of the larger cities of this country. In regard to the second principle, the instances demanding its enforcement will be in cases of gross unprofessional or dishonorable conduct, such as occurs in flagrant quackery, persistent inebriety and criminal abortion. A bill is now pending before the Pennsylvania legislature not granting to the board this power. In other respects the proposed bill is quite ideal, however. Under the third principle, the statute should provide a minimum of time to be spent at lectures and in study, before permitting a party to undergo an examination for a license to practice. The necessity of this proviso is quite obvious. Minnesota was the first State to enact this proviso. Its effect has been most salutary. Excuse for its existence will cease with the adoption of the four years' requirement by the colleges of this country. That this time is near at hand there can be little doubt. Commencing with this year's session every college in the United States will require three full courses of lectures before graduation. Now that teachers witness the increased popularity of the high grade schools together with the increased attendance, there will be less lagging in the future. There will be just as many students under the four year course with an income just twice that of former years. There will be a smaller number of schools with a larger corps of instructors.

The new system of instruction demands greater laboratory facilities with increased expenditure for equipment and an increased number of instructors. Its benefits will be phenomenal. We will have with the four year curricula a better class of men entering the profession and men graduating that are very much better equipped for their life work. The result will be a better public service at the hands of the profession. The number of students will probably not lessen with the adoption of the four year course but will probably not increase with the same proportion as in the past. If every college in the country were to adopt the four year course at once, the demand would still remain for the existence of the State regulation of medical practice. The demand for its

existence would be the same as that of the various countries of Europe. It would be a means of stimulating the different colleges to better work, as these boards work are the best channels through which we witness the true character of instruction being afforded the student of medicine by the various colleges of the country. In a question so important to the people and profession, it becomes the duty of the friends of medical legislation to bury prejudices and look at this question in its broadest light. Regarding the *personnel* of the board you should only require that the board be composed of men of experience and good repute in their respective communities.

The question of school of practice cuts little figure. Experience has proven that these representatives of the various schools of practice meet and perform the duty imposed in their trusts without any manifestation of jealousy or friction.

This has been the experience in Illinois, Minnesota, New York, Missouri, Iowa and many other States and will be the experience of States in the future that are vested with the execution of medical legislation.

ENDOWMENTS FOR MEDICAL SCHOOLS.

The subject of medical educational methods is always of interest to physicians, and particularly is such the case at this time, because of the absolute evolution that is taking place, as manifested in the demand made by State Boards of Health, State Boards of Examiners, and the great National Societies, requiring more thorough study on the part of students, and longer courses of instruction given by the colleges.

This condition is brought about by the progress made in our art and science during the past decade.

That the change is not acceptable to a large number of students and to some of the colleges is not surprising, for there are and always will be, an unfortunately large number of aspirants for medical honors, who desire to slip along and through their student life with a minimum of study and of expense.

This is greatly regretted by all right thinking men, for it indicates a lack of appreciation of the work necessarily entered upon by those who propose for themselves a physician's career.

On the part of the colleges which propose to cater to students seeking short terms of instruction, the apology is made that however much they desire to keep step, forward and upward in the march, they cannot financially afford to meet the advance requirements.

Such institutions are in an unenviable dilemma, for they cannot stand still or paddle along in the old beaten paths. They are destined to either fall back into an innocuous dissuetude, or are obliged by the

new conditions to gird themselves anew for the exigencies that are before them.

The new conditions imply a provision of the necessary means for creating modern laboratories with accompanying apparatus and accessories of all kinds. Such needed adjuncts, including a trained corps of teachers are to be obtained only through munificent endowments provided and bestowed by those who are bountifully blessed with this world's goods, or by State aid.

Such resources as those named afford the only practical solution of the much discussed medical educational problem.

* * * * *

Endowments or State aid, should only be given to medical schools having a practical relation with a university or academic college, as one of the post graduate departments of such institutions. A nominal affiliation is not a sufficient condition. The one must be an integral part of the other. Such a relation naturally fosters and encourages a suitable preliminary course of study for those who propose entering the medical department, the curriculum of which should be *de facto*, one of the post graduate courses.

Teachers of the Science of Medicine in university medical departments should be paid regular salaries, the same as teachers in other departments, and open prizes offered for results of original research.

Teachers of the Art of Medicine need not necessarily be salaried men, as other emoluments naturally flow in to the occupants of such chairs.

Large endowments have recently been made to the medical department of the University of Pennsylvania, the medical department of the University of California, the medical department of the Columbia University, the medical department of Johns Hopkins University, the medical department of the Western Reserve University, at Cleveland, to the medical department of the Chicago University, the medical department of the Northwestern University, the medical department of Dartmouth, and perhaps others; material, if not munificent State aid, is annually given by the legislature of Michigan to the medical department of the State University; the same may be said of the legislature of Minnesota and perhaps of other States.

Such are the measures necessary for the promotion of the higher grades of medical instruction, and without such substantial foundations, medical colleges, the managers of which are conscious of their shortcomings, must make a change of front, squarely meet the issue that is before them, and show by their works, an honest acceptance of the educational situation.

To the best of our knowledge neither State aid, or financial endowments have ever in any instance been bestowed upon Commercial Medical Colleges, nor is it

likely that we shall be called upon to make mention of such an institution. Moneyed men are usually too shrewd to give of their wealth for such individual aggrandizements.

TENDON ANASTOMOSIS IN INFANTILE PARALYSIS.

In May, 1892, DR. PARRISH, of New York, performed this novel operation. The tendon of the paralyzed extensor pollicis was joined to the tendon of the healthy anterior tibial muscle. Soon after this the child experienced another acute attack of infantile paralysis affecting the posterior tibial muscle. A second operation was done in November, joining the tendon of the posterior tibial to the gastrocnemius. The junction was made with catgut sutures, and the wounds closed without drainage.

DR. A. M. PHELPS, working independently and without knowledge of DR. PARRISH'S experiment, in September, operated in a like manner, joining the tendon of the paralyzed gastrocnemius and soleus to the tendon of the healthy long flexor of the toes.

In both instances a marked gain has been noted. It is possible, then, to join the tendon of a paralyzed muscle to that of a neighboring healthy muscle, closing the wound without drainage, and obtain firm union, an improved position and more or less voluntary control over the movements of the part. So much gain immediately after the operation implies a greater gain as time goes on, in a more equal muscular balance, a diminished tendency to increasing deformity, and a lessened time during which retentive appliances must be used.

THOSE wishing to read papers at Milwaukee in the Section of Obstetrics and Diseases of Women will please send me their application with title of paper at once. Those who are going to read should know it early, and thus have abundance of time to prepare carefully.

JOHN MILTON DUFF.

DOMESTIC CORRESPONDENCE.

Revision of the Code of Ethics.

Dear Sir:—"INQUIRER," in his letter to THE JOURNAL of January 21, 1893, does not object to the matter of the Code but "to the form and method employed in giving expression to the precepts which it inculcates." The erudite and scholarly Percival composed his Code of morals at a time when precision in language and in methodical arrangement were as much valued as it is at the present date. The literary taste of the eminent members of the National Association who adapted Percival's maxims to the use of Americans will scarcely be questioned, even by "INQUIRER" whose standard of style and arrangement is apparently so high, when the code is critically examined in respect of the minutest particulars of arrangement and of literary treatment. The writer will not attempt to convince "INQUIRER" who can better satisfy his own doubts by examining the whole subject at leisure. The writer has, however, this request to

make in the most respectful tone and with the best motives; to-wit: that "INQUIRER," when he shall have reexamined the manner of the code, will frankly state his convictions whatever they may be. It is gratifying that he so fully endorses the matter of the code and the writer's views, on that part of the subject, expressed in the letter to THE JOURNAL of January 14, 1893. By continuing the analysis of the *News* editorial, the writer will endeavor to adduce sufficient reasons why the Code should not be curtailed on the lines of this editorial in any particular whatsoever.

1. The *News* editorial proposes that the greater part, if not the whole, of the first chapter of the code be suppressed; the reasons alleged being that, like other parts, it is unnecessary, and that there is much in it, "which well deserves the criticism it has received." By this, the author of the editorial probably means to say that the code deserves, and has received reprobative censure. May not the censors have been hasty and unduly severe in their judgment?—Every close student of literature and science knows how difficult it is to form a correct judgment of the merits of some productions even after repeated exhaustive examinations, and that fair, unbiassed, just criticism is not easy to any reviewer, besides being one of the most unenviable tasks. The "well deserved criticism" is a seeming contraction of the author's statement that "the general sense of the profession" is favorable to the Code as it stands. If the general sense of the profession is for retention of the code, surely the censors are in the minority, especially if "Iowa" be correct when he says: "It is safe to affirm that nine-tenths of the profession heartily agree with the views stated by 'CONSERVATIVE' in his letter of Dec. 10, 1892." Furthermore, "Iowa" suggests that "every annual meeting in the history of the Association has offered an opportunity to cancel or revise the Code . . . and that it has retained that freedom from disapproval due to its excellence and origin." The assertion that the Code "contains much that is unnecessary and useless, and that a respectable number of members of the profession demands its revision and are dissatisfied with certain of its provisions," was originally made, even in more peremptory language than this, by a small minority of physicians who rendered themselves ineligible as delegates to the national association. It is seemingly under their inspiration that the proposition was made to revise the Code. Doubtless the association, through the Judicial Council, will give a fair hearing to the plaints of the disaffected, but will probably exercise the right of asking them to state clearly the nature of their grievances, to tell precisely why they are dissatisfied with any of the provisions of the Code, to furnish a logical argument why they consider that certain provisions of the Code should be curtailed or abrogated, to say if they can show that the Code is injurious to the profession and to the public, and, moreover, will probably subject them to the most searching cross-examination. They will be on trial who have disfranchised themselves by refusing to abide by the laws of the Association, and who now wish to dictate terms on which to reenter its portals.

2. The *News* editorial condemns article III, chapter II, of the Code, relating the duties of physicians as respects vicarious offices, on the ground that it refers to a question ordinarily regulated by custom. Most moral laws being based upon good customary practices, the substantive plural morals being derived from *mores*, customs, and ethics from *ethos* custom, it would not be illogical to regard, as essentially ethical, a question regulated by custom. But newly fledged physicians are not supposed to have intuitive knowledge of the customs which regulate professional conduct. They must be supplied with proper information, with a criterion, with a written code of customs. If any reader

should have doubts of the propriety of retaining this, or indeed of any other article of the Code, all these doubts will be speedily removed if he take the trouble to read Doctor Flint's commentaries on the Code.

3. The author of the *News* editorial says that the "Code should clearly and distinctly define the attitude of the profession and provide certain rules for professional conduct." The Code does all this to perfection, and yet he seems disposed to despoil it of much of what he indicates that it should embrace.

4. This same author further says that the eliminations he proposes "would leave the Code with all of its useful provisions and reduce its length more than one-half." He then "throws out as tentative suggestions what seem . . . the most important points." Since he invites free discussion thereon, it may be proper to comply with his wish as well as to strive to answer specifically the question of "INQUIRER" and of others who, from a casual reading, may regard "the tentative suggestions" as representing a highly compressed abstract of the Code. If, however, they re-examine each section of these suggestions and compare it with corresponding provisions of the American code, it is very likely that they will change their views and perhaps think that the Code is short enough and does not contain "unnecessary and useless provisions." The following is the result of a re-examination of the *News*' suggestions.

5. These "tentative suggestions" are divided into seventeen sections, two of which comprising several paragraphs. The first paragraph of Section I provides that "every member of the profession knows what constitutes 'a regular or an irregular practitioner, but this should be clearly defined.'" How can he consistently take this position after asserting that the Code should not include maxims that "go without saying?" According to his own view, if every physician "knows what constitutes a regular or an irregular practitioner" there is no need of stating what every physician knows or what "goes without saying," and his first paragraph should be expunged as unnecessary. A definition of what every physician knows being, according to the editorial, unnecessary and useless, it follows that the second and third paragraphs, which define "a regular and irregular practitioner," are unnecessary and that therefore the whole section is useless.

6. The second section, which is in general accord with the spirit of the Code, is, in letter, entirely too elastic. The explanatory declarations appended to the American code besides being more explicit than this second section, are extremely liberal, both in letter and in spirit, and will surely satisfy all reasonable persons.

7. As physicians instinctively know their duty in cases of emergency, it is an inconsistency on the part of the author of the suggestions to make provision in his third section for such circumstances, if he adheres to his notion of things that "go without saying." Moreover, in the explanatory declarations, which now constitute a part of the Code, there is a wise provision for emergencies in fewer words than are printed in the third section of the "tentative suggestions."

8. Sections 4 to 11 inclusive are certainly no improvements on those of the American code relating to consultations, which contain every necessary detail in letter, and much in spirit. It is, however, gratifying that the author of the editorial has retained the substance of the clauses in the regulations, relating to consultations, which are so much decried by some of those who are "dissatisfied with certain of the provisions" of the Code.

9. Section 12 does not seem to possess any advantage over Section 9 of Article V, Chapter II, of the American code, which contains more necessary matter with only twenty-four words in excess of Section 12 of the "tentative suggestions."

10. Section 13 is very unsatisfactory and insufficient when compared with Section I of Article V, Chapter II, of the Code, which contains only nine words more than Section 13, of the suggestions. Section 2 of this sixth article of the Code necessary to the completion of the statement of the law in cases of differences between physicians.

11. Section 14, concerning confidential relations with patients, is not explicit. The provisions embodied in Section 2, of Article I, Chapter I, of the Code, without being unnecessarily long, give clearer, fuller, and better directions than those of the fourteenth section of the suggestions.

12. Nearly all of the eight paragraphs of Section 15 of the "tentative suggestions" are either embodied in the Code or may be regarded as pertaining to its spirit. In respect to newspaper interviews, there is no excuse for the appearance of the name of the interviewed physician. He may give the desired facts to the newspaper correspondent, but on condition that, instead of attaching his name to the document, it be stated: "This information was obtained from a reputable physician." The public is likely to be satisfied when such a declaration appears in a responsible newspaper.

13. Physicians, holding public positions, who regard the spirit of the Code, will not be apt to abuse the privilege accorded by the sixteenth section of the suggestions and, unless their ordinary signature is indispensable in an official document, would be more likely to sign: "The physician in charge, the chief medical officer, or the medical commissioner," just as in the case of the seventeenth section it would be in better taste to sign a bulletin in case of "illness of a public personage:" "By order of the attending physician." These provisions are unnecessary in the letter of an ethical code. The spirit of the Code is likely to be rightly interpreted by high minded physicians, whose arts are not indicative of bad taste or a desire for notoriety.

14. The concluding paragraph of the editorial, referring particularly to the "tentative suggestions," is as follows: "These rules are simple, distinct, and easily understood. If some such code as suggested were adopted by the American Medical Association and recommended for adoption by the different State Societies, it is probable that it would meet the views even of the Medical Society of the State of New York. Should this happy result follow the labors of the committee on revision of the Code of Ethics, it would be difficult to find a logical basis for dissensions on questions of medical ethics." Already it has been shown that these simple, distinct and easily understood rules are not all explicit, and are incomplete, and insufficient for the information of young physicians. It seems to be hoped by the author of the suggestions that the National Code will be abrogated and a new system of ethics recommended for adoption by every State Medical Association, to satisfy the unjust demand of an unreasonable minority, from one State, to the entire disregard of the wishes of all the other States in the Union. The author of the editorial, it seems, would regard this scheme in the light of a happy result, if it should be accomplished! . . . History has often shown how the most liberal concessions on the part of legislative bodies have failed to satisfy agitators, and history is constantly repeating itself. The explanatory declarations, liberal as they are, do not satisfy the dissenters who do not appear to wish to be conciliated. The National Association, which is not, and cannot be on trial, and is not subject to humiliation, has only to maintain firmly and resolutely its dignified attitude, and pay no other attention to dissenters than to vote them down. The right-minded, able, eminent and reputable members of the profession will surely stand by and continue to perform an abundance of useful work in peace and harmony, and thus preserve to the Association the highest standard of morals and of scientific acquirement.

15. By this examination of the "tentative suggestions," the writer is led to the conclusion that their author has offered, for the American Code, a substitute which cannot, in any respect, be considered as an improvement.

16. It appears that the alleged object of revising the Code is "that it may be liberalized." But not one of the liberalizers has offered substantial proofs that the Code is illiberal in a single particular, or that its teachings are injurious. What then is there to liberalize in moral laws which advocate unbounded freedom to do good, and frown upon evil practices? It is hoped that the Code, so broad, so liberal as it is, will not be converted into a document for granting license to do wrong, and that the vast majorities of physicians, in and out of this great National Association, who love liberty and discountenance license, will unite in their might and put down the existing heresy.

17. It is strange that the author of the *Medical News* editorial should have so misapprehended the situation when at p. 331 of the *News* of September 17, 1892, he said, . . . "but the fact that many of those who, through the State Society, have repudiated the Code, are permanent members . . . puts the Association in a false and illogical position if their membership be recognized, or excludes certain able consistent, and honest co-workers if the laws of the Association be rigidly enforced." Assuredly he has been misinformed, and this only is accountable for the assertions just quoted. Any person, not entitled to membership, who may arrogantly demand admission on his own terms, will naturally be denied its privileges, but the Association has never and probably will never exclude able, eminent, and honest workers, or honest workers of average ability, or physicians of good repute, who subscribe, in good faith, to the Constitution and Code of Ethics. It is well known that no physician can become a permanent member until he has subscribed to the Constitution and Ethics, and that in signing the registration blank, at the time of a meeting of the Association, the signer thereby subscribes to the ethical code. But if he signs his blank, or any other document relating to membership, with "mental reservation," it is at the sacrifice of self-respect; he must be conscious that he is thus perpetrating a fraud which renders him unworthy of membership. If he subscribes to the American Code and belongs to another society that repudiates this Code for an antagonistic code to which he subscribes, then he is disloyal to both organizations. Those who refuse to abide by the Code while they retain their membership, place themselves, but not the Association, in a "false and illogical position." Those who are not willing to comply with the laws of the Association are not obliged to join, and others, already admitted, who have become dissatisfied with those laws are not forced to continue their membership. The Association has an ample contingent of "able, eminent, and honest workers," and is large and powerful enough to withstand the exodus of all malcontents, turbulent spirits, and disorganizers.

18. The author of the *News* editorial is evidently sincere in what he asserts, but surely he has been wrongly informed, and if he takes sufficient pains to gather more evidence he may perhaps arrive at different conclusions.

19. The facts pertaining to the real situation may be summarized as follows: A minority of physicians, principally of one State, make a peremptory demand that the majority, representing all the other States, shall yield to their mandate; in other words, one State arrogates the right to legislate for all the other States in the Union. That State, which repudiates laws enacted by the consent of each and every one of the other States, insists upon their unconditional surrender. The question is whether they will accede to this imperious command.

A CONSERVATIVE MEMBER.

ASSOCIATION NEWS.

THE MILWAUKEE MEETING, JUNE 6-9.

The Committee of Arrangements are well organized and give assurance of a thoroughly aroused and interested local profession, and that steps are being taken to make the ensuing meeting a complete success.

The following are the Committees:

EXECUTIVE.

U. O. B. Wingate, M.D., Chairman.	Wm. Mackie, M.D.
W. H. Washburn, M.D., Sec.	F. E. Walbridge, M.D.
L. H. Montgomery, M.D., (Asst. Sec. A. M. A.).	Jos. Schneider, M.D.
Wm. Fox, M.D.	E. Copeland, M.D.
Solon Marks, M.D.	Jas. Cavaney, M.D.
Jas. Dorland, M.D.	H. V. Wurdemann, M.D.
Samuel W. French, M.D.	G. D. Ladd, M.D.
	A. B. Farnham, M.D.
	L. F. Frank, M.D.
	A. J. Puls, M.D.

TRANSPORTATION AND HOTELS.

F. E. Walbridge, M.D., Chairman.	Wm. Mackie, M.D.
Solon Marks, M.D.	Wm. Fox, M.D.
	H. M. Brown, M.D.

COMMITTEE ON PLACE OF MEETINGS OF SECTIONS.

Ernest Copeland, M.D., Chairman.	H. V. Wurdemann, M.D.
	A. J. Burgess, M.D.
	F. J. Tower, M.D.

COMMITTEE ON PRINTING.

H. V. Wurdemann, M.D., Chairman.	R. N. Hawley, M.D.
	G. Kamheimer, M.D.
	J. S. O'Brien, M.D.

COMMITTEE ON REGISTRATION.

Jas. Cavaney, M.D., Chair- man.	J. R. McDill, M.D.
Jas. Dorland, M.D.	A. H. Levings, M.D.
	A. Grettinger, M.D.

COMMITTEE ON FINANCE.

Wm. Fox, M.D., Chairman.	Jos. Schneider, M.D.
	C. C. Rogers, M.D.
	The Chairman to appoint four other members.

COMMITTEE ON ENTERTAINMENT.

S. W. French, M.D., Chair- man.	W. A. Bachelor, M.D.
L. F. Frank, M.D.	H. E. Bradley, M.D.
H. V. Ogden, M.D.	J. A. Bach, M.D.
	L. Schiller, M.D.
	H. P. Wenzel, M.D.

COMMITTEE ON INFORMATION.

A. B. Farnham, M.D., Chairman.	W. H. Neilson, M.D.
A. J. Puls, M.D.	L. G. Nolte, M.D.
	J. N. O'Brien, M.D.

COMMITTEE ON EXHIBITS.

U. O. B. Wingate, M.D., Chairman.	W. H. Earls, M.D.
	I. J. Hayes, M.D.

COMMITTEE ON R. R. DEPOTS, ETC.

Wm. Mackie, M.D., Chair- man.	Fred Shimonek, M.D.
G. D. Ladd, M.D.	J. W. Coon, M.D.
T. H. Hay, M.D.	J. L. Williamson, M.D.
A. B. Grider, M.D.	E. W. Bartlett, M.D.
	Ralph Chandler, M.D.

COMMITTEE ON RECEPTION.

Solon Marks, M.D., Chairman, with all the members of the Association residing in the city at the time of the meeting, not appointed on other committees, and such members of the Association residing outside of the city, in the State, not exceeding twelve in number, as the Chairman may select.

COMMITTEE OF LADIES' RECEPTION AND ENTERTAINMENT.

Mrs. Solon Marks, Chairman, with such assistants as she may select.

MISCELLANY.

MEDICAL SOCIETY OF THE MISSOURI VALLEY.—The next meeting of this society will be held in the city of St. Joseph, Mo., March 16, (Thursday) and continue in session one day. Members contributing papers must send titles to the secretary prior to February 25, so they can appear on printed program, mailed March 1. Applications for membership, can be sent to Dr. J. M. Richmond, St. Joseph, Mo. chairman committee of arrangements.

F. S. THOMAS, Secretary.

The Ninth Annual Meeting of the Fifth District Branch of the N. Y. State Medical Association will be held in Brooklyn on Tuesday May 23, 1893. All Fellows desiring to read papers will please notify the secretary, E. H. Squibb, M.D., P. O. Box 170, Brooklyn.

MEDICAL SOCIETY OF THE STATE OF NEW YORK.—The Eighty-seventh annual meeting of the Medical Society of the State of New York will be held in the City Hall, at Albany, Tuesday, Wednesday and Thursday, February 7, 8, and 9, commencing at 9:15 A.M., on Tuesday and ending at 1 P.M., on Thursday.

The Relation, in the Male and Female, of Genital Disease to Mental and Nervous Affections, by Landon Carter Gray, M.D., New York.

Topic—Epilepsy.

1. The Epileptic Interval; Its Phenomena and their Importance as a Guide to Treatment. William Browning, M.D., Brooklyn.
2. Reflex Disturbances in the Causation of Epilepsy. William C. Krauss, M.D., Buffalo.
3. Mental Epilepsy. J. Montgomery Mosher, M.D., St. Lawrence State Hospital for the Insane, Ogdensburg.
4. The Development of Epilepsy after Traumatic Injury to the Skull. B. Sachs, M.B., New York.

The Treatment of Uramic Convulsions. R. C. M. Page, M.D., New York.

The Registration of Midwives. J. L. Kortright, M.D., Brooklyn.

Topic—The Relative Value of Certain Obstetrical Operations.

1. General Review of the Operations to be Discussed, by Egbert H. Grandin, M.D., of New York.
2. The Limitations of Embryotomy, by N. Clifton Edgar, M.D., of New York.
3. The Limitations of the Cesarean Section, by Robert A. Murray, M.D., of New York.
4. The Anatomical Limitations of Symphysiotomy, by J. E. Kelly, M.D., New York.
5. The Clinical Limitations of Symphysiotomy, by Chas. Jewett, M.D., Brooklyn.

General Discussion, to be participated in by Drs. E. P. Davis, Philadelphia; H. A. Kelly, Baltimore; H. C. Coe, New York; Reynolds, Boston.

Practical Antisepsis and Asepsis, with stereopticon demonstrations (by invitation), by Howard A. Kelly, Baltimore.

Epitaphs from the Tombstones of Medical History, with stereopticon projections of many old and rare medical portraits, by Joseph H. Hunt M.D., Brooklyn.

Topic—The Management of Suppuration Complicating Tuberculous Disease of the Bones and Joints.

Papers by Drs. V. P. Gibney, of New York; Roswell Park, of Buffalo; Henry Ling Taylor, of New York; and Louis A. Weigel, of Rochester.

Topic—The Present State of Knowledge as to Carcinoma.

1. The Pathology of Carcinoma. H. C. Coe, M.D., New York.
2. The Etiology of Carcinoma. Roswell Park, M.D., Buffalo.
3. The Value of Internal Medication in the Treatment of Carcinoma. Jarvis S. Wight, M. D. Brooklyn.
4. The Results obtainable from the use of Anilin Products in Carcinoma. Willy Meyer, M.D., New York.
5. Caustics in the Treatment of Carcinoma. Daniel Lewis, M.D., New York.
6. The Knife in the Treatment of Carcinoma. N. Jacobson, M.D., Syracuse.

Discussion to be opened by Dr. George R. Fowler, of Brooklyn.

Tubercular Epididymitis, by Herman Mynter, M.D., Buffalo.

Topic—Newer Methods of Diagnosis and Treatment of Stomach and Intestinal Diseases.

1. The Practical Value of the Newer Methods of Examination in the Diseases of the Stomach, with a Consideration of the Indications given for Diet and Treatment by such Examinations, by Henry L. Elsner, M.D., Syracuse.
2. The Methods of Obtaining and Examining the Stomach Contents in Disease for the purposes of Diagnosis, by J. Fuhs, M.D., Brooklyn.
3. The Disturbances of the Motor Function of the Stomach; their Diagnosis, Symptoms and Treatment, by C. G. Stockton, M.D., Buffalo.
4. The Physiological Effects of Electricity in the Stomach, the Indications for its Administration and Use in Gastric Disease, and the Methods of using the same, by Max Einhorn, M.D., New York.

Anniversary address by the President in the Senate chamber.

Topic—The evolution of the American Surgeon.

Report of a Case of Severe Abdominal Injury terminating in Recovery. J. S. Cooley, M.D., Glen Cove.

The Treatment of Inguinal Hernia. Alex. Dallas, M.D., New York.

Certain Types of Septicæmia Resulting from Abortion. Andrew F. Currier, M.D., New York.

Puerperal Sepsis, its Prevention and Cure. Wm. W. Potter, M.D., Buffalo.

Hoarseness. W. Franklin Chappell, M.D., New York.

The Diagnosis and Nomenclature of Fevers. Nelson G. Richmond, M.D., Fredonia.

Congenital Opacities of the Lens. Wm. F. Mittendorf, M.D., New York.

Is Stoerk's Blenorhoe and Laryngitis Sicca One and the Same Disease? W. Freudenthal, M.D., New York.

The Committee on Credentials will meet at the Delavan House Monday evening, when members and delegates can register.

The committee consists of Dr. Walter B. Chase, of Brooklyn; Dr. Charles M. Culver, of Albany; and Dr. J. P. Creveling, of Auburn.

Communications regarding papers should be addressed to the Business Committee: Dr. Seneca D. Powell, 12 W. 40th St. New York; Dr. William Maddren, 1 Hanson Pl., Brooklyn; Dr. John O. Roe, 28 W. Chester St., Rochester.

OFFICIAL LIST OF CHANGES in the Stations and Duties of Officers Serving in the Medical Department, U. S. Army, from January 13, 1893, to January 19, 1893.

First Lieut. Thomas A. Raymond, Asst. Surgeon, is relieved from further duty at Vancouver Bks., Washington, and will report in person to the commanding officer, Ft. Canby, Wash., for duty at that station, relieving Capt. Edward C. Carter, Asst. Surgeon, who, on being thus relieved, will proceed to Vancouver Bks., and report in person to the commanding officer of that post for duty there.

Capt. Guy L. Edie, Asst. Surgeon U. S. A., is relieved from duty at Ft. Niobrara, Neb., and will repair to New York City, and report in person to the attending surgeon in that city, for duty in his office.

Capt. Jefferson D. Poindexter, Asst. Surgeon U. S. A., is granted leave of absence for four months.

First Lieut. Samuel R. Dunlop, Asst. Surgeon U. S. A., leave of absence granted is still further extended to include January 31, 1893.

First Lieut. Samuel R. Dunlop, Asst. Surgeon U. S. A., resignation has been accepted by the President, to take effect January 31, 1893.

OFFICIAL LIST OF CHANGES in the Medical Corps of the U. S. Navy, for the Week Ending January 21, 1893.

P. A. Surgeon F. A. Hassler, ordered to receiving ship "Vermont."

Asst. Surgeon George Rothganger, to the Navy Yard, Mare Island, Cal.

Surgeon P. M. Rixey, ordered to the U. S. S. "Dolphin," February 6, 1893.

P. A. Surgeon J. D. Gatewood, detached from the U. S. S. "Dolphin," and granted two months' leave from February 6, 1893.

P. A. Surgeon H. N. T. Harris, to special duty in the Bureau of Medicine and Surgery.

ORIGINAL ARTICLES.

A PECULIAR NUCLEAR SAFRANIN REACTION AND ITS RELATION TO THE CARCI- NOMA COCCIDIA QUESTION.

An inaugural thesis read before the Pathological Section of the Chicago
Academy of sciences, January 12, 1893.

BY A. P. OHLMACHER, M.D.,

PROFESSOR OF EMBRYOLOGY AND BIOLOGY, COLLEGE OF PHYSICIANS
AND SURGEONS, CHICAGO

The employment of a large number of chemical reagents is one of the unfortunate features of modern microtomy. No one can become familiar with the long list of substances employed in microscopical research, nor with the bewildering combinations of fixing agents and staining agents, without realizing the possibility of many of these substances being used without a definite knowledge of their effects. The history of microscopic anatomy is full of instances, in which the results of some pioneer investigator have been attacked, on the ground that the results which he obtained were the effects of the reagents employed in the study. In fact, it is even now not uncommon to have the question of the reagent effect brought up, when intricate microscopical studies are being prosecuted. Without doubt, the suspicion that many of the marvellous findings of the cytologists are the products of unknown micro-chemical changes, is still entertained by many individuals.

The controversy between Henle,¹ Flemming,² and others, concerning the nuclear fragmentation observed in leucocytes and pus corpuscles, is a notable instance of the skepticism relating to the interpretation of microscopical findings. Henle maintained that the multi-nuclear condition of leucocytes and pus corpuscles was the result of the acetic acid, or other reagent, used in studying these bodies. This view was strongly opposed by Flemming, who observed multi-nuclear leucocytes in various situations in living objects, and who further noted that no change was produced in these cells by killing them with acetic acid, save that the nuclear structure became more apparent.

Every histologist will remember the discussion which arose when the discovery of the reticulated condition of the protoplasm of the cell and nucleus was announced; a considerable number of investigators arraying themselves on the side which maintained that the reticulum was either a faulty optical interpretation, or was the product of the changes induced by the chemical substances employed in the technique. But Flemming and his followers apparently put the subject at rest, by not only demonstrating the nuclear and cytoplasmic reticulum, but

also by following the processes of direct and indirect nuclear division in *living tissue*; these observations being made by the aid of the most perfect optical appliances.

While the employment of reagents is a prime necessity of microscopical technique, it is nevertheless a fact, that such reagents produce a variety of compounds with each other and with the substances of the tissue, the exact natures of which are either unknown, or but imperfectly understood. It follows then, that until our knowledge of ultimate micro-chemical cellular and nuclear reactions be complete, we must regard with a reasonable skepticism, many of the startling microscopical novelties of the day.

The open questions in this connection are many. What is the exact nature of that part of the so-called chromatin of the nucleus, which retains certain anilin stains when employed by the "indirect method?"³ What is the effect of the fixing medium on this chromatin? What is produced by the combination of the nuclear chromatin and fixing agent, which allows a certain dye to stain precisely, and another one to fail? Many queries of this character confront the microtome at every turn, and impress him with the profound character of the many unsolved biological problems. It cannot be said, however, that the absorbing subject of the micro-chemistry of staining agents, particularly the anilins, has been entirely neglected; for the work of Ehrlich⁴ and his students on the reactions of leucocytes, and "mastzellen," indicate the tendency to investigation in this direction.

In this connection also, may be mentioned the work of Auerbach,⁵ Watasé,⁶ and others, on the two chromatin substances which are distinguished by their micro-chemical and staining reactions. These authorities go so far as to indicate the *sexuality* of the two nuclear substances; the erythrophile, being the preëminently male constituent, and the cyanophile, essentially female. Manifestly, such work opens a wide field for research, the bearings of which must be felt in every department of biological or pathological investigation.

* * * * *

Among the many staining substances employed in the new microtomy as inaugurated by Böttcher and Hermann and improved by Flemming, one, safranin, has come into very extensive use. When employed after the "indirect" or Flemming method, safranin gives a precise chromatin stain, which compares in color and durability with carmine. The solutions of safranin in common use are two, viz., the alcoholic

(Pfitzner's and Flemming's), and the anilin-water (Babs, Zwaardemaker). It is very necessary that the safranin employed be of the right quality and in this respect the products of Grübler meet all requirements: his "safranin spirituslöslich" being adapted for the alcoholic solutions, and the "safranin wasserlöslich" for the anilin water solutions. These staining solutions can only be employed with sections of tissue; and it is further true, that safranin only gives its best result in sections of tissues which have been fixed in a chromic acid mixture. The practice of safranin staining consists in allowing the section to attain an over-stained condition in the coloring solution, and then washing out and fixing the stain, then clearing the dehydrated section, and mounting it in balsam. A variety of agents have been employed in the washing and fixing of the safranin, as acidulated alcohol (Flemming⁷), strong picric acid alcohol (Podwyssozki⁸), iodine after Gram's method (Prenant⁹), and chromic alcohol (Martinotti and Rescogotti¹⁰).

The action of the hydrochloric acidulated alcohol, or plain alcohol, when employed in washing out, seems to be merely a solvent one. The excess of stain dissolves in the spirit, and the remainder is held by the nuclei, which apparently have the greatest affinity for the color. With chromic acid, or iodine, however, the effect seems different, as suggested by Lee,¹¹ who considers it probable, that these agents have a sort of "mordant" action on the nuclear chromatin, inducing in it a marked affinity for the staining material. In this connection it is important to direct attention to the fact, that chromic acid, picric acid and iodine, all possess the property of precipitating safranin from its solutions. The experiment may be tried by adding a drop of the washing and fixing mixture (chromic acid solution, picric alcohol or iodine solution) to a drop of the safranin solution on a glass slide: here the precipitation may be carefully observed by the aid of the microscope. In the case of the chromic acid solution, an amorphous yellowish precipitate is instantly produced when a drop is brought into contact with the safranin mixture. With an alcoholic iodine solution, *a mass of deep red, needle-shaped crystals is produced immediately*. When picric acid alcohol, and anilin water safranin solution are mixed, the precipitation is much more tardy; but sooner or later, a crystalline deposit may be observed *which resembles very closely that produced by iodine and safranin*. All of these deposits are soluble in alcohol.

* * * * *

In a modified method recently proposed, Heidenhain¹² advises the employment of tincture of iodine in treating the sections of tissue fixed in corrosive sublimate, previous to staining, with the object of removing the crystals of sublimate which often remain in the tissue. This process consists in treating sections of paraffine imbedded tissue, which have been fixed on the slide, and previously treated by xylol and alcohol, with strong tincture of iodine. After the iodine has acted ten or fifteen minutes, the section is washed in changed alcohol, and is then ready for any kind of staining.

While engaged in the preparation of some frog's tissue after Heidenhain's method, which was to be stained in safranin, I made the mistake of placing the section in the staining solution (Pfitzner's alcoholic safranin mixture) before it had been treated with the tincture of iodine. It occurred to me to try the tincture of iodine *after* the safranin, in the hope of still being able to remove the sublimate crystals.

The first section on which the procedure was tried was from the heart of the frog, which had been stained for twelve hours in the safranin. The iodine tincture was applied to the section immediately on its removal from the staining solution, and was allowed to act for two or three minutes. A brief washing with 95 per cent. alcohol followed, by means of which the excess of stain was removed and the section dehydrated. The object was cleared with clove oil, and mounted in xylol balsam.

On examining this section of the frog's heart, microscopically, I was struck by the remarkable appearance presented by the tissue. Under the low power (Leitz objective 3), the appearance of the section at first sight resembled that of precise safranin staining when carried on after usual methods; *i.e.*, the nuclei were prominent by their deep stain, while the ground substance appeared nearly unstained. More careful observation even by the low power, demonstrated a peculiar granular appearance in the nuclei, as something entirely unusual. On employing a higher power (Leitz objective 8), the nature of the granular appearance of the nuclei became more apparent. The nuclei of the heart muscle were exceedingly prominent, because of the presence in their interior, of irregularly arranged, deep red stained masses, quite distinct from the usual chromatin framework of such nuclei. At first superficial examination it seemed as if all the nuclei of the heart muscle were undergoing the process of karyokinesis, particularly, as some of the red stained masses assumed attitudes not unlike certain chromatic figures of indirect nuclear division. This idea was dismissed, however, on closer observation; for aside from the many usual shapes presented by these intra-nuclear bodies, it was noticed that the usual stages of karyokinesis were not reproduced, and that the nuclear membrane was always intact. The idea of the bodies being bacteria presented itself, but was at once abandoned, because of their irregularity in size and shape, and because of their constant presence within the nucleus.

A more prolonged study, and particularly with the aid of the twelfth inch oil immersion lens, brought out the characteristic features of these safraninophile masses. Their prominence was due to the intensity of their deep red color which allowed them to stand in relief, even when strong substage illumination was employed, as is the case with well stained bacteria in tissue, and with nuclear figures. The shape of these bodies exhibited all variations from the nearly spherical, to the rod-like; and the bodies were sometimes single and again thrown together in masses. The rod or stick-like forms predominated, and these varied greatly in their dimensions; and some exhibited blunt round ends, while others were pointed, or "lance-like." Undoubtedly, the variety of shapes was in part due to the relation of the bodies to the plane of the optical section. A little ingenuity in comparison would have made it easily possible to describe

among these bodies such forms as "lance-like," "whetstone-like," "sickle-like," "boat-like," and "button-like." The number of these formations in a nucleus, varied from half a dozen, to twenty or more; some nuclei showing but a few, others being entirely filled with them. The size varied from minute granules, to long masses which equaled and sometimes exceeded in length, the diameter of the nucleus. The color of the formations, as indicated above, was a homogenous deep reddish brown. Occasionally a mass of rod-like forms gave a yellowish or brownish reflex with strong illumination.

Figure 1 gives an idea of the variety in shape, size, and arrangement of the forms in question, and represents fairly well the deep color and its contrast with the pinkish hue of the nucleus proper.

More extensive study of the section with the high powers, brought out several interesting facts. In many muscle nuclei containing the safraninophile objects, the ordinary chromatin framework with its nucleoli could be detected by its faint pinkish color. Many nuclei of the muscular tissue were also noted, in which the pink chromatin framework was visible, but which contained none of the deep red bodies in question.

In the red blood corpuscles of this preparation, the peculiar formations occurred in some of the nuclei, but here the uniformity observed in the muscle nuclei was absent; and it was further observed that the safraninophile bodies when present, were much smaller than in the muscle. In fact, it may be here remarked, that the described formations bore a very constant relation to the size of the nucleus in which they were found. Often the nuclei of the red blood cells appeared a homogeneous deep red color; again, they appeared entirely filled with fine red granules; and finally many nuclei could be seen in which the deep red bodies appeared distinctly visible on a pinkish background. A pink chromatin network could occasionally be seen in the nuclei of the blood corpuscles. The three red corpuscles in Fig. 2, show the variations in the nuclear contents.

The leucocytes in the sections from the frog's heart prepared by the safranin-iodine method, usually exhibited a faint pink nuclear network, it being only exceptional to find nuclei containing the deep red safranin bodies.

A number of sections from the same piece of tissue were stained in the above described manner, and they uniformly showed these strange nuclear contents. Several control sections were cut from the same piece of tissue, stained in the same safranin solution, but washed in alcohol acidulated with hydrochloric acid (1 to 1000); and in these sections the bodies were never found, but the nuclei only presented the ordinary chromatin pictures.

As these remarkable appearances were noted, a number of queries arose as to the nature and significance of the strange intra-nuclear bodies. Were these striking forms a normal structure of the nucleus brought out by this peculiar staining combination? Were they artificial products of some combination of the reagents employed? If so, were they produced by a combination of the sublimate and iodine and colored by the safranin; or were they the result of the iodine and safranin reaction? To answer these questions, I proceeded to make a number of experiments on sections from a variety of animal tissues prepared with various fixing and staining

combinations. The normal tissues studied, were from the salamander, frog, snake, turtle, cat, dog, sheep, pig, ox, and man. The pathological tissue was mostly from carcinomata and sarcomata. The objects from these sources had been fixed in Flemming's solution, Hermann's solution, absolute alcohol, and corrosive sublimate (Heidenhain's solution). In all cases in which the safranin-iodine stain was employed, control sections were stained with safranin, gentian violet, or other stain, after the common methods.

As a summary of these experiments, I may say that it was possible to produce the characteristic safranin bodies in all of the tissue, no matter what its source, or in what medium it had been fixed. That is to say, the safranin-iodine staining combination developed the deep red formations in sections of tissue fixed in Flemming's solution, Hermann's solution, and absolute alcohol, the same as in sublimate fixed tissue. The only difference to be noticed in the effects produced by the fixing agents, was that the ground stain in sections of tissue from an osmic acid fixing solution, was of a more brownish hue, in contra-distinction to the pink ground color of the sublimate sections. This was particularly true of tissue which had remained long in the osmic fixing mixture.

While it was always possible to demonstrate the deep red bodies in some portion of a section, none of my subsequent preparations gave the remarkably uniform appearance of the nuclei of the heart muscle of the frog. Many times the nuclei of one portion of a section were either unstained or showed the normal chromatin framework, while the nuclei of another portion would contain the safraninophile masses. It was particularly noted that the nuclei about the borders of a section seemed to retain the safranin bodies most persistently. In some sections also, dark brown spots, visible to the unaided eye occurred, and on examining these spots microscopically, they were found to be composed of a dark red mass of safranin bodies which resembled very closely those found in the nuclei. Again it was noted, that the safranin bodies were not always confined to the nuclei, even in sections showing none of the large masses; for in many preparations they occurred in the cell protoplasm. Concerning this diversity in the amount and situation of the formations, it was found that it depended upon the duration of the washing with alcohol which followed the staining; a short washing leaving many of the bodies, and a more prolonged washing making them less numerous, and more precisely confined to the nucleus. As in ordinary anilin staining, a stage could be reached with prolonged washing, in which all stain could be removed from the section.

As stated above, the size of the safraninophile bodies varied with the size of the nucleus; and in the same degree the shape of the individual forms seemed to vary, so that, instead of the preponderance of the rod or stick-like forms of the frog's heart muscle, an indescribable number of shapes often presented themselves.

With regard to the behavior of the various tissue elements, besides the fact already mentioned, that the peculiar condition could be produced in the nuclei of all the tissue studied, I will only direct especial attention to the reaction of the non-nucleated red blood corpuscles of mammalian tissue. In normal tissue fixed in Flemming's solution, and

stained by the safranin-iodine combination, the red blood corpuscles usually assumed a uniform brownish tint, and the *safraninophile bodies were often found in their interior*. The significance of the observation will appear later.

Several experiments with various solutions were made, and it was found that the peculiar reaction could be produced in sections stained in Babe's anilin-water safranin, as well as with the alcoholic solution. The most perfect result was obtained when strong (U. S. P.) tincture of iodine was allowed to act a minute or two. Weaker solutions of iodine in alcohol did not act so perfectly, though the safranin bodies were still formed if the iodine was permitted to act longer. In the few experiments I made, it was impossible to produce the characteristic appearance when safranin stained sections were treated with an aqueous solution of iodine and iodide of potassium.

My conclusion as to the nature of these safraninophile bodies is that they are *artificial crystalline products, the result of a safranin and iodine reaction*. That their production is in no way due to sublimate fixation, as at first surmised, is clear from their occurrence in tissue fixed in other media. I believe them to be of a crystalline nature, not only because of their resemblance to crystals when examined with high powers, but also from the fact that crystals of similar appearance may be produced by mixing safranin solution and tincture of iodine on a slide, as previously mentioned. The fact that these crystals are soluble in alcohol would account for the varying appearance presented with the varying duration of the washing process, following the staining.

The remarkable affinity of these crystalline safranin bodies for the nuclei, seems to me due to the fact, that the nuclear chromatin naturally attracts the stain most strongly, and retains it most persistently; and it is in the nucleus, therefore, that the safranin-iodine reaction is most intense, the production of crystals most pronounced; and the nucleus is that portion of the tissue from which the crystals would be last dissolved in the washing out process.

* * * * *

At the time in which I had made the observations on the safranin-iodine crystals, I was deeply interested in the investigations relating to the etiology of carcinoma, and it was at this time that the contribution of Podwysozki and Sawtschenko¹³ came to my notice.

This work is of much importance in connection with the carcinoma organism question, not only on account of the high scientific reputation of the principal author, but also because of the very positive manner in which these investigators argue for the presence of coccidia in a variety of carcinomata examined by them.

After reviewing the literature of the subject, Podwysozki proceeds to describe his own investigations, and claims to have found certain intracellular bodies in twenty cases of carcinoma examined by him, which he can interpret only as true sporozoa.

The technique which gave the best results to these authors, consisted in fixing the tissue in Flemming's solution, staining in anilin-water safranin, and washing in *picric acid alcohol*.

The bodies described as coccidia were round or

oval forms, of varying size, usually of a brownish tint, and containing in their interior safraninophile "nuclear" substance. It is upon the presence of the safraninophile substance in these bodies that the authors lay the greatest stress, and in the varying relations and situations of these deep red particles, the writers interpret the different developmental stages of the coccidia. Of especial importance is the presence of "sickle-formed" and "spindle-formed" red masses, in the bodies which they designate coccidia; and bodies filled with these "sickle-formed embryos" they consider as ripe individuals especially diagnostic of coccidia or sporozoa. Certain masses or conglomerations of the round or oval bodies with safranin "nuclear" substance, and usually found in the lymph spaces of the carcinoma, are looked upon as spore cysts. Aside from the method of propagation by spores, a form of direct division is suggested, in which a mass of "nuclear substance" is found at each pole of a coccidium.

These investigators remark that the only tissue element which assumes a brownish tint similar to the so-called sporozoa, in carcinoma tissue fixed in Flemming's solution and stained by the safranin-picric acid method, is the red blood corpuscle; but the feature which distinguishes their coccidia-like cells from the red blood cells, is the *presence of the safraninophile substance in the coccidia, and its absence in the blood corpuscle*.

In a paper published some time previous to that of Podwysozki and Sawtschenko, Stroebe¹⁴ examined some fifty tumors, mostly carcinomata and sarcomata. He fixed his tissue in Flemming's solution, and stained the sections in safranin, then washed them in alcohol acidulated with hydrochloric acid, and finally with *alcohol to which picric acid was added*. In studying these preparations he noticed, aside from the usual chromatin network, homogeneous, round or oval bodies, containing deep red formations of a "lancet" form, "whetstone" form, and "navicelli" form, which were often seen singly and again in masses. Stroebe was uncertain as to the significance of the cells containing the dark red particles, though he evidently inclines to the opinion that they are parasitic forms. From his plate, which is unfortunately uncolored, it is seen that the safraninophile bodies of various shapes, sometimes occur in the nuclei, and again in the cell protoplasm. In Fig. 7 he shows a cell with a nucleus in mitosis, in the protoplasm of which two darker segments occur with "sickles" or "navicelli" forms. In Figs. 8, 9 and 10, he shows "vacuoles" pushing the nucleus aside and containing in their interior the irregular chromatic particles.

Podwysozki inclines to the view that the forms described by Stroebe are probably identical with his coccidia, and he believes that since Stroebe did not find the cells filled with "sickle-formed embryos" which he regards as so positively characteristic, he was not able to take a positive stand.

Without going further into a discussion of this subject, which has so many tempting aspects, I will proceed to a brief description of my own studies.

Even before I had made preparations after Podwysozki's method, I was struck with the resemblance of some of his figures to the safranin-iodine crystals

¹³ Podwysozki und Sawtschenko. Ueber Parasitenmus bei Carcinomen nebst Beschreibung einiger in den Carcinomgeschwülsten schwarotzenden Sporozoen. Cent. f. Bak. u. Parasiten., XI, Band, No. 16, 17, 18, 1892.

¹⁴ Stroebe. Zur Kenntniss verschiedener cellularer Vorgänge und Erscheinungen in Geschwülsten. Beitr. z. path. Anat. u. z. Allgem. Path., II Band, Heft. 1, 1891.

found in normal tissue. A reference to his beautiful plates, VII and VIII, showed in the first place, that many of the nuclei of the epithelial cells contained deep red, irregular masses, quite distinct from the lighter red of the chromatin proper. Among the inclusions, it was noted that the stained masses in their interior, exhibited the peculiar dark red color, and the diversity of shape, so characteristic of the safranin-iodine crystals. Particularly convincing in this respect were the safraninophile particles in the inclusions in Figs. 16, 17, 18, 19, 20, 25, 26 and 27, and also in the masses in the lymph spaces, in Figs. 21, 22 and 24.

I now proceeded to study some sections prepared after the process advised by Podwyssozki, employing for this purpose some carcinoma tissue which had been carefully fixed in Flemming's solution. For want of well fixed tissue, it has not been possible for me to extend my experiments as far as seems desirable: but in the half a dozen carcinomata from various sources, and in a well preserved piece of rapidly growing osteo-sarcoma, kindly furnished me by Prof. Van Hook, the results were quite uniform, so that, it seems to me, they should be judged qualitatively, and not quantitatively.

The sections of the paraffin imbedded tissue were fixed on the slide, stained with Babe's anilin-water safranin, washed in picric acid alcohol, cleared in clove oil and mounted in balsam. Other sections from the same pieces were stained in the safranin, and washed with tincture of iodine, followed by alcohol. Others still were stained in safranin, and washed with alcohol acidulated with hydrochloric acid: or they were stained with gentian violet, after Bizzozero's method.

One of the first objects studied was from a carcinoma of the larynx, and in sections of this tumor, prepared as advised by Podwyssozki, I was surprised to find in many of the nuclei, particularly at the border of the section, *safraninophile bodies which appeared identical with those produced by the safranin-iodine reaction*. These bodies occurred not only in the nuclei of epithelial cells, but also in the nuclei of the other tissue elements. Their color was the familiar brownish-red of the safranin-iodine crystals, and the size and shape of the bodies varied in the same manner as has been described. In the epithelial cells, the "lancet-like" forms predominated, and these were present either singly or in heaps.

In Fig. 5 is seen a group of epithelial cells from one of the sections of the carcinoma of the larynx, and it gives a good idea of the appearance of a group of cells in which these bodies are plentiful; though it was rare to find so many neighboring cells in a single preparation, showing the safranin bodies.

Fig. 6 shows four cells from the small-celled infiltration, in the same section as the above, two of which present well defined lanceolate safraninophile bodies.

The three large cells in Fig. 7 were found in another section of the same tumor, in a portion which appeared to be degenerating. From their surroundings, I am inclined to regard these cells as pus corpuscles, or other degenerating cells, containing the usual deep red masses. Particular attention should be directed to the shape of the safraninophile bodies in this figure as corresponding with Podwyssozki's "button-like," "crescentic," "sickle-like" and "navicelli" particles.

Upon discovering these safranin bodies to be produced by the safranin-picric acid method, I extended the staining method to sections of other carcinomata, and to sections of normal tissue. It was found that while the peculiar red particles were not invariably present in a section stained after Podwyssozki's process, they did occur occasionally in the sections, both of carcinomata and of normal tissue. So that it is clearly a fact, that brownish-red safranin bodies of a variety of forms are not found in carcinomata alone, when the safranin-picric acid stain is employed.

For the sake of comparison, sections from the same pieces of tissue as those employed in the last experiments were stained by the safranin-iodine method. Here the usual safraninophile particles were produced, and so far as microscopical appearances were concerned, the resemblance between these crystals and the bodies occurring in the safranin-picric acid stained sections was so great, as to lead me to the opinion that they were similar in nature. That is, that in both cases, the peculiar deep red formations were of a *crystalline nature, and the result of the safranin-iodine or safranin-picric acid reaction*. This opinion gained additional weight from the fact that it was possible to demonstrate a crystalline precipitate when safranin solution and picric alcohol were mixed, directly. It was observed also, in referring to this experiment in another part of this paper, that the production of the precipitate by safranin and picric acid was much more tardy than in the safranin-iodine reaction. This, it seems to me, would explain the preponderance of the safranin-iodine crystals, and the relative scarcity of the crystals of the safranin-picric acid reaction.

I regret not having had the opportunity, up to the present time, of extending my studies over a considerable amount of well fixed carcinoma tissue, because, for this reason, I cannot speak with confidence of a number of Podwyssozki's findings in this communication, which therefore, must be regarded in the light of preliminary report. Particularly is this true of the intra-cellular cysts containing safraninophile particles, for I must confess, that my search for such bodies as shown in many of Podwyssozki's figures has been poorly rewarded. Nevertheless, the deep red particles of "sickle-form," "spindle-form," "half-moon" form, and other forms described by these authors, and upon which so much stress is laid, bear so great a resemblance to the artificial safranin crystals of my experiments, that I cannot do otherwise than regard them as identical. Another point upon which I lay much stress is the presence of illy-defined deep red particles in the *nuclei of some of the epithelial cells* of Podwyssozki's figures, which he has so faithfully portrayed. If one of the deep red intra-nuclear particles were transferred to an intra-cellular cyst, it would make a safraninophile body precisely identical with many of those he has figured. As an example, the deeply stained particle in the nucleus of the epithelial cell in Fig. 17, plate 8, resembles in every way the "sickle-formed" chromatic bodies in the larger inclusion in the same cell.

I have encountered the heap-like collections of cells with safranin particles, which are designated "spore cysts" by Podwyssozki, in several of my preparations; particularly in those portions which were degenerating. Such masses I have regarded as leucocytes, and the deep red particles as safranin-picric

acid crystals. Many such leucocytes undoubtedly contain ingested chromatin, from cells which have degenerated. In Fig. 24, plate 8, Podwyssozki represents a mass of "sporozoa" occupying the place of an epithelial cell, which, according to his idea, has degenerated. If we recall Noeggerath's¹⁵ observations on the relations of leucocytes to carcinoma, wherein he describes very accurately the manner in which wandering cells take up the dispersed chromatin of degenerating carcinoma cells, and in which he mentions the possibility of leucocytes filling the devoured cell, then this figure of Podwyssozki's could be explained. His "sporozoa" would become leucocytes filled with particles of dispersed chromatin, aside from that which belonged to them naturally. This would account for the irregular arrangement and variety of color of the contained safraninophile particles. Aside from this, the fact that these leucocytes contained an excess of chromatin would naturally make them attract more safranin, and thus give them opportunity for developing more safranin-picric acid crystals than ordinary leucocytes.

It has been previously stated, that Podwyssozki and Sawtschenko observed that the red blood corpuscles were the only tissue elements which assumed the brownish tint characteristic of the sporozoa, in preparations fixed in Flemming's solution, and stained in anilin-water safranin, and picric-alcohol; but that the absence of safraninophile particles in the red blood cells always distinguished them from the coccidia. In the description of the safranin iodine method, I have referred to the fact that in normal tissue fixed in Flemming's solution, the red blood cells not only were stained a well marked brownish color, but that they also often contained the safraninophile crystals. Extending my studies to carcinoma tissue fixed in Flemming's solution, and stained by the safranin-iodine method, it was often possible to discover red blood cells, both within and without the vessels, of a brownish color, and containing the same safranin bodies observed in the blood corpuscles of normal tissue. Fig. 3, represents a mass of such red corpuscles, and especial attention is directed to the shape and arrangement of the safraninophile bodies, since they resemble so closely some of Podwyssozki's coccidia. Two of the corpuscles contain the chromatic particles at the poles, which calls to mind Podwyssozki's "direct division" of the sporozoa. If the nature of the cells in this figure were not otherwise clear, the corpuscle (a) at the right of the heap, which presents a profile view with the usual bi-concavity of red blood corpuscles, would remove all doubt.

But the occurrence of safranin bodies, in the red blood cells, was not confined to Flemming fixed carcinoma tissue stained by the safranin-iodine method; for I was also able to demonstrate similar deep red particles in the blood corpuscles of preparations stained by the safranin-picric acid method. Fig. 4, from a preparation of an *osteosarcoma* of the humerus, fixed in Flemming's solution, and stained in safranin-picric acid alcohol, shows three red blood corpuscles in a connective tissue space, every one of which contains safranin bodies. In this preparation the nuclei of the sarcoma cells showed a brilliant red chromatin network, which made a strong contrast with the deep brown tint of the blood corpuscles, and the

deeper red of their safranin bodies. From these observations it is therefore evident, that the red blood corpuscles, both of the safranin-iodine and safranin-picric acid preparations, do contain safraninophile substance; and from my other studies of this subject, I am prepared to assert that the safraninophile substance is an artificial product, and the result of a safranin-iodine, or a safranin-picric acid combination, as the case may be.

This being true, one of the most weighty supports is removed from the arguments of Podwyssozki and Sawtschenko. Now, if red blood corpuscles, leucocytes, and pus corpuscles, can contain the foreign safranin bodies, it is not unreasonable to presume that the blood platelets may also become the seat of similar chromatic formations; and if this be true, it is possible to furnish an hypothesis to account for many of the findings of these investigators. Without entirely committing myself, therefore, I desire to suggest, that many of the included cells with safraninophile particles figured by Podwyssozki, are red blood corpuscles, or blood platelets, or degenerating forms of these cells which have escaped into the tissue, and which have become the seat of artificial deep red precipitates.

Applying the preceding observations to the work of Stroebe, it does not become difficult to conclude that the intra-nuclear and intra-cellular bodies, which excited his curiosity, are closely related to, or identical with, the safraninophile particles produced in my experiments. This conclusion seems justifiable for several reasons. In the first place, Stroebe employed the safranin-picric alcohol stain in his preparations. Then the bodies described by him are decidedly safraninophilous. Their shape and size recalls the safranin-picric acid particles. Finally, the facts are equally suggestive that these safranin bodies occurred free, both in the nuclear and cell substance, and that they were sometimes single and again aggregated into heaps.

In connection with the recent studies on the structure and etiology of carcinoma, it is interesting to note that the question of the reagent effect has been mentioned by Hansemann.¹⁶ In his latest defense of his theory of asymmetrical mitosis, against the attack of Stroebe, Hansemann objects to certain of Stroebe's observations on the ground that the preparations contained artificial products which obscured the karyokinetic pictures. In this condemnation Hansemann includes, also, the preparations of Podwyssozki, Coën, and Fischer, which were employed by Stroebe, and he says that while these preparations were doubtless useful for the purpose intended (studies in tissue regeneration) they were not available for studies in irregular mitosis. Now, if the preparations of Stroebe were useless for the study of nuclear phenomena, on account of the presence of foreign products, they certainly should be excluded in the more exacting researches required in determining the nature of the minute cell inclusions, which forms the subject of the work on the carcinoma organism.

The arguments herein presented may be epitomized as follows:

1. A precipitation of deep red material may be produced when the solutions of safranin and iodine, or safranin and picric acid are mixed, directly.

¹⁵ Beiträge zur Struktur und Entwicklung des Carcinoms. E. Noeggerath, Wiesbaden, 1892.

¹⁶ Ueber die Anaplasie der Geschwulstzellen und die asymmetrische Mitose. D. Hansemann. Virchow Archiv., Bd. 129, Heft 3, 1892.

2. A precipitation of similar deep red material is produced *in tissue*, when safranin and iodine, or safranin and picric acid are employed in the staining process.

3. The precipitate occurs in any of the elements, either of normal or pathological tissue; and may occur either in the nucleus or in the cytoplasm.

4. This artificial product occurs in the cells of sections of carcinoma tissue, prepared as directed by Podwyssozki and Sawtschenko.

5. Therefore, the multiform red particles occurring in the cells of carcinoma tissue prepared by the safranin-picric acid method, are artificial products; and since Podwyssozki and Sawtschenko base their arguments on the presence of these red formations in their so-called "cocidia," their conclusions must be valueless.

It is not my purpose to deny that some of the bodies seen by Podwyssozki and Sawtschenko, and also by Stroebe, may have been sporozoa. Much less do I intend, in this work, to dispute the presence of cocidia in carcinomatous tissue, or to enter upon the question of the possible etiological relation of protozoan microorganisms to these neoplasms. However, since these investigators employed a micro-technical method, which my experiments lead me to believe is a faulty one, because it gives rise to dangerous foreign products; and since they make the bodies which I believe to be foreign, the decisive issue of this work, it can only remain for me to take an opposing attitude.

It certainly seems an opportune moment to point out the errors of Podwyssozki's method; for not only is the work of Podwyssozki and Sawtschenko extensively quoted, and credited; but many investigators are straining their eyes to discover the all important lanceolate, crescentic, semi-lunar, falciform, and "navicelli" bodies; and finding these characteristic formations in carcinoma tissue they must confirm the work of these authorities.

To correct a point which may not have been made altogether clear, I desire to state that it is not my intention to throw discredit on safranin as a valuable staining substance, for, when followed by a washing with alcohol aciduated with hydrochloric acid, I believe it gives results which all of our knowledge of staining reactions leads us to believe are reliable. But to follow safranin staining with a subsequent washing with a solution containing iodine or picric acid, I regard as not only unscientific, but positively dangerous.

EXPLANATION OF PLATE.

All of the figures were drawn by the aid of the Abbé camera lucida, with a tube length of 160 mm.; drawing paper on the table. The Abbé sub-stage condenser was employed in obtaining illumination.

Figs. 1 and 2 were made with Bausch and Lomb's one-twelfth inch oil immersion objective (Continental Series), and Leitz ocular 4. The remaining figures were all drawn with the Leitz one-twelfth inch oil immersion objective, ocular 4.

FIG. 1. A group of nuclei from the heart muscle of the frog, representing the appearance of the safranin-iodine crystals as first discovered. The relative size and the shape of the bodies is well shown, together with the contrast of their reddish-brown color, with the pinkish hue of the nucleus proper. The nucleus (a) is seen in transverse optical section.

Preparation.—Corrosive sublimate, Pflüger's safranin, and tincture of iodine.

FIG. 2. Three red blood corpuscles from same section as Fig. 1. The safraninophile particles are seen in the nuclei

of the corpuscles. The nucleus (a) is nearly filled with a finely granular, deep red mass, giving it an almost homogeneous deep red color. In (b) only a few safranin bodies are seen. They present a variety of shapes, which doubtless depend upon the attitude from which the bodies are viewed. In the nucleus (c) the bodies are larger and more numerous. These three corpuscles represent approximately well the difference which was often observed in the nuclei of the tissue elements of a single section.

FIG. 3. A group of red blood corpuscles from a carcinoma of the larynx. Illustrating the brownish tint of the corpuscles, and the deep red of the safranin bodies. At (a) is shown a corpuscle which presented a profile view, and which exhibited well defined bi-concave surfaces. The safraninophile particles in (b), (c), and (d), cause them to bear a great resemblance to the "direct division" of Podwyssozki's cocidia.

Preparation.—Flemming's solution, Babe's anilin-water safranin, and tincture iodine. The tissue had remained some days in the Flemmings solution, and the section exhibited a marked brownish tint from the osmic acid staining.

FIG. 4. From a rapidly growing, medullary, osteo-sarcoma of the humerus, showing three red blood corpuscles in the sarcoma tissue, which are distinguished by their brownish color and their deep red safraninophile particles. A number of blood corpuscles were found exhibiting a similar appearance in various portions of this section, which, from their relations, and resemblance to other corpuscles, left no doubt as to their identity.

Preparation.—Flemming's solution, Babe's anilin-water safranin, and picric acid alcohol.

FIG. 5. A group of epithelial cells from a carcinoma of the larynx (same tumor as Fig. 3). These cells were found near the border of the section, and their nuclei presented a large number and variety of safranin-picric acid bodies. The excess of the "lancet forms" will be noted.

Preparation.—Flemming's solution, Babe's anilin-water safranin, and picric acid alcohol.

FIG. 6. Four cells from the small-celled infiltration of the same section as Fig. 5. A variety of deep red safranin particles are seen in the nuclei.

FIG. 7. From a degenerating portion of the carcinoma of the larynx. Three large cells, showing crescentic, semilunar, falciform, "navicelli," and "button-like" safranin formations. These cells were lying free in a granular detritus which contained fragmenting leucocytes, degenerating carcinoma cells, etc. These cells are doubtless degenerated leucocytes (pus corpuscles); and their contained bodies are safranin-picric acid crystals, since they resemble the safranin-picric acid bodies found in other portions of this section.

Preparation.—Flemming's solution, Babe's safranin, and picric alcohol.

In all cases, the tissue employed in this study was cut in small pieces immediately on its removal from the body, and at once dropped in the fixing solution.

IDEAL SURGERY.

Read before the St. Louis Medical Society.

BY G. WILEY BROOME, M.D.,

PROFESSOR PRINCIPLES OF SURGERY AND CLINICAL SURGERY, WOMAN'S MEDICAL COLLEGE; SURGEON TO THE WOMAN'S HOSPITAL; CONSULTING SURGEON TO THE ST. LOUIS CITY AND FEMALE HOSPITALS, ETC.

Mr. President:—It is plainly apparent to the student of medicine that the practice of modern surgery is wholly unlike the practice which prevailed, and was approved, only a few years ago.

In the light of advanced surgical pathology, bacteriology, and the now more familiar processes of regeneration and repair, modern surgical methods bear but slight resemblance to those that were practiced a very short time ago.

It is furthermore clearly apparent that the whole tendency of modern surgery is to secure ideal results, and at the same time to keep the practice well abreast with the revolution necessitated by the indications discovered through intelligent clinical observation, scientific investigation and experimental research.

The scope of this modern ideal surgery—it may

be emphatically stated at the outset—does not embrace a rule necessitating the adjustment of a class of cases to a certain mechanical device, in order to secure ideal results; but it does require to act intelligently and institute such methods of treatment as will best serve the purpose in each particular case.

Modern scientific surgery can only contemplate such rules in the light of impediments to its progress, as true science is not and never was dogmatical. The orthodox apparatus must be eliminated from the instrumentarium of the surgeon whose aim is to achieve the ideal of liberal scientific surgery.

I recently heard a distinguished surgeon state in one of his lectures, "that one great hindrance to progress is the inexorable *penchant* of the masses of the profession to adapt cases to old established plans of treatment. One mounts a hobby and soon others follow. Nothing, he thought, could have a more pernicious effect upon universal scientific surgical advancement."

In consequence of the disparity of opinions expressed here a few evenings ago in the discussion of a report presented by Dr. Outten to this Society. I believe that a brief inquiry respecting the present status of progressive surgery will not be considered untimely or inappropriate. With reference to the treatment of compound fractures of the thigh

bone. I wish to reiterate what I then said respecting the use of the Hodgen splint, and which was forcibly illustrated in the case shown here by Dr. Outten. The man's injured extremity got well, it is true, after nearly two years of close confinement; but in consequence of the position in which the limb was kept, the knee-joint became perfectly stiff and unyielding, with also great angular deformity at the site of fracture.

I wish to state here that very soon after I graduated in medicine, I was employed as the chief surgeon of the Wabash Railroad Company, and held that position during eight years. It was after practicing a year or so in this field of surgery, that it became painfully apparent to me that the Hodgen splint proved to be defective in two essential particulars, namely: first, that it did not retain the ends of the broken bone in apposition; secondly, that by applying extension at the foot, and the leg retained in a position nearly straight, there was entailed great impairment of the functions of the knee-joint.

You will bear in mind that Dr. Hodgen himself applied his splint to many of my cases, as he, until the time of his death, was the chief consulting surgeon at this end of the line of that railroad company. The attorneys of that company frequently complained that the assessment of damages against

the company for personal injuries was quite as large in consequence of the impaired knee-joint (a condition wholly the effect of the splint), as it was for the injury itself. Actuated by a sense of duty toward my employers, and for the welfare of these patients, about this time I devised and made this splint which I now show you. As may be seen, my modification of the suspension apparatus is constructed upon the plan of a double incline plane. The limb is dressed in a more physiological position—that is, semi-flexed, with the extending force fixed in front of the knee instead of the foot. By this splint the knee-joint is completely protected from overstrain and its baneful consequences. You will also observe that the splint is so constructed as to enable the surgeon to readily adjust it to any sized limb, including the arm. In adapting the apparatus to the suspension of the arm the distal rods must be disconnected at the middle joints, the thigh braces proper may then be used at once as a complete suspensory apparatus for a shattered arm. (This is the part of the splint used for that purpose.)

I exhibited the same to Dr. Hodgen, and he expressed to me his approval of my modification. I continued to use this splint during the years I remained with the company, and no more complaints or excessive demands for compensation were ever made from persons with disabled knee-joints after the treatment of broken thigh bones. (This device, together with an illustration of the splint, were published by Dr. Borek, of this city, in 1879—fourteen years ago.)

Now while this apparatus protects the knee, and in that respect it is a great improvement on the Hodgen splint, nevertheless it is still defective, and does not fully come up to the requirements of ideal surgery. But it was one step in that direction.

Modern surgery received its first impulse at the time when Virchow published his scientific discovery of cellular pathology, in the year 1858.

The demonstration that cells are derived from pre-existing cells came as a revelation to most physicians throughout the world.

The principles of cellular pathology have become to such an extent an integral part of medical thought, that we can hardly estimate, to-day, all that this discovery meant a generation ago.

To do this we must put ourselves back, in thought, to a time when all organized pathological products, pus, tubercle, cancer and all tumors, were supposed to be formed out of a primitive blastema—an exudation of some kind.

Under the influence of such ideas, any coherent or intelligent opinion as to the nature and development of morbid processes would be quite impossible. The never-ending strife between humoralism and solidism would probably be going on to-day had it not received its deathblow from cellular pathology.

The ontological conception of disease processes passed out of the horizon of scientific medicine when this discovery was made.

With the recognition of this great discovery, it became clearer than ever before, that the laws in disease are not different from those in operation in health, but are simply subject to different conditions.

The second splendid era of scientific value to the modern surgeon was inaugurated through the labors of the distinguished botanist Schleiden, whose brilliant conclusions, as they were drawn from the study of vegetable histology, were at once extended by Theodor Schwann to the animal kingdom; and then soon followed the demonstration of the migration of the leucocytes from the vessels and of the specific cellular germs of disease; now the inestimable discovery of W. Fleming designated by the term karyokinesis, or the indirect mode of cell reproduction, was published to the scientific world.

Out of those researches the function of the cell, in the process of regeneration and repair, became better understood; and it was soon demonstrated that the function of cell life includes, in a condition of perfect health in the matured body, the normal waste incident to the increasing activity of the tissues; and is balanced by the reparative process, while during the development of the body, an excess of material is added.

From a surgical aspect, cell reproduction or regeneration observed in the healing of wounds produced by severe injuries, and the complete or partial restoration of parts damaged or destroyed by this, and various destructive inflammatory processes caused by the presence of specific pathogenic microorganisms, is a study essential to secure ideal results in the practice of surgery.

There is no doubt existing now in the proposition, that an injury, defect, or the loss of considerable substance, will be repaired from proliferation of preëxisting cells, which compose the structure sustaining the injury, defect or loss of substance. The fixed tissue-cells at the site of injury being endowed from earliest embryonal life with intrinsic power of adaptation to existing conditions surrounding them, assume active tissue proliferation; and the embryonal cells thus produced constitute the granulation tissue, which toward the completion of the healing process, is transformed into mature cells, representing the injured parent tissues which have undergone the reparative process.

The third era, constituting the simple conception, the basis of early antiseptic procedure in surgery, that a wound to which bacteria gain access becomes infected in the same way that a sterilized infusion of meat undergoes putrefaction when a single suitable germ enters, has, it is true, been greatly modified; but the establishment of this truth even before its complete demonstration and the introduction of wound treatment based upon it, must remain forever the merit of the immortal Lister. It is the knowledge of the "how" to obtain aseptic healing of wounds, that has revolutionized surgical practice and made *modern ideal surgery possible*.

Soon the fourth era of this brilliant evolution in the progressive stages of scientific surgery began to take form. It was not long after cell life was cleverly understood until Metschnikoff and others, by certain methods of scientific investigation, demonstrated the fact, that the living tissues were not passive breeding places for bacteria, but that they were able to offer a very considerable resistance to the growth of microorganisms. This discovery was a great boon to the surgeon, for by it he was emancipated from the superstitious dread attending a particular surgical procedure where, from unsurmountable circumstances, the *débridement* is unavoidably imperfect and a limited number of bacteria gain access to the wound.

It is owing probably to this fact of phagocytosis that many cases of imperfect asepsis in surgical operations often heal well. It has been demonstrated by Cheyne and others that doses of less than 18,000,000 of the proteus vulgaris when injected into the muscular tissue of a rabbit seldom cause any result, and it requires as large a number as 250,000,000 to produce a circumscribed abscess.

But of course the condition of the serum, together with the macrophagi and microphagi at the point at which the organisms are arrested, is also a matter of great importance. Tissues which have been damaged by injury, bad surgery, or defective surgical appliances, are not so resistant to the action of bacteria as when in a state of health. A healthy peritoneum may receive and absorb a large number of bacteria; but if damaged during a laparotomy, so that a considerable portion of its absorbing surface has been impaired, and at the same time considerable oozing of blood and serum has taken place from the injured surfaces, a soil favorable for the growth of the organisms is produced and a septic peritonitis may result, even though the operative procedure in other respects may have been conducted under an ordinarily intelligent aseptic detail. Tense sutures also are more likely to be followed by stitch abscesses than where the suture margins are so coaptated as not to destroy the chemotactic properties of the leucocytes and other elements concerned in phagocytosis.

In the light of these discoveries we have learned that suppuration means a destructive process, the significance, and remote effects of which, can only be fully appreciated, by the surgeon, whose best efforts are exercised in behalf of humanity, and the *ideal* of scientific work; suppuration itself means microbial action upon healthy tissue elements, in which *leucocytes and embryonal cells are converted into pus corpuscles*. And it has for some time been known, that long continued suppuration of a wound produces amyloid degeneration of organs remote from the seat of suppuration; that is, by the accumulation of the ptomaines of pus microbes, coagulation necrosis may be produced in other organs of the body, and amyloid degeneration as a consequence.

Hence, after prolonged suppuration the patient can never hope to regain his former functional vigor, therefore the importance of preventing or arresting all suppurative action.

Scarcely long ago made the assertion that pus microbes are the immediate and essential cause of suppuration, inflammation and pus formation; and no one has as yet been able to successfully contradict

that assert on. So that the etiological explanation, of wound infection, and suppuration, is based wholly, upon the presence, and action of the pyogenic bacteria and their ptomaines.

The chief aim, and object, of ideal surgery, is to prevent suppuration, and secure the healing of a wound, by the first intention, and without suppuration. In a wound where there has been so much loss of substance, as to prevent a proper approximation of the parts, it must of necessity heal by granulation. In the ideal treatment of wounds, the classification into "open" and "subcutaneous" wounds, there is no longer the same practical importance, as an open wound is at once placed under the same favorable conditions for satisfactory and rapid healing, as a subcutaneous wound. It was stated here by several gentlemen who took part in the discussion of Dr. Outten's paper, that an open wound must be exposed to frequent inspection, and that it must also have drainage tubes passed through it.

The fundamental principle underlying ideal wound treatment, as I have stated, consists in preventing suppuration. To prevent suppuration in an open wound, the wound and its environment must be kept aseptic. I do not believe that any progressive surgeon will attempt to deny the force and truth of this assertion.

The indications to be met in a compound fracture of the thigh, for example, are first, the disinfection of the entire wound and its environment; second, the approximation of all the structures implicated as near as possible to their normal anatomical relations, *i.e.*, bone to bone, periosteum to periosteum, muscle tendon and nerves to muscle tendon and nerves, skin to skin, and direct fixation, over which is applied a thick hygroscopic dressing, then immobilization. If these indications have been completely fulfilled, the dressing should not be disturbed for from four to five weeks. *This is ideal surgery.*

When the profession can realize that fractures must be treated in the same manner, as the soft parts, in order to secure union by the first intention, then and not till then, will humanity have ceased to suffer from the surgery of dogmatism. The traditional methods, which depend upon provisional callus, in the union of a broken bone, have no place in modern methods.

The orthodox apparatus which demands the adjustment of all cases to any antiquated system, and necessarily to defective notions, has been eliminated from the instrumentarium of ideal surgery.

There is no longer any room for argument against the danger involved and the unsurgical system of treating wounds by the open method. That era belongs to the past and to history, a practice which modern surgery looks back upon with horror; a wound treated in a manner that constantly exposes it to infection and consequent suppuration and amyloid degeneration of other organs, receives no consideration from ideal surgery. As to the use of the drainage tube, I cannot express my own views more forcibly, than in the words of the celebrated surgeon and author, Thomas Bryant, of London, who said, "I always regret to see a rubber drainage tube passed through a wound; it may be through a joint, or through a thigh, or stump; such a drainage tube is a seton, and is not necessary." If a drainage tube through a wound in the thigh acts like a *seton*—as this distinguished surgeon says it does—then the sur-

geon who places it there may be held responsible for the baneful sequence of long continued suppuration.

Roswell Park, of Buffalo, who is not only a great surgeon but also a pathologist of world-wide fame, stated before the congress of American Surgeons two years ago, "That drainage is mainly practiced from habit or from fear. The promiscuous practice of drainage is a confession of fear or weakness; both of which are unscientific and unfortunate." I might multiply evidence in this direction, but to an intelligent body of scientific men it would seem superfluous. As suggested, when discussing Dr. Outten's case, the favorable progress and termination of such a wound, depends almost wholly upon how perfectly the wound has been purified and the first dressing applied. By "purifying" is meant securing a most thoroughly aseptic condition, by cleansing the entire interior of the wound in every nook and recess of possible infection; and in order that the wound may be rendered perfectly free from microbial contamination, it may be necessary, at varied intervals, to allow the patient a few whiffs of an anæsthetic, that the work may be properly performed without great pain. After securing this moderate degree of anæsthesia, the surface of the limb from the abdomen to the toes is thoroughly shaved and washed with hot water and brush. If grease or other filth of this nature from machinery is found in the wound, rubbing with sweet oil or with turpentine and alcohol before scrubbing with soap and water, greatly facilitates complete asepticism. Wounded vessels must be tied, all parenchymatous oozing stopped, blood clots and foreign particles removed, divided muscles, tendons and nerves sutured, the ends of the fragments trimmed, if necessary, and destroyed tissues cut away. This work completed, the wound is now thoroughly irrigated with hot solutions of first sublimate and then chloride of zinc. The latter penetrates the tissues and acts as a stimulant to the disabled structures; besides it possesses well known germicidal properties. The ends of the broken bone may now be approximated and fixed by wire sutures or ivory nails or some such device. In the event that there has been loss of bone substance, Bercher suggests the implantation of a solid bone cylinder adequate to compensate for the loss.

Senn, the pioneer of bone surgery, appreciating more completely than perhaps many others the scientific value of cultivating the implantation of even a foreign substance in bone in order to fill up a space made vacant by any loss of substance, wires a hollow bone cylinder between the ends of the shattered bone, thus imitating nature as perfectly as possible; and the healing process proceeds upon the same principle, so beautifully illustrated in the healing of wounds, beneath a moist blood clot, first brought into practical utility by the renowned Schede. Even though a muscle, a nerve, or a tendon, may have sustained a considerable loss of substance, by the violence producing a compound fracture, and the ends cannot be properly approximated, they must be sutured, just the same. Large cat-gut sutures, must be used for the purpose, and several sutures introduced; these suture strands, will serve as a "false work" over the breach, upon which the embryonal cells, may construct a more substantial bridge, gaining thereby almost perfect *restitutio in integrum* and the attainment of a perfect functional result will be secured in a short time; otherwise the muscle, nerve or ten-

don having sustained the loss of substance, will retract, and their ends heal by granulation and cicatrization with almost total loss of functional activity, as in Dr. Outten's case. An efficient external support is applied to the thigh and this together with the dressings are allowed to remain for several weeks. If death of any portion of the injured tissues takes place, it will be *aseptic death*, and no harm can follow. Thus, *ideal results are achieved, and the ideal of scientific progress consummated*, and the further advance toward that which we should all desire the most, namely, the *prevention of deformities, the relief of suffering humanity, and the prolongation of human life and usefulness.*

The special points in the foregoing remarks that I wish to emphasize, may be epitomized in the following brief conclusions:

1. That by the development of cellular pathology the process of cell proliferation, and the discovery of the laws of repair and regeneration, and the introduction of Lister's antiseptic system, the principles underlying the practice of surgery have undergone a complete revolution within the last few years.

2. That the principles of scientific surgery are so intimately interwoven with the advances in bacteriological pathology, that a progressive knowledge of the latter is essential, in order to be able to intelligently appreciate its value, in practical surgery, or to comprehend the principles upon which ideal surgery is founded.

3. That the observation made by Cabot, "That every surgical operation is an experiment in bacteriology," proves to be full of wisdom.

4. That the merely antiseptic era has been passed by modern surgery and the trend of the surgery of the future is to purely aseptic procedures; antiseptics is gradually being supplanted by asepsis and disinfection is made unnecessary by avoiding infection.

5. That to secure ideal results in the treatment of compound fractures the injury of the bone must be treated upon the same general principles that are applied to secure union by the first intention of wounds in soft parts; that is, by carrying out in detail the rules of asepsis and antiseptics, immediate and perfect reduction, approximation with direct fixation, efficient external support, and immobilization.

SUPPURATIVE PERFORATIVE OSTEO-MYELITIS OF INFERIOR MAXILLA,

AND MULTIPLE SUPPURATIVE OSTEO-MYELITIS OF TIBIAL SHAFT, IN ANOTHER PATIENT.

BY THOMAS H. MANLEY, M.D.,

SURGICAL CLINIC AT HARLEM HOSPITAL, NEW YORK.

Dr. Manley stated that he had been specially fortunate, in being able at the same clinic to exhibit two very interesting cases of an identical pathological process, in two different subjects, who, in each, presented, however, very widely diverse conditions, as to age, general condition and the seat of lesion.

The first case was a young woman, born of healthy parents, in Germany 27 years ago. She was cigar-maker by occupation and always enjoyed good health until two years ago. He said you will notice that she is of slight build, fair complexion, bright eyes, but of anæmic appearance.

Two years ago she had the left lower bicuspid and

first molar tooth extracted. Since then she has had constant trouble with the left lower jaw. At first there were neuralgic pains, then swelling and tenderness along the ramus of the left lower jaw; and finally, something about fourteen months ago, an abscess formed and burst, just a little posterior to the anterior surface attachment of the masseter muscle into the same jaw-bone, in other words, about three lines posterior, to the point at which the facial artery winds over the free border of the jaw. She has been under various practitioners' care, trying, in turn, antiseptic solutions, iodoform ointment, poultices, and caustics; but in no instance with any substantial benefit. It had been dried up or healed, in this time, twice; but each time with the closure of the drain her sufferings were aggravated, until it reopened.

Along with the disfiguring effect of the opening, she has to continually wear some sort of absorbable material to soak up the drip, which intermittently escapes from it. Now, the question arises what is the nature of this lesion and where is the precise source of this discharge?

She denies specific disease, and it surely is not malignant: this case, then, is one which in modern times is known as tubercular. But how did she acquire tuberculosis? She did not inherit it, nor has she been subjected to contagion. The fact of it is, she has what our fathers in medicine would have designated a strumous-diathesis. At the time of the extraction of these teeth the alveolar arch was damaged by misdirected forceps pressure, or else the dentist has left the necrosed fang of a tooth imbedded in the jaw. This has acted as a splinter or foreign body, so that we have a condition present, dependent on two distinct conditions. First, a constitution-cachexia, plus a traumatism. The precise source of this sinus which opens through the soft parts, is in the osseous elements of the jaw.

The prognosis, in tubercular disease in bone is said to be unpromising in adults. This is correct, when the process extends into, and involves the joints; but it certainly is not when the lesion is limited to the shaft or diaphysis, as in this case; for though I have treated a considerable number of this description, I have yet to see one which did not promptly and permanently recover. The operative technique, in this case, will consist of the application of a few simple principles of surgery. First, go into the mouth and make a deep furrow, with the scalpel down on to the alveolar surface of the bone, at the suspected point. If we come on a fang, and I think I can feel one, freely strip and extract it. Next, make a free opening over the small sinuous fistula and trace it to the point of disease in the bone. Scrape away all the softened carious bone, trim away the cicatricial, calloused edges of the ulcer and firmly seal in the cut with fine silk. We will do the draining through the mouth. The patient being ready, the first step in the operation was to enter the buccal cavity and extract the long angular necrosed root of a tooth. Now, the operator seized a small pointed gouge and scraped the cavity from which the dental substance had been removed. He said that here the bone was so rotten and friable that he could push his little finger entirely through the bone shaft into the opening in the skin. A direct communication was now made, the cavity of the mouth being continuous with the external opening. After grattage

and irrigation the external wound was pared and carefully sutured, when the usual aseptic dressings were applied.

The second patient, was a boy ten years old with the following history: Six months previously he had scarlet fever, after which he suffered from nephritis, and rheumatic pains in the lower limbs. About three months ago, two suppurative points broke out on the inner surface of the left leg, from which a sero-purulent matter has since issued. After awhile along the same plane, and on the same surface, many other purulent foci erupted, and now as can be seen, one side of the limb, from the knee downward, is covered with port-holes which communicate with necrosed bone. Twice the pus has made its way to the surface. All severe pain in the limb has ceased.

What is the pathological character of the process which has led to such extensive bone disease? Is the lesion tubercular? In answer to this one might ask, is the specific germ present? We may say, that it has not been proved. In fact, I attach no importance whatever, to the presence or absence of this germ, for it is incontestably true that we may, and do have strumous disease, so-called tuberculosis without the bacillus. And, again we often find myriads of them, in the laudable pus of a healthy strumous wound. The fact is, that the basis of this boy's disease is blood change. The poison of scarlet fever is terribly destructive to the blood, and the vasomotor nerves. In this case, the deeper layers of bone, lining the medullary canal have simply perished, through mal-nutrition. It may be noted that although there is extensive disease of this boy's leg, yet he walks without a limp. This is commonly found in all cases, where the bone lesion is at a considerable distance from an articulation.

On an examination of the limb, I find a probe will enter any one of those apertures and penetrate deeply into the medullary cavity. Small, loose particles of sequestra can be felt at the top of the probe. Now, I will by surgical interference endeavor, at least, to do to this boy no harm; that is, I will simply enlarge those openings and endeavor to pick out with the dressing forceps, the fragments of remaining dead bone, which the natural processes of life are, unaided, rapidly disintegrating and throwing off, by liquifaction. It might be said that as I have not very extensively opened the cavity of this bone some microscopical foci of the disease may have remained. But, in my experience the generalization of tubercle is never dependent on a local lesion; hence, I am confident that in operating in these cases, it is better to err on the side of conservatism, than to take chances on an extensive mutilation and consequent damage to structures, which might have been preserved, if nothing whatever had been done, other than by a tentative therapy.

PRACTICE OF MEDICINE IN ANCIENT ROME.

BY J. F. JENKINS, M.D.,
OF TUCUMSER, MICH.

In an early day, the practice of medicine in Rome was chiefly confined to foreigners, principally Greeks. Most of the physicians whose names are handed down to us are of Greek origin, yet there were many Egyptians and Syrians, who practiced medicine in Rome as well as in the provincial cities.

If we go still further back in the history of Rome,

we find wealthy families who kept many slaves, and would have one of their number skilled in the medical art, who would gratuitously practice for the household but received compensation from those outside of the household.

During the reign of the Cæsar's, and the century following many physicians in Rome became very popular; some of them received large fees which would compare very favorably with the fees of the popular physicians of the present day.

Pliny the Elder states that an ex-prætor, who had leprosy paid a physician 20,000 sesterces, about \$8,000, but he does not state how long he attended him, whether it was for one visit or for several of them. The same author states that there were five physicians in his day whose annual income amounted to 250,000 sesterces, equal to \$10,000 per annum. The physician to the emperor Claudius, Stertinus by name, received 500,000 sesterces, or \$20,000 per annum, still he claimed he could make in private practice 600,000 sesterces or \$24,000 yearly. The amount which this physician received from Claudius is probably equal if not greater than the salary of any modern court physician.

Sertinius and his brother who was also a physician, left a fortune of thirty millions of sesterces, or one million two hundred thousand dollars, besides making large donations during their lifetime to the city of Naples. Pliny mentions another physician, named Cranus of Marsailles, who gave largely, and spent money very freely, yet, notwithstanding his extravagant life, left a fortune of ten million sesterces, a sum equal to four hundred thousand dollars.

In the Roman empire, there was no law regulating the practice of medicine consequently many, as in our day commenced the practice of medicine with little or no preparatory education; many left trades and other occupations, and with a large supply of effrontery commenced the practice of the healing art. Like their modern type, some succeeded while others failed.

During the first century of the Christian era, there had developed all sorts of specialists; there were surgeons, gynecologists, oculists, aurists, dentists, etc., in all probability as great a variety as the nineteenth century has developed—in this way we find history repeating itself. Different schools of medicine existed, among which may be mentioned the "wine-givers" who no doubt were very popular in their day; the cold water doctors, one of whom named Antonius Musa gained the reputation of saving the life of the first Roman emperor, Augustus, although it is said that he killed Marcellus.

Pliny makes a statement that we very often hear at the present day, that physicians frequently try experiments upon their patients, and that the doctor is the only man in the community who may kill people without punishment.

Doubtless medical knowledge had made some progress since the days when Hippocrates taught the healing art under that famous old tree in the Isle of Cos, but our means of knowing how much progress was made is very limited, yet when I looked over the house of the surgeon in Pompeii, and examined the instruments that were taken out of this house, (which are in the museum at Naples), I am led to believe that the educated physician and surgeon of that day was in every way equal to the civilized society of the first century.

EYE TROUBLES WHICH CONSTITUTE A FRE-
QUENT SOURCE OF HEADACHE, VER-
TIGO AND NAUSEA, AND OTHER
NERVOUS DISORDERS.

Series of four lectures delivered at the Fourth Special Course of the
Chicago Polyclinic.

BY F. C. HOTZ, M.D.,

PROFESSOR OF OPHTHALMOLOGY.

LECTURE IV.—SUPRA-ORBITAL NEURALGIA AND
GLAUCOMA.

Fourth group.—While in all the affections of the three preceding groups the eye-ball showed no sign of disease, but exhibited an absolutely normal appearance, it is always decidedly changed in the fourth and last group of ocular affections we have to deal with. And while in the three other groups your failure to connect the headaches and other nervous symptoms with the ocular affections would have no serious consequence, it may result in the loss of the eyesight, if you fail to recognize at once the disease of the fourth group as the cause of the violent migraine with nausea and vomiting your patient wants you to relieve him of.

Gentlemen, I am referring to the fact that the severe neuralgic pain and the violent gastric disturbances, induced by acute glaucoma, have been taken and treated for "rheumatic or malarial" neuralgia while the ocular disease has not been recognized until it was too late. I have seen several instances of this mistake: one was an especially sad case which impressed me so much that I shall never be able to efface its picture from my memory. Though fifteen years have gone by since I have seen the unfortunate patient her image is before me now as vivid and distinct as if I had seen her but yesterday. Two months before I saw her, she had been seized with fever, nausea, frequent vomiting and violent pain extending over the entire left side of the head. Her physician pronounced her trouble to be gastritis and "sick headache," and when the old lady called his attention to the fact that her sight was getting poorer every day (and she could see with the left eye only; for the sight of the right eye had been destroyed by glaucoma ten years previously) he assured her she need not worry about it; that her sight would return as soon as the stomach trouble was cured and the neuralgia in the head relieved. Having implicit confidence in her physician she believed his word and though her sight soon had vanished completely she waited hopefully for the day when the darkness would be lifted again from her eye, and patiently endured the constant, most violent headache which robbed her of rest and sleep by day and night. For two weary months this poor woman suffered and hoped; but then her patience was exhausted and much against the will of her physician she went to consult an oculist. Poor woman! It was too late. The continued high tension of glaucoma had done its deadly work upon the optic nerve too thoroughly; and although the iridectomy effectually reduced the intra-ocular tension and promptly relieved the patient of the terrible headache so that after the operation she could enjoy a good quiet sleep—for the first time in eight weeks—the woman has never seen a ray of light again—the awful result of a mistake in diagnosis!

But such mistakes should not occur; they are inexcusable; for they can easily be avoided. It is a

very fortunate coincidence that to-day there is in our clinic a case of supra-orbital neuralgia and a case of glaucoma because they afford a good opportunity of pointing out to you the several features by which the simple neuralgia may be distinguished from the glaucomatous neuralgia.

This young man has for the last three days suffered with severe pain over the right side of his head: the pain began every morning about eight o'clock, starting over the right eye and extending upwards and backwards, but never over to the left side of the head. It increased in intensity till about 10 o'clock, continued for several hours and then gradually subsided. By three o'clock p.m., the paroxysm was over to begin again at eight o'clock the next morning. At the present time the attack is pretty well on; you can tell by the patient's countenance that he is suffering, and he will tell you so too. The supra-orbital notch is quite sensitive to the pressure of my finger; the eye is red, weeping and quite sensitive to light. But its vision is not impaired; the cornea is clear and bright, the pupil of normal size and readily responding to the influence of light. The fundus can well be illuminated by the ophthalmoscope and appears normal; the eye is not tender to the touch and shows a normal degree of tension. This then is a true supra-orbital neuralgia, and the regular periodicity of its paroxysms would indicate its malarial character.

Now the attack of acute glaucoma also begins very suddenly with supra-orbital pain which spreads over the whole side of the head, and is also strictly limited to the one side. And if in addition it is ushered in by a chill, and accompanied by nausea and vomiting, as it often is, the similarity with "malarial" or "sick" headache is indeed very great; and like the sick headache, the glaucoma paroxysm may last only 12 or 24 hours, to return after several weeks or months. Usually, however, this terrible pain continues in unabated fury for several days, and this long duration and great violence should make any physician cautious not to regard the trouble a simple neuralgia until the most searching examination has failed to find a tangible cause and until he has especially satisfied himself that there is nothing wrong with the eye, even if the patient makes no complaint about his sight. For in the agonies of pain and with the sight of one eye perfect, the patient may not notice at all that the sight of the other eye has been rapidly failing since the beginning of the dreadful neuralgia, and that he may be scarcely able to distinguish light.

During the paroxysm of acute glaucoma the eye always shows great and characteristic changes; the upper lid is swollen; the palpebral conjunctiva œdematous, the sclera covered with engorged dark red veins; the cornea looks dull and smoky; the pupil is dilated and does not respond to the influence of light, and often shows a muddy, greenish color. The iris appears pushed forward toward the cornea, so that the depth of the anterior chamber is more or less reduced. The interior of the eyeball cannot be inspected by the ophthalmoscope because of the cloudy condition of cornea, aqueous humor and vitreous body, and most important symptom of all! the eyeball shows a very high tension; that is to say, when you place your finger gently upon the upper lid and slightly press down on the eye, you feel a much stronger resistance than

the normal eyeball offers. The intra-ocular tension has rendered the globe so hard that you imagine you are touching a solid marble, and not an eyeball.

The typical attack of glaucoma is usually preceded by slight disturbances, which, however, many patients pay little attention to and consider of no consequence. But a careful observer remembers that long before the glaucoma attack, he had noticed on some days his sight grew dim for several hours, and at the same time he felt a dull pain in the forehead and a fullness in the eye, and if he happened to look at a gas or lamp light, he saw a rainbow colored halo around the light. At first these premonitory signs of the approaching storm last but an hour or two, and reappear at long intervals, or perhaps on special occasions, (after great mental excitement, bodily exertion, too great indulgence in the pleasures of the table, etc.), but sooner or later they return at shorter intervals and remain longer, until finally the full attack breaks forth.

The duration of the glaucomatous attack has no limit; it may last but one day, or it may only abate in fury, but never let up entirely until the sight is thoroughly extinguished. When the attack subsides quickly, the sight soon returns, and the patient congratulates himself upon the happy result. But sooner or later he will have another attack which may not be so severe as the first one, but after which the sight does not return any more as completely as before. And after another pause there comes a third, and a fourth attack and so on, each one leaving the sight in a more impaired condition, until finally the last glimmer of perception is wiped out.

Or after the first outbreak of glaucoma the patient is never troubled with severe neuralgic pain; but the intra-ocular tension remains permanently increased, slowly but surely doing its destructive work upon the optic nerve fibres, achieving their complete atrophy and producing that peculiar excavation of the disc so characteristic of chronic glaucoma.

We distinguish three kinds of excavations of the optic disc: the physiological, atrophic, and glaucomatous one.

The *physiological excavation* is a funnel-like depression in the center of the disc: it varies greatly in extent but—and this is the very important feature—it never occupies the entire area of the disc: there is always a ring of nerve substance between the edge of the disc and the margin of the physiological excavation.

The *atrophic excavation* caused by tissue waste in the optic nerve, is a shallow depression extending over the whole disc, its surface gradually sloping down from the edge to the center.

The *glaucomatous excavation* also occupies the entire area of the disc, but it is steep, cup-shaped and much deeper than the atrophic excavation because the lamina cribrosa (which constitutes the bottom of the excavation) has been pushed backward by the continued high pressure upon it. This great and steep depth of the glaucomatous excavation produces a peculiar and very characteristic ophthalmoscopic picture: the floor of the sunken-in disc presents the pale, whitish, mottled appearance of the lamina cribrosa: the central retinal artery and vein do not appear to emerge from the center, but near the nasal border of the disc, and when the vessels reach the periphery of the disc they make a sudden sharpe curve upwards to ascend the side of the

excavation in order to get over the edge and into the plane of the retina. Where the excavation is very deep and the sides very steep, the bent of the blood vessels may be so sharp that the ascending piece is hidden from our view, and the vessels crossing the disc seem to have no direct connection with the vessels we see proceed from the edge of the disc. And when we move our head slightly while inspecting the glaucomatous disc we observe a distinct parallax displacement, the vessels on the disc appearing to move in the same direction with our head, while the vessels at the edge of the disc appear to move in the opposite direction. Moreover, we cannot see the bottom and the edge of the excavation distinctly at the same time; if we see the bottom plainly, the edge is indistinct, and if we adjust our sight for the edge, the details of the bottom become faded and hazy, because they are situated beyond the plane for which our sight is adjusted.

Whichever course glaucoma may pursue, absolute blindness is the inevitable final result, unless the disease is arrested by surgical interference. No medical treatment (local or general) can permanently stop the progress of glaucoma; but a properly executed iridectomy performed at the early stage, will stay the progress of the disease and save the sight. It was in 1856 when Dr. Graefe made known his great discovery, one of the grandest triumphs of modern surgery; and thousands upon thousands of men who would have been doomed to blindness for the rest of their lives, owe the preservation of their sight to the genius of Graefe.

The success of the iridectomy depends largely on the duration of the malady; in acute glaucoma especially it should be performed at the earliest moment; and you will, therefore, now realize that it is every physician's sacred duty to study the symptoms of glaucoma that he may recognize its presence and look for it as the possible cause of violent persistent sick headache, especially if this occurs in a patient beyond the age of 40; for glaucoma is a disease of advanced age, most frequent between the years of 50 and 70, and seldom found in a person under 40.

Gentlemen, I am just being reminded that the hour has expired. Let me then thank you for the close attention you have paid to my lectures. I have not dwelt upon the details of the treatment of these various eye troubles, because it would have been impossible to crowd so large a subject in the small compass of four lectures; and because I do not regard it the duty of the general practitioner to treat these ocular affections. His duty it is to know that they are often the cause of nervous disturbances; his duty it is to understand the symptoms of these ocular affections so that he is able to recognize their presence and to urge upon his patients the necessity of having his eyes attended to. His duty it is to look for these eye affections in all nervous troubles for which he cannot find any other satisfactory cause.

The task I had set before me in these lectures, was to make you acquainted with the principal types of these ocular affections; to explain how they affect the nervous system and to impress upon you the importance and necessity of their treatment.

Let me hope that I have succeeded in my endeavors. Let me hope these lectures will help you to solve many perplexing problems in your practice, and to bring relief where you vainly had exhausted

your medical skill before. And if then you feel that these hours in the Chicago Polyclinic were well spent for the knowledge you received, let me hope you will also kindly remember him who has given you this information.

A SIMPLE TOURNIQUET CLASP.

Read before the Philadelphia Academy of Surgery, January 9, 1893.

BY H. AUGUSTUS WILSON, M.D.,

CLINICAL PROFESSOR OF ORTHOPEDIC SURGERY, AT THE JEFFERSON MEDICAL COLLEGE, PHILADELPHIA.

It must be evident to everyone who has occasion to use the elastic tourniquet and Esmarch's bandage, that the simplest form of all methods of fastening it, when applied, is either not known, not efficacious, or possesses other disadvantages. The method referred to, is to pass the loop of rubber bandage underneath one of the last turns as it is applied, which by contraction holds the end in place. The rubber tourniquet, as sold by the shops in this coun-

try, is always provided with a chain, of about six or eight inches in length, for the purpose of holding the end of the bandage and keeping it from slipping. The use of this chain necessitates the application of the entire length of the bandage whether it is required or not. It was in order to dispense with this chain that I advised the simple form of clasp that is shown in the accompanying illustration. Messrs. E. A. Yarnall & Co., surgical instrument makers, in this city, have made the clasp, following my directions. It consists of a simple letter S made out of one-eighth inch German silver wire, and is so simple in its construction that any one can twist a piece of wire into the necessary shape, as I did with the original design. The manner of using the clasp is so

clearly shown in the cut that a description is not at all necessary. Its advantages are, simplicity of construction and use; that the tourniquet may be clasped at any point; that while in use it cannot slip, and that the tourniquet may be unclasped with the greatest ease. It would appear that there was some necessity for a form of clasp of this nature, in view of the extensive advertisements in English medical journals of a patented appliance of very much more elaborate construction and therefore quite expensive. Continued trials of this simple clasp, when used with ordinary elastic rubber tubing, have shown that it was all that was required for the purpose, and it is hereby given to the profession, with the hope that it may tend to displace more cumbersome and unsatisfactory methods of accomplishing the same end.

PNEUMONIC FEVER—ITS SYMPTOMOLOGY.

BY EDWARD F. WELLS, M.D.,

OF CHICAGO.

FEVER.

Very early in the attack, during the chill if it is present, other important symptoms arise. Thus in almost every case the body heat is elevated above the normal and so remains until the advent of convalescence, when for a few days, it often falls below the standard of health, after which it regains its proper equilibrium.

The curve of elevated temperature usually ascends abruptly during the first few hours, and in some cases speedily reaches a great height, as shown in the following table:

TABLE I.—SHOWING RISE OF TEMPERATURE EARLY IN THE ATTACK.—UNSELECTED CASES.

Age.	Hours After Access.	Temp.	Age.	Hours After Access.	Temp.
63	2	99.0	8	11	102.0
77	14	97.0	5	8	102.0
27	4	99.0	4	4	102.0

13	6	102.0	28	8	103.2
18	1	102.0	29	11	103.2

Baginsky observed a temperature of 104.7° in a child two hours after the initial chill. Fox has known of a case in which the thermometer marked a temperature of 105° within a few hours after the first sensations of illness. In a

1 The remarkable rapidity with which the fever is recognized and recognized by Alexander, of Tralles. See Opera Omnia, p. 170, 171, so early as the sixth century.

—Reynold's Syst. Med., Phila., 1889, Vol. II., p. 17.

series of five cases given by Juergensen¹ temperatures of 101, 101.7, 105.8, 104.4, and 104.4 was observed 2^h, 4, 4, 7 and 8 hours respectively, after the access of the disease. Mounthuis, in one case found the temperature, during the chill 100.9; fifteen minutes later 102.7°, and at the end of an hour 105.8°. In one of Pepper's cases the temperature reached 105° within an hour of the initial chill.² Scheef³ saw temperatures of 101, 104.6, 103.8, 104.6 and 105.6 at 4, 3, 1 and 6 hours, respectively, after the onset of the symptoms. Thomas⁴ in two adults marked temperatures of 104.9° and 105°, nine and twenty-three hours respectively, after the beginning of the attack. Ziemssen⁵ observed a temperature of 102.5, in a child four hours after the beginning of the attack; and temperatures of 103.5° and 104°, respectively, in two children twelve hours after the initial symptoms.⁶

Ever since the comparatively recent reintroduction of the thermometer into practical medicine⁷ it has been the desire of physicians to make it a certain guide, a veritable mariner's compass in the diagnosis, prognosis and treatment of diseases,⁸ and charts have been constructed showing what their authors are pleased to term the "normal temperature curve" of various maladies. Pneumonic fever has not escaped attempts at being made to fit one of these charts. My observations have convinced me that such generalizations have usually been deduced from insufficient and unreliable data, and that the deviations from the average are so numerous and wide as to render such charts misleading. Let us here pause to hear what a few of the systematic writers have to say on this subject:—

Aitkin,⁹ states that the diagnosis may be established by the range of temperature alone, and that a patient exhibiting the general typical symptoms of pneumonic fever, but with a temperature not ranging above 101.7° may be safely considered as having his lungs free from inflammatory exudate.

Flint¹⁰ says that "the thermometer in the axilla indicates more or less increase of heat, the increase, in mild cases, not exceeding 104°."

Fox¹¹ says "one of the most marked features of pneumonia, which is almost sufficient to distinguish it from other diseases, is the sudden and considerable rise of temperature which marks its invasion and which, with some exceptions, is then maintained, with slight morning remissions and evening exacerbations throughout its course until crisis occurs. The rise of temperature during the rigor is common to most diseases but its subsequent maintainance at a very high standard during the succeeding first hours and days is limited to a small class of inflammatory affections."

Green¹² says that the thermometer will range from 102° to 105°, being lowest at about 8 A.M., and highest in the early evening.

Holt¹³ says that "the temperature fluctuates slightly during the day, being 102° to 103° in the morning and 104° in the evening, until the sixth or seventh day, sometimes not until the tenth, when it suddenly falls to or near the normal."

⁹ It appears that Sanctörinus first had the idea of measuring the temperature of the body in disease by the thermometer at the end of the sixteenth, or early in the seventeenth century. Baumler, Quain's Dic. Med. N.Y., 1883, p. 1615;—Cleghorn, Epidem. Dis. Minorica, London, 1762;—was the first, so far as my information extends, to make use of this instrument in investigating pneumonic fever, in 1745. Donné, Arch. Gén. de Méd., 1857, and Roger, *Ibid.*, T. vi., made observations upon the temperature in this disease previous to 1810.

¹⁴ N. Y. Med. Rec., Feb. 11, 1885, p. 174.

Juergensen¹⁴ says that the temperature speedily rises to 102° or 103° and remains so, with morning remissions, and evening exacerbations of from 1.8° 2.7°, to rapidly sink to the normal at the termination of the fever.

Schuyler¹⁵ says that the temperature rises suddenly to the maximum shortly after the onset of the malady, is maintained at a high level during the course and rapidly falls to a degree or more below the normal at defervescence.

Sturges¹⁶ repudiates ready-made charts, but says that there is high temperature at the beginning and to the end of the first week, with but slight morning remissions and liable to sudden elevations. He says, with much truth that this, nor any other isolated symptom can be trusted as a measure of the gravity of the disease,¹⁷ as a temperature of even 107° may be met with in successful cases.¹⁸

Trousseau¹⁹ says that the temperature quickly rises after the chill to 102° and continues at this point, with slight oscillations, until the crisis, when it falls rapidly to, or below the normal.

Waters²⁰ says that the temperature rarely rises above 106°. In a series of 106 cases the temperature only once reached 106°, and in only a small proportion did it pass beyond 105°. The general course is a very definite one—a high temperature is maintained for some time, a so-called crisis comes and there is rapid defervescence.

Wunderlich²¹ would call all cases severe in which the temperature ascends beyond 104°.

Ziemssen²², speaking of the disease in children, says that the temperature ascends rapidly and remains at its acme, about 104°, until the crisis, when it falls to or below the normal, remaining so for several days. The highest and lowest temperatures met with by him were 106.7° and 97.1° respectively.

It will be seen from the above selections that writers generally have believed that in this disease the temperature runs a very definite course. This, however, is by no means the rule; neither can the conscientious observer make one case in ten fit the ready-made charts as prepared by some systematic writers. I have the records of the temperature of several hundred cases of this disease, collected from the published writings of others, in addition to my own 498 cases, and a study of these show in a graphic manner the shifting sands forming the foundations upon which, after too hasty generalization, has been erected the superstructure of thermometry in pneumonic fever. Take the temperature of any large number of cases and represent them graphically in charts and any unprejudiced observer must acknowledge that he has before him a trackless wilderness of unmeaning lines.²⁷

In view of these facts we can say that, in general, the corporeal heat is elevated from two to five degrees, Fahr., above the normal, continues so for about six days, and falls rapidly to or below the standard of health. That in a few cases the temperature attains a great height and in yet a few others it is but little or not at all exalted and may even be subnormal throughout the attack. Finally that there are so many exceptions to these rules that it were well to ignore them altogether.

The temperature, corresponding with the normal diurnal variations, is usually higher in the evening than in the morning.²⁸

As a general rule the severity and dangerous tendencies of the case may be measured, in part, by the height of the temperature, and, by common consent, the 104th

degree is considered the dividing line between the mild and moderately severe cases and those which are very severe and dangerous.²⁷ In my own practice I have met with several cases with a temperature of more than 101°, yet recovery ensued in the majority, and in some of these no alarming symptoms whatever were noticed. In many of the fatal cases the thermometer at no time indicated a very exalted corporeal heat, and in some instances death was preceded by a subnormal temperature. Generally, however, death was anticipated by a great elevation of the temperature. The highest temperature recorded in my case-book is 108°, noticed in an aged lady an hour before death.²⁸ The lowest axillary temperature met with was 94°, in several cases—fatal and non-fatal. A gradual and persistent rise of temperature after the fourth day has generally portended a very grave or fatal case. In my cases the average temperature at the height of the disease has been much lower than I was led to expect from the statements of the text-books.

In children the temperature usually ranges higher than in adults; attaining, in most cases, a height of from 102° to 105°. The rise at the beginning and the fall at the close of the attack are usually remarkably abrupt. In senile cases the temperature curve is somewhat lower than in adults, although some of the highest markings I have made were in such patients. In males the temperature is said²⁹ to be slightly above that of females, but this is not proven by my records. Juergensen³² says that in the case of females about menstruating, the temperature is apt to be quite high until the flow is established, after which it usually declines very considerably. This statement is in accord with my own observations. Many writers affirm that the portion of lung affected exerts a considerable influence over the temperature curve, it being higher when the localization is in the upper lobes than when the lower parts are involved, but my experience does not confirm this opinion.

Shortly before death the temperature often rises to a great height³³—108.9°,³⁴ 109.4°,³⁵ 110.6°,³⁶—and continues to rise to a slight extent post mortem.³⁷

As convalescence approaches the temperature often pursues a peculiar course. Instead of there being a morning remission, the temperature will probably remain high, with considerable perturbation of the general system. In the evening, however, the body-heat begins to fall rapidly until it reaches the normal, or a sub-normal point, in the course of a few hours. In some cases the fall of temperature is very gradual and prolonged,³⁸ occasionally one to three

weeks being occupied in the de-escalence. The physical signs disappearing equally slowly.

When de-escalence is very rapid³⁹ the temperature commonly descends to below the normal. This occurred in more than 60 per cent. of my cases. It usually begins to fall during the first week, and this is generally coincident with improvement of other important symptoms and the beginning of convalescence.

Of my cases the fall of temperature began before the third day in 5 per cent.,⁴⁰ during the third day 10 per cent., during the fourth day 15 per cent., during the fifth day in 20 per cent.; during the sixth day in 20 per cent.; during the seventh day in 10 per cent.; during the eighth day in 10 per cent.; during the ninth day in 5 per cent., and after the ninth day in 5 per cent.⁴¹ It usually began in the evening after a most promising morning.

A sudden fall of the temperature without any amelioration of the general symptoms is often⁴²—but not always—of evil import.⁴³

It has long been an interesting question as to what were the limits of corporeal temperature above and below the physiological zero endurable by the human body without causing death. That a rise or fall of a few degrees is injurious to the system has been almost universally accepted, and probably upon insufficient grounds.

The death lines of Uhle,⁴⁴ 106.1; Goodhart,⁴⁵ 107; Fiedler⁴⁶ and Wunderlich,⁴⁷ 107.6°; Liebermeister,⁴⁸ 108°; Richet, 109.4°; Bäumlér,⁴⁹ 110°; Anderson,⁵⁰ and Barnard,⁵¹ 111.2°; Dalton,⁵² 113°, and others have been so often transgressed with impunity that these arbitrary limits are by no means so significant as their respective authors would have us believe. To show to what extent "hyperpyrexia" has been recovered from I have constructed Table II.

In the face of the above facts is it not putting the point to great tension to say that a high temperature is, *per se*, a cause of death? And if death does come in the wake of an exceptionally elevated corporeal heat, as is no doubt very frequently the case, does it always and necessarily follow that the event is directly due to the hyperpyrexia? May there not be other factors involved upon which depend both the excessive temperature and the fatal issue?

Sturges,³³ speaking of this says, and I think truly, that "it happens in fatal cases of pneumonia with exceptionally high temperature, that death reveals a condition of the lung absolutely irrecoverable; the high temperature is but the index of a condition which must under any circumstances have ended in death. For myself, I do not know of any case of pneumonia dying with such exceptional temperature that could be said to die of it, that from the state of the lung must not have died anyhow."

ninth and tenth days—it was 99°, 99° and 98.4° respectively. On the eleventh day it was 100°, and between this and the fourteenth day it ranged from 100° to 101°, after which there was a gradual decline to the normal on the thirty-fifth day. The physical signs continued to the sixtieth day.

²⁷ In one of my cases the temperature fell 10 degrees in forty-eight hours, and Ziemessen records a case in which the decline was 6° in sixty hours.

²⁸ In round numbers, approximately.

²⁹ Of Bermann's.—Lungenentzündung, 1880, S. 33.—43 cases the temperature began to fall on the first day in 2, on the second day in 8, on the third day in 11, on the fourth day in 11, on the fifth day in 5, on the sixth day in 1, on the seventh day in 3, on the tenth day in 1, and on the eleventh day in 1. In seven of these the fall began in the morning at 1 to thirty-six in the evening. For further information see Sauter, Inaug. Dissert., Breslau, 1881, S. 17;—Scheff, Inaug. Dissert., Tübingen, 1882, S. 32;—Stortz, Inaug. Dissert., Würzburg, 1884, S. 57.

³⁴ Lebert.—Berliner k. Wochenschr., Sept. 4, 1871,—says that in the majority of cases the rise of temperature is favorable until asphyxia or collapse announce the end. This has very seldom occurred in my experience—in almost every fatal case remarkable thermometric changes were noticed for some time before death.

³⁵ Several such cases are in my collection, but the point is illustrated by the one reported by Fox.—Reynold's Syst. Med., vol. 11, p. 179. A boy, aged 15, of good general health, became chilled and had a rigor on the following morning, with the development of pneumonic fever, locally affecting the lower lobe of the right lung. Severe gastric catarrh was a complication. On the fourth day the temperature was 105°. On the eighth,

* No attempt has been made to make this table complete as to the published cases.

Other writers are also of the opinion that a high temperature is not in itself dangerous, and is not certainly prognostic of a fatal issue. Thus Ziemssen¹ says, that "there is no doubt as to the dangers of hyperpyrexia, but it seems that the high temperature has usually not the significance which Liebermeister at first attributed to it. The severe cerebral symptoms, the cardiac degeneration, renal trouble,

the trophic disturbances do not seem to be the effects of the high temperature, but effects of the dangerous process, the infection causing the fever." Welsh² says: "There is no doubt that temperatures of 110° to 113° produce serious symptoms, but whether or not ordinary temperatures of 105° to 107° exert any serious action on the body, is a question which is certainly unsettled. It has been shown that rabbits can be kept in a box, with a continuous rectal temperature of 107° for at least two weeks, provided the precaution is taken to keep the box well ventilated and the animals well supplied with moist food. Patients may have a perfectly clear brain and no grave symptoms with a temperature of 106° or 107°."

Opposite views are held by others.³ Thus Lynch⁴ says: "As I grow older and my experience enlarges I become more and more convinced that fever is the lethal agent which destroys life in almost every disease in which that functional derangement is present."⁵

In this connection the question arises whether a high temperature may not be salutary, by destroying or preventing the multiplication of the germs of the disease." This opinion has been advanced,⁶ but with our present knowledge I cannot accept it.

Physicians generally have been so absorbed in recording temperatures above the normal that but little attention has been given to the markings of the thermometer below the physiological zero. It is no less true, however, that occasionally cases of various acute diseases, and especially pneumonic fever, run their course with a temperature curve below that of health.⁷ This fact is not usually mentioned, and, although not unknown, its importance is not always fully appreciated.

Doubleday,⁸ in analyzing 251 cases of this disease, found that in three the temperature was sub-normal—in one as low as 92.4°. Fox⁹ says: "Such cases must be extremely rare, and require data as to the day of the disease upon which they came under observation. The majority of cases in hospital practice are rarely admitted before the third day, and it must be remembered that even at this early period the temperature may in some cases fall from a pyrexial height to the normal standard. I have never seen a case of pneumonia unattended with pyrexia free from this suspicion." Schuyler¹⁰ says "that the entire process of acute lobar pneumonia may occur without fever," and in another place¹¹ he records a case of this kind:—A German, aged 24, a grocer's clerk, whose duties led to early morning exposure whilst insufficiently clad, and who had not been strong for some weeks was, without chill, thirst or heat, attacked with pneumonic fever, characterized by prostration, anorexia, rusty sputa and scanty urine. When seen on the second day, the temperature was 97°, rising, three days later, to the normal, but at no time transcending the latter point.

I have met with several cases in my practice in which the temperature was normal or sub-normal.

A lady, aged 31, was suddenly attacked, at 1 p.m., Dec. 10, 1882, by a very severe lancinating pain in the region of the right nipple, followed in a few minutes by a profound chill and rigors. In due season all the ordinary signs and symptoms of pneumonic fever, locally affecting the lower lobe of the right lung, appeared. Convalescence was declared on the fourth day and a speedy recovery ensued. The highest tem-

⁹ N. Y. Med. Jour., May 11, 1887, p. 512.
¹⁰ Ibid., Sept. 8, 1883, p. 277.

eratures noted were 99°, 98.6°, and 96° on the second, third and fourth days respectively.

A lady, 44 years of age, was suddenly attacked, at 5 p.m., Nov. 15, 1878, with a severe chill, followed by the ordinary symptoms of pneumonic fever. The entire left lung became consolidated and convalescence was not assured before the eighth day. The highest temperature recorded on each day was: second day, 98.2°; third day, 98.6°; fourth day, 98°; fifth day, 98.7°; sixth day, 98°; seventh day, 98°, and eighth day, 97.6°.

A robust young man, aged 23, was suddenly attacked by a light chill at 3 a.m., May 7, 1881, followed by the usual symptoms and signs of pneumonic fever, locally affecting the lower lobe of the right lung. Convalescence was declared on the fourth day. The temperature was, first day, 99°; second day, 98.5°; third day, 98.4°, and fourth day, 98°.⁶⁶

In another series of cases the temperature was considerably elevated in the beginning but quickly fell to, or below the normal, without improvement in other symptoms.

A young lady, a deaf mute, aged 24, was taken suddenly with a profound chill at 5 a.m., Jan. 29, 1875. The ordinary symptoms of a severe attack of pneumonic fever followed. Headache, sleeplessness, and delirium were prominent symptoms. The upper lobe of the left lung was the part locally affected. Convalescence was declared on the seventh day. The highest temperatures noted were, on the second day 100°; on the third day, 99°; on the fourth day, 98°; on the fifth, sixth and seventh days, 98°.

In yet another series the course of the disease was apyrexial, except on one or two occasions when, for a short time the temperature was elevated.

A widow, aged 60, had had pain in the left side, cough and diarrhœa for a week, when, on April 25, 1881, at 3 p.m., she felt chilly and ill and took her bed. I saw her two hours later. There was noticeable dulness over the lower lobe of the left lung, posteriorly, and in this situation crepitan râles were heard. There was a severe cough, with pain in the left side and a scanty, viscid, white, translucent expectoration. The appetite was lost and thirst slight. She had vomited once and had a dysenteric diarrhœa. As time passed the expectoration became in turn free, hæmorrhagic, dark, scanty and suppressed. The vomiting continued, the tongue became dry, sordes formed on the teeth and lips and the diarrhœa became frequent, acrid and involuntary. The urine became scanty, was passed involuntary, and finally retained. Her mind, at first acute, became dulled and delirious, and from wakefulness she passed into drowsiness, stupor and coma. Respiration became more and more frequent and embarrassed and she died at 5 a.m., on the fourteenth day. The temperature was on the first day, 96°; second day, 98.5°; third day, 100.6°; fourth day, 99°; fifth day, 98°; sixth day, 98.1°; seventh and eighth days, 99°; ninth day, 98.2°; tenth and eleventh days, 99°; twelfth day, 101.5°; thirteenth day, 101°, and fourteenth day, 101.5°.

In a considerable number of cases the local peripheral temperature was studied, but with, to me, unsatisfactory results. In a large number of cases the affected side was warmer, sometimes remarkably so,⁶⁷ than the healthy one, yet in a very considerable number but little, if any, difference could be detected between the two sides,⁶⁸ and in some cases the surface temperature was highest on the healthy side.⁶⁹

Jonas and Benezur⁷⁰ say that a decided difference in the surface temperature may be noticed by the hand over solid

organs—liver, heart, spleen, etc., and the lungs, it being highest over the latter. If they are hepatized, or if there is considerable pleuritic effusion this does not obtain.

SOCIETY PROCEEDINGS.

American Electro-Therapeutic Association.

Second Annual Meeting, held in New York, October 4, 5, and 6, 1892.

WILLIAM J. MORTON, M.D., PRESIDENT.

FIRST DAY—OCTOBER 4—AFTERNOON SESSION.

(Continued from page 107.)

Now let us take a straight glass tube, 50 centimetres long, with a uniform interior cross section of say 1 square millimetre. Suppose the tube filled with a homogeneous liquid whose resistivity is 10 ohms. Then since a block of this liquid 1 cm. long, and 1 sq. cm. in cross section offers ten ohms, a column of the tube 1 cm. in length, having a cross section of 1-100th. of a sq. cm., will offer 1,000 ohms, and the total resistance of the entire 50 cm. column in the tube will be 50,000 ohms. Next suppose that a steady current of one milliampère is forced through this tube. By Ohm's law, the total difference of potential necessary to produce this current will be 1-1000 x 50,000 or 50 volts. While this current flows, there will be 50 volts potential difference between the ends of the tube, or a uniform gradient of potential of one volt per centimetre of its length. Consequently, if a unit charge of positive electricity could be placed in a little insulated capsule and introduced within the tube, there would be an electric force exerted upon the capsule of 1-300th. dyne, urging it forward, assuming that the electric force in water is the same as that exerted in air.

It seems to be a general law that the contact of any two dissimilar substances gives rise to an electrification and difference of potential between them. At the surface of contact between liquid and glass, there is an electrification, and once the liquid particles next the glass receive a charge, they are urged along the tube with a force depending on their electrification and on the gradient of potential. If the cross-section of the tube be sufficiently large, the moving electrified particles will tend to set up local convection currents, and the motion of the liquid near the tube's centre may be opposite in direction to that at the walls, but if the cross-section be very small, the whole column of liquid will be urged forward. For any given tube and liquid, the contact electrification of the liquid particles will be definitely established, and the moving force will depend only upon the gradient of potential, which in turn will be directly proportional to the current strength; for if we send two milliampères through the tube, the terminal difference of potential will rise from 50 to 100 volts, and the gradient will be increased from 1 to 2 volts per cm.

This moving force continually exerted upon the liquid particles will accelerate them until the friction due to their forward velocity balances the moving force. This will determine the rate of electric transfusion through the tube for the particular strength of current employed.

It is evident that the rate of transfusion would not be altered by any change in the length of the tube, for suppose it were increased to 1 metre. In order to sustain 1 milliampère through this doubled length and liquid resistance, we should have to double the terminal difference of potential, and employ 100 instead of 50 volts. The gradient of potential would still be 1 volt per cm., leaving the relation of moving to retarding forces unaltered. Again, suppose that instead of using one tube, we had five similar tubes of 50

⁶⁶ This list might be extended, but these are fair examples of the remaining cases.

ems. length, side by side, and all connected in parallel. One milliampère through the set would give 1-5th of a milliampère through each singly. Also each tube having 50,000 ohms resistance, would demand a terminal potential difference of 10 volts for its share of current, and thus establish 1-5th of a volt gradient per em. in all. The flow in each would thus be five times less, but since all live tubes are coincidentally active, the total transfusion would be the same. If then a porous diaphragm be regarded as a framework supporting a collection of parallel capillary tubes, the fact that in actual diaphragms, these tubes would not be all straight, continuous, or of uniform calibre, does not alter the principle or affect the average result. According to this view, the only function of the electric current in cataphoresis, is to establish against the resistance encountered, a gradient of potential, and the contact of the liquid with the solid walls, causes force to be exerted upon the electrified particles, while we have seen that neither the thickness of the diaphragm, nor its active surface should affect the rate of transfusion under those conditions; results according to experimental observation.

It was observed by Faraday that water, by contact or friction with other substances, became positively electrified in all the trials to which he subjected it, and its positive nature as an electric was more distinctly characterized than even that of the proverbial cat's skin. This property accounts for the general tendency of aqueous solutions to move from the anode towards the cathode in cataphoresis, down the gradient of electrical potential. Independent observations upon the movements of free particles suspended in glass tubes, filled with liquids, and traversed by electric currents, have supported this view.

It is evident according to the same theory, that for a given diaphragm-substance, aggregation-density and size of capillary tubes, as well as liquid within them, the transfusion per coulomb of electricity, or the rate of transfer per ampère, will be directly proportional to the resistivity of the liquid, since on this will depend the fall of potential in the tubes. The higher this resistance of the liquid, the greater must be the electrical pressure between the surfaces of the diaphragm to maintain the same current strength, and the moving force upon the liquid particles will be augmented in corresponding measure. The resistivity of the liquid is advantageous in, and only in, the diaphragm, for resistance offered to the passage of the current by the liquid masses on each side of the septum, will demand a certain increase in electromotive force to be expended locally in themselves, without any addition to the cataphoric transfer. Consequently the conditions for producing the greatest transfusion with a given number of volt's pressure, would be to place the electrodes as near as possible to the diaphragm, on each side of it, so as to develop almost the entire difference of potential within the capillary tubes, and produce the greatest available current strength. The area of diaphragm surface involved, does not, as we have seen, affect the rate of transfusion, but only the rate of transfusion per unit of area; so that it might still be independently advisable to keep that active surface above a certain limit, lest the density of current in the tubes might develop too much heat or be otherwise detrimental.

Whenever it is desired to produce the greatest possible transfusion of an aqueous solution of any salt, for a specified electrical transfer in coulombs, or amperehours, the solution should be as weak as possible so as to increase its resistivity, since pure water is almost a non-conductor. When on the contrary, the greatest transfer of the dissolved salt, and not of liquid merely, is needed, a very weak solution is evidently no longer indicated. Wiedemann's experiments on solution of salts, showed that roughly, the transfer of liquid

was inversely proportional to the percentage of solid contents. If this were strictly true, the strength of solution would evidently be a matter of indifference, since doubling the solid contents of the solution would just halve the liquid transfer, and leave the transfer of dissolved substance unchanged.

To a first approximation therefore, the strength of solution does not alter the transfer of solid matter per coulomb, and with a given diaphragm and solution everything depends on the strength of current. Strictly speaking, however, this rule is far from being clearly defined, for on the one hand, the conductivity of aqueous solutions of salts generally increases more slowly than the percentage of solid contents, so that on this account it would be advantageous to employ stronger solutions for a maximum transfer of salt per coulomb. On the other hand the effect of increasing the strength of solutions upon their contact electrification, is not yet clearly determined, and the loss in moving force on this consideration might in strong solutions more than offset the gain in greater resistivity per solid content, especially as greater frictional forces, retarding the motion might also be looked for. In the experiments of Freund with earthenware diaphragms, the transfusion increased with moderate densities of solution for CuSO_4 and ZnSO_4 , but on the contrary with $\text{Cu}(\text{NO}_3)_2$ and $\text{Zn}(\text{NO}_3)_2$, weak solutions appeared to possess the greater transfusive constants.

A large and inviting field seems to be here open to experimental research, for although the theory of cataphoresis appears to satisfactorily explain the facts, the measurements that have been yet made with standard diaphragms and solutions seem all too few.

CATAPHORESIS.

By Prof. Edwin J. Houston, Philadelphia, Pa.

By cataphoresis is meant the introduction of drugs or medicaments into the human body by means of the electric current.

Cataphoresis is dependent for its operation on cataphoric action or electric osmose; or, as the latter is, perhaps, more frequently called, electric endosmose.

Cataphoric action, Porret's phenomenon, electric endosmose, electro-capillary phenomenon, electro-vection, and electro-filtration are sometimes used as synonymous terms.

Since cataphoresis or cataphoric action appears to be a modified variety of osmose, it may be well, before inquiring into the peculiarities of electric osmose, briefly to review the principal phenomena of simple or ordinary osmose.

By osmose, as the term is employed in physics, is meant the unequal diffusion or admixture of two liquids of different densities, through the pores of a thin wall or septum, separating the liquids from each other; two currents are thus established, each liquid tending to flow towards and mix with the other. These two currents are unequal in strength: the flow through the pores of the separating wall or septum towards one of the liquids being greater than it is towards the other.

There results, therefore, a tendency to produce a difference of level in the two adjoining liquids; so that, if, as is generally the case, the two liquids are at the same level at the start, there is soon produced a higher level in that liquid towards which the greater flow is directed.

The phenomena of osmose were first studied by means of a bladder filled with a saline solution, and fitted with a vertical glass tube. The bladder was plunged into a vessel filled with pure water. Under these circumstances two currents were established; one through the walls of the bladder from the water outside of it towards the saline solution it contained, and the other from the solution inside the bladder towards the water outside it.

The inequality in the strength of the two currents thus established is shown by the fact that the liquid mounts to a higher level in the tube than in the outer vessel.

The current flowing from outside the bladder inwards was formerly called the endosmotic current, and that flowing from within the bladder outwards, the exosmotic current.

It was soon evident, however, that these terms lacked any real distinctive character, since, if the saline solution be placed in the outer vessel, and the pure water in the bladder, the direction of the endosmotic and exosmotic currents is reversed.

In order to avoid this difficulty it is now generally agreed to call the endosmotic current that current which is directed towards the higher level, and the exosmotic current that current which is directed towards the lower level.

The phenomena are, however, by some designated by the simple term osmosis, or by still others diosmosis.

Becquerel has pointed out the fact that as soon as a difference of level has been produced by the action of osmose, a filtration ensues through the separating wall or diaphragm from the higher towards the lower level.

M. Becquerel, on pp. 50-52 of the *Comptes Rendus*, of July 8, 1872, says, as regards the exosmotic current: "We have now some conception of the possible origin of exosmose; it is due partly to diffusion and partly to the filtration resulting from the pressure of the column of liquid resulting from endosmose. I conceive that it was hardly sensible in the experiments of Graham, who operated with large surfaces affording but little elevation to the liquid columns resulting from the endosmose. Dutrochet was right in saying that exosmose transports more of salts than endosmose, as exosmose results partly from pressure, which causes the liquid to filter through with the salt which it holds in solution."

The phenomena of osmose have been carefully studied by Graham who found them to be intimately associated with those of diffusion, or the admixture of fluids of different densities, without the interposition of permeable septa.

According to Graham the rapidity with which diffusion takes place varies with the following circumstances, viz.:

1. With the chemical composition of the fluids, the action in general being most rapid with acids, next with alkalis, and least of all, with fluid albumen, gelatine, and gums.
2. With the temperature; the higher the temperature the greater the rapidity of action.
3. With the degree of concentration of one of the solutions as compared with that of the other.
4. With the difference between the densities of the two solutions; when this difference is constant, the rapidity of action is greater with weak than with concentrated solutions.

A curious variety of osmotic action has been studied by Graham for which he gave the name of dialysis. By its means he showed how crystallizable substances or crystalloids can be separated from non-crystallizable substances or colloids, by means of a porous membrane or diaphragm.

The separation is effected by means of an apparatus called a dialyser, which consists essentially of a glass dish with a bottom of artificial parchment. The mixture of crystalloids and colloids is placed in the dish which is then floated upon pure water. The crystalloids, the molecules of which are as a rule small, readily pass through the pores of the septum while the colloids, the molecules of which are large, remain behind.

If this be the correct explanation, it would seem that a more rapid separation of such substances by dialysis might be obtained by the aid of centrifugal force, by placing the mixture in a separating centrifugal machine, the walls of which are formed of suitably supported septa, placed in a vessel kept filled with pure water.

It would also be interesting in this connection to try

whether dialytic separation would not be accelerated by the passage of an electric current through the septum.

The phenomena of osmose are influenced by the character of the septum, the nature of the fluid substances as regards their action on such septum, as well as on each other, the physical conditions of the septum, as regards the dimension of the capillary spaces and their freedom from being clogged, and, to an extent as yet undetermined, by the presence of electrical currents that appear invariably to attend such liquid flow.

Discussion.

BOOK REVIEWS.

INTERNATIONAL CLINICS: A QUARTERLY OF CLINICAL LECTURES ON MEDICINE, NEUROLOGY, PEDIATRICS, SURGERY, GENITO-URINARY SURGERY, GYNECOLOGY, OPHTHALMOLOGY, LARYNGOLOGY, OTOTOLOGY, AND DERMATOLOGY. By Professors and Lecturers in the leading Medical Colleges of the United States, Great Britain, and Canada: Edited by JOHN M. KEATING, R.D., Colorado Springs, Col., Fellow of the College of Physicians, Philadelphia, etc., JUDSON DALAND, M.D., Philadelphia, Instructor in Clinical Medicine, and Lecturer on Physical Diagnosis and Symptomatology in the University of Pennsylvania, etc., J. MITCHEL BRUN, M.D., F.R.C.P., London, England, Physician and Lecturer on Therapeutics at the Charing Cross Hospital, D. W. FINLAY, M.D., F.R.C.P., Aberdeen, Scotland, Professor of Practice of Medicine in the University of Aberdeen, etc. Vol. II. Second Series, 1892. Philadelphia. J. B. Lippincott & Co.

The second volume of this series opens with a good portrait and biographical sketch of the late Dr. David Hayes Agnew. The sketch is from the pen of Dr. John Ashurst Jr., whose former association with Dr. Agnew afforded the opportunity for collecting the most interesting notes. The profession will undoubtedly welcome such biographical articles, and they ought to have a most wholesome and stimulating effect on ambitious young men.

The first two lectures in the section on medicine are upon myxœdema by Drs. D. W. Finley and Thos. Oliver. The first is illustrated by two, and the second by four, portraits of typical cases. They record the good effects of jaborandi, which increased the excretion of urea and the injection into the tissues of freshly prepared juice from the thyroid gland of a sheep.

Dropsy is the subject discussed by Dr. P. H. Pye-Smith, of Guy's Hospital, in a much more satisfactory manner than is usually encountered in text-books. He believes that in acute and subacute nephritis there is an inflammation of the principle lymphatic spaces of the body, viz., the loose connective tissue under the skin, of the air vesicles and interlobular connective tissue of the lungs, and of the cavities formed out of the great pleuro-peritoneal lymph-sac.

The various forms of dropsy and their treatment are presented in a thoroughly scholarly manner.

A very rare clinical study is presented by Dr. James Hendrie Lloyd, in the Philadelphia hospital clinic, in a case of sporadic cretinism. A vivid description is given, and two portraits show a front and a profile view of the patient. The supposition that the drinking of water impregnated with lime is responsible for the pathological condition seems hardly tenable. The case under consideration "grew up in Philadelphia on Schuylkill water." Perhaps it would be well for our quaker brothers to boil their Schuylkill water.

General paresis of the insane, the subject of a brief lecture in Vol. I, by Dr. B. Sachs, of New York, is given a short notice here. Six pages are devoted to the etiology, differential diagnosis and treatment. The only dissatisfying feature is, like that of the first lecture, its brevity. Such important subjects cannot be accorded due consideration in so few words.

Dr. Kosw. H. Park, of Buffalo, presents a case illustrative of the continuous immersion management of lacerated and compound fractures. He keeps the wounded limb for two or three days in a hot, weak solution of mercuric chloride, 1-7000, until a healthy granulating surface shows itself, and then applies the ordinary antiseptic dressing and splints.

Dr. Robert Sandby, of Birmingham, occupies 18 pages in the section of surgery with a valuable lecture on stone in the kidney. The subject is discussed from a medical standpoint, and it should naturally have been placed in the section of medicine. Other peculiar ideas of classification are observable in the locating of Dr. James Tyson's lecture on diabetes mellitus in the section on genito-urinary and venereal diseases, and one by Dr. Charles B. Nancrede on stone in the bladder in the section on general surgery.

Dr. G. M. Loefferts' paper on the treatment of acute and chronic pharyngitis is rather disappointing.

Dr. C. H. Burnett contributes an article on some common forms of diseases of the ear in a way that will be useful to general practitioners. He makes a slip of the pen on page 365 that is surprising in such a careful writer. The types make him say: "A foreign body in the middle ear may be a very simple matter: in fact, it is usually a simple matter so long as it is an inanimate foreign body." Of course he did not mean the middle ear, but the external auditory canal.

It is impracticable, with the space at our command, to give more than a general idea of the character of these lectures by forty-one writers on more than sixty-three subjects, filling 373 pages. There are thirty illustrations, many of which are exceptionally beautiful from a medical point of view, besides eighteen figures.

A few of these clinical lectures never would have been suspected of being such, were they not so labeled. They no more bear the impress of a clinical lecture than do the ordinary papers read before medical societies. Their authors seem to be of the opinion that these publications do not call for their best endeavors, and they content themselves with a few pages of indifferent material thrown unmethodically together. The result is that their so-called clinical lectures do not reflect the advanced thought and practice of our day, and they read like excerpts from some of the musty text-books of the past. The editors should prod them with the reminder that these books are expected to represent their best work and the most modern methods of treatment.

As a rule the lectures are studiously prepared, represent mature experience and are worthy of a place in such a collection. They cannot help but prove exceedingly useful to the mass of the profession—the general practitioners.

A TEXT-BOOK OF THE PRINCIPLES AND PRACTICE OF MEDICINE, for the use of medical students and practitioners. By HENRY M. LYMAN, A.M., M.D., Professor of the Principles and Practice of Medicine in Rush Medical College. Chicago. One hundred and seventy illustrations. Philadelphia: Lea Brothers & Co. 1892.

We may well ask ourselves, in these book-making days, what are the proper requisites of a text-book. Not many years ago a text-book was supposed to, and many did contain all that was then known regarding a particular department of medicine. Increased knowledge in every branch of medicine has served to emphasize the wide discrepancy existing between the actual knowledge on any one subject and that contained within the covers of any one volume. To meet this defect we have had the various encyclopædias, systems, etc., in this country and the ponderous many-volumed "hand-books" so much favored by our German confrères. With this wealth of knowledge we must judge the capacity of a text-book writer to-day, more by what he leaves

out than by what he puts into his work. Not only has widening knowledge called for a modification of our text-books but methods of teaching have so changed within a few years that of necessity books for the use of undergraduates must be put together on somewhat different lines. The lengthening of professional curricula, the adoption of a graded system, lessening of didactic with increase in recitation work all call for a modification of our text-books. With these preliminary considerations we may ask what characteristics the text-book of to-day should have. It should not be written for the purpose of exploiting the particular news of the writer, especially if he thinks it necessary to support them by argument. It should be a true reflex of the most generally accepted views of the profession. It need not be original. Indeed the days of "originality" in text-book making have long since passed. It should be a symmetrical survey of the entire field which it purports to cover and it should be written in clear, terse English.

With these requisites in mind we may proceed to the examination of this work upon these lines.

The writer has wisely departed from the divisions adopted in our older works on practice, at the same time he has retained a brief statement of the general principles of pathology to serve as an introduction to the special topics. This first part includes some seventy-six pages devoted to a consideration of the following topics: growth and development, regressive disturbance of nutrition, progressive disturbances of nutrition, tumors, disorders induced by disturbance of circulation, contagion and infective diseases, inflammation, fever. It is needless to say that none of these subjects are handled exhaustively, and yet they form an excellent introduction to the special pathology which follows.

We are introduced to special diseases by a consideration of those disorders caused by microscopic animal parasites, which include the intestinal worms, then follow the protozoa, malarial fever and dysentery. Chapter five opens that portion of the work dealing with disorders caused by vegetable parasites, these include actinomycosis, malignant pustule, typhoid fever, influenza, diphtheria, tetanus, tuberculosis, glanders, syphilis, cerebro-spinal meningitis, erysipelas, mumps, rotheln, measles, scarlet-fever, whooping-cough, dengue, relapsing fever, cholera, typhus plague, yellow fever, chicken-pox, small-pox, and hydrophobia. This portion of the work closes with a chapter on the general management of the infective diseases.

Part three is devoted to a consideration of the diseases of the alimentary canal. Part four, to the liver, pancreas, peritoneum and spleen. This is followed by diseases of the respiratory organs and organs of circulation.

Part seven and eight are devoted to a consideration of the diseases of the blood and nutrition. Diseases of the kidneys and genito-urinary organs are considered in part nine. The remaining portion of the work is devoted to a consideration of the disorders of the nervous system.

A careful perusal of the work will convince the practical teacher that the writer has produced a valuable text-book for undergraduates. It is at once apparent that the writer has mastered the art of literary digestion, and while the best work of the great masters in medicine are presented, yet each chapter bears the stamp of the writer's individual experience as a practitioner. It is, however, from the standpoint of the practical teacher that the value of the work is best shown. Its condensed practical and slightly dogmatic style render it of especial service to the beginner in internal medicine.

BILLROTH and other German surgeons report success in the use of celluloid to replace portions of the skull which have been loosened by injury, necessitating their removal.

THE
Journal of the American Medical Association
PUBLISHED WEEKLY.

SUBSCRIPTION PRICE, INCLUDING POSTAGE:
PER ANNUM, IN ADVANCE \$5.00
SINGLE COPIES 10 CENTS.

Subscriptions may begin at any time and be sent to
THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION,
No. 68 WABASH AVE., CHICAGO, ILLINOIS.

All members of the Association should send their Annual Dues to the
Treasurer, RICHARD J. DUNGLISON, M.D., Lock Box 1274, Philadelphia, Pa.

MEMBERSHIP IN THE AMERICAN MEDICAL ASSOCIATION.

This is obtainable, at any time, by a member of any State or local Medical Society which is entitled to send delegates to the Association. All that is necessary is for the applicant to write to the Treasurer of the Association, Dr. Richard J. Dunglison, Lock Box 1274, Philadelphia, Pa., sending him a certificate or statement that he is in good standing in his own Society, signed by the President and Secretary of said Society, with five dollars for annual dues and subscription for THE JOURNAL. Attendance as a delegate at an annual meeting of the Association is not necessary to obtain membership. On receipt of the above amount the weekly JOURNAL of the Association will be forwarded regularly.

SATURDAY, FEBRUARY 4, 1893.

THE INDEX CATALOGUE.

Our readers will regret to learn that the comparing false economists in the House of Representatives, have stricken from the Sundry Civil Appropriation bill, the usual appropriation for the continuation of the great Index Catalogue of the Library of the Surgeon-General of the Army.

No scientific work could possibly be of more value to the medical profession than this, and we appeal to physicians everywhere to use their utmost efforts to have this appropriation restored.

The work which has received the highest commendation from scholars and librarians throughout the world is now near completion, and it would be a source of infinite regret, if the work should fail of completion through parsimonious legislation.

We call on our Indiana brethren, to arouse the Honorable Chairman of the Appropriations Committee, JUDGE HOLMAN, to a realization of the great wrong he is perhaps unwittingly inflicting on the medical profession, by his stoppage of the book.

THE ETIOLOGY OF CARCINOMA.

Carcinoma is the most important of all tumors on account of its frequency and its malignancy. Its study from various aspects has consequently produced the bulkiest literature, and to-day the unsolved question of the etiology of this tumor is engaging the attention of investigators the world over. The ancient theory that carcinoma was the local manifestation of a general dyscrasia due to the excess in the body of a certain humor, is now of historical interest only: the humoral theory gave way to the belief that carcinoma was primarily of local origin, becoming general later in its course, and it is unnecessary at

this time to enumerate the many clinical and anatomical facts and reasons which have led to the general acceptance of belief in the primarily local origin of carcinoma. In order to explain the origin in loco of tumors in general, COHNHEIM advanced his theory of misplaced remnants of embryonal tissue which may begin to proliferate in a remarkable manner at any time and he defines carcinoma as due to a typical multiplication in an embryonal matrix of epithelial cells with an intrinsic tendency to invade surrounding tissues irrespective of origin and of structure. In this age of biological investigation the misplaced embryonal remnant theory did not long remain unquestioned and undisputed; while it was a very ingenious and broad explanation of the origin of tumors in general. Yet its shortcomings were too many and too serious to pass without notice. Thus it was soon pointed out that it was a purely speculative theory, built upon probabilities; no one was able to demonstrate an actual misplaced embryonal matrix of epithelial cells, for instance, from which a carcinoma might develop; again, embryonal folds, fragments of which might go astray, exist at one time in all multicellular organisms, but nothing has ever been found in the inferior animals resembling a carcinoma although they are stated to be quite frequently subject to various forms of new growths of demonstrative parasitic origin. If all that is essential for a carcinoma to develop is a misplaced fragment of an embryonal fold, it is not clear why invertebrates should be so invariably exempt from such growths as they appear to be. But the supposition that carcinoma might be of parasitic origin was quite uniformly rejected partly because the disease never appeared in endemic or epidemic form, partly because transmission from one individual to another did not occur, and also because the numerous inoculation experiments in animals all appeared to be fruitless. In the meantime, clinical and anatomical facts with an unmistakable tendency towards strengthening the parasitic origin theory began to accumulate. The statistical study of carcinoma showed conclusively that various forms of local irritation played quite a part in the etiology. Quite a number of authentic cases of secondary implantation carcinoma were observed, as, for instance, flat-celled carcinoma of the œsophagus ulcerating and giving rise by implantation to similar tumors upon the mucous membrane of the stomach, or, after perforating the gullet, upon the mucous lining of the deeper bronchi. Then HANA, HAHN, WERR and others finally succeeded in inoculating carcinoma from man to animals, from animal to animal, and from one part of the body of a carcinomatous patient to another. The discoveries of KOEN led to the search for bacteria in carcinoma by the cultivation method especially, but this was soon practically

abandoned, in part because it became apparent that the various forms of pyogenic and saprophytic bacteria were present solely by accident, but principally because the application of the refined micro-technique of FLEMING and his followers to the study of carcinoma led almost immediately to the demonstration of bodies which were interpreted as protozoic parasites and during the last few years a whole series of publications have appeared embodying the results reached by ardent investigators in many lands in their efforts to establish animal parasites as the primary cause of carcinoma and other tumors. In connection with this it is very interesting to note that VIRCHOW in 1851 described peculiar cavities in the interior of cancer cells which he considered were formed by endogenous cell division and in this opinion WAGNER coincided. Since 1889 continuous refinement and improvement in technique has aided in the investigation and study of carcinomas for animal parasites, but it was soon shown that in the multitude of new micro-technical methods at command lay possibilities of grave error; intra and intercellular bodies have been described and figured and interpreted as veritable parasites, which subsequent critical re-investigation showed to be in all reasonable probability various forms of cell and nuclear degeneration, or cell inclusions of dead blood corpuscles, or artificial products of the particular staining method employed. The parasites of the earlier investigators in this line, such as NEISSER, DAVIS, WICKHAM, THOMA, SYÖBRING, and many others, were thought by BONEL, KLEBS, RIBBERT, SCHUTZ, WELCH, MACALLUM, and many more to be "pseudo-parasites," including under this term the degeneration products, nuclear fragments, foreign substances, etc. Some investigators, however, believe that among the bodies described there might possibly exist true parasites, and while the quite recent demonstrations of SOUDAKENITCH, STROEBE, PODWYSSOZKI and SAWTCHENKO, RUFFER and WALKER have been subjected to considerable criticism, yet they have received confirmation and approval from numerous sources, and it was even thought that some of these observers had described a certain number of missing stages in the development of the alleged carcinoma parasite. Thus STROEBE, PODWYSSOZKI and SAWTCHENKO claimed that they had discovered falciform bodies in several instances of carcinoma. This claim has already been attacked by METSCHNEKOFF, and we print elsewhere in this issue of THE JOURNAL a communication presented at the last meeting of the Pathological Section of the Chicago Academy of Sciences, by PROFESSOR OHLMACHER, in which it can be seen that he shows quite conclusively that the falciform and other bodies of PODWYSSOZKI and his followers are artificial products due to the use of safranin and iodine or safranin and picric acid in the staining

process. OHLMACHER's work is of importance not only because it annihilates the claims of the investigators mentioned, but also because it pointedly indicates the liability to form wrong conclusions from the appearances produced by the use of some of the rapidly multiplying, new micro-technical procedures and because it shows that safranin and iodine, and safranin and picric acid alcohol must be regarded as unsafe and unreliable combinations. Our knowledge of ultimate nuclear and cellular chemistry and the chemical and physical changes induced in protoplasm by the numerous and complex fixing and staining agents now in vogue, is so extremely limited that it behooves the investigators working to demonstrate the obscure etiological agent in carcinoma and other tumors by means of micro-technical methods to formulate their conclusions only after the most mature deliberation, and after the greatest care has been exercised to eliminate all possible sources of error. Indeed it would seem that the fate of SJÖBRING's parasite at the hands of RIBBERT, of RUSSELL's organisms at the hands of SHATTOCK and BALLANCE, and of PODWYSSOZKI's and STROEBE's falciform and other stages at the hands of OHLMACHER would warn investigators in this field from such reckless announcement of positive results as has hitherto been the case and particularly should this warning be heeded because there is as yet but very little opportunity if any, for control experiments in staining with known pathogenic sporozoa. It is not improbable that among the many forms and bodies demonstrated in carcinoma actual parasites may be found and investigators generally seem to lean to the view that they will come to belong to the coccidia, the same protozoan class which furnishes the organisms in malaria, in coccidiosis of the rabbit's liver, in epithelioma contagiosum of chickens and pigeons, in psorospermic cysts in man, etc., but it really appears that the limit of what can be learned from simple microscopic examination of neoplasms has been reached. The biology of the coccidia must be still much further elucidated in order that a safe foundation for their study as pathogenic agents can be obtained; they must be cultivated artificially in order to enable us to deal with them with the same scientific accuracy as with bacteria; and in the instance of carcinoma it would seem that experimentation would have to be directly along entirely new paths because it has been fully shown that it is only with the very greatest difficulty, and in some exceptional instances that carcinoma can be successfully inoculated into animals, and this would indicate that animals are very largely, as a general rule, immune to the specific cause of carcinoma in the form in which he exists in the growing tumor; whether the organisms of carcinoma, if found outside of the body, will then be demonstrated to be pathogenic in

animals belongs to the problems that future investigation must solve before this obscure chapter in pathology can be fully elucidated.

REMOVAL OF THE OVARIES AS A THERAPEUTIC MEASURE IN PUBLIC INSTITUTIONS FOR THE INSANE.

The State Board of Public Charities of Pennsylvania has recently been induced to take action upon the sexual mutilation of insane women, for therapeutic purposes, which has lately been introduced and practiced in one of the State institutions for the insane. The attention of the Board was directly called to this subject by its Committee on Lunacy, which made a special report upon the subject of "Removal of the Ovaries as a Cure for Insanity." This was accompanied by a statement of opinion as to the propriety of the operation, from the legal member of the board. As it is precisely the legal aspect of this subject which hitherto has been, apparently, overlooked, we will give this brief opinion in full, after making some abstracts from the report of the Lunacy Committee above referred to, a copy of which was directed to be sent, with the unanimous approval of the Board of Public Charities, to the Trustees of the State Hospital for the Insane, at Norristown, Pa. The following note appears upon the office copy of the report:

This action was taken upon a report of the committee's secretary, on Oct. 29, 1892, that four insane cases were seen by him in a separate annex ward of the Norristown Hospital which were just rallying from the operation of oöphorectomy, performed there by Dr. Joseph Price, in consultation with Dr. Alice Bennett, with the consent of the Hospital Trustees.

It was further intimated that fifty cases had been already marked for operation, by this method, in the wards of the same institution.

The committee's report states that modern advances in abdominal surgery have greatly stimulated operations within the pelvic cavity, and that surgeons and gynecologists are now enabled to remove the uterus or ovaries with facility and relative safety. It also refers to the fact that the operation of oöphorectomy has been performed, both in this country and Europe, in cases of mental disease thought to originate in, or be maintained by, diseased or disordered states of these organs, in the hope that the mental and physical diseases would be cured. In this country, these operations upon lunatics have been, with few exceptions, confined to private practice, or to general hospitals; but only very recently the trustees of the State Hospital for the Insane, at Norristown, have set apart a separate building for such purpose, and several insane patients there have already had their ovaries extirpated. In general practice, these operations have been very frequently performed for the relief or cure of many forms of uterine and ovarian disease and

functional disorder, including those nervous and mental maladies which appear to depend upon, or to be otherwise aggravated by, such local conditions. The increasing frequency of these experimental mutilations and their doubtful ultimate success, have caused conservative medical opinion to halt and to dispassionately discuss the whole subject, and to inquire not only into the immediate, but also the future results of such operations. The medical literature and statistics of the subject are relatively scanty, compared with the large number of operations performed, which is, in part, due to the difficulty of keeping the subjects under observation for years afterward, as it is absolutely necessary to do in order to arrive at the positive results. Many insane, epileptic, and hystero-epileptic women, who have been thus mutilated, have subsequently found their way into hospitals for the insane, and are heard of no more. This is also the case in many instances where insanity has *resulted* from this operation, which is by no means an unusual occurrence. Those whose duty it is to care for the insane in institutions are familiar with these ultimate failures, whose last condition is worse than the first. As a rule, to which there are but few exceptions, medical superintendents of hospitals for the insane now regard with disfavor the castration of women as a cure for mental disorders, even in those cases where there appears to be some causative or irritative connection, or sympathy, between the disordered brain and the ovaries. From whatever physical disorder the insanity may have developed originally, or may be aggravated by, the centers of the brain and spinal cord undoubtedly receive, early in the pathological change, such a profound impression as will persist long after the removal of the alleged offending organs.

Extirpation of the ovaries in lunatics is only practiced as a last resort, after every other expedient has been unsuccessfully tried, and in such cases the brain and cord have doubtless become permanently altered, or impelled to disordered action, and functional, if not organic, deterioration has taken place. It is to these nervous centers, diseased or disturbed as the case may be, that we must look in such cases for the real focus, or irritating influence; and we learn, by the abundant examples of failure, not to hope for the relief of a central lesion by the removal of distant organs, even though these may *appear* to periodically aggravate the mental condition. The ovaries of insane women, it is true, sometimes present such gross forms of disease as to absolutely demand extirpation, and the Committee makes no objection to the operation, where gross lesions exist, or when life is obviously in danger. Allusion is not here made to such exceptional cases; but it has been lately recommended and practiced where the mental disorder only

appear) to be more or less influenced by the generative apparatus. "In such cases," says the Committee, "in our opinion, this operation is not justifiable. As a general rule, to which there must be an occasional exception, we are forced to regard experimental operations upon insane women, for the purpose of restoring their reason, with disfavor, and to consider it unwarrantable and indefensible. As to the practice of such operations in our State hospitals, it is a matter of grave doubt whether a relative or guardian of an insane woman has the moral or legal right to give consent to the unsexing of the insane person, whose power to give or withhold consent is temporarily or permanently in abeyance. What redress would such a person have, if, in recovering her reason, she objected to her mutilated condition?" This, at once, brings up the question as to the personal rights of the insane, and an opinion being requested from the legal member of the Committee, MR. THOMAS W. BARLOW, he wrote as follows:

I am of opinion that the operation of oöphorectomy upon insane women, as recently practiced and as proposed to be practiced in one of our State Hospitals for the Insane, unless necessary to save life, is not only illegal, but, in view of its experimental character, it is brutal and inhuman, and not excusable on any reasonable ground. To quote a learned medical opinion: "To operate on organs not diseased for the relief of undefinable symptoms, hysterical symptoms, and epileptic symptoms, is unwarranted." A lunatic cannot give a legal consent to the performance of an experimental operation. Nor can her relatives legally give such a consent in her behalf, and therefore a surgeon practicing oöphorectomy upon an insane woman, unless to save life, takes a great risk. He may take the risk of a criminal prosecution.

It is regarded by the best medical authorities as a useless and improper expedient for the cure or relief of insanity, and the operation of oöphorectomy in a public hospital upon indigent insane women must be regarded as largely experimental, and for that reason is bound to reflect upon hospital authorities now boasting of modern humane methods.

The Committee on Lunacy of the Board of Public Charities has full authority under existing statutes to prohibit the performance of such operations. It is the duty of this committee to "regulate the treatment of the insane," and this, whether it involves the restraint used, the character of food furnished, or the medical and surgical methods exercised in their behalf. The zeal of the gynecologist is being carried to an unusual extent when it proposes to use a State Hospital for the Insane as an experimental station, where lunatic women are to be subjected to doubtful operations for supposed cures. If it is to be permitted in some forty or fifty cases, as proposed, it might be well to practice the experiment upon the entire female lunatic population, so that the gynecologist may have the large opportunity he doubtless craves to see just what would happen. At the expense of some lives, the continued and aggravated insanity of most of his subjects, with a few supposed cures and improvements, he could read his conclusions learnedly to his gynecological brethren, with the resultant added forward movement up his ladder of fame.

Dr. Wharton Sinkler, in a paper recently published in the *University Medical Magazine*, and which he read before the Association of American Physicians, in September, 1891, says, "as to the benefits derived by patients who have undergone oöphorectomy for insanity, epilepsy, hysteria, and the different forms of neuralgia and nervous troubles, the opinion of different observers varies to such an extent that we might believe that totally different beings and conditions were considered. Certain writers give the most glowing accounts of the benefit obtained by almost every patient operated upon, while others regard the result as being always so unfavorable that the operation is never justifiable."

All of which proves that the operation is wholly experimental, of great uncertainty, and of very doubtful expediency.

This is the operation that it is proposed to make upon a large number of indigent insane women.

As a member of the State Board of Charities, I deem it to be my duty to protest against such a proceeding, and, as the legal member of the Committee on Lunacy, I pronounce it to be illegal and unjustifiable.

This, to the gynecologists may seem like an unwarrantable interference with questions which they alone are competent to decide. When it is remembered that the report is from the pen of the distinguished chairman of the Lunacy Committee, DR. THOMAS G. MORTON, who has been for many years upon the surgical staff of the Pennsylvania Hospital, the character of the opposition to this innovation in the treatment of insanity may be appreciated. If this were not sufficient, however, the opinion of MR. BARLOW should make future operators cautious before assuming the legal responsibility of castrating helpless and mentally afflicted patients in public institutions, who, even if they should recover their reason, might properly object to their mutilated condition.

Some of the pioneers in gynecology are also protesting against the abuses of oöphorectomy. PROFESSOR GOODELL in the main agrees with DR. MORTON in the points made, and declares that "the whole business of removing the ovaries has been horribly abused;" and "was glad that DR. MORTON had taken such a firm stand in this matter." DR. JOHN B. CHAPIN, Superintendent of the Pennsylvania Hospital for the Insane, and President of the Association of Superintendents of American Hospitals for the Insane, expresses much satisfaction and gratification which he experienced on reading the preceding paper. He thanks the Committee and State Board for coming forward to exercise the powers of their office to save the hospitals and the profession from what threatens to become a scandalous proceeding. "To erect a hospital, or propose one, where women were to be castrated in companies of fifties, with the hope of a cure of insanity, would be generally regarded, in the present state of meagre knowledge upon the subject, as revolting." . . . "In a case in England, DR. ROBERT BARNES declined to perform the operation without the consent of the Commissioners of Lunacy." . . . "Hospitals for the insane might easily lose a portion of the slender hold they now have upon the public and friends of patients, if it were understood that the patients were subjected to experimental operations of hazardous nature."

On the other hand, DR. JOSEPH PRICE has published a letter, denying either the brutality of the operation, or that it is, in selected cases, experimental in its nature. He construes it all as a personal attack upon DR. ALICE BENNETT, and as intended, indirectly, as a condemnation of her course in this matter. This appears, to an impartial out-

sider, as an attempt to side-track the main question, and to belittle the important interests under consideration. Dr. MORRIS says that insanity is not a disease of the ovaries, nor of any other part of the body which is accessible to the surgeon's knife, and Mr. BARLOW says that legal consent of the patient for such mutilation can not be obtained.

DOMESTIC CORRESPONDENCE.

Government Check.

We hardly ever go to the postoffice without finding a letter or a circular from some firm who is anxious to instruct us in the practice of medicine. Each letter has advice as to what remedy is best to give in certain maladies, and we are told that these remedies are giving wonderful results and the greatest satisfaction. If all we are told in these circulars and letters is true, the medical schools had just as well close up shop and quit business. I am confident that I have received letters describing the treatment of nearly all, if not quite all, the diseases that the human family is subject to, and these letters tell us how to cure consumption, cancer, and other maladies, that we had been taught were incurable. It may seem that we are ungrateful if we do not appreciate all this kindness, and I must not forget to say that most of these firms propose to furnish us with a sample bottle of their medicine, with directions free, if we will only pay express charges. Think of it, a remedy for any disease, free of charge.

Now, all I have to do (if these firms are telling the truth) is to find the cases and give the medicine. They will do the rest. I have always thought that we lived in a great and glorious country, and that people were liberal hearted to some excess, but I had not believed before that there was a class so liberal hearted as to give away such valuable information and such grand remedies. I had thought that when man learned to cure all manner of diseases they would first make a fortune out of their wonderful discoveries, and then give the formula to less favored individuals, but not so. To-day, when a firm learns that a certain compound will cure a certain malady; they make up large quantities of it, bottle it up nicely, learn the names of all the poor country doctors, and write them all about the remedy, where it was discovered, the great number of people who use it, and propose to give each doctor a bottle, who, if he is not sick himself, can give his bottle (or if he is not liberal, sell it) to some one who is sick, and thereby increase his reputation and wealth. All this liberality makes us sorry that we had lost so much time and money in trying to learn something about disease. If I had only waited until this year and put out my shingle, all I would have had to do, would be to read the mail matter that these liberal firms send me, and write them word to send me the medicine. (The patients themselves could have told me what was the matter with them.) Just think of it, nothing to do but answer letters. A few stamps and a few sheets of paper would be all the capital I would have needed to start with. I could have made money from the start. Most of my remedies would cost me twenty-five cents (express charges) and I could sell them for a dollar, and in a few months I could go it wholesale and soon be a Gould—but being an old fogey, I let the medical schools, instrument maker and drug stores “do me up,” now I am a century behind, and men are *giving* the profession all they need. Woe, is to me and my fellow practitioners, who are so far behind, so foolhardy and selfish as not to accept all these good things.

Now, Mr. Editor, I am sick and tired of these kind of gentlemen. The last one who wrote me said that he did not presume to dictate to me what remedy to use in any disease, but he had a wonderful remedy for young girls who were tardy about menstruating. I would love to know how to get rid of these kind of gents. Advertising them in any way, would be the thing they want. If you can suggest any remedy through *THE JOURNAL*, you will be a benefactor. Doubtless you are bored to some extent with these same kind of gentlemen. If no other plan will do, I would suggest that at the next meeting of the Association, a resolution be passed condemning the prescribing of any advertised remedy, whose formula is not known to the prescriber. These gentlemen need a little of their cheek knocked off of them, and if the Association will condemn their practices they will probably reform. Very respectfully,

Oran, Mo.

W. D. HOWLE.

“Collateral Associations.”

To the Editor of the *JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION*:

Sir:—Referring to the editorial on “Collateral Associations” in your issue of January 21, I may be permitted to remind you that for several years I have been advocating the very subject of your writing—the encouragement and facilitation by the American Medical Association of the meeting of these collateral organizations in connection with its own annual session. You say these “societies would very greatly enhance their own usefulness and prosperity by arranging their place of meeting to correspond with the same place, and either the week before, or after, that of the American Medical Association.” But very few men in the profession can afford to sacrifice the time or incur the expense of two continuous weeks of attendance as you propose. The American Academy of Medicine has tried the experiment of meeting on the Saturday and Monday immediately preceding the meeting of the American Medical Association, but the intervening Sunday has shown the very decided objection to this course. To attempt to meet on the Saturday and Monday succeeding the adjournment of the American Medical Association would prove even more objectionable, since under present circumstances a large proportion of the members of the Association do not remain for the last day of the session on Friday.

The arrangement which I have advocated, and which I still believe the only one practicable, is for the Association to hold its sessions on Wednesday, Thursday, Friday and Saturday, leaving Monday and Tuesday not only for these collateral associations, but for its own standing committees—the Board of Trustees, the Committee on General Business, the Judicial Council and the Executive Committees of the Sections to prepare, with proper deliberation, the work which can now only be done hastily and in a makeshift fashion, during the intervals of the general sessions or at the sacrifice of attendance upon the latter or the Section meetings. A further considerable advantage will be the opportunity for preliminary registration, so that upon the formal opening of the session, if on Wednesday, the heretofore impossible spectacle may be witnessed of the assembly of the great body of the Association prepared to listen to the address of the President. Moreover, it has not unfrequently occurred that important questions have presented themselves on which delegates, who alone are entitled to vote and then only after having been duly registered, have not hesitated to act, although they have not yet been able to register—an unpardonable inconsistency in a body so tenaciously insistent upon the strictest conventionality. I am confident, were the experiment tried, that the assignment of Monday and Tuesday for all work

foreign to the general sessions of the Association, would so expedite its business that Wednesday, Thursday and Friday would actually suffice for the general addresses and Section papers and discussions, and leave little for Saturday beyond the formality of adjournment.

The collateral associations you enumerate—the American Academy of Medicine, the American Medical College Association, the American Medical Temperance Association, the American Microscopical Association, the Association of Military Surgeons of the National Guard of the United States, the Association of Railway Surgeons, and others, as the American Climatological Association, the American Health Resort Association, the Association of Acting Assistant Surgeons, etc., are in no sense antagonistic to the American Medical Association, while their purposes are such as do not come within the scope of, or permit their absorption by, any of the eleven Sections of that body. You state: "It is no exaggeration to say that nine-tenths of the members of these organizations" (referring to only two of them), belong to the American Medical Association. Hence, it is easy to see how desirable it is to them that they may be able to save time and money by such a concentration of meetings as suggested."

The certain result would be to transfer their entire membership after their adjournment on Tuesday night, to the American Medical Association on its meeting the following (Wednesday) morning. The danger now is that the community of interest among the members of these several minor bodies may prove so attractive that they may prefer to attend them to the neglect of the older body, or, as in 1889, when the American Climatological Association met on the Monday and Tuesday of the week of the American Medical Association's meeting, members shall be compelled to elect whether to sacrifice attendance upon the last day of the one or the first day of the other, both thus suffering a loss, which need not have occurred had the American Medical Association begun its proceedings on Wednesday.

I have, however, so often presented these views in the Association that I am quite willing to leave the solution of the question to the course of events. Those who earnestly wish to see the American Medical Association become greater in its membership and influence, cannot but agree with your statement respecting the "focalization" of the collateral National medical organizations that "in a unification of work and purposes will be found the greatest good to the greatest number."

ALBERT L. GIBON, M.D.

145 E. 21st St., New York City.

Asepsable or Aseptizable.

To the Editor of the JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION:

In a recent issue of THE JOURNAL appeared a note from a firm of instrument manufacturers, asking for a word to describe the character of instruments which were susceptible of being rendered aseptic, in order to conform to the requirements of modern surgery. I would suggest "Aseptizable" in preference to "Asepsable," because the verb *aseptiser* is already used in French surgical books and "aseptisable" or "aseptizable" in English would be in harmony with continental usage, and therefore should be preferred to the entirely new word. Moreover, we shall soon be employing the verb "aseptize" to describe what is to be done to the instruments before operating and perhaps also the noun "aseptization" to express the result of the procedure.

MISCELLANY.

THE INTERNATIONAL CONGRESS OF CHARITIES, CORRECTION AND PHILANTHROPY, JUNE 12-18, 1893.—*Sub-Section on the Training of Nurses.*—In accordance with the general program of the Section, Nurses will take part in the general session and in two sectional meetings, and will hold in addition three separate meetings—June 13, 14, and 17.

For these three separate meetings papers on subjects of special interest to Nurses will be prepared and discussed. The following are suggested as subjects to select from:

Training Schools in England and America. Proper Organization of Training Schools. Nursing in Infirmarys and Almshouses. Nursing of the Insane. Obstetric Nursing. Nursing of Infectious Diseases. Nursing in Sanatoriums and Home Hospitals. Private Nursing. Nursing by Religious Orders. Work of Graduate Nurses.

All communications relating to this portion of the work of the Section should be addressed to

MISS ISABEL A. HAMPTON, *Chairman*,
The Johns Hopkins Hospital,
Baltimore, Md.

AMERICAN SURGICAL ASSOCIATION.—The preliminary program for the meeting to be held at Buffalo, N. Y., May 30, 31, and June 1, 1893, is as follows:

President's Address.

1. The Modern Treatment of Compound Fractures. By Dr. Nicholas Senn, Chicago. Discussion by Drs Roswell Park and F. S. Dennis.

2. Hypertrophies and Degenerations of Cicatrices and Cicatricial Tissue. By Dr. J. Collins Warren, Boston. Discussion by Drs. C. H. Mastin, G. R. Fowler and W. H. Carmalt.

3. Surgery of the Gall Bladder. By Dr. M. H. Richardson, Boston. Discussion by Drs. J. Ewing Mears, A. Vander Veer, W. H. Carmalt, and Theo. A. McGraw.

4. Surgery of the Rectum. By Dr. A. G. Gerster, New York. Discussion by Drs. L. S. Pilcher, H. H. Mudd, and L. McLane Tiffany.

5. Surgical Treatment of Cervical, Thoracic and Abdominal Aneurism. By Dr. C. B. Nancrede, Ann Arbor. Discussion by

6. Surgery of the Prostate. By Dr. J. William White, Philadelphia. Discussion by Drs. Hunter McGuire, T. F. Prewitt, R. F. Weir, and F. H. Gerrish.

7. Treatment of Carbuncle. By Dr. F. Lange, New York. Discussion by Drs. Robert Abbe, J. B. Roberts, and J. S. Wight.

In addition to the above specially selected subjects, the following papers have been offered:

1. Unreduced Dislocations of the Astragalus. By Dr. Stephen Smith, New York.

Fellows who propose to present volunteer papers are requested to send to either of the undersigned the titles of their proposed papers as soon as possible, in order that they may be properly classified and arranged for the final program.

Fellows are also requested to notify the Chairman of the Committee whether they will take part in the discussion upon any of the special subjects given in the above list.

NICHOLAS SENN, *President*,
J. R. WEIST, *Secretary*,
J. EWING MEARS, *Recorder*,
F. S. DENNIS,
JOHN S. BILLINGS,
Business Committee.

OFFICIAL LIST OF CHANGES in the Stations and Duties of Officers Serving in the Medical Department, U. S. Army, from January 21, 1893, to January 27, 1893.

Capt. Freeman V. Walker, Asst. Surgeon U. S. A., is granted leave of absence for four months, on surgeon's certificate of disability, on condition that he spend the period of leave as a patient in the Army and Navy General Hospital, Hot Springs, Ark.

OFFICIAL LIST OF CHANGES in the Medical Corps of the U. S. Navy, for the Week Ending January 28, 1893.

P. A. Surgeon W. F. Arnold, detached from U. S. training ship "Richmond," and granted three weeks leave of absence.

ORIGINAL ARTICLES.

A CONSIDERATION OF SOME OF THE OPERATIVE MEASURES EMPLOYED IN GYNECOLOGY.

The President's Address, delivered at the Annual Meeting of the Gynecological Society of Boston, January 12, 1893

BY AUGUSTUS P. CLARKE, A.M., M.D.,
OF CAMBRIDGE, MASS.

In looking over the records of our work of the past year for a theme for the President's address, many subjects present themselves as worthy of consideration. For the cure or for the relief of many affections which occur in the pelvic and other organs, abdominal section still holds a prominent rank among the procedures to be adopted. It is gratifying to learn that there has been an increasing success attending operations necessitating abdominal section; this has been shown not only in the cases in which strict antiseptic precautions have been instituted, but also in a large class of cases in which no other precautions were enjoined than the maintenance of a good degree of cleanliness on the part of the operator.

In the abdomen and pelvis there not unfrequently occur diseases or lesions which are not amenable to surgical procedures. Malignant disease of the internal organs, or adhesions of the ileum or other portion of the small intestine to the sigmoid flexure or to other parts of the colon may offer insurmountable obstacles to success. So also may adhesions that follow the presence of hernia of long standing. An operation for relief of any of these may fail or be attended with much inconvenience. Hæmorrhage from the presence of large plexuses of veins, or hæmorrhage as the effect of violence to the vascular tissues abnormally distributed to the deeper organs and structures may be the cause of serious if not of fatal results. In dealing with cases in which any such adverse elements have entered, there can be no doubt that the recent advances attained in gynecic surgery are continually offering greater immunity against the occurrence of these mishaps. It hardly seems too much to hope that ere long, by further development of the latent possibilities of our art, we shall be enabled to achieve much more in this direction. The application of aseptic animal sutures by a method recently carried out is often a most effectual precaution against the occurrence of hæmorrhage. The continuous suture performed somewhat after the manner of the stitch of the cordwainer may be employed with most excellent results. Aseptic animal sutures are unquestionably the most effectual for such service. Antiseptic catgut ligatures were employed by Mr. Lister in 1868, and were used principally for the deligation of arteries. Before this date, however, Mr. Lister had used other kinds of antiseptic ligatures. After he had tied the artery

or vessel the ends of the ligature were cut short. The ligature was then left to be disposed of by absorption or otherwise. Surgeons at that time had much hesitancy in adopting their use, for their employment was sometimes attended with untoward symptoms. In one case¹ at least the catgut underwent a change; it altered, softened and disintegrated by the heat and moisture of the living tissues, and the clot formed at the point where the ligature was applied was forced onward into the cerebral arteries, causing embolism and fatal results. An early published record we have of the employment of the kangaroo tendon for surgical purposes is that by Dr. T. M. Girdlestone,² of Melbourne, Australia, in 1877. Dr. Girdlestone exhibited to the Medical Society of Victoria some carbolized kangaroo tendon prepared for use in lieu of catgut. They had been preserved in carbolic oil after the manner recommended by Professor Lister. In Melbourne at an early date they seem to have been used in ovariectomy, vesico-vaginal fistula, in hernia, varicocele and in other plastic operations. In 1878 Mr. Callender,³ the President of the Clinical Society of London, showed some specimens of tendon ligature which had been obtained from Dr. Girdlestone through the kindness of Mr. Hulme, of Guildford. The tendons were from the tail of the kangaroo, and were considered preferable to the catgut ligature in their angular form, allowing of their being tied securely, the knot not slipping, and their solution not taking place so rapidly as the catgut. In Melbourne before this date the tendon was much used for sutures, but since the supply of kangaroo tails was limited, Mr. Callender then proposed to obtain ligatures from the tendons of the tail of the horse. About that time Mr. Garner proposed the use of ligatures from the tendon of the ox; they were roughly made by simply splitting up the tendons with a penknife and soaking them in carbolic acid.

In the *British Medical Journal*⁴ of May 2, 1885, is a contribution by C. B. Keetly on "Buried Sutures." That author speaks of the importance of suturing separately periosteum to periosteum, muscle to muscle, deep fascia to deep fascia and skin to skin after deep incisions of all kinds. He makes mention of aseptic animal sutures, such as carbolized catgut to be used separately as buried sutures. He concluded his paper by saying that it is only in strictly antiseptic surgery that he would venture to recommend the use of such sutures. Soon after this Schroeder employed layers of continuous catgut sutures in the operation for the restoration of the perineum. Each layer was so adjusted in the parts as to superimpose or bury the other. Thomas about this time used buried continuous catgut sutures in closing the abdomen in his laparotomy cases. In the Section of

¹ Lancet, June, 1869.

² Australian Medical Journal, Vol. xxii, 1877.

³ Lancet, 1878.

⁴ Journal of the American Medical Association, Vol. Iv, 1885.

Gynecology of the Ninth International Medical Congress, at Washington, 1887, Dr. Cordis read for Dr. Veillet, of Geneva, Switzerland, a paper on the buried suture. In the operation for vesico-vaginal fistula Prof. Veillet used iodolized silk; he claimed that the application of such sutures is innocuous and is efficient. Dr. Marcy contributed a paper to the Section on Surgery, at the thirty-ninth annual meeting of the American Medical Association, May, 1888, on the surgical advantages of the buried animal suture and its adaptability to special purposes. He made mention of Lister's method and the application which that writer had early made of antiseptic catgut for ligatures to arteries. Dr. Marcy stated that the buried suture at that time had become one of the chief factors in his method for restoration of the perineum. He spoke of its use in closing the abdomen in laparotomy for any cause, of its use in hernia operations, and in operations on the rectum. Dr. Marcy stated that he had extended the application of buried suturing to the treatment of wounds in nearly every part of the body. So pleased had he become with this method of procedure in operations for the restoration of the perineum that he had discontinued the use of his "safety-pins" in operations, as described by him in a paper² which he read before the Section of Obstetrics and Gynecology of the Suffolk District Medical Society, February 16, 1887. Dr. Marcy, as he thought needful, had used the deep buried tendon suture in the cases in which he had used the safety-pin of his own device. In the paper which Dr. Marcy read in 1888 mention is made of the report of two cases of strangulated inguinal hernia, one of which occurred in my practice, in February, 1871, the other which he also saw with Dr. W. W. Wellington, of Cambridge, in April of the same year. The case occurring in my practice was the first of all that was treated in this manner antiseptically. After the stricture had been divided, the sac unopened was pushed upward, with its contents, into the abdominal cavity. As we were about to close the canal with sutures in order to prevent an immediate return of the hernia, it then occurred to Dr. Marcy that the use of catgut sutures instead might be of benefit in helping to bring about an obliteration or agglutination of the inguinal ring. I readily concurred in the suggestion, for I had previously read Mr. Lister's article on antiseptic animal ligatures, as first published in the *Lancet* of April, 1869, an abstract of which appeared in *Braithwaite*, part 59, p. 101, July, 1869, and I had regarded Mr. Lister's deductions as of much importance.

Dr. Marcy immediately went to his house, which was at some distance, while I in the meantime kept the patient under the influence of the anæsthetic. After his return, two stitches of medium-sized carbolized catgut were taken through the walls or pillars of the canal. The external wound was closed in the ordinary way by means of silk sutures. The dressings to the wound were moistened by the frequent application of carbolic acid in solution. The parts did not heal altogether by the first intention, and by some misunderstanding on the part of the nurse the full strength of the five per cent. solution of the acid for awhile was employed. This however appeared to do no harm; it rather favored than otherwise, union of the deeper parts, by adhesive inflammation. The sutures gave no apparent trouble; they must have

been absorbed, for careful daily examination showed no trace of their appearing in the open wound. An abundant deposition of new tissue could be felt in the line of the opening about the walls of the canal and along the internal ring where the sutures had been applied. June 14, 1871, there came into my practice another case of strangulated inguinal hernia. The case occurred in a man aged forty-four years. Taxis failing, an operation was resorted to. Assisted by the late Dr. A. F. Holt, I made an application of carbolized catgut ligature to the pillars and internal ring; there followed an immediate and permanent cure. Since that time the application of carbolized catgut or aseptic animal sutures in herniotomy has been continued with excellent results.

The record of these cases in which carbolized animal sutures were employed would seem to antedate all others of this class that have been operated on in America, if not also in other countries. Another subject in gynecology worthy of special consideration is that known as Trendelenburg's posture. This subject has been most ably presented in a paper read by Dr. Florian Krug before the American Association of Obstetricians and Gynecologists for 1891.

The posture, as doubtless all are aware, consists in raising the patient's pelvis and letting the body slant down at an incline of 45 to 60 degrees to the horizontal. It was first employed by Prof. Trendelenburg, of Bonn, in supra-pubic cystotomy. Since the close of the year 1887 Trendelenburg has extended its use to gynecic surgery. In abdominal surgery it was first used in cases in which special difficulties in the deeper portions of the pelvis were to be encountered. The advantages offered by this method were shown to be so great that its use was finally extended to almost every kind of abdominal and pelvic operation. In its employment the operator is enabled to get a better view of the organs and tissues of the cavity in which his work is engaged. There is less risk of accidental injury to the structures beneath; injuries to the ureters and to the bladder can be avoided. Adhesions of the intestines to the omentum or to other parts can be overcome with greater facility and safety. Operation for the removal of the tubes and ovaries is greatly assisted by the adoption of this procedure. The abdominal viscera gravitate or fall toward the diaphragm.

Trendelenburg's posture does not interfere with the due administration of anæsthetics; in cases of hæmorrhage, syncope, or of extreme exhaustion its employment is of incalculable advantage. Dr. Krug has shown that a similar posture was employed by Fabricius ab Aquapendente in the sixteenth century. We learn that that eminent Italian anatomist and surgeon, in conducting treatment for cases in which strangulated hernia existed, first tied the hands and feet of his patients, then suspending them with the head low down, violently shook them in order to effect reduction of the hernia. It appears that other physicians before and since the time of Fabrizio had employed for abdominal trouble procedures not unlike those above described. Further researches show that this kind of proceeding is in fact only an extension or modification of the ancient mode of performing succussion, a representation of which has been given by Vidus Vidius in the Venetian edition of the works of Galen, and a description has been preserved in the Hippocratic treatises on articulations. When the spinal gibbosity or hump is below the neck, ac-

² Boston Medical and Surgical Journal, Vol. cxvi, p. 429, 1887.

according to Hippocrates, succussion with the head downward, as it was thought, is most likely to be of service. The patient was placed upon a ladder well padded with leather or cushions, he was then fastened at the ankles and at other parts of the body to the ladder with some firm but soft bands and with other appliances. The ladder upon which the patient was secured was then hoisted either to a high tower or to the gable end of a house, sometimes the ladder was lowered from a tower or from the mast of a ship, and the ladder was fastened at its base with cordage or with other means. In certain cases of sudden occurrence of injury Hippocrates admitted that the spine might be rectified; he rather praises the principle, though he says succussion was chiefly practiced by those physicians who seek to astonish the mob. To such persons, he says, these practices appear wonderful; people always extol such practices and never give themselves any concern as to the final results. Hippocrates further says that those physicians who practice succussion were for the most part a stupid class. In referring to the above I would not be understood as underrating in any manner the importance of Trendelenburg's posture. I have referred to it rather to show that this measure of proceeding, like many others of great value, before reaching the proper place for usefulness, has not been unregarded as an expedient of doubtful utility. Whenever for any considerable length of time Trendelenburg's posture in a laparotomy case is to be employed, precaution in the changing or discontinuance of it should be taken to prevent dangerous or fatal syncope. In a case of laparotomy in which I was in attendance with Dr. G. W. Jones, January 3, 1893, the patient on being placed in a horizontal posture changed almost immediately into a condition which excited the greatest alarm. As soon however as the patient could be placed again in the Trendelenburg posture the cardiac, respiratory and cerebral centres began to give evidence of normal activities.

Another subject deserving of consideration is the relation of chronic hysterical mania to uterine or pelvic disease. There can be no doubt that many cases of mania occurring in the female are superinduced or at least are intensified by the existence of ovarian or tubo-ovarian disease. Gynecologists from their observation and increasing experience are coming to believe that alienists are inclined to overlook this fact or that they too often fail to appreciate the significance of certain local lesions. Though not wishing to make any unfriendly criticism upon the methods and management carried out by those who have assumed to act as experts in matters relating to mental and nervous affections, I feel nevertheless constrained to remark that the gynecologist should exercise all reasonable influence in directing those who have the care of insane females, to a greater study and investigation respecting the disturbing factors having their origin in the abdominal and pelvic organs. Combined gynecological operations is a subject which has of late been gaining much prominence. Recent advances made in surgery have enabled the operator to do much more at one sitting than formerly. Such combined surgical procedures are no doubt of almost infinite benefit to the patient, for by this means she can often be saved from much physical and mental suffering; valuable time can also be saved, and the expense incident to operations performed at different times can in large measure

be prevented. In cases of multiple lesions or diseased processes careful discrimination as to what shall be selected for one sitting cannot be attended otherwise than with the most satisfactory results. In a combination of which a difficult or tedious abdominal section may be an essential part, all things being considered it might be deemed best to defer to a later date other important surgical procedures. In a combination excluding laparotomy the operator should be governed by the patient's strength and by the time required for the proper employment of anesthetics. In a paper on combined gynecological operations contributed by Dr. G. M. Edbohl, gynecologist to St. Francis Hospital, New York, mention is made of nephrorrhaphy for movable kidney undertaken in combination with curettement for chronic endometritis and catarrhal salpingitis, also its being performed at the sitting with curettement and trachelorrhaphy. On another occasion curettement, shortening of the round ligaments and nephrorrhaphy were performed together. The same author regards curettement with salpingo-oöphorectomy for diseased tubes and ovaries as the simplest of the combinations into which an abdominal section enters. Curettement amputation of the cervix or trachelorrhaphy and shortening of the round ligaments is a combination most frequently called for. Next in frequency come anterior colporrhaphy and colpo-perinorrhaphy; also amputation of the cervix, shortening of the round ligament and perineorrhaphy. When curettement, amputation of the cervix anterior and posterior, colporrhaphy, perinorrhaphy and ventro-fixation of the uterus are indicated, the author referred to favors an operation in which all are done at one sitting, for the reason that when each is done singly the union occurring in the restored parts is liable to yield or to be overcome for want of other necessary supports. In all these operations the strictest antiseptic precautions should be observed and all improved methods of procedure should be enjoined. This plan of operating has evidently been productive of much success. In the present light of gynecic surgery it is easy to see why under the old *régime* of operating by piecemeal so little of importance for the comfort of the patient was accomplished.

Tubal or ectopic pregnancy as it is now called, has given rise to a vast deal of discussion. The causation of this condition has been variously considered. Mr. Tait's views at one time were regarded as authoritative. That writer, as others hold, believes that impregnation of the ovum normally occurs in the uterus; that in those cases in which the extra-uterine foetation occurs, the tubal cilia have been worn away, or destroyed by a salpingitis more or less severe. This view presupposes that the tubal cilia in their normal state act as an impassable barrier against the entrance of the spermatozoa. However plausible and engaging these views may often appear, they cannot be accepted as sufficient explanation for the occurrence of the majority of cases in which tubal pregnancy exists. Surgical and pathological records whether taken individually or collectively do not justify such a conclusion. In those cases of ectopic pregnancy, in which the tubal epithelium has been found destroyed or impaired, positive evidence has often been found wanting to show that that condition has been due to salpingitis. May not the impairment or the loss of the cilia be due to the new condition of things consequent on pregnancy?

The views which some of us learned in our student days, and which were forcibly enunciated by Prof. O. W. Holmes, that it is in the tube where the ovule first receives its fructifying or vitalizing influence, though much digression has been indulged in have not as yet been disproved. There are undoubtedly many factors which enter into the causation of the obstruction to the progress of the ovule. Entrance of the ovule into the uterine cavity according to G. A. Moses, may be delayed from nervous influences, from shock or from organic changes in the tissues of the tube and from proliferation and ecstasis of the vascular tissue incident to the parturient state. In the treatment of ectopic gestation I have no doubt that we should all agree that as soon as the condition is fully recognized laparotomy should be performed. Though some evidence of late has been adduced tending to show that recovery after the occurrence of rupture may take place spontaneously it nevertheless appears that early operative interference affords the only safe course of procedure; leading gynecologists in all countries have advised this.

Cancer of the uterus is still receiving special attention by the German profession. Extirpation when practicable seems to be the only remedy at this time worthy of consideration. By recent advances in the technique and by the observance of strict precaution against sepsis the percentage of mortality has been greatly reduced. The statistics of high amputation or incision indicate that much success has of late been attained. One great drawback to the attainment of the highest success in operative interference is from failure in arriving at an early diagnosis. There is often displayed on the part of the medical attendant too much conservatism: or a hope is often indulged in that the disease may not be really malignant. The primary symptoms of the disease are often overlooked; the sanious discharge, the menorrhagia, the pain, the obstinate sciatica and other symptoms indicative of the presence of cancer are looked upon as the result of processes that are altogether benign in character. After the occurrence of the menopause the uterus should be regarded as a useless organ and a foreign body, for its functions at that time have ceased. Scarcely so can it be said of any other organ. Though the spleen is an organ, the importance of whose functions has been much questioned, it certainly acts at times as a diverticulum. After the menopause the uterus, with its appendages, will have appeared to have exhausted its activity. In accordance with a law that has been well recognized nature sets up eliminative processes. The uterus is tolerated (?) in position at best only by feeble props or supports. Accidents to the perineal tissue occurring during the parturient process should be looked upon rather as conservative than otherwise. The occurrence of these point to the way for vaginal extirpation that the surgeon should be ready to complete when cancer or other lesions appear, with which the uterine tissue has often been invaded. I have spoken thus much on matters relating to our work, and would have gladly extended my remarks to the discussion of other subjects of interest had there been more time for such disposal. Suffice it to say that the Gynecological Society of Boston should still continue to congratulate itself on the good work it has accomplished. Many interesting and important papers have of late been presented and much able

and valuable discussion has been advanced on matters pertaining to our charge. I exceedingly regret that much of the record of our work has been withheld from the medical journals owing to the enforced absence of our accomplished secretary. Against this we seem to have been unable to provide. We are looking forward for a greater activity; with the development of the infusion of new blood we shall expect to accomplish much more. The twenty-fifth anniversary is fast dawning; the proper observance of this will show that the founding of our society antedates all such special societies that have been formed in this and in other lands. I would recommend therefore that in due time some action be taken toward a due regard for this coming event. In the history of our society are interwoven many important movements; we foresaw at an early date the coming sentiment in regard to the status in the profession of the opposite sex. So notwithstanding the frowning by the majority of the profession outside of our number, we were the first to open the doors to the admission to membership of properly qualified women. Upon the wisdom of this measure I will not enter into any consideration. Our records show that women are still being added to our number and that the meetings to some extent are being graced by their presence and their intelligent discussion by on themes of much moment.

As I pause for a retrospect, I am saddened with the thought that many faces once familiar are no longer with us. When, however, I recall the names of Martin, of Warner, and of Bowditch, I am strengthened with pleasant memories. Martin, honest, true, a walking encyclopedia of medical and surgical lore; he did not hesitate to use to the best advantage his withering sarcasm in exposing shams and deceit. We shall never see his like again. Warner, bright and cheery, had an inexhaustible fund of humor; he could use his wit to amuse as well as to sting. Of Bowditch, I would briefly say that we loved and respected him for his great worth and for his unsullied honor. Others also, who in the years gone by, have added prominence and dignity to our meetings, I can now recall. Each has left a good record, a priceless legacy that has been an inspiration to me, and doubtless to most of you, who have had the good fortune of maintaining such long and intimate acquaintance.

RESULTS OF MILITARY SERVICE AS EXEMPLIFIED BY CASES FOUND IN THE NATIONAL MILITARY HOMES.

Read at the First Meeting of the Wisconsin Society of National Guard Surgeons, at the Milwaukee Military Home.

BY SURGEON WALTER H. LEIGHTON.

Gentlemen:—It would not be consistent, either with a proper respect for you or a fair consideration of the subject involved, to give you this paper without an apology, felt more by me than it can possibly be by you, for now, in the presence of my peers, I am weak indeed. Words fail to express the gratitude for the honor conferred by your attendance here—yet, in the presence of one of the most eminent surgeons in the world, judge of my embarrassment in attempting anything; but, as I have always been used to obey, I will try to do the very best I can, and hope that I shall be able to do that which will make

you feel repaid for the trouble you have taken to be with us to-day. If I succeed I will thank you, and the account will be fully settled. How little do we know of the long hours of anxious research and study of those *real* students who burn the midnight oil, that science may finally triumph over disease. The *minutia* is the real thing, but who of us can get down to it? Only one in ten thousand. No; we reap the advantage of the work of the tireless students, and often the searcher himself is lost sight of. But thank God, there are those who toil, and those who reap, and in God's providence probably each has his compensation. The one, glad that he can do a little; the other, in the firm conviction that God has allowed him to be the means of doing so much for his fellow-men. I should like to have been one to originate, or probe to the bottom, yet still I am thankful that with the vast improvement, the great advance of the present day, I am in it at all. The change, if not the advance, is great, and undoubtedly it will be found that the new is not all right, or the old all wrong; but still, on the whole, we feel sure there has been a forward movement. Blood-letting had its day, and went out as a snuffed candle, but doubtless, among the profession, there is a feeling that the angle or divide was too abrupt and sudden, and regret that the public sentiment rendered the practice almost disreputable, and that, for the benefit of humanity, it would have been better if a middle course had prevailed. Wonderful strides have been taken since Lister came to the front with his claims for aseptic surgery, yet if we are ever so unfortunate as to have another war, we shall as heretofore, in my opinion, be compelled to face all the mischief and evils inherent thereto, for advanced science can never obviate the results of exposure and privations. of the long and weary march, the night vigil on the lonely picket, or the malarial poison of the swamps—it cannot prevent, with our present knowledge, rheumatism, intermittent fever, cerebrospinal meningitis, or disease of the heart, liver or lungs, hernia, varicose veins, diseases of the nervous system and brain, for even now the causes of most if not all of these are still in dispute, and have yet to be proved. We cannot, even with our most advanced knowledge of sanitation, prevent disease in any great measure; at least, under the trying ordeals of actual war, nor can we prevent shock from wounds or injuries. We may perhaps by aseptic surgery, when it is convenient and possible, prevent in a degree inflammation, suppuration, and their concomitant evil results, and the ambition of our eminent Surgeon-General, Prof. Senn, for a man to be his own antiseptic panacea, is certainly original, and preëminently grand, but still we must always face nostalgia, shock, inflammation, ulceration, suppuration, necrosis, and the thousand and one remote results of camp exposure and camp life. The conditions and the surroundings on the battlefield must always be different than in private practice. Why let us look to one condition. We were often glad during the late unpleasantness to get men for assistant surgeons who had not even had the advantage of reading medicine with a country doctor, but (as tradition has it) had only taken care of his horse. Undoubtedly, knowledge of surgery and medicine has been gaining ground rapidly for the past twenty-five years, and to-day, the intelligent physician or surgeon who faces disease or wounds with long pre-

scriptions or meddlesome surgery, hoping by a shotgun policy to hit somewhere, is numbered with the errors of the past. Yet still we are faced by the fact that man must die. Therefore preventive ways will always prove more reliable than all cures put together. Gross has a passage in his *Manual of Military Surgery* of 1861, where he says: "The duties and requirements of military surgery are essentially similar to those of civil surgery."

Now gentlemen, I leave it to those of my peers who served in the late civil war to say (with all due deference to the great surgeon, Christian man and teacher who to have his name appended to my diploma is one of the greatest honors) whether the requirements of military surgery do not differ in a greater degree than those from civil practice. To be brief, I remember at the battle of Cold Harbor, to have been one of the assistants to one of the best surgeons (in my opinion) furnished in the late Rebellion, when unexpectedly the Rebels got a range of our field hospital, where we were operating for the resection of the elbow. The operator suddenly got tired, and turning to one of the assistants said, "Can't you finish this operation?" and without waiting for an answer gave up the knife, and he afterwards said in my presence, "By Jingo, he did that better than I thought he could." Circumstances must be different on the battlefield, and the advice of the revered professor of surgery, S. D. Gross, in his manual to young surgeons in 1861, is too good to be omitted here. He says: "The sole object which prompts me to publish this little book, is an ardent desire to be useful to the young physicians who have so hurriedly entered the volunteer service, perhaps not always with a full knowledge of the weighty responsibilities of their position. I pray the young men, into whose hands this manual may happen to fall, to be careful of the health and lives of the poor soldiers committed to their professional keeping. I exhort them to perform their duty as skilful surgeons and physicians, as men of courage and as Christians, in order that when they return to their homes and their friends, after the tumult and peril of war shall be over (if war there should unfortunately be), they may be able to render a good account of their stewardship, and so entitle themselves to their country's benediction. I would also exhort them in a special manner to take good care, not only of the lives of their countrymen, but also of their limbs mutilated in battle. Conservative surgery has, at the present day, claims of paramount importance upon the attention of every military practitioner. For, in the language of good old George Herbert:

"Man is all Symmetric!—Full of proportion one limb to another, and all to all the World besides! Each part calls the furthest brother, for head with foot hath private amity and both with winds and tides."

We of the past numbers, reverently regard this advice from an old and revered teacher. But, gentlemen, I am wandering away from my subject. I have endeavored to get together a few cases, and give you a paper to illustrate some of the results of military service, as exemplified by cases found in the National Military Homes—established by a generous people, and a grateful Government, for the disabled veterans of the wars of 1776, 1812, 1846 and 1816.

These Homes were first established in 1866, since which time there has been one built at Togus, Me.,

Dayton, O., Hampton, Va., Leavenworth, Kan., Santa Monica, Cal., Marion, Ind., and our own in Milwaukee, Wis.

More than \$2,000,000 are annually appropriated by Congress for their support, and about 25,000 veterans are cared for. The only requisite for admission is an honorable discharge, and the surgeon's certificate of disability, recommending applicant for admission on account of being unable to support himself by manual labor, upon which he is taken in by the Local Manager. The Homes are gaining rapidly in numbers, and it is calculated that they will continue to increase for ten years. The cost of medical supplies of the five branches of the National Homes, during the year 1889, was \$36,553.26.

Cost of medical supplies per capita, \$2.33. The number cared for at this Home during the year 1890 was 2,781, against 2,710 for 1889, and the average number present, and absent for 1891 was 2,420, as against 2,104 for 1889. The maximum was 2,050, the minimum 1,663. The amusements provided for the old veterans in Memorial Hall cover nearly all of the fall and winter months, and last year cost \$2,796, which is paid out of the Post Fund—nearly all of which money is made by the sale of beer on the Home grounds.

We have band concerts (by the Home band) in the open air, daily during the summer, which are attended by thousands of the best people of Milwaukee; and in winter there is a concert every Sunday evening in Memorial Hall. The Home library has over 5,000 volumes, and billiard, bagatelle and card tables are furnished for the veterans in the smoking-room. This too is paid for by the sale of beer, which in the opinion of the managers has proven effective in lessening intemperance, as it tends to keep the members at home, and so under control of the management.

The sanitary regulations are under control of the surgeon, and whatever suggestions are made by him, conducive to the health and cleanliness of the members, or other preventives of disease, are fully carried out. Weekly inspections are made of the members and quarters every Sunday, by the officers of the Home, also frequent week-day inspection by the surgeon.

Men with chronic diarrhoea or piles, and a good hospital war record, get good big pensions; while the veterans who served during the war, and came out with honorable bullet and sabre wounds (but no hospital record) receive the miserable pittance of two dollars per month. But to business. The first case to which I call your attention as preëminently suggestive, as a result of the war, is that of John Donahoe, Company G, Fourth Massachusetts Cavalry. It is a case of hypertrophy with dilatation (associate diseases), bronchitis and asthma. Although I think the so-called asthma is really dyspnoea caused by the heart trouble. He has never suffered from vertigo, and worked as a laborer until 1882, when he was obliged to enter the Home at Hampton, Va. The etiology of the case can readily be traced to heavy marching and the strain and excitement of battle. Another soldier of this Home is suffering from rheumatism and disease of heart, stenosis of aorta and hypertrophy, suffers much from vertigo, unable to go up or down stairs without difficulty, associate diseases—injury to spine and chronic gastritis. An exceedingly interesting case is that of

Nelson V. Day, who has hypertrophy and dilatation of the heart, with mitral insufficiency, associate diseases, rheumatism dislocates his left hip at will, cannot stand with eyes closed, cannot shut his eyes and touch his nose, absence of knee-jerk, want of coördination in movement—in fact, I have no doubt as to rapidly developing locomotor ataxia. Fourth case. Chas. Sounen, late of Company A, Thirty-fifth Wisconsin Infantry, enlisted in 1863, served three years. Has suffered ever since the war with rheumatism. I find hypertrophy with dilation and slight aortic stenosis, suffers frequently from dyspnoea and vertigo—associate diseases, neuralgia of face with angina pectoris; suffers much from rheumatism, being laid up four or five months at a time.

Gentlemen, I might go on indefinitely with these cases, as it is thought by some good authorities, that over fifty per cent. of all the cases admitted into the Homes, are afflicted with hypertrophy of heart, stenosis, etc. Not a few cases of tabes dorsalis are found in the Homes, and next year I will endeavor to give you, with other diseases, a tabulated statement or history of some cases, with results as to treatment, etc. But I know I must have wearied you already; and yet, feel that I ought to give you a short account of a case of which you may have already read in the newspapers.

The case of Henry Aulfuss, who was thought to have been murdered by tramps near the Home grounds last May. The man had been a member of the Home for a number of years, and when admitted, the physician's certificate claimed that Aulfuss was disabled by paralysis, but at the autopsy no lesion of brain or cord was found, and on looking up the man's hospital record, I found that about a year ago I had diagnosed his case as heart disease and rheumatism, which the post-mortem verified. The following was our report:

We found that the deceased, Henry Aulfuss, had received in some manner unknown to us from twenty to twenty-five scalp wounds, only three of which penetrated through the skull cap, the most serious wound being about three inches in length and cutting into the external table of the frontal bone. The internal table of the skull was found intact. The membranes were uninjured; no clot, or any evidence of disease or injury, was found in any part of the brain. The trachea was free from any evidence of injury, or any unusual secretion. On removing the lungs they were found to contain air, and floated on being placed in water. Both lungs were congested. On examining the heart, the right ventricle was found hypertrophied and the left fatty, and the walls very thin. The left ventricle contained clotted blood. Two small vegetations were found in the pulmonary valves. One of the most frequent causes of trouble here in the Home is alcoholism, but when we think of the temptations to which the young soldier was exposed, and the privations suffered and the hardships endured by the men who fought to save the country, we would fain draw around them the mantle of charity. One poor fellow in the guard-house said: "You have no business to blame us; you learned us the bad habit, and now we are reaping the results."

No doubt there is much truth in this, for if we consider the youth who, full of energy, fire and patriotism, rushed to the front in 1861 to 1865, many of them nothing but boys (prevaricating as to their

age to get there), and then remember the consequences, when the real life of the soldier began to dawn upon them; when they stood fast and firm through the dreadful carnage, and saw one by one of their comrades in arms (or even their childhood's playmates) drop out—then when the battle was won or lost, or stopped by the welcome shades of night, only to be renewed at dawn, can we fail to realize the shock to the young heart. Then perhaps, after a hurried dipper of coffee with the hard-tack, the inevitable detail for picket falls to the lot of the poor wearied fellow; is it to be wondered at that an artificial stimulant was necessary before he was able to take another step forward? No; and then the habit was formed, the appetite created which to many thousands was worse than the crack of doom itself. General Sherman said, "War is hell"—and it was. The deadly minie bullet was not the worst part of that hell. Let Uncle Sam continue to be grateful to his defenders, and take the best care possible of them in their old age. There is only a very narrow line between prosperity and adversity, between success and defeat; and they saved to the freest and best of Governments; a government for the people, and by the people, and money cannot pay for the boon.

Gentlemen, change in medicine and surgery should be governed by natural laws, but unlike other advances, it is often subject to the whims of ignorant professionals and the caprice of the community at large. So it is up-hill work for those who seek its improvement.

There are many set-backs, and progress is necessarily slow. Yet with all that we can look ahead, and find much to encourage. Disease in all probability will continue to flourish, in spite of the most advanced science; and although some enterprising Yankee may originate a sublimate filter to wear over the entrance to the trachea and œsophagus, to prevent the inhalation or swallowing of bacilli, yet the improbability of its success is still in the air. Therefore let us not forget that it has been the sad experience of the past, and is likely to be that of the future, that theories and speculations (however promising at first), have been abandoned one by one, and would fill quite a respectable burying-ground, while the utmost difficulty usually bars the way to progress. The road to knowledge has ever been a rocky one; and due praise should always be awarded to the prodger after the truth.

America ought to go to the front. And the claim that this country is young or poor, cannot longer be sustained.

The Government of this great and growing country should help forward the advance and growth of medical and surgical science, by means adequate to the importance of the subject involved. Its honor is involved, and what better use can its treasures be put to than the protection of its citizens against disease, and bring about this much wished for result; so that America, and not Europe, may be pointed to as the foremost of all the nations of the world in encouraging scientific research. We have among us men with the real keenness for such pursuits, and education fully fitting them for investigation; ripe in scholarship, only waiting for the opportunity when they can shake off the worry and drudgery of private practice, to take up the nobler pursuit of working in the interest of their fellow-men the world over. We

read nowadays of efforts to bring into the United States representatives of nations of the globe, so as to bring together the highest products of man; a place where can be gathered for the education of all the industry, energy, skill and character of the world's people. But I ask, where millions are spent for these things, because they bring monied wealth to the United States, where is the Government spending anything for surgical or medical science? Is it not time that the people should recognize the fact that without health, wealth is of no permanent benefit; that without a sound physical and mental organization, money is of no worth; that only with both, can men, women and children enjoy life and the pursuit of happiness. Is it not high time for our Government to encourage the advance of medical and surgical science, by protecting those who are ready, enthusiastic and qualified for this great work?

Let us hope, pray, and above all, work for this great object.

SARCOMA OF THE PONS AND GLIO-SARCOMA OF THE CEREBELLUM.

Read before the January, 1893, Meeting of the Chicago Academy of Medicine.

BY LUDWIG HEKTOEN, M.D.,
OF CHICAGO.

The following two instances of tumor of the brain are reported in order to increase the number of such cases recorded and described in medical literature.

Case 1. Sarcoma of the Pons.—This case occurred in the Cook County Hospital, where Dr. E. T. Edgerly ascertained and wrote down the clinical history as well as the results of the physical examination; the writer made the post-mortem examination and examined the tumor microscopically.

Man, single, baker, German by birth, 37 years old, was admitted to the Cook County Hospital of Chicago, April 5, 1890. He was his parents' only child; the parents were both dead, the cause of death being unknown. He denied having had any venereal disease, said that he drank beer in moderate quantities, and that he had never been ill before his present sickness, which began with headache three months ago, since which time he had been unable to work on account of the pain, which was of a dull persistent character, with nocturnal exacerbations, principally frontal, but often extending over the entire top of the head. Two days before admission he fell on the sidewalk in a fit of faintness, but did not lose consciousness entirely; he had been troubled with dyspepsia; the bowel and urinary functions had been subjectively normal. The patient on admission is mentally dull and a clear cut history cannot be obtained.

Present Condition.—Patient is well nourished; he lies in bed groaning and complaining loudly of pain in the head, which he grasps with his hands; the right eye is tightly closed, the left is half open; the pupil of the right eye is somewhat contracted, but both pupils respond to light. Movement of the eyeballs seem to be limited, particularly as regards motion upwards and to the left. The tongue is normal and does not deviate on protrusion; the lines in the face seem better marked on the right side. Physical examination of the chest and abdomen is negative; there is no ankle clonus; the patellar and cremasteric reflexes are normal; muscle reflexes are universally present; rough tests indicate the tactile sensibility to be much impaired, thus two points three inches apart cannot be distinguished on the hands or the feet; when half an inch apart on the tongue the two points cannot be separated. Taché cerebrale is very distinct.

Pulse 64, respiration 16, temperature 97.6°.

Ophthalmoscopic examination by Dr. Mary C. Fowler: The discs cannot be outlined at all, yet the vessels are not large and do not pulsate. This condition is more marked in the left eye than in the right.

April 12. Patient suddenly became unconscious while eating and unable to swallow the mouthful of food he had taken; the extremities became cold, profuse perspiration broke out on the skin and the pupils dilated. Patient is taking iodide of potassium in increasing doses.

April 14. Lies in stupor; requires catheterization; refuses food. Right pupil dilated, does not respond to light. Supra-orbital pressure arouses patient sufficiently to answer questions. The right side of the body seems to respond to stimulation more quickly than the left, and often he moves the right side in response to irritation of the opposite half.

At 8 p.m. Dr. Murphy removed a button of bone with the trephine from the skull on the upper end of the right Rolandic fissure. The dura was dense. An aseptic aspirating needle was passed into the brain in all directions from the trephine opening, but no abnormal fluids were obtained nor resisting body encountered. Replacement of button, suture. 12 p.m. Death.

CLINICAL CHART.

Date.	Temp.		Pulse.		Resp.	
	A.M.	P.M.	A.M.	P.M.	A.M.	P.M.
4-5-'90	97.6	98	64	66	16	16
4-6-'90	99	99	70	72	16	16
4-7-'90	98.6	98	66	58	16	16

Section twenty four hours post-mortem:

The trunk cavities were empty. The heart was of normal size, the semilunar valves competent to water; the mitral and tricuspid orifices admitted three and four finger tips respectively; the endocardium was smooth and the muscular tissue firm and light greyish-red in color. The fossa ovalis presented many small perforations. The lungs contained much frothy and bloody fluid. The abdominal organs presented no special change, contained no tumors. In the scalp over the right parietal eminence was a curved incision and beneath the flap thus outlined was a circular opening in the skull containing an accurately fitting button of bone. The dura was free from thickening, the Pacchionian granulations were exuberant. The pia was quite universally adherent to the surface of both the vertex and the base of the brain. There were small clots of blood in the right Sylvian fissure at the base; there was a small clot along the postcommunicant artery, but the vessel itself was intact. In the region of the upper third of the right pre- and post-central convolutions, beneath the trephine openings, were many small punctures in the membrane and in the brain substance. There was some clear fluid in each lateral ventricle. The brain substance in the hemispheres was macroscopically normal and free from any focal disease. On the internal half of the ventricular aspect of each thalamus were slate-colored, slightly raised areas, and on the left thalamus was a gelatinous body as large as a flax-seed.

The choroid plexus and the pineal gland were thickened and the peduncles of the pineal gland contained some slightly discolored areas. The slaty areas in the thalami extended into the substance for about 1 mm. There were no areas of softening in the thalami or in the crura. The pons was larger than normal, but the enlargement was symmetrical, at the widest portion it measured 5 cm. across from right to left. In the central portion of the pons, inclining perhaps to the right, was an oval, firm mass, 3.5 cm. in diameter and 5 cm. long, the long diameter lying in a dorso-ventral direction. The tumor was but loosely imbedded in the pons, having no organic connection with the pontine substance, and on attempted manipulation it slipped out entirely. It weighed 17 grams; it was of firm consistency, greyish in color on the cut surface, with many small hæmorrhagic areas, old and young, scattered through its substance. The fourth ventricle was empty; the medulla and cerebellum were normal. The spinal cord was not examined.

Microscopic examination of the tumor, after hardening in Mueller's fluid, shows that it is made up of rather delicate, quite small round and spindle shaped cells, with distinct deeply colored nuclei, densely packed together; there are places consisting principally of round cells, and in other spots mostly spindle shaped cells are found; no distinct stroma can be made out, perhaps on account of the

dense crowding together of cells. There are a number of irregular spaces without any plain wall separate and distinct from the tumor structure; in some places the cells immediately surrounding these spaces are, however, much like normal connective tissue cells, often these spaces are quite empty; some contain red blood corpuscles only or corpuscles mixed with tumor cells; there are also found quite large areas consisting of blood infiltrating with the substance of the neoplasm; in such foci the fibrinous mesh-work is usually plain. At the margin of one of these areas of infiltration is seen a distinct, thin-walled blood-vessel, filled with blood which in one place seems to be breaking into the tumor. There are also found a few areas of amorphous, yellowish material. The areas of discoloration observed with the naked eye upon the caudal surface of the thalami consist of masses of round cells, irregular in outline and in size, some being large and some small, and a few seem to be intravascular; here the cells are large and not so closely aggregated as in the pons.

Diagnosis.—Round and spindle celled sarcoma of the pons; secondary foci in the thalami.

Remarks.—It will be seen at once that the symptoms presented by this patient are readily explained by the nature and the position of the intrapontine tumor. The general symptoms such as headache, attacks of fainting and ophthalmoscopic retinal changes, occur in tumors of the pons as well as in other parts of the brain. The headache was intense, of rather uncertain localization and well-nigh continuous. In view of the fact that the pain in such cases is situated in the dura mater, it might perhaps be more reasonable to speak of the headache in this case not as a general but as a focal symptom, due to local compression or irritation of some part of the fifth nerve, near its origin, this being the nerve which supplies sensation to the dura.¹ The varying intensity of many of the symptoms was due in all probability to the occurrence of hæmorrhages into the tumor, which would cause sudden increase in the intracranial pressure. Thus, for instance, the attacks of fainting would result from increased pressure or sudden irritation of the nerve tracts passing through the pons due to the hæmorrhagic extravasations into the neoplasm. The examination after death showed the presence of old and recent, large and small, foci of hæmorrhage into the tumor. In fact the variations in all the symptoms was undoubtedly caused either by varying intracranial pressure or by varying direct compression of important structures in the vicinity of the tumor dependent upon the repeated congestions and hæmorrhages. The rather slight evidences of motor and sensory disturbances during the time the patient was observed in the hospital are attributable to the nature and the position of the growth; it was circumscribed, not in any way infiltrating but rather displacing, and consequently its effects upon the surrounding structures would be due entirely to pressure. The rather indefinite ocular paralysis or paresis and the equally imperfect left hemiplegia was due to the gradually increasing pressure of the tumor upon the tissues around it. The paresis of left side of the body might, for instance, be caused by pressure on part of the tumor in the right upper third of the pons before the decussation of the pyramidal tracts or in the lower left third after decussation. The symptoms were not distinct enough to decide this from a clinical standpoint, and the position of the tumor in the central part of the pons gives no clue as to which part of the tracts would be most compressed unless, indeed, it be those in the right half.

¹ Wernicke, Lehrbuch der Gehirnkrankheiten, Berlin, 1883.

It will be observed from the temperature chart that the occurrence of hæmorrhage into the substance of the tumor was not followed by fall of temperature. Gerhard observed that hæmorrhage into gliomas did not like genuine cerebral hæmorrhage cause persistent lowering of temperature, and proposed to utilize this observation in the diagnosis of this form of brain tumor; vascular sarcoma consequently appears to agree with glioma with respect to the point mentioned. The sudden death may have been due to the operation of trephining; it might also have resulted from lesions of the vagus centres due to the tumor.

The varieties of tumors occurring in the pons are practically two, glioma and sarcoma; a third is formed by a combination of these two into gliosarcoma. Gummata, tubercular foci, parasitic cysts give rise to symptoms identical with those produced by true tumors. The glioma is more frequently met with than sarcoma. Starr² collected thirty-eight cases of tumors of the pons in children and youth; of these nineteen were tubercular, ten gliomatous, five sarcomatous, two gliosarcomatous, one cystic and one unknown. Glioma of the pons and the pons medulla transition usually take the form known as gliomatous hypertrophy; a name which Hun³ says was first proposed by Kümmel⁴ because the growth is not circumscribed but appears in the form of a diffuse hyperplasia of the parts affected, resulting in great increase in size and but little distortion of normal configuration. This name, gliomatous hypertrophy, has been used by quite a number of writers in reporting cases, and among them may be mentioned Hun³ and Spitzka.⁵

Gee and Percy Kidd⁶ termed the same condition gelatiniform enlargement of the pons in their description of cases in the St. Bartholomew Hospital Reports. Glioma is nearly always an infiltrating tumor. Histologically it consists of branched neuroglia cells many of which may be multinucleated; it takes its origin from the neuroglia and grows by proliferation of its cells; as it grows it infiltrates the brain substance, and nerve fibres and ganglia cells swell up and disintegrate as they become encroached upon, though both these elements may persist surprisingly long.⁷ It is consequently a really destructive growth in many instances.

Gliomata are frequently telangiectic. Klebs⁸ maintains that the nerve fibres and ganglion cells take part in the proliferation, and he consequently calls the tumor neuoglioma. Spitzka⁹ describes an excellent instance of neurogliomatous hypertrophy of the pons medulla transition which in parts showed actual destruction of nuclei and nerve fibres; compact nerve strands seemed to present resistance to its destructive efforts, while ganglionic and capillary districts favored its extension.

Sarcoma of the pons may occur as an independent growth, unattended by neuroglia proliferation, and it is thought to be developed from the sheaths, or the actual walls, of blood-vessels. As in the present instance they usually present rounded, extremely loosely connected, sharply defined masses of various sizes; sometimes they possess a distinct vascular

membrane. The histological structure does not in any way differ from that of sarcoma elsewhere, and when hæmorrhagic foci are present in great number the vessel wall will usually be found to consist of embryonal connective tissue. When some gliomatous structure is present, then the tumor is usually spoken of as a gliosarcoma, and it may manifest the infiltration tendency usually observed in the glioma. Thus Simon¹⁰ reported a case of gliosarcoma of the pons which consisted of small round cells, neuroglia cells and in places large cells, with a manifest tendency to infiltrate surrounding structures. Most authors expressly state that sarcoma of the pons is not infiltrating as a general rule (Zeigler, Wernicke, Eichhorst); Henoch,¹¹ however, details an intra-pontine sarcoma which presented no sharp boundary, but which seemed to extend diffusely into the substance of the pons from a number of minute foci secondary to the principal mass.

While glioma and neuro-glioma of the pons as well as of other parts of the brain usually appear single, sarcoma tends to give rise to vascular metastasis, which is also shown in the present instance in the secondary foci in the thalami, some of which are quite distinctly intra-vascular.

Case 2. Gliosarcoma of the Cerebellum.—The following case was in the Cook County Hospital in a homœopathic ward in the spring of 1890, but there is no record extant of the case from that time, and consequently I can only give such clinical facts as have been gathered from family and friends after the patient's death.

Man, age 45, was in good health up to May, 1885, weighing 200 pounds and of imposing physique. At about that time he was engaged in raising an old building, and his son crawled under the building; fearing some injury he attempted to drag him out and during his efforts the building fell, striking him on the back of the head and the neck and driving his face into the sand. Owing to his great strength he was able to extract himself, producing in so doing lacerated scalp wounds. He recovered from his wounds and did not complain of any pain until the following winter, when he suffered for several months with severe headache which was diagnosed by his attending physician as neuralgia. The summer following he did his usual work, but he never seemed quite well. The second winter the pain in the head returned, was principally occipital, and this time it was worse than before; he also had vertigo and nausea. The remissions in the headache grew shorter and the attacks longer, and from this time (1888) until his death July 5, 1890, the pain in the head steadily increased until he at last died from exhaustion. For a short time before death he was totally blind. He was treated from time to time in hospitals, by ordinary practitioners and by authoritative specialists, under various diagnoses, a favorite one being spinal meningitis; he was blistered and burnt and received all the anodynes in the pharmacopœia. The above facts were obtained principally from Dr. Charles Caldwell, of Chicago, to whom I am greatly indebted for the request to make the post-mortem examination. The doctor adds: I knew him personally for many years, but I never had him under my professional care. I have never in a practice of twenty-five years' duration seen any one suffer such terrific pain as did this man.

The post-mortem examination was made twenty-seven hours after death. The neck and head only were examined.

Examination of the cervical spine, of the cervical portion of the spinal cord and of the organs of the neck was negative. The calvarium was free from any change; the dura was very tense and could not be pinched up into a fold anteriorly near the crista galli; there was no fluid in the subdural space; the brain filled the cavity completely, the convolutions were much flattened, the sulci apparently obliterated. The pia showed uniform injection of its vessels, large and small, and at a little distance it presented a rosy or pink color. It was not adherent to the dura, but it peeled from the cerebral surface with difficulty. On removing the brain, clear fluid spouted like a fountain

stream from the vicinity of the base beneath the hypophysis. Inspection of the brain shows uniform pinkish color due to vascular injection; this is the case both in the dorsal and the ventral portions. The brain substance is very firm, the encephalic cavities contain much clear, almost colorless fluid and they appear enlarged, dilated; the velum over the third ventricle is distended and appears like a greyish band; the fourth ventricle is empty; the oblongata seems compressed. Underneath the tentorium is seen a hard, nodular projection from the left cerebellar hemisphere, it is covered by a thin stratum of cerebellar substance and by thickened pia in which run large, tortuous vessels. To be more accurate—it is found that the postero-superior lobe of the left hemisphere is occupied by an oval tumor, presenting a projection beneath the tentorium. The long, or dorso-ventral diameter of this tumor is 2, the short or verted $1\frac{1}{2}$, and the transverse $1\frac{1}{2}$ inches; it encroaches some on the vermes, *i. e.*, beyond the median line; it is everywhere surrounded by cerebellar substance which dorsally is very thin, and in the thickened pia are numerous large, tortuous vessels, especially around periphery of the tumor projection. The cut surfaces of the tumor show areas of hæmorrhage of irregular size and age, large and small districts of homogeneous, greyish-yellow gelatinous substance in a bed of firm, whitish-grey tissue. The tumor seems simply imbedded in the cerebellum, it has no distinct capsule, and yet it has no distinct connection with the cerebellum except the vessels seem to pass into it on all sides—especially, however, from above. It cannot be said that there is much softening around the tumor.

Microscopical examination shows this tumor to consist of various kinds of tissue. In places, especially at the peripheral portions, it is composed of branching cells like the neuroglia cells; the fibrils are delicate and the cells small with large nuclei; in an occasional cell more than one nucleus is seen. In the central portions there are areas of pure round cells without projections and in every way like the cells in round-celled sarcomas; then again there are more or less homogeneous areas without any definite cellular structure; there are also foci composed of granular brownish pigment and blood corpuscles as well as areas of recent hæmorrhagic infiltration. The vessels are numerous and large, comparatively speaking, with many saccular dilatations, and the vessel walls are all very thin and, in places, are simply canals, containing blood, without distinct walls; in two places blood is seen in the act of passing into the tumor through the embryonal wall.

Diagnosis.—Telangiectatic glio-sarcoma.

Remarks.—In this case one interesting feature is the apparent causal connection between the injury and the development of the tumor. Quite a few cases presenting just as distinct, apparent traumatic origin, if not more so, are found in the literature. Eichborst records two cases in which a sarcoma of the cerebellum and a glioma of the pons followed injuries to the head in two boys, resulting in death one and one-half and eight months respectively, after the trauma. Curschman, cited by the same author, observed a sarcoma develop at the site of an injury causing a fracture of the skull. Starr remarks that there seems to be no doubt that blows and falls on the head may cause intra-cranial tumors, and in fact many writers attribute the frequent falls of children on the back of the head as explaining in part the greater numbers of tumors in the posterior cranial fossæ in early life.

The fact that the tumor has developed immediately after and is apparently the result of an injury is thought by Bramwell to suggest that it is either a syphilitic growth, a sarcoma, a glioma, or a scrofulous tumor.

The length of time intervening between the receipt of the trauma and the appearance of symptoms in the case described, was about six or eight months; during this time the tumor may have been latent, the general symptoms being due to the gradually increasing intra-cranial pressure and the encroachment of the growth upon the vermes, because

it is only when this portion becomes affected that vertigo, nausea and vomiting and other symptoms, more or less characteristic of cellular growths, appear.

Death in this case undoubtedly occurred in coma in consequence of the continually increasing intra-cranial pressure.

Anatomically the tumor appears to be a quite typical example of glio-sarcoma with large and embryonal blood-vessels, and consequently presenting a favorable condition for the occurrence of hæmorrhages, congestions and areas of softening, with the sudden exacerbation of symptoms usually observed on this account in similar growths; exacerbations which by some authors are utilized in the differential diagnosis between the various kinds of tumors, because they can only occur in vascular or telangiectatic growths, such as sarcoma and especially the soft varieties of glioma. This tumor illustrates well also the production of internal acquired hydrocephalus due to pressure at the base of the brain upon the veins of Galen, and perhaps upon the passage between the third and fourth ventricles.

A NEW KNOT TYER.

BY A. H. CORDIER, M.D.,

OF KANSAS CITY, MO.

In doing abdominal and pelvis surgery much valuable time is often expended in tying sutures and ligatures in the recesses found in these localities. Feeling the necessity of some device to minimize the time in doing this difficult part in this class of surgery I have devised an instrument known as the "Cordier knot tyer." The working of this instrument has proved to fill in every respect my greatest expectations. Its application has a wide range and will I trust prove to be as invaluable to others as it has been serviceable to me.

I will briefly mention a few of the many operations in which this instrument can be used to a good advantage in saving time and doing good execution.

In a vaginal hysterectomy where the uterus is fixed and it is impossible or unadvisable to drag the organ down within easy reach and where the operator is using ligatures on the broad ligaments or even in the vaginal vault, where the sutures are introduced to stitch the peritoneum to the cut edge of the vagina as is recommended by Martin, the application of the tyer here is indispensable.

If an artery is divided in an inaccessible locality, to tie with the hands, the tyer will quickly secure the vessel and permit of the forceps being removed at once. In vesico-vaginal fistulæ the sutures can be tied in an incredible short period by the aid of the tyer.

In performing an Emmet's operation on the cervix in a small vagina or on a cervix that is not within easy reach and where the operator is using silk or catgut or even silver wire or silk worm gut, the knot can be run up and tightened as quickly as if on the surface of the body.

In performing the Eastman operation or total abdominal hysterectomy, the instrument is indispensable as a time saving device.

In supra-pubic cystotomy for the removal of tumors or an enlarged prostate of ligatures or sutures are to be used, the operator is certainly working to a great

disadvantage without an instrument of this kind to do the tying quickly.

Where the surgeon is operating to remove an impacted gall stone in the cystic or common duct and it is found necessary to split the duct over the site of the stone, the tyer will aid him very much in tightening the sutures when he comes to closing the opening made in this canal.

In the small capillary bleeding hæmorrhoids where the hæmorrhage may be so great as to endanger the life of the patient, the quickest and surest procedure is to ligate the small raspberry like tumor: the tyer here is of much service, making a tedious procedure very quickly and easily performed. This variety of hæmorrhoidal tumors is usually situated high up in the rectum. Allingham has well said: "The secret of the well being of your patient (in ligating internal hæmorrhoids) depends greatly on this tying—a part

the blades (see cut) is the loop carrier, which carries the loop down to the exact place where the surgeon desires the knot to be tightened, this carrier holds the loop or knot stationary while the blades are being separated and the knot tightened. The ends of the ligatures are held in the left hand of the surgeon. As soon as the knot is tightened down on the vessel or the suture is so secure that it will hold its place the carrier automatically retracts. The sutures may be tightened even with more force than it is possible for the hands to stand without the ligature cutting the fingers.

These are a few only of its many applications. The tyer is manufactured by Wm. H. Armstrong & Co., Indianapolis, Ind.

Kansas City, Mo., 1024 Walnut St.

SKIN GRAFTING UPON THE CRANIUM.

Presented before the Chicago Medical Society.

BY FREDERICK C. SCHAEFER, M.D.,

OF CHICAGO.

PROFESSOR OF CLINICAL SURGERY, NORTHWESTERN UNIVERSITY MEDICAL COLLEGE; PROFESSOR OF SURGERY, WOMAN'S MEDICAL COLLEGE; SURGEON TO WESLEY HOSPITAL.

The patient I present this evening has been cured for five years. I exhibited her before the American Medical Association in the spring of 1887, when the new scalp covered about three-fourths of the skull. In September, 1887, the case was reported in the International Medical Congress in Washington. At this time there remained an open spot upon the head corresponding to the dimensions of a silver half dollar; a month later this was also covered. The scalp is complete and has been in this condition ever since November, 1887. It may now be appropriately entered upon record as a cure.

Since the subject of skin grafting was first introduced by M. M. Reverdin and Frank Hamilton, innumerable and varied trials have been made to close wounds by this procedure, with variable degrees of success, all over the civilized world, but an extensive search of the medical literature gives very meager information concerning skin grafting upon the cranium.

This young lady, twenty-four years of age, was at work in a laundry under a revolving shaft, July 9, 1886. The shaft was between four and five cm. below a heavy beam, and about twenty-five dm. above the floor; it was making 225 revolutions a minute, as computed by the engineer. The girl was said to have reached up for something on the wall, when the wind blew her hair toward the shaft; instantly she was drawn against the beam and shaft, and fell back to the floor without her scalp.

The narrow space between the beam and shaft doubtless saved her life. She then walked up stairs (the accident occurred in a basement), where I found her sitting in a chair moaning piteously, presenting a most ghastly, heartrending appearance. The entire skull was laid bare, from the margin of the eyelids to the neck. The nasal bones were uncovered and broken, exposing the superior nasal meatuses. The skin of the eyelids was removed from within three mm. of their edges. The border of the wound was traceable from the lower portion of the left external angular process of the frontal bone and margin of the left upper eyelid, downward and backward below the left ear, which was entirely removed; thence the

of the operation by no means easy as all practical men know, to effect."

Of 29 cases of spleenectomy 14 died directly from hæmorrhage and 3 from shock. The difficulty in tying the vessels and the great shock produced by dragging on the pedicle can be avoided by the use of the tyer. The application of the instrument has a wide range.

The tyer as the reader will see by the cut has the same arrangement governing the movements of the blades as is used in the Knott's detent dilator. The carriers have automatic threading ends, this permits the ligatures to be quickly placed in position to be tightened as soon as the handles are closed. Between

wound extended across the neck five cm. below the superior curved line of the occipital bone, and could be traced forward through the lower third of the right auricle, to the right external angular process of the frontal bone and margin of the right upper eyelid, across the right lid, nose, and the left lid to the point of commencement. The superior border of the left zygomatic process was broken, exposing the cavity within the process. Every vessel and nerve supplying the scalp was torn off, and the pericranium was lost in three places; one spot, corresponding to

poral, occipital and posterior auricular arteries had to be tied.

I came to the patient within three-fourths of an hour after accident occurred. Controlled hæmorrhage, examined the scalp, wrapped the head up in carbolized gauze. The scalp was thoroughly mangled and covered with fragments of hair on its inner surface, which had to be removed. In order to save time, I sent for my friend and neighbor, Dr. J. D. Skeer, to assist in the immediate treatment of the case. Dipped the scalp in warm carbolized water,

the center of the forehead, was oval in contour and measured 5x7 cm.

The other exposed surfaces of the bones were located on either side of the calvarium, on the corresponding parietal and temporal bones; were elliptical, eight cm. long, six cm. wide. The neck flap of the wound fell away from the muscular structures beneath it, exposing the trapezius muscle almost halfway to the shoulder-blade. The trachelo and sterno-mastoid muscles were also uncovered, the latter to the extent of seven cm. The right ear was

picked off the broken hairs from its inner surface, and cut off the hair from the outer surface, while Dr. Skeer prepared the head for the reception of the scalp. Together we freshened the edges of the wound, stitched the scalp back by continuous suture, and sewed the right ear in its position. Applied iodoform over the entire suture, and coiled small narrow sacks filled with warm sand about the head to keep the scalp warm.

After three days, uncovered the head and cut

torn through its lower third, and hung at the side of the neck by an isthmus of skin less than five mm. in width. The exposed surface of the wound measured forty-five cm. in length from before backward, and thirty-nine cm. in width near its central portion. The sutures of the cranium were distinctly seen at several places. There were only a few muscular fibres left upon the head—a portion of the temporal muscles on either side, and the levator palpebræ muscles in the orbits. Hæmorrhage was profuse; the tem-

through the scalp in several places to let out the pus which had accumulated beneath it. On the seventh day removed all dressings. The scalp was now permeated with gases of decomposition, and baked firmly against the calvarium in many places. Removed it. The right ear was warm and joined at the sutures. During the first three weeks we had little hopes for the patient's life. Her pulse varied from 90 to 130 per minute, while the temperature fluctuated between 100° and 140° F. Was delirious about

three weeks, having lucid intervals; her head had to be propped up with pillows. After the second week her neck became stiff, the muscles were rigid, neck turning to one side. To overcome this tendency, had the bed turned so that it became necessary for the patient to move her neck in the opposite direction. Also had her exercise the neck by rotating and bending it. The optic nerves were extremely sensitive. Vision weak at $\frac{1}{20}$. She complained of noises in

lation tissue, the others near the edge of the wound upon the eyelids, where there was the least suppuration. The head at this time was covered with granulations from the pericranium, excepting in places where the periosteum was lost; these were gradually covering in also, from their margins. The grafts were held in place with fish skin, and the bandages were permitted to remain in position forty-eight hours, when the four grafts upon the vertex presented

both ears. Hearing distance, right ear, $\frac{6}{40}$; left ear, watch C. During the fifth week she left her bed and walked about the room.

Six weeks from the day the accident occurred, I concluded that skin grafting might be most promising of satisfactory results. Suppuration was very

a pink color, and five of the grafts over the eyelids were washed away by the pus. I then attached eighteen grafts, eight on top and ten near the margin, as before. After another forty-eight hours all on the top of the head were pink, the four previously planted were spreading. Those near the margin of the wound remained also, but did not look as good.

free at this time, and the patient was too feeble to permit of any treatment requiring extensive operative procedure. I therefore, on the 15th day of August, took thirteen epidermal grafts from the flexor side of her sister's arm and placed them upon the patient's eyelids four mm. apart. By way of experiment, four of them were placed upon the center of the cranium in direct contact with the granu-

The constant accumulation of pus interfered with the growth of the marginal grafts. I was therefore lured on to place the greater portion of them near the vertex in semicircles, coming forward to meet those which were growing over the lids. October 12, my notes say there is a piece of transparent skin, thirteen cm. long and seven cm. wide, extending from the eyelids backward, besides twenty pieces, varying in size from a ten cent piece to a quarter of a dollar,

noon the sides. On the 15th of October, noticed, that the new skin began to liquefy in spots. October 17, 2 o'clock A.M., a copious hemorrhage occurred from one of the venous channels between the tables of the right parietal bone; the blood ran forward and to the left side, beneath the front half of the new skin, which was thus destroyed. A few days later the other half was perforated by many small ulcers. In ten days more it also disappeared. Over two months' work was destroyed in as many weeks. The amount of tissue lost would be represented in one piece by an oval measuring fifteen cm. by 11 cm., to produce which 915 grafts were required. Although somewhat discouraged by this disaster, we were not dismayed, but endeavored to retrieve our loss by vigorous grafting.

Having noticed that the skin derived from the epidermis, chiefly, was very thin, immovable and short lived, I resorted to *dermal* grafting, picking up each time, also, a few fibers of subcutaneous connective tissue. Suppuration having greatly diminished, all of them were placed about the circumference of the wound. About sixty-five per cent. lived. During this month, November, two irregular pieces of bone measuring 3x2 cm., were removed from the outer table, where the pericranium was gone.

December 1st, there was an irregular band of skin around the entire head, six cm. wide in front, and four cm. wide at the back and sides. The last two series of grafts did not thrive. Up to this time heterodermal grafts only were brought into requisition from her sister and three brothers. As the patient was now able to walk out of doors, she gained in strength, and the thought occurred to us—Dr. Skeer, who called to see her at this time, and myself—that tissue taken from her own person might do better than the heterodermal material. On the 24th of December, commenced taking grafts from her left arm. The rapidity of the growth of her own grafts was simply marvelous. For example: One day thirty were placed in a double row, set three mm. apart. In thirty-six hours they put on a pink color. Three days later they were joined in one piece. The connecting parts were slightly depressed, and of course quite thin. By the eighteenth day a few hair like vessels were detected in the new tissue. Eight times after our first misfortune, numerous ulcers started at different places. At one time there were eighteen of them. They were evidently caused by the contraction of the subcutaneous tissue, whereby the fine vessels were broken.

Many of the ulcers healed of themselves, but the larger ones were assisted by autoplasmic grafts; 4,500 grafts were planted, of which the patient supplied 1,800.

May 1, 10th month, there remained uncovered four spots, each a trifle larger than a silver dollar. I expected to complete the scalp in four weeks, when suddenly her strength gave out. She took a severe cold, suppurative inflammation of the left middle ear followed, the mastoid process became very tender, and a dozen new ulcers appeared; two large ones, each about twelve cm. long and from one to three cm. wide. The combined area of all might have been represented by a circle sixteen cm. in diameter. The patient was almost disheartened; she slept only three hours of a night for three weeks; her head ached, sight grew dim, and I feared leptomeningitis was about to occur. Gave her opiates and

tonics. After three week's depression she reacted, when grafting was resumed. Occasional discouragements have been met with since, but now she feels good; says the head and eyes seem as strong as before the accident occurred. Her hearing has greatly improved also.

From the beginning, the entire wound was treated antiseptically with carbolic acid, iodoform, and corrosive sublimate. It was dressed with strips of carbolized gauze prepared with 2½ per cent. solution. The strips were 6 cm. wide, 30 to 35 cm. long. A layer of them, which came in direct contact with the granulations, was anointed with vaseline, so that it could be readily removed, then a series of strips was superimposed upon each other; next a piece of lint covered on one side with vaseline was placed over these and external to the lint a roller bandage made of cheese cloth was wrapped about the head. This formed convenient and serviceable dressing. The lint and strips were easily removed. The interstices of the gauze, by capillary attraction, drew the secretion from the wound's surface; the lint prevented too rapid evaporation whereby the dressings were kept from baking against the wound. The outer bandage retained the other parts in place. Thinking the lint heated the head, by way of experiment it was left off; but each time the dressings were stuck against the cranium, so that they were removed with difficulty, therefore continued using it.

At first the grafts were held in place by means of a piece of fish skin, which after thirty-six hours began to liquefy, and could be removed with a sponge. Repeated experiments caused me to discard this. The fish skin would break down, commingle with the secretion and help to macerate the grafts. Next tried McIntosh dressing. This heated the tissue too much, and the grafts were often found floating in the fluid beneath it. Having observed that the secretion always clung to the gauze dressing, that as a rule the thicker the layer of gauze used, the less discharge remained upon the wound's surface, I concluded to place a pad of oiled carbolized gauze upon the grafts instead of the rubber or fish skin. This worked remarkably well. Six or eight thicknesses of gauze, extending two or three cm. beyond the grafts in all directions, were applied. This had the desired effect of absorbing the secretion, reducing the heat to a minimum, while the grafts generally remained in place. The grafts usually assumed a pinkish appearance in forty-eight hours. Occasionally a series of the autoplasmic grafts when the patient felt exceptionally good, would be almost pink in twenty-four hours. Many of them, however, gave no evidence of being alive until after seventy-two hours. Several times grafts which hung to the dressings, covered with serum after forty-eight hours, being replaced, took hold and lived.

The progress of the growth of the new skin was similar to the description of M. Riverdin. A narrow, one mm. zone of hyaline tissue, somewhat depressed, surrounded the grafts in ninety-six hours; this grew with variable degrees of rapidity until the grafts were joined, then it grew thicker. After three weeks, sometimes a few days earlier or later, fine vessels were traceable in this new tissue; these increased in size until the skin was literally a network of vessels. As they continued developing it was noticed that the larger ones were directed upward. Later some of them assumed very nearly the position of the

normal arteries, like the temporal, occipital, etc. Now many of them have a bluish color, being evidently veins. The grafts were derived from her sister, three brothers, and herself, aged respectively seventeen, nineteen, twenty-four, twenty-seven and thirty years. They varied in size averaging about four by three mm., the central portion consisted of the entire *derma* with subcutaneous tissue, the marginal portion comprised epidermis only. Simply a fold of the skin was lifted with the sclerotica forceps and hastily snipped with iris scissors. When removed their under surfaces curved inward. They were then spread out and laid in direct contact with the granulations. The peculiar form of the grafts seemed to exert a favorable influence upon them. Their inward curvature caused them to cling closely to the granulations and an immediate suction action took place. The patient said she could feel them draw as soon as they rested upon the head. I have no doubt that the empty vessels in the grafts expedited this process.

Many times grafts six by seven cm. were tried without success. Tissue with hair was also applied; but the hair bulbs atrophied. Ten to one hundred grafts were planted at a sitting. Most of the time twenty to thirty only were used. Usually two days intervened between the graftings. Frequently, however, several weeks' rest had to be given the patient, on account of her weak condition.

All of the skin from the margin of the superior eyelids upward presents the characteristics of the normal skin. It is pliable, soft and movable. The lower half can be pinched up in folds. It imparts a velvety sensation to the fingers when touched. Furrows with pores opening into them are plainly visible with the hand glass. Follicles are abundantly present.

Her head sweats freely all over, and the new skin feels to the patient like the skin in other portions of her body. The eyelids are somewhat retracted, less, however, than they were four months ago. The younger portion of the tissue appears quite red, myriads of small vessels can be seen in it. As the skin grows older, the smaller vessels gradually disappear from view; others appear larger; the integument assumes a more normal appearance as to color and consistency. It also becomes more movable owing to the development of subcutaneous connective tissue. One cannot see where the new skin begins upon the eyelids. The lids close perfectly so that the lady sleeps with closed eyes.

Our works on surgery give no statistics, although at different times such accidents have occurred in the manufacturing States of our country. After having written many letters to physicians for information, concerning cases which came under their observation or treatment, I received responses from two only. I have imperfect reports to give of six cases:

Case 1.—A girl, nineteen years of age, lost her scalp fourteen years ago, in the Elgin Watch Factory, Elgin, Ill. Dr. E. Powell, of Chicago, informed me that the wound extended across the forehead above the eyebrows and that her ears were not touched. Skin grafting was tried repeatedly in this case, with no results. Was told by a surgeon who saw her recently that one of her eyes was lost since by exposure occasioned by retraction of the eyelids.

Case 2.—Gross' "Surgery," last edition, makes mention of a young lady who lost her scalp in a factory in Philadelphia, 1869. He simply says the wound cicatrized over.

Case 3.—Reported in the "Surgical History of the War,"

Part 1, p. 315. A conductor on the Union Pacific Railroad, was scalped by the Sioux Indians, near Cheyenne, in 1869. Wound as indicated by the illustration given, was elliptical, measured about 10x8 cm. A portion of the outer table of the cranium was removed. The wound healed over.

Case 4.—Reported by her employer, Mr. E. F. Smith, Miss Hattie Thomas, of Union City, Conn., March 29, 1871, in a button factory, placed her head under a swift running shaft, to pick up a button when her hair was caught by the shaft and her scalp taken off from the nape of her neck to her eyebrows. Her physician was Dr. S. C. Bartlett, now deceased. He cleaned the scalp and placed it upon the head about two hours after it was torn off, but it did not stay long. Then commenced skin planting. Had the head almost covered twice. Each time it was lost. A third effort proved successful in healing the wound, so that she was able to work after two years.

Case 5.—Miss Newman, Bristol, Conn., had her scalp torn off by her hair catching in the machinery in a mill where she was at work during the past winter. The entire scalp was gone, an eyelid and an ear slightly torn. She was treated by Drs. Wilson and W. E. Way, of Bristol. Result of treatment not given. "The Hartford Times" of last July, contained an advertisement for volunteers, to furnish skin for grafting.

Case 6.—Reported by Dr. W. W. Horton, of Unionville, Conn., June 12, 1885. Rosa Flynn had her entire scalp torn off by her hair catching in the shafting of a paper mill, Unionville, Conn. The scalp was torn from the back of the neck around, just above ear to the nose, taking the eyebrows. There was also flap torn down the right side of the face nearly to the mouth. I treated her for one month, then sent her to the Hartford Hospital, where skin grafting was tried. Both human and rabbit skin was used. It was a failure. Lids are retracted. The wound is still open. Hemorrhage occurs from the capillaries when her head gets on a lower level than her body. Expect the wound will cicatrize over in another year. It will be noticed that in none of these cases was the wound as extensive as in the one under consideration.

Deductions from experience in this case.

1. When grafts are set within five mm. of each other, a stronger skin is produced than when they are placed further apart.

2. A graft will grow to many times its dimensions, so that a circular graft three mm. in diameter will form a piece of skin eighteen mm. wide, but the skin will not be as strong or of as good a quality as when the grafts are closer together.

3. *Dermal* grafts with a few fibres of connective tissue form a smooth, soft, pliable, movable skin, presenting the characteristics of normal integument.

4. Epidermis placed on the cranium produces only a thin film, which ulcerates readily.

5. Auto-dermal grafts are more reliable than hetero-dermal grafts, providing the subject is healthy.

6. Grafts from a person near the patient's own age do better than from one much older or younger.

7. With *dermal* grafts the follicles are preserved, whereby the patient is made more comfortable, the skin produced is more natural, hence more durable.

8. The most reliable skin is formed by grafting about the circumference of the wound, say one or two rows, producing a narrow strip one cm. wide, and waiting until the blood vessels are well developed in it, then plant another series close to the last ones. By this plan, contraction in the marginal tissues takes place in advance of the subsequent graftings, diminishing the liability for the ulcerative process to occur by reason of such contraction.

9. The new skin is fed by the tissue upon which it rests, probably by osmosis, but depends for its permanent sustenance upon the vessels growing into it from the circumferential tissue. This fact is thoroughly established in my mind, as it was frequently demonstrated by the death of the patches of new skin removed from the marginal tissue. Time and ma-

terial can therefore be saved by constantly grafting from the circumference in large wounds.

10. All things considered, grafts will grow better in a new wound than in an old one; and the more recent the wound the more certain are they to thrive. In the present case, during the last three months, notwithstanding the improved physical condition of the patient, only twenty per cent. of the auto-dermal grafts took, while six months ago eighty-five per cent. could be depended upon.

582 Washington Boulevard.

DOMESTIC CORRESPONDENCE.

PHILADELPHIA LETTER.

The fortnight of Siberian winter which prevailed during the early part of January, has been succeeded by a general thaw, which has filled the streets with indescribable compost, and the air with germs and moisture. Diphtheria and scarlatina are still with us; but are on the decline. No cases of small-pox or of typhus have appeared in this city for many months, but typhoid fever and phthisis claim entirely too much prominence in the weekly death returns. The City Board of Health is not as fully sustained by public sentiment as it should be, and in fact has been criticised for the continuance of diphtheria, of which there have been from ten to twenty cases daily. It probably should have done much more; but it has had difficulty in securing sufficient funds for properly carrying on its work. The method of dealing with contagious disease in the city is as follows:

All practicing physicians are required to report every case of contagious disease (not including consumption) within twenty-four hours, under a penalty of \$50 for neglect.

So soon as a case of diphtheria or other contagious disease is reported, no matter what the circumstances of the family may be, a medical inspector is promptly sent to the place to make an inspection. If he finds that it is a case which cannot be properly cared for at home, he sends it to the Municipal Hospital, and institutes proper measures for disinfection, and holds the place under observation until the period of incubation of the disease has passed. If the disease is one which does not require such rigid measures, he holds the case under supervision during its entire continuance. It is his business to supply families with circulars, giving plain instructions as to the management of the disease from beginning to end, and after convalescence; or after death, should it occur.

A medical inspector is sent to coöperate with the medical attendant in all necessary precautionary measures, and, if disinfection cannot be properly carried out by the family, a disinfectant is placed in charge of the work, the disinfectants, chloride of lime, liquid carbolic acid and sulphur, being furnished gratuitously. If there are children in a family where contagious disease exists, it is the practice to notify the principal of the school where the children attend, to that effect. A patient is always isolated and the family cautioned to prevent intercourse with the house. When this advice is not taken, and where there is a lack of confidence of the ability of a family to carry out sanitary measures, it is the practice to place watchmen before the premises to see that the instructions of the Board are complied with.

The Board, also offers freely to the poor the use of disinfecting chambers and cremation furnaces at the grounds of the Municipal Hospital, for disinfecting such articles as cannot be done at home. The rules governing the burial of bodies are strictly enforced. The medical inspectors, of

whom there are 15, are giving the greater part of their time to the supervision of diphtheria cases, while five disinfectors are employed to purify houses where diphtheria is prevalent.

The Health Officer, Major Veale, has to contend with doctors who are loth to report contagious diseases until the cases terminate fatally, and with others who hold to the theory that diphtheria and scarlet fever are not contagious. He thinks that there ought to be a building, or series of buildings, where persons who are liable to contagion could be taken and kept under observation, their homes in the meanwhile being thoroughly disinfected. The city at present, generally speaking, is in a fair sanitary condition.

There is a movement now on foot to establish a special hospital for the treatment of diphtheria, or of infectious diseases other than small-pox, for which a Municipal Hospital already exists. Provost Pepper of the University, has come out with a strong appeal in the *Public Ledger* from which we take the following paragraphs:

"When will the people come to be willing to pay for the inestimable blessings of preventive medicine? Do they not know that modern methods of isolation and disinfection enable us to prevent the spread of infectious diseases, if the patients are placed under proper conditions? The germs of these infectious diseases retain their vitality and their virulence for a long time. They attach themselves to furniture and clothing. They are carried by physicians, by nurses, by relatives. Infected linen is sent to the laundries, and a fresh centre for the spread of the disease is created. Cases in families, after arriving at a hotel, develop. There is no suitable place to send the patient. The occurrence is concealed as far as possible. Isolation is impossible. Disinfection is imperfectly carried out. The germs of the disease remain in the apartment and may also be diffused widely. So long as there is no attractive, properly constructed and well administered special hospital for contagious diseases, with isolation wards for each of the chief affections, it is impossible for the community to escape the grave consequences of their neglect.

"The Municipal Hospital answers an excellent purpose, but there is needed in addition a special hospital, more centrally situated, with accommodations adapted to the various classes of patients, and with a staff of attending physicians of large experience in the treatment of these diseases. There need be no objection to the location of such a hospital near the centre of large cities. A sufficient space should be secured, but it would not require an extensive tract. Proper construction and careful administration would remove any chance of the disease spreading in the neighborhood.

"The prompt removal of each case of contagious disease from hotels, public institutions and as far as possible from private residences to such a hospital would effect a vast saving in life and in the risk of the disease spreading. As a matter of fact, the well-to-do classes will not allow one of their family to go to the Municipal Hospital save under the constraint of law, in the case of small-pox. As a further matter of fact, it would be essential that all respectable physicians in the community must have the privilege of attending patients whom they may send to such a special hospital as is here urged. Otherwise it would be idle to hope for the coöperation of the profession or the support of the community."

This proposed hospital has met with general favor among physicians and Dr. Robert B. Cruice has made the suggestion that, as the Government has no further use for Fort Mifflin, this island in the Delaware would provide an admirable location for a hospital for infectious diseases. Thus far, however, no steps have been taken towards carrying out these important suggestions.

While discussing hospitals, it should be noticed that the friends of the late Prof. D. Hayes Agnew have concluded, very opportunely, to erect a memorial ward at the hospital of the University of Pennsylvania, devoted particularly to the treatment of surgical diseases and injuries of children. This memorial seems especially appropriate, since Dr. Agnew was known to be opposed to the post-mortem

vanity of statues and monuments; and, although his marriage was childless, was very fond of children. The "D. Hayes Agnew Memorial Children's Ward" will probably hold from thirty to fifty beds. The sum required will be \$150,000, of which two-thirds are expected to remain as an endowment, and the remainder to be expended on building and furnishing. A permanent association has been formed, which will shortly address an appeal for funds for this purpose, to the friends of the late Dr. Agnew, in different parts of the world. Joseph G. Rosengarten, Esq., of this city, is the secretary of the organization.

The recent election of Dr. George E. DeSchweinitz as Clinical Professor of Ophthalmology, at the Jefferson Medical College, by the Board of Trustees, is considered an eminently proper appointment and both the new incumbent and the College can be congratulated. The Alumni Association of the Jefferson College, however, has had its attention directed by the public press to the fact that Dr. DeSchweinitz had hitherto been identified with the University of Pennsylvania; and furthermore that the trustees had given no notice of their intention to hold an election, so as to allow the alumni of Jefferson a chance to compete for the prize.

Attention has also been directed in the public prints to the alleged preponderance of University influence in the Jefferson faculty and to the custom of filling vacancies with university graduates. It does seem rather hard upon the specialists who fill subordinate positions and work for many years in dispensary and clinic, to find that when their reward is almost within their grasp, it is tantalizingly withdrawn and handed to an alien; and not even to a brother alumnus. At the annual meeting, held Jan. 14, Dr. W. W. Keen in the chair, however, the whole matter was happily dismissed by adopting the following resolutions:

"WHEREAS, Resolutions have been circulated among the alumni of the Jefferson Medical College and given wide newspaper publication, conveying the impression that they were an official utterance of the Alumni Association of the Jefferson Medical College, and conveying the inference that the faculty and Trustees of Jefferson Medical College are not conducting the affairs of the institution in accordance with principles of loyalty to the college and its alumni, and thereby had incurred the hostility of the Alumni Association, be it

Resolved, That the Alumni Association of the Jefferson Medical College, in annual meeting assembled, tender a vote of confidence to the faculty of the Jefferson Medical College for their energy and activity in furthering its best interests; for their efforts to maintain its high standard of medical education, and for their cordial coöperation with the alumni of the college in advancing the mutual interests of the institution and its graduates; and to the Board of Trustees of the Jefferson Medical College for the wise and progressive character of their present administration."

The resolution was adopted without discussion, as was also a resolution declaring it to be the sense of the Alumni Association that it would be to the best interests of the college if there should be representation from the alumni upon the Board of Trustees.

The association elected these officers: President, Dr. W. W. Keen; Vice-Presidents, Dr. J. C. Wilson, Dr. J. M. Barton, Dr. Morris Longstreth, Dr. John Fay Allen, Dr. J. F. Saunders, of Germantown; Dr. J. A. Lippincott, of Pittsburg; Dr. Thomas Addis Emmett, of New York, and Dr. S. L. Kurtz, of Reading; Corresponding Secretary, Dr. Richard J. Duglison; Recording Secretary, Dr. Orville Horwitz; Treasurer, Dr. E. L. Vansant.

A State Board of Medical Examiners for Pennsylvania is among the possibilities of the near future. The Medical Society of the State of Pennsylvania has approved the bill which is now before the legislature, and which the following is an abstract:

I. The Board shall consist of nine members, graduates of

some legal medical school, "no two of whom shall be residents of the same county, and none of whom shall be a member of the faculty or staff of any medical school or university."

2. The members shall be appointed by the Governor by and with the advice and consent of the Senate.

3. All physicians commencing practice in Pennsylvania after July 1, 1893, "shall be examined in anatomy, physiology, chemistry, pathology, hygiene, toxicology, differential diagnosis, surgery, and obstetrics; and each applicant, upon receiving from the secretary of the board an order for examination, shall draw by lot a confidential number, which he or she shall place upon his or her examination paper, so that when said papers are passed upon, the examiners shall not know by what applicant said papers have been prepared, and upon each day of examination all candidates shall be given the same set of questions."

4. The examination papers and marks shall be preserved and shall be open to public inspection in case of dispute. "No one shall be excluded or rejected on account of adherence to any special system or school of practice."

5. "Each applicant who shall have passed a satisfactory examination shall receive from the said board under seal a license to practice medicine and surgery in the Commonwealth of Pennsylvania."

6. "Nothing in this act shall be construed to prohibit service in cases of emergency or the domestic administration of family remedies."

7. The applicant shall pay an examination fee of ten dollars and "in case of failure at any examinations shall have the privilege of subsequent examinations without the payment of an additional fee."

With consistent unwisdom the members of the homœopathic sect in this locality, it appears, are actively opposing the bill; which does not interfere with the modes of practice; but merely pertains to the essentials of medical education. Is this a confession of incapacity on the part of homœopathic educational institutions; or is it an acknowledgement that the less of medicine a candidate knows the more likely he is to belong to the homœopathic ranks? The daily papers are almost without exception unanimously and enthusiastically in favor of the bill, because "it treats the graduates of all medical schools alike; and makes competency and honesty the only qualifications."

A hospital for the chronic insane is now building near Wernersville, under the direction of a Commission appointed by the State. Dr. Thomas G. Morton, Chairman of the Lunacy Committee of the State Board of Charities, made an address at the ceremony of laying the corner-stone, November 29, 1892. In this address he stated that this is the first institution for the treatment of the chronic insane in Pennsylvania. Inasmuch as many of these patients are harmless lunatics and chronic demented, who do not require restraint and would be benefited by open air exercise and light labor, Dr. Morton argued that their separation from the acute cases would afford immediate relief to the overcrowding of the five existing State hospitals. Moreover, as these patients require less attendants than the acute cases, this plan would be also in the interest of economy as well as of humanity. The State has appropriated the sum of half a million of dollars for the purchase of ground and the erection of the asylum, which is to be on the plan of a parallelogram of semi-detached buildings with the latest improvements in hospital construction. The place selected has long been celebrated as one of the most attractive health resorts of the eastern slope of the Alleghanies, and is in proximity to the city of Reading.

"The Medical Club of Philadelphia" is the name of a new social organization which has just been formed. Its laudable object is to encourage among the members of the profession a more friendly and intimate social acquaintance. The discussion of refreshments of various kinds, it is hoped will take the place of the stereotyped medico-scientific subjects, which are excluded by the articles of the association. Dr. J. H. W. Chestnut is President, Drs. P. D. Keyser and

H. A. Hare, Vice-Presidents; Dr. Lemuel J. Deal, Secretary; and Dr. Roland G. Curtin, Treasurer. About three hundred physicians have signified their intention of connecting themselves with this society, and are putting themselves in training for post-prandial elocutionary honors.

At the January election at the College of Physicians, Dr. S. Weir Mitchell was re-elected President.

The friends of Professor Roberts Bartholow will be glad to be apprised of his return to health and to his practice, as announced editorially by the *Medical News*.

The coroner of Philadelphia has at last furnished the frightful example that the comic papers have long been instituting inquiry for. A boy, 13 years of age, who was said to be an inveterate cigarette smoker, who smoked constantly during his waking hours, was attacked by a violent headache one morning, and this was followed by severe convulsions, which terminated fatally. A verdict of "death from convulsions from excessive cigarette smoking" was rendered, according to the daily papers, which however fail to state whether or not any lesions were discovered in the brain at the post-mortem examination. Without the autopsy it would seem that something would be required, even more potent than the authority of the coroner, to establish a positive diagnosis, or even a diagnosis by exclusion, of death from cigarette smoking.

The report of the Philadelphia Cremation Society shows a steady growth of public sentiment in favor of incineration. Since the establishment of the Society there have been 186 incinerations, divided as follows: During 1888, 14; 1889, 28; 1890, 31; 1891, 51; 1892, 62. There are 205 certificates now in force.

Revision of the Code of Ethics.

To the Editor of the JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION:

Dear Sir:—The writer's letters to THE JOURNAL of January 14 and 28, in answer to "INQUIRER," consist of detailed statements of the reasons why he considers revision of the American code unwise and inexpedient, but now it becomes necessary to state some facts connected with the history of the repudiation of the Code, and with the present status of the advocates of the movement, which has proved so beneficial to the profession in the city and State of New York. The text for these remarks is suggested by an editorial in the *Medical News* of January 28, 1893, but the writer will give first the result of an examination of certain sentences, contained in the *News* editorial of September 17, 1892, not before criticised. These will be quoted and commented on to show that their author has received wrong impressions or has been misinformed.

1. The dissatisfaction with certain provisions of the Code says the author of the *News* editorial of Sept. 17, 1892, expressed itself in the State of New York, especially, to such an extent that one of the most important sections of the Code—one, indeed, which has done more than any other to maintain the dignity of the profession—has been repudiated." A dissatisfaction is expressed, but no reason is offered in explanation, no argument is made to give it form, and no just cause for it is assigned. A few persons are dissatisfied because they are dissatisfied, therefore the world must and shall satisfy them at any cost! This is substantially the kind of reasoning that appears with their demand, and the author of the *News* editorial seems to think that something must be done to appease the wrath of individuals who cannot say why or whence their choler and general discontent. A few disaffected physicians repudiate just and time honored laws, and gather around themselves others who know little or nothing of these laws, blindly follow their misguided leaders, and adopt new laws which tend to

lower professional dignity. Not content with this, they are now striving to disorganize the national body that made the laws, which they seem to consider too strict. The author of the editorial acknowledges that the part of the Code which is sought to be abolished, *i.e.* the consultation clause, "has done more than any other to maintain the dignity of the profession." Notwithstanding this acknowledgement, he wishes to substitute for this clause one which, in letter, is but a very imperfect representation of the original!

2. Another statement in the editorial is as follows: "The antagonisms, produced by this act of repudiation on the part of the *Medical Society of the State of New York* have led to bitter dissensions, and created for a time a serious division in the profession." Until the year 1882, the profession in the city and State of New York was harmonious. A few years before that time, ten or twelve physicians formed a cabal which they extended to the State society and which resulted in the repudiation of the American code, and the adoption of a "new code." Had the dissenters stopped at this point, a simple protest would have been made, but they insisted that the whole profession in the State should adopt their "new code," bitterly denounced all those who differed from them, and spoke in the most disrespectful terms of the National Association in public medical gatherings, in medical journals, and even in newspapers. This was naturally resented by the defenders of the Association in the city and State of New York. The extent of the division of which the editorial speaks was ascertained at the time, for in 1883, the State was canvassed with the following result: Five thousand and two physicians received each, a communication asking certain categorical questions, of this number, 3,826 sent corresponding answers; 34 sent indefinite replies, and 1,142 did not reply. This leaves for "no code" and the "new code" together 1,279, and for the National code 2,547, or within a small fraction of, two to one, in favor of sustaining the Nation's code. In the year 1883 this was the extent of the division of the profession in the State of New York. Since then many of the uncommitted and of the "new code" adherents, have declared themselves in favor of the National code and many more will doubtless do so when they have studied critically the American code.

3. Again the editorial says: "This division, however, is now practically healed, as far as the individual relations of members of the profession in New York are concerned"; . . . This is not strictly correct, for the leaders of the "new code" movement are now as bitter as ever in their denunciations, but the rank and file have already begun to realize that they were easily led into error—by misrepresentations—owing to their want of knowledge of the provisions of the Code, which they do not regard as a set of oppressive laws.

4. The same editorial contains the following: "One familiar with the Code contest in New York nine years ago, in looking back, must recognize the fact that this contest led to action that the majority of the partisans of the two sides would now willingly modify." It is evident from the above sentence, that the author of the editorial, is not familiar with the history of the contest to which he refers. The defenders of the American code, consider that they have acted in good faith in this defense and that they have not been guilty of any act that, in truth, can be characterised as unbecomingly honest and loyal members of the profession, and that therefore there is nothing that requires modification. They stand as firmly as before in the support of the Code. The author of the editorial speaks of "partisans of the two sides." The defenders stood where they had always been, and made their protest, when the public overt acts of the disaffected, came to their knowledge. There was only one set, that deserved the name partisan, for the members thereof adhered closely and fanatically to a faction, and

opposed most vehemently, and traduced, the National Association. These crafty partisans, by sundry dark devices, have long been striving to induce some unsuspecting delegates to take steps toward causing the abrogation of the Code, and have succeeded so far as to bring about the revision proposition; their objective point being the consultation clause, whose suppression they hope to effect in case of failure, to set aside the whole of the Code. If the author of the *News* editorial had been familiar with the "code contest" he would have understood the real motive of the revision proposition and would probably have written a very different editorial, for he is loyal to truth and justice.

5. The author of the editorial speaks for the National code supporters, but evidently without warrant. "The supporters of the Code would now be willing to see it stripped of useless provisions and redundant language, to say the least." It does not appear that consistent supporters of the Code are likely to wish it stripped of what it has not; they would be most illogical to express any such desire, especially after the announcement in the *News* editorial that the "general sense of the profession" is favorable to the Code as it stands.

6. What may now be the views of the majority of those who, years ago, endorsed the "new code," the writer does not know absolutely, but he believes that if they will honestly devote one hour each day, for a week, to the study of the American code with Dr. Flint's commentaries, they will be most likely to abjure the "new code" and adopt the American code.

7. The author of the editorial is now axiomatic and says: "It is time for the adherents of scientific medicine to come together and stand on common ground." This is devoutly hoped for, if he means that the common ground shall imply a common medical faith as expressed in the existing morals of the National Association. If the great majority, or if all of those who so unwisely opposed the national ethics will for a time set aside the self-love, which has probably prevented an acknowledgment of wrong, and band in unison with the national confraternity, with the one laudable object of sustaining scientific medicine, then the American medical profession, with its 100,000 members, will surely exercise an immense power for the good of individuals as well as of the whole nation. Therefore let the same zeal animate all, that the general good may become the good of each, for, divided, though the dissenters be in the smallest minority, the profession can have but little influence with the people, the great masses of which are now led astray medically, by ignorant and crafty charlatans of all sorts; many of whom are liable to become members of State Legislatures, and to make bad laws for the profession and for the people.

8. The editorial very properly suggests "leaving agitators and belligerents in the background. There is no doubt that the agitators and belligerents, *i. e.*, those who so persistently opposed the Nation's code of medical morals, should be left in the background if they refuse to submit to these laws, as there is no other punishment for them but to be left in the background.

9. The author of the editorial further says: "We believe that the great majority of those who have repudiated the Code have no desire to degrade the profession to the level of those classed as irregular practitioners, or to meet such practitioners on terms of professional equality; but rather that they honestly believe in the right to render their services to all, whether the patient be at the moment under the care of a physician or of an irregular practitioner." Whatever may be their desire, they can degrade only themselves by obstinately acting contrary to well established laws. The profession could be degraded only if the majority of its members should be guilty of persistent violation of these laws.

10. The defenders of the Code will doubtless thank the author of the editorial for the following, which appear to be the first conciliatory words he has uttered in their behalf. "We believe also that the defenders of the Code resisted its modification on the highest moral and professional grounds." The defenders of the Code were actuated by the sole motive of preserving law, order, and good professional conduct. They maintained that the standard of medical morals can never be too high. The author of the editorial thinking, very properly of course, that the defenders had done nothing more than their bounden duty, metaphorically pats their backs, saying, Well done, worthy defenders, but you must yield to the evil doers. Like some righters of wrongs, he is for encouraging the erring minority, and for forcing the loyal majority to compromise the honor and dignity of a great National organization, in order to satisfy the unjust demands of this wrong-headed minority. This is the inevitable logical conclusion of the case.

11. The writer's examination of the *News* editorial of September 17, 1892, leads him to believe, that its author has been too hasty in expressing views which do not appear to have been based upon an exhaustive study of so grave a question of morals as is involved in this discussion. It is hoped that this author, whose editorial shows sincerity and honesty, will re-examine the whole subject, that he will study Dr. Flint's book on "Medical Ethics and Etiquette," and then frankly state his conclusions in a new editorial.

12. A few remarks will now be made in respect of the *News* editorial of January 28, 1893. The author of the editorial asserts that the Code "contains unnecessary matter that obscures its meaning, and that its provisions fail, in certain respects, to meet the present requirements of the profession." Will he be so kind as to make and publish a convincing argument that the Code "contains unnecessary matter that obscures its meaning, and that its provisions fail, in certain respects, to meet the present requirements of the profession?" Will he also please to say, which of these provisions fail, etc., and which are the obscure provisions, wherein lies their obscurity, what it is that he fails to understand, and what are the present requirements of the profession, particularly of that "formidable minority," in respect of moral laws? Will he pardon the writer for saying that, after long and careful study of the Code, he has failed to detect the obscuring redundancy and the defects to which the author alludes, but that, on the contrary, he has found the Code definite, distinct, easily understood, and pregnant with meaning and most salutary precepts. Perhaps these qualities have rendered it objectionable to its repudiators.

13. The author of the editorial says that he "should approve of the Code as it is, were it not that there is a vigorously expressed dissatisfaction with it on the part of a formidable minority of the profession." The bare assertion of dissatisfaction is not sufficient, this minority should state why it is dissatisfied, and what is dissatisfying in the Code. What may be expected of this minority, when it ceases to demand but more becomingly requests, has been stated in the writer's letter to *THE JOURNAL* of January 28, 1893. If the Code must be revised, because this is demanded by the "formidable minority," what is to be done with the majority which prefers that it shall not be revised? But suppose that the "formidable minority" should become the majority, this would still leave a "formidable minority" in favor of the Code as it was, and this minority would have the same right to demand its restoration. If this could happen, when would revision end, and when would there be harmony? Is it just and proper that all the other States in the Union should yield to the whim of one State when the grandest moral principles are assailed by that State? Can the author of the

editorial show that there is the faintest spark of equity in the position taken by the opponents of the code?

14. The assertion "blind adhesion to the Code" is in keeping with the "expressed dissatisfaction." The defenders of the Code do not blindly adhere to it, but approve it because they are fully aware of its literary merits, and of the great value of its moral precepts, from having studied it long and critically. The majority of those who repudiated it, knew very little of this Code, and many confessed that they had never read it, while others boasted they would never do so.

15. The writer offers an apology to the author of *The News* editorial for having unintentionally misquoted him in one regard, in the letter to *THE JOURNAL* of January 14, 1893. This inadvertence is scarcely pardonable, but the writer trusts in the generosity of the editor of *The News*, who will kindly convey to the author this poor explanation.

16. Before closing this communication the writer will state a few additional facts relating to the status of New York, in respect of representation in the National Association. When, in 1884, the Medical Society of the State of New York still persisted in advocating the "new code," despite the remonstrance of a large majority of the members of the profession in the State, the defenders of the American code organized the New York State Medical Association in order to secure to New York a proper representation in the National Association. This new Association has since grown to be a power in the State, and now numbers over seven hundred and fifty active members eligible as delegates to the American Association. This statement is now made because many members of the National Association, are under the impression that New York is entirely disfranchised. In accordance with the rules of the American Medical Association, the New York State Medical Association is entitled to send seventy-five delegates annually, and all of its 750 members are eligible to permanent membership.

17. *The News* editorial of Sept. 17, 1892, talks of the exclusion of "able, eminent, and honest co-workers," as if ability, eminence, and honesty could not be found outside the domain of its specified "able, eminent and honest co-workers." The country in and out of New York, is full of able, eminent and honest men who prize the National code of morals. Among the members of the New York State Medical Association, not far from one hundred have been, or are professors or instructors in the medical schools of the city or State of New York. Many of them are authors of eminence in medicine, surgery, obstetrics and gynecology. A large proportion of the members are connected with public institutions, and are performing valuable work for the relief of human suffering and for the advancement of science. During the nine years of the existence of the New York State Medical Association over four hundred essays of a high order of merit, have been read before this Association, on medicine, surgery, obstetrics, gynecology, materia medica, therapeutics, physiology, pathology, hygiene, State medicine, toxicology, medical jurisprudence, insanity, bacteriology, organic chemistry, etc. In the meetings of this Association, no time is devoted to the discussion of ethics, nor is there any such need, for all the members are agreed on the ethical question.

18. The writer has lately seen a list of the members of a local society whose headquarters are in the city of the New York. This society, organized in 1884, under the title of the New York County Medical Association, is in affiliation with, and makes an annual report to, the New York State Medical Association as is indicated in the transactions of this Association. The number of members of this County Association is eight hundred and five, and is said to be rapidly

increasing. In the list of members may be noticed the names of the most eminent physicians and surgeons of New York City. Therefore, the whole of New York State is not disfranchised, and it has an abundance of "able, eminent and honest" workers who are loyal to the National Association.

19. The preceding and following statements should dispose definitely of the cant about "able, eminent and honest co-workers." The diffusion of knowledge is such in this free country that talent does not now need a metropolitan stamp to be recognized. The great universities of the South, of the central part of the Union, and of the far West, have developed genius, in a relatively greater proportion within this decade, than have done those of the Eastern and Middle States in the last half century. "Able, eminent and honest" workers are to be found in abundance everywhere in this land. The disaffected eminent workers must reform, try to be just, or take the "background."

20. The American Association is warned, that the proposed revision of the Code is only a subterfuge to cause the abrogation of the consultation clause. If this clause had never appeared in the document, most probably the question of revision would never have been raised. It now becomes necessary for the Association to suppress the rising disaffection in its ranks, remembering that reformation is too often undertaken only when abuses have become extreme, and that then it is generally futile. It is when an evil is embryo that it should be stamped out forever, or its eradication is no longer possible. Let the American Association then, beware of the hydra of disaffection that unceasingly rises from the depth of distorted minds; that has already shed its venom of discord over one State, and that may spread it throughout this broad land, unless the reptile is speedily destroyed. The demon of the Code heresy will surely renew its onslaught in some form or another after it is believed to have been exorcised. Again and anon will the same or similar turbulent and evil spirits assert themselves with nefarious intent. Therefore, let the Judicial Council—the guardian of good order—be ever on the alert, ready for exorcism, and let the Association raise its mighty voice and annihilate the monstrosity with truth and justice.

A CONSERVATIVE MEMBER.

SOCIETY PROCEEDINGS.

American Electro-Therapeutic Association.

Second Annual Meeting, held in New York, October 4, 5 and 6, 1892.

WILLIAM J. MORTON, M.D., PREST.

FIRST DAY OCTOBER 4—AFTERNOON SESSION.

(Continued from page 131.)

The want of time forbids any elaborate discussion of the physical causes of the two opposite liquid currents, the endosmotic and the exosmotic currents, produced by osmotic action. Suffice to say that they are now generally recognized to be more complex than they were formerly believed to be. They depend, apparently for their action, among other causes, on the phenomena of simple diffusion as modified by capillary action, on the affinities of the liquids for each other or for the septum, and, in some as yet not thoroughly understood manner, on the action of electric currents. So far as the influence of diffusion and capillarity are concerned they depend on intermolecular action, resulting, through the inter-action of cohesion and adhesion, in surface tensions.

Let us now examine what occurs when an electric current is passed through two liquids across a porous wall or

septum which separates them, that is, when the liquid and the septum form part of an electric circuit. Under such circumstances a movement of the liquid takes place in the direction of the current; or, in other words, the level of the liquid rises on the side of the negative electrode and falls on the side of the positive electrode.

Calling as before, the endosmotic current that which is directed towards the higher level, then the electro-endosmotic current is that which passes through the septum in the same direction as the electric current.

Now regarding the skin and other membranes of the human body as septa, if electrodes moistened with medicinal substances, such for example as a soluble iodide, cocaine, quinine, etc., be applied to different parts of the body, and an electric current be passed between such electrodes, a flow of the solutions placed in or around the electrode takes place in the direction of the electric current, by means of which said solutions are carried into the tissues of the body. The introduction of drugs or medicaments into the human body by such means is called cataphoresis, and I have been asked to state the principles of cataphoresis from the standpoint of the physicist.

The task is a difficult one for the following reasons: Even if the physics of the phenomena of simple osmose were thoroughly understood, a discussion of the causes and phenomena of electric osmose would be a matter of considerable difficulty, since the introduction of the electric current would considerably modify the results. But when to the complexity arising from the introduction of an electric current into the problem, is superadded the complexity arising from the effects of vitality, of modified nutrition, of alterations in the contractility of the tissues, the results are so profoundly modified that the study of the phenomena of cataphoresis from the standpoint of the physicist only, or, in a more limited manner, from the standpoint of the electrician only, must necessarily fail of its best results unless supplemented by the study both of the physiologist and of the practicing physician.

The exact causes of the phenomena of simple diffusion are by no means thoroughly understood. The fundamental causes of the phenomena of electric endosmose in non-living matter are still involved in dispute. The causes of the phenomena of cataphoresis, or electric endosmose in living matter must, therefore, of necessity be involved in considerable obscurity.

The effect of an electric current passing through a tissue of the body in determining a flow of liquid through such tissue in the direction of the electric current was first observed by Reuss of Moscow, and afterwards by Porret, who called it electric endosmosis. It is now sometimes known as Porret's phenomenon. Porret observed that when an electric current is passed through a living, fresh, sarcoous substance, the contents of the muscular fibre at once take on a flowing or streaming movement in a direction which is the same as that in which the current is assumed to flow; viz., from the positive towards the negative pole, and that there results from this movement a swelling of the fibre at the negative pole.

The problem is still further complicated by the belief, that has existed for a long time, that the phenomena of simple osmose are invariably attended by the presence of electric currents. If this is true, and it certainly appears probable, then the presence of such currents cannot be without its influence on osmotic phenomena.

According to Graham, a chemical action on the material of the septum invariably attends osmotic action. For this reason, the phenomena are practically absent in neutral solutions, and are most marked in acid and alkaline solutions. In the case of a membrane of ox bladder, Graham

found that the loss of weight of the septum in various experiments varied from 20 to 40 per cent. according to the character of the solution, the kind of septum employed, and the time of duration of the experiment. In the case of such mineral septa as unglazed earthenware, he found alkaline solutions to produce a greater action than acid solutions, because they exerted a chemical action on the septa.

Since chemical action produces electrical currents, it is not improbable that such currents are produced whenever osmose occurs.

But an observation of Graham renders the presence of electric currents in all osmotic currents almost certain. He asserts that one of the surfaces of a membrane or septum through which osmotic action is taking place is invariably acid, while the other is basic, and that this state is invariably connected with the progressive decomposition of the substance of the septum. In other words, the membrane is polarized; an electro-motive force exists which is definitely directed, and presumably, electrolytic decomposition takes place.

But apart from such consideration it is a well-known fact, that when a liquid is forced through the capillary pores of a porous wall or partition, electric currents called diaphragm currents are produced. That is, the phenomena are interchangeable.

Take for example the case of the capillary electrometer, in which a drop of sulphuric acid is placed in a capillary tube filled with mercury. When a current of electricity is passed through the mercury across the drop, it will cause the drop to move in the same direction as that in which the electric current is flowing. If, however, when the electric current is absent from the tube, the drop of liquid is forced to move by the application of pressure, then a current of electricity is produced which flows in such a direction as would tend to move the drop in the opposite direction to that of the motion it is forced to take by the pressure. As you are probably aware, an operative electro-capillary transmitting and receiving telephone has been constructed on these principles.

Since ordinary osmose is attended by the forcing of liquids through capillary spaces, there must, it would seem, be set up electro-motive forces as the results of such liquid flow, and these electro-motive forces would presumably tend to oppose such liquid flow.

The cause of the electric current produced by the motion of the drop of sulphuric acid is generally explained as follows: The contact of acidulated water and mercury possesses a definite surface tension. The two liquids do not, however, actually touch; a small interval or space exists between them. This space acts as a small accumulator. Since different liquid substances are in contact, they acquire different potentials. If the shape and contact of these surfaces are altered by any means, the capacity of the condenser is altered, and consequently an alteration occurs in the difference of potential. The mere shaking or heating of the liquid in such a capillary tube will, therefore, be attended by the production of electric currents. Conversely, an electric current sent across such contact surfaces will produce motion from the change in the value of the surface tension.

But apart from the question as to whether or not there exist electric currents or differences of potential in the case of ordinary osmotic phenomena, there is no doubt that the passage of an electric current from one liquid to the other, through a septum which separates them, causes a modification in the value of the endosmotic current. In most cases it increases such current; according to the observations of Napier, the direction of endosmosis is changed by changing the direction of the electric current.

When flowing in one direction, therefore, the electric current adds to the ordinary endosmotic current a liquid current of its own; when flowing in the opposite direction, it opposes or reverses the direction of the endosmotic current.

Napier alludes to this in a paper on electrical endosmosis contributed to the Chemical Society of London December 15, 1845. I append the following extract from the paper, viz.:

"That two dissimilar solutions separated by a porous partition, will pass the one into the other, is a phenomenon long observed, the only necessary conditions being that the liquids have a strong tendency to combine and that the one is more capable of entering into or wetting the porous partition than the other. Liquids eminently fitted to effect this are alcohol and water and saturated solutions of some salts and pure water. But the phenomenon of endosmosis takes place also when an electric current passes through liquids separated by a porous partition. When all the above conditions are absent and even when these conditions are present, the endosmotic current will follow the electric, although in a contrary direction to that which it would take were there no electric current passing, showing that, under these circumstances, it has its origin in the passage of the electric force. This fact was first made known by Mr. Porret in the *Annals of Philosophy* in 1815."

So too Beard and Rockwell, alluding to this subject, say on page 190 of their "*Medical and Surgical Electricity*":

"The electric currents also exercise a positive and very interesting influence over endosmose. By the passage of a galvanic current the endosmotic phenomena may be both stimulated or reversed. This is shown in the following experiment of Dutochet: A tube containing gum-water is closed at one of its ends by animal membrane and dipped in a vessel containing common water. By the ordinary operation of the laws of endosmosis the water rises in the tube on account of the entrance of some of the ordinary water through the membrane into the tube. But if the positive pole of a galvanic battery be placed in the common water and the negative pole in the gum-water, the endosmotic action is stimulated to such a marked degree that the level of the gum-water rises with much greater rapidity; if we reverse the poles the level of the gum-water in the tube sinks instead of rises. The faradic current from the secondary coil produces no such effect. The current from the inner coil—the extra current so-called—produces these effects to a less degree. It is pretty clear, therefore, that these phenomena depend on the *chemical* and not on the *mechanical* power of the current."

An extended study has been made of the phenomena of electrical endosmose. Besides the observation of Reuss and Porret, already referred to, many other able investigators have worked in this field of research.

I will cite only the following generalization of the results of many experiments by De la Rive, viz.:

"The force with which a galvanic current tends to transport a liquid through a porous partition from the positive to the negative wall is measured by a pressure which is directly proportional to the intensity of the current, to the electric resistance of the liquid, to the thickness of the porous partition and inversely proportional to the surface of that partition."

When an electric current is caused under certain conditions, to pass through compound substances a chemical decomposition, or, as it is generally called, an electrolytic decomposition of such substance occurs.

It is almost certain that when an electric current is caused to pass through certain liquid substances across a wall or septum separating them, that if not in all cases, at least whenever the strength of the current reaches a certain value, electrolytic decomposition takes place, and that there-

fore another cause is introduced to still further modify ordinary osmotic action.

As we have already seen Graham has shown that a decomposition of the septum occurs with a polarization and progressive decomposition of its substance.

That foreign liquid substances as medicaments can be successfully introduced into the body by electric endosmose does not admit of doubt, and an extremely extended and valuable field is thus opened up to the electro-physiologists. This part of the problem, belongs gentlemen to you as electro-physiologists and electro-theraputists. To me as a physcist, there remains only to be added a few conclusions or generalizations which I think are correct concerning the cataphoric effects of an electric current. These conclusions are as follows, viz.:

1. That the presence of electric endosmose is more general than has heretofore been suspected.

2. That whenever a constant electric current is sent through the human body whether for ordinary therapeutic treatment, as well as for some definite cataphoretic treatment, a true cataphoretic action must occur. There must be determined through all the membranes or membranous substances which lie in the path of the current, a flow of certain of the fluids of the body in the direction of the current. The result of these cataphoric currents must be to engorge certain parts and deplete other parts: and, it is possible, that in many cases the therapeutic value of the current may arise mainly from such action, by the transportation of morbid matters from one part of the path to another part, or to a more uniform condition of pressure in certain parts by the transportation of fluids from gorged to depleted tissues.

This in all probability explains why in so many cases one electrode only acts as the therapeutic electrode, and the other as the indifferent electrode.

3. That since cataphoric action presumably accompanies the passage of an electric current through the body, the resistance of the entire human body, or of the parts of the human body, cannot remain uniform. Besides the variations of resistance that attend variations in the condition of the skin, and those that must result from the polarization accompanying electrolytic decomposition, there are those produced by cataphoric action in varying the distribution of the fluids of the body engorging certain portions and depleting others. Moreover, since the cataphoric action increases with the strength of the current, the resistance of the human body will necessarily vary with the strength of current employed to measure such resistance. This fact should be born in mind in measuring the electric resistance of different parts of the body.

In calling attention to the probable variation in the resistance of the human body with the strength of the current passing, I am not referring to that change in the electric resistance which arises from its electrolytic polarization; *i.e.*, to the variation in its resistance produced by the counter-electro-motive force of polarization. Such a resistance is asymmetrical, *i.e.*, possesses a different value in opposite directions. The change in the resistance due to cataphoric action should be symmetrical; *i.e.*, should possess the same value in either direction.

I do not know in point of fact whether such differences in the resistance of the human body actually follow changes in the strength of the currents passing through the human body, or variations in the duration of the time such currents are passing. I merely throw out the suggestion as what appears to me to be logical conclusions, and what I believe will be found to exist as actual facts.

In conclusion, then, there would appear to be two varieties of cataphoric action; viz.:

1. Normal cataphoresis, by means of which disturbance is effected in the distribution of the constituents of the body, by the passage of an electric current.

2. Abnormal cataphoresis, by means of which is effected an introduction of fluid substances into the body from without, by the passage of an electric current.

(To be continued.)

THE
Journal of the American Medical Association
PUBLISHED WEEKLY.

SUBSCRIPTION PRICE, INCLUDING POSTAGE:
PER ANNUM, IN ADVANCE \$5.00
SINGLE COPIES 10 CENTS.

Subscriptions may begin at any time and be sent to

THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION,
No. 68 WABASH AVE., CHICAGO, ILLINOIS.

All members of the Association should send their Annual Dues to the
Treasurer, RICHARD J. DUNGLISON, M.D., Lock Box 1274, Philadelphia, Pa.

MEMBERSHIP IN THE AMERICAN MEDICAL ASSOCIATION.

This is obtainable, at any time, by a member of any State or local Medical Society which is entitled to send delegates to the Association. All that is necessary is for the applicant to write to the Treasurer of the Association, Dr. Richard J. Dunglison, Lock Box 1274, Philadelphia, Pa., sending him a certificate or statement that he is in good standing in his own Society, signed by the President and Secretary of said Society, with five dollars for annual dues and subscription for THE JOURNAL. Attendance as a delegate at an annual meeting of the Association is not necessary to obtain membership. On receipt of the above amount the weekly JOURNAL of the Association will be forwarded regularly.

SATURDAY, FEBRUARY 11, 1893.

THE TREATMENT OF MYXŒDEMA BY THYROID
EXTRACT AND THE FUNCTIONS OF THE
THYROID GLAND.

An intense interest in this subject is apparent on the part of the British medical profession, as is evident from the fact that at least a dozen articles have appeared in the leading journals in the last three months. The reports of the cases thus far recorded are very favorable, and the results are astonishing.

Naturally, in this new interest in the effects of thyroid disease, the question of the function of this gland comes into increased significance. On this point there can be no certain stand taken at present, though the promise of a solution of this difficult physiological problem seems near. In his most recent work on the functions of the thyroid gland, VICTOR HORSLEY (*British Medical Journal*, January 30, and February 6, 1892), favors three hypotheses, viz.: 1. That it is directly a blood-forming organ. 2. That it is indirectly a blood-forming organ. 3. That it modifies or destroys substances in the circulating blood which are harmful to the general economy. To these three theories GIBSON (*Ibid.*, January 14, 1893) objects. He maintains as the results of his observations and experiments, that no reduction in number of red blood cells, and but very little alteration in the number of colorless cells, follows extirpation of this organ; and that it therefore can have no blood-forming function. He believes, further, that the hypothesis of the secretory function of this gland is the more probable, the secretion being of a nature which permits its absorption into the blood, where it is essential to life. In this he agrees with SCHIFF, and with SAUQUINCO and CANALIS, who extend SCHIFF's hypothesis by suggesting that the substance secreted by the thyroid is necessary for the nourishment of the central nervous system. In this way the cachexia strumipriva could be explained on the ground that it was the result of

retrograde metabolism from a lack of the normal nervous stimulus. From a clinical point of view, this theory of the secretory function of the thyroid seems the more adequate to explain the symptoms of myxœdema and cretinism, and the results which follow the treatment of these diseases by the administration of thyroid extracts.

The grafting of the thyroid gland of the lower animals for cachexia strumipriva, myxœdema and cretinism, has been practiced by various surgeons since 1883, with the unanimous verdict of an improvement in the symptoms in cases in which the gland survived. In the paper above mentioned GIBSON reports an interesting case of myxœdema and cretinism in a child of six years, in which, on two occasions, he grafted the thyroid gland of a sheep into the mammary region, and into the abdominal cavity of the child, with remarkable improvement in the patient, as shown most conclusively in the series of photographs.

The subcutaneous injection of the extracted juice and extraction of the thyroid was put into practical use by MURRAY (*Ibid.*, October 10, 1891), who employed this extract in the treatment of myxœdema. The cases in which MURRAY's treatment has been applied have all exhibited marked amelioration of the distressing symptoms of the disease, amounting, in some cases, to an apparent disappearance of the disease. As a rule, the improvement began after the first treatment, and progressed while the treatment was continued: the countenance became brighter, the skin softer and more pliable, the swelling of the body disappeared, with a corresponding loss in weight, the temperature increased to normal, the speech and intellectual faculties became natural, the sensations were re-established; in fact, all of the symptoms of the disorder abated or were improved. It was soon noted, however, that unless the injections were continued at occasional intervals, relapses were prone to occur; nor were the injections entirely devoid of danger, as shown in the cases of MURRAY, LUNDIE and others, in which profound depression bordering on collapse has followed the injections. Aside from this, infection, and abscess at the site of the injection, seems to follow this treatment very frequently.

These objections to the administration of the thyroid extract, by subcutaneous injection, led to experiments with the remedy given by the mouth, and in the cases published by NAPIER (*Glasgow Medical Journal*, September, 1892), MACKENZIE (*British Medical Journal*, October 29, 1892), FOX (*Ibid.*, October 29, 1892), BARBER (*Ibid.*, January 7, 1893), LUNDIE (*Ibid.*, January 14, 1893), and ANDERSON (*The Practitioner*, January, 1893), the results seem in every way equal to those obtained with the MURRAY injections. It was found that not only the thyroid extract prepared by MURRAY's or by other extraction pro-

cesses, but also the *fresh gland itself*, was available as a remedy in this disease, when given by the mouth. Cases in which the feeding with fresh thyroid glands was employed are reported by MACKENZIE, FOX, BARBER and others, and up to the present time the same improvement as followed the administration of the extracts, either hypodermically or by the mouth, has been recorded. DR. MACKENZIE advises that the treatment of myxœdema by the fresh glands be commenced with either one thyroid (from the sheep) every other day, or half a thyroid every day. The gland is to be minced and mixed with the food in any manner which suggests itself. Lightly *fried* sheep's thyroid has been employed by Fox (*loc cit.*), which was then minced and mixed with currant jelly. However, BARBER believes the heat of hot liquids to be detrimental to the best effects of the remedy, as he found in one of his cases in which the chopped gland had been taken in hot soup.

It certainly appears, that we have in this new treatment a remedy, which was suggested by a physiological and pathological study of the thyroid gland; in other words, we have a remedy founded upon scientific deductions. Whether the ultimate results of the remedy will fulfil the present remarkable promise, remains to be seen. In the meantime, let the treatment receive the thorough trial its present importance merits, and its present record justifies. In the meantime, let us not forget the advice of DR. T. McCALL ANDERSON, and employ along with this treatment, such remedies as arsenic, iron and the tonics, together with baths, and friction.

The present position of the newly inaugurated treatment, for the effects of thyroid disease, is well expressed by DR. ANDERSON: "From whatever point we regard it, there can be no doubt that a valuable new remedy has been discovered for the relief of a very serious disorder, and one which may pave the way for similar discoveries in other fields."

TUMORS OF THE BRAIN.

The report by DR. HEKTOEN of sarcoma of the pons and of glio-sarcoma of the cerebellum, which we print in this number of THE JOURNAL, will call attention to many interesting points in connection with such growths. The difficulties of diagnosis and of localization are well illustrated; the tumor in the centre of the pons appears to have been quite misleading, although the symptoms were rather those of a lesion at the base than of the cortex. The interesting observation made by GERHARD that hæmorrhage into vascular gliomas is not followed by the somewhat persistent lowering of the temperature characteristic of ordinary extravasations of blood into the brain appears to be true of sarcoma as well, although it may be that the infiltrations into the pontine tumor described were not large enough to

warrant any definite conclusions on this point. It would have been very interesting to have observed whether the faradic current applied to the dura over the motor areas through the exploratory trephine opening made shortly before death would have been followed by any abnormal manifestations or not.

The relation of trauma to the development of the the tumor in the cerebellum appears to be quite distinct and the number of recorded and reliable observations calling attention to the predisposing etiological effect of head injury to the growth of cerebral tumors is now sufficient to make this point in the clinical history of such cases one of diagnostic value. This case illustrates well the latency of cerebellar lesions with respect to localizing symptoms unless the vermes be involved, and it also shows the production of internal hydrocephalus and greatly increased intracranial pressure for the temporary relief of which trephining, and even tapping and drainage of the ventricles, have been recently proposed and performed.

The clinical study of tumors and other lesions of the brain is one of extreme interest primarily, of course, from the diagnostician's point of view, but also because an exhaustive clinical study of such cases from all possible aspects during life, completed by a careful anatomical examination after death, sometimes yields conclusions as to the function of cerebral areas and as to the localizing symptoms that could only be equalled by the most painstaking and elaborately planned experiments upon animals. American medical literature contains a few solid contributions embodying the result of this high grade of work. SPITZKA's classical contribution to the morbid anatomy and symptomatology of pons lesions, based upon the accurate clinical observation of a case of hæmorrhage into the left half of the pons and the careful anatomical study of the secondary degeneration of the nerve tract initiated by the hæmorrhage is perhaps one of the best sustained and most completely balanced studies of this kind in existence. The degeneration observed in his case proved to be one of the best sustained and most conclusive instances of tract disease recorded. SPITZKA's communication appeared in the *American Journal of Neurology and Psychiatry* for November, 1893. The observations of PROFESSOR DONALDSON, of the Chicago University, upon the brain and sense organs of the blind deaf-mute LAURA BRIDGMAN (*American Journal of Psychology*, Vol. III. No. 3 and Vol. IV. No. 4) led to important conclusions as to the extent of sensory cortical areas, especially that of the visual area, and also to the very important deduction that the early destruction of sense organs and the subsequent examination of the cortex in animals will be the means of experimental determination of the limits of the several sensory areas.

The histological study of lesions of the nervous system has received important aid through the introduction of the improved staining methods of WEIGERT and of PAL which differentiate readily between the ganglion cells, the nerve fibres, connective tissues, and areas of degeneration and sclerosis. In all investigation of diseases of the brain the use of these methods are indicated and it should not be forgotten, as we have so frequently noticed, that the tissue around the foci of disease of various kinds should be carefully examined not only because tract lesions may have been initiated but also because unsuspected degenerations of neighboring brain substance may have taken place for some distance away from the tumor or tubercular mass on account of circulatory disturbances and this may have caused symptoms during life not explainable by the gross lesion. WEIGERT'S or PAL'S method will here be of great service because they make it possible to accurately study the nerve fibres.

ON CERTAIN CONDITIONS IN REGARD TO THE INFECTIVE NATURE OF CARCINOMA.

In an address read before the Medico-Chirurgical Society of Glasgow, on October 7, 1892, (*British Medical Journal*, Jan. 14, 1893), DR. JOSEPH COATS presents his most recent views on the etiology of cancer. He proposes to analyze the characteristics of carcinomata in the same manner as tuberculosis was analyzed, and its infective nature proven, long before the discovery of the tubercle bacillus. According to this authority, COHNHEIM'S theory is satisfactory in explaining the origin of the benign (non-nulastatic) tumors, but it does not apply to carcinoma. The difference in the lesions of the infective granulomata and of cancer are pointed out, with the conclusion that the infective microbes produce homoplastic irritative tissue lesions, while carcinoma is a true tissue growth—a heteroplastic epithelial proliferation, well supplied with blood and lymph vessels and with connective tissue. The metastases of cancer are tissue growths of an elaborate and finely adjusted character which often reproduce with wonderful fidelity the characters of the primary tumor. When a graft is planted in an epithelial organ, the cells of this organ take no part in the tissue growth, they are merely pushed away by the growing tumor. Carcinomata are widely different in their characters, as is shown by the varying tendencies to burrow in the tissue, or to extend laterally instead of towards a free surface; by the varying tendencies to ulceration, to colloid metamorphosis; in fact, cancer exhibits none of the constancy in tissue lesions which characterizes tuberculosis. Cancer extends along the surface in its primary seat only by continuity of tissue; it does not scatter in its primary seat, but extends, the entire primary tumor being one contin-

uous whole. Secondary tumors do occur, it is true, but these tumors must be regarded as parts of the primary tumor—as grafts which have become transplanted. Cancer then, is a tissue growth, whereas the lesions of microbial infection thus far known, are inflammatory tissue products, the results of irritation. These considerations lead COATS to believe that if a parasitic organism has to do with the causation of carcinoma, it must be something very different in its mode of action from the bacteria with which we are acquainted.

In answer to the question, "Can a tissue growth be produced by a parasitic agency?" COATS first refers to two of his own cases. The first was a case of malignant goitre in a woman, of sixteen years standing, in which, about a year and a half before death, a secondary tumor appeared over the occipital bone, which grew to considerable size and was accompanied by other smaller tumors. On microscopical examination the secondary tumor was found to reproduce exactly the structure of the thyroid growth. If we accept the view that goitre is an infective disease, then we have an example of a true tissue growth of a complex character induced by morbid poison introduced from without; and in this light, the case just described, would be of much importance in comparing it with cancer.

The author, also refers to a case of cancer of the stomach, in which he found a number of wart-like growths of epithelium on the interior of the lower end of the œsophagus. This case, which was a marked exception to the rule that the primary tumor confines itself to the first invaded organ, suggested to COATS the idea of an infective character in the primary tumor, as though the causative organ had been regurgitated from the stomach to the œsophagus. The alleged occurrence of lowly animal organisms in *molluscum contagiosum* is noted, though the author wisely refrains from committing himself on this subject. The psorospermiosis of the lower animals is referred to, particularly the works of LEUKART and DELEPINE, and others is laid on the fact that the primary lesions in the coccidia diseases of the lower animals are associated by an overgrowth of epithelium.

The works of RUSSELL, SOUDAKEWITCH, SAWTSCHENKO, RUFFER, WALKER, and STEINHAUS on the protozoan carcinoma organism, are mentioned, and on this subject also, COATS maintains a reasonable skepticism.

The author concludes his address by stating that he listens with more favor than formerly to the suggestion that cancer is due to an infective parasite introduced from without. The vegetable parasites are not capable of producing tissue growth as observed in carcinoma, but it does seem possible that minute animal organisms, by entering into the substance of

the cells and there undergoing their stages of evolution, could produce phenomena of a kind similar to those of cancer. Even after the discovery of a specific parasite, there would be many problems in the characteristics of cancer which would demand solution, so that, at present, we must assume a waiting attitude.

NO FEAR OF CHOLERA.

In an interview with DIRECTOR-GENERAL DAVIS, of the Columbian Exposition, in the *Chicago Tribune*, of Feb. 7, this functionary is reported as saying: "The anxiety existing about a possible outbreak of cholera this year arises largely from the agitation of the subject by alarmists, principally of the medical fraternity, with whom the discussion of the probability of an epidemic of some nature is a professional fad."

We would most respectfully ask DIRECTOR-GENERAL DAVIS who he would expect to be alarmists in case of a threatened invasion of contagious disease, if not those whose profession makes it necessary for them to be the active combatants in the fray that is so portentous at this time? Does the Honorable Director-General of the Columbian Exposition look to the Board of Trade, the writers for the daily press, the fire insurance companies or the marines for a code of sanitary laws and suggestions pertaining to quarantine regulations? All of these bodies are both respectable and reputable, and have been found capable of formulating and solving many intricate business relations, and having done this, DIRECTOR-GENERAL DAVIS would have the people to know that they are also equal to the task of frightening away the cholera, which he would, from the abundance of his wisdom have the world to know is only casting the shade of a shadow in the direction of the Columbian Exposition.

Of a truth, Director General is the King Canute of the Western Continent. The fiat has gone forth. With the great Columbian sceptre in his hand the Director General has entered the Decree. Thus far shalt thou come, dire and dread disease, but no farther. The fiat of the Director General, like unto the laws of the Medes and Persians, is never altered or made subject to revision by a human court.

Why have the fathers and sons of Æsculapians for more than twenty centuries been delving in the unknown for new truths, to be recorded for a guidance in the prevention and treatment of disease, which after all, is only a business professional fad? When all that is necessary in order to keep the infectious germs from migrating, is a waft of the wand of an Imperial Director-General of a Columbian Exposition, vulgarly termed a World's Fair.

Before this modern Director-General of the Columbians we your unworthy subjects bow in humble sub-

mission. We now know the cholera and its coming is a veritable fad expressly gotten up for business purposes. We know it won't, it dare not come in the face of the Decree,—but all the same when it does come and the Director-General himself begins to feel the peculiar wriggles and contortions of the exceedingly active comma bacillus, when it takes on Delsarte movements, and lightly skips from side to side as it meanders along the serous coat of the Director-General's bowels—perish base figment of an imaginative imagination, there is neither a possibility or probability of such a movement, for the Decree is entered up and is now in full force and unimpeachable by any professional or scientific theory that may be conceived by medical men.

Let us henceforth cease to be agitators and theorists, or make further efforts to create corners in comma, spirilla-shaped or other germs. These things are all on the Director-General's side. They are every one of them in favor of work every day in the week, both nights and Sundays. Thereby they increase in numbers.

The medical profession has been regarded as an exemplar in morals, for it is the only profession or calling, the members of which have for their own guidance a written Code of Ethics. This high estate of morality in which they live, leads them to deprecate all attempts to abrogate the Sabbath as a day of rest. These infectious, hard to control bacilli are constant Sunday workers, hence it is they are on the side of the Director-General of the Columbian Exposition, and squirm against all medical opposition.

The Director-General is Monarch Shoo-Shoo of the germs.

THE KEELEY CURE INSTITUTES.

Going, going, going and gone!

Advertisements similar to the following may now be found in the current daily newspapers:

At 42 South Curtis St., this Tuesday morning, 10 o'clock, auction sale contents Keeley Institute. Iron bedsteads, hair mattresses, good bedding, sheets, blankets, slips, etc., etc. Folding beds, office furniture, range, plated ware, crockery, etc., etc. Sale peremptory.

ELISON, FLERSHEIM & Co.,
Auctioneers.

The sustaining efforts of PARSON TALMAGE, the gullible press and philanthropic spasms of KEELEY himself were not sufficient to sustain the fad for the half of a half decade.

STATE MEDICAL SOCIETIES.

The following gives secretary's name, with time and place of meeting, 1893.

Alabama—T. A. Means, Montgomery; Selma, April 11.

Arkansas—L. P. Gibson, Little Rock; Batesville, May 31.

California—W. W. Kerr, San Francisco; San Francisco, April 18.

Colorado—A. S. Lobingier, Denver; Denver, June 20.
 Connecticut—N. E. Wordin, Bridgeport; Hartford, May 24.
 Delaware—W. C. Pierce, Wilmington; Cape Henlopen City, June 13.
 Florida—J. D. Fernandez, Jacksonville; Jacksonville, April 4.
 Georgia—D. H. Howell, Atlanta; Americus, April 19.
 Illinois—D. W. Graham, Chicago; Chicago, May 16.
 Indiana—E. S. Elder, Indianapolis; Indianapolis, May 10.
 Iowa—C. S. Chase, Waterloo; Burlington, May 17.
 Kansas—W. S. Lindsay, Topeka; Topeka, May.
 Kentucky—Steele Bailey, Stanford; Frankford, May.
 Louisiana—P. B. McCutcheon, New Orleans; New Orleans, May 9.
 Maine—C. D. Smith, Portland; Portland, June 14.
 Maryland—G. L. Taneyhill, Baltimore; Baltimore, April 25.
 Massachusetts—F. W. Goss, Boston, Boston, June 13.
 Michigan—C. W. Hitchcock, Detroit; Muskegon, May.
 Minnesota—C. B. Witherle, St. Paul; Minneapolis, June 21.
 Mississippi—H. H. Haralson, Forest; Jackson, April 19.
 Missouri—L. A. Berger, Kansas City; Sedalia, May 16.
 Montana—T. H. Ellis, Butte; Great Falls, April 19.
 Nebraska—Geo. Wilkinson, Omaha; Nebraska City.
 New Hampshire—G. P. Conn, Concord; Concord, June 20.
 New Jersey—Wm. Pierson, Orange; Spring Lake, June 27.
 New York—E. D. Ferguson, Troy; New York, Oct. 10.
 North Carolina—R. D. Jewett, Wilmington; Raleigh, May 9.
 N. Dakota—D. S. Moore, Jamestown; Jamestown, May 25.
 Ohio—T. V. Fitzpatrick, Cincinnati; Put in Bay, June.
 Oregon—C. H. Wheeler, Portland; The Dalles, June 13.
 Pennsylvania—Wm. B. Atkinson, Philadelphia; Williamsport, May 16.
 Rhode Island—W. R. White, Providence; Providence, June 1.
 South Carolina—W. Peyre Porcher, Charleston; Sumpter, April 19.
 S. Dakota—R. C. Warne, Mitchell; Huron, May or June.
 Tennessee—D. E. Nelson, Chattanooga; Nashville, April 11.
 Texas—H. A. West, Galveston; Galveston, May 2.
 Vermont—D. C. Hawley, Burlington; Rutland, Oct. 12.
 Virginia—L. B. Edwards, Richmond; Charlottesville, October.
 Washington—G. D. Shaver, Tacoma; Tacoma May 10
 W. Virginia—D. Mayer, Charleston; Parkersburg.
 Wisconsin—C. S. Sheldon, Madison; Milwaukee, May 3.

BOOK REVIEWS.

KIRK'S HANDBOOK OF PHYSIOLOGY. By W. MORRANT BAKER, F.R.C.S., late Surgeon to and Lecturer on Physiology at St. Bartholomew's Hospital, etc., and VINCENT DORMER HARRIS, M.D., F.R.C.P., Demonstrator of Physiology in the University of Durham, etc. 13th edition, with upwards of 500 hundred illustration, including some colored plates. Philadelphia. P. Blakiston, Son & Co. 1892.

The fact that this work has passed to the 13th edition is good evidence of the high esteem in which it is held. The reviewer remembers the pleasure and satisfaction with which he read one of the earlier editions during his medical course, and after this lapse of time—never mind how long—it provokes no feelings of disappointment to traverse the same journey again. The account of Physiology is brought up, as far as possible, to the present time. It does not profess to be exhaustive, for it is intended especially to furnish the medical student with a foundation upon which a knowledge of physiology may be safely based.

The book has been thoroughly revised and the scope of the work somewhat enlarged, yet the book has been kept within a very convenient limit as a hand-book, although it contains 884 pages. One secret of this is the very thin paper on which it is printed.

The chapter on food and digestion is full of such instruction as is needed by physicians and nurses, and in fact everyone who eats. The table showing the relative nutritious properties and digestibility of foods, and the rules laid down for their preparation, are of the utmost practical importance.

Thirty pages are devoted to a description of the kidneys and their functions.

In the chapter on nutrition it appears that the editors do not credit the American fasters with subsisting for 40 days on air and water alone. Several reputable physicians and disinterested laymen known to the writer watched one of the fasters and certified to the genuineness of the fast.

Although this work as a whole is one of a high standard of excellence, it is susceptible of improvements. On page 560 correct directions are given for laryngoscopy, but on the opposite page the illustration of the examination shows the light concentrator away below the proper level, and out of range with the forehead mirror, a mistake any laryngologist would notice at a glance. On page 624 another error occurs. In enumerating the effect of paralysis of the facial nerve they mention "the loss of power in the muscles of the internal ear." Of course the middle ear is meant.

It will be necessary to have some of the cuts renewed or improved for the 14th edition. They have served long enough to be retired on a pension. For example, on page 702 as many as nine of the letters of reference are missing and unaccounted for, except in the text. A most diligent search has failed to find them in the cut. In some of the other illustrations the letter or figures are so badly worn as to render their reading impossible.

The publishers have made a beautiful book, but the night reader will never forgive them for using mirror-paper.

The language is generally perspicuous, but in some instances it becomes as ambiguous as that of the theologians. Mention is made of this peculiarity because of the severely critical attitude of some of our English friends towards writers on this side of the pond. They may retort that Americans cannot understand Bacon. They will learn better next summer.

FISSURE OF THE ANUS AND FISTULA IN ANO. By LEWIS H. ADLER, JR., M.D., Instructor in Diseases of the Rectum, Philadelphia Polyclinic and College for Graduates in Medicine. Detroit: George S. Davis. 1892.

In this little brochure the author deals systematically

with his subject-matter. It forms an interesting addition to the Physicians' Leisure Library Series, and will amply repay an attentive perusal. Practitioners will find here an aid in diagnosis and treatment of these distressing ailments.

ACNE AND ALOPECIA. By L. DUNCAN BULKLEY, A.M., M.D., Professor of Diseases of the Skin, New York Post-Graduate School. Detroit: George S. Davis, 1892.

We have here another addition to the Leisure Library Series, which deals with subjects interesting to the general practitioner as well as to the specialist. In no branch of medicine will careful attention to details give more satisfactory results than in dermatology. Dr. Bulkley has here given us an interesting and instructive treatise on subjects that come under the everyday observation of most physicians.

PRINCIPLES AND PRACTICE OF BANDAGING. By GWILYUR G. DAVIS, M.D., Demonstrator of Surgery, University of Pennsylvania. Detroit: Geo. S. Davis, 1891.

The author here takes for his subject-matter a very important adjunct of surgery. A close attention to and faithful practice of the principles outlined will amply repay the young surgeon for the time so employed. The book will prove a valuable aid to students and young practitioners.

MISCELLANY.

THE INTERNATIONAL CONGRESS OF CHARITIES, CORRECTION AND PHILANTHROPY, JUNE 12-18, 1893.—Section Four on the *Hospital Care of the Sick, the Training of Nurses, Dispensary Work, and First Aid to the Injured.*—One of the series of International Congresses to be held in Chicago in 1793, is to be devoted to the subjects of Charities, Correction and Philanthropy, and Fourth Section of this is to consider all matters relating to the Hospital Care of the Sick, the Training of Nurses, Dispensary Work, and First Aid to the Injured. The Committee of Organization of the Congress has appointed Dr. John S. Billings, Surgeon U. S. Army, as Chairman of this Section, and Dr. Henry M. Hurd, Superintendent of the Johns Hopkins Hospital in Baltimore, as its Secretary, and has authorized and requested them to complete its organization, to extend invitations and to prepare a program for its work. Miss Isabel A. Hampton, Superintendent of the Training School for Nurses of the Johns Hopkins Hospital has been appointed Chairman of that part of the work of the Section which relates to the training of nurses.

This Section will hold five sectional meetings of about two hours each, commencing June 12, 1893, and will also have charge of one of the general sessions of the Congress, viz: that held on the morning of June 14.

It is desired that this shall be a truly international gathering for conference on the subjects allotted to this Section, and all who are interested in Hospitals, in Training of Nurses, in Dispensaries, or in First Aid to the Injured, are cordially invited to be present, to contribute papers and to take part in the discussions.

The papers and proceedings will probably be printed as a separate volume, and it is hoped that this will represent the best methods, and the best work in each of these departments in all parts of the world.

The following are suggested as subjects for special consideration in papers to be prepared: 1. Hospital Organization—Governing Bodies—Relations of the Medical Staff and of Nurses' Training Schools. 2. Hospital Finances—Means of Support—Mode of Keeping Accounts—Cost. 3. Plan and construction of recently built General Hospitals, embodying the latest improvements. 4. Relations of Hospitals to increase of Knowledge; to Medical Education, and to the Medical Profession. Hospital Records, Statistics and Reports. 5. Pay Patients in Hospitals. 6. Isolating Wards and Hospitals for contagious Diseases. 7. Hospital Diets, Dietaries, Kitchens, etc. 8. Hospital Amphitheatres and Operating Rooms. 9. Hospital Laundries and Disinfecting Establishments. 10. Army and Navy Hospitals—Emergency Hospitals in Time of Epidemics—Temporary and Movable Hospitals. 11. Small and Special Hospitals, Cottage Hospitals, School Hospitals, Private Hospitals, Sanitor-

iums, etc. Convalescent Hospitals, and what to do with Incurables. 12. History and present condition of Hospitals in the large cities. 13. Training Schools for Nurses. 14. Dispensaries—Relations to the Public and to the Medical Profession. Dispensary Records. 15. First Aid to the Injured. Associations for best means of popular instruction in and its place in General Education.

Persons desiring to present papers, or to share in the discussions of this Section, are requested to communicate with the Secretary at once. The period of time allotted for the preparation of the program is necessarily brief, and it is essential that all who are willing to assist in this work should act promptly. Address all communications to Dr. Henry M. Hurd, The Johns Hopkins Hospital, Baltimore, Md.

JOHN S. BILLINGS, M.D.,
HENRY M. HURD, M.D., Secretary. Chairman

MEDICAL EXAMINATIONS—Candidates applying for a license (after the July 1893, meeting of the State Board of Medical Examiners) to practice Medicine in New Jersey, will be examined in the following subjects arranged in sections, as follows, viz: Sec. 1, *Materia Medica and Therapeutics*; Sec. 2, *Obstetrics and Gynecology*; Sec. 3, *Practice of Medicine (including diseases of the Skin, Nose and Throat)*; Sec. 4, *Surgery (including Surgical Anatomy, and diseases of the Eye, Ear, and genito-urinary organs)*; Sec. 5, *Anatomy*; Sec. 6, *Physiology*; Sec. 7, *Chemistry*; Sec. 8, *Histology, Pathology and Bacteriology*; Sec. 9, *Hygiene and Medical Jurisprudence.* The following percentages will be required, also, after that date, before a license will be issued, viz: candidates examined in the first class, *i. e.* graduates of five years or more, shall obtain a total average of eighty (80) per cent.; candidates examined in the second class, *i. e.* graduates of less than five years, shall obtain a total average of seventy-five (75) per cent., providing that in no one section shall the percentage be less than thirty-three and one-third (33 $\frac{1}{3}$) per cent., in which case, however, should the total average percentage in all the other sections, be above seventy-five (75) per cent., the candidates may be granted a second examination, immediately, upon that section; candidates examined in the third class, *i. e.* non-graduates, who have taken three full courses of lectures in a reputable Medical school, shall obtain a total average of eighty (80) per cent., and candidates taking their preliminary or final examination, shall obtain a total average of eighty (80) per cent., at each of said examinations.

THOS. PERRY WATSON, M.D., Secy.

OFFICIAL LIST OF CHANGES in the Stations and Duties of Officers Serving in the Medical Department, U. S. Army, from January 28, 1893, to February 3, 1893.

Capt. Louis A. La Garde, Asst. Surgeon U. S. A., is relieved from duty at Ft. McHenry, Md., and will proceed to Chicago, Ill., and assume his duties in connection with the World's Columbian Exposition.

Capt. C. N. Berkeley Macauley, Asst. Surgeon, now awaiting orders at Baltimore, Md., will report in person to the Superintendent of the U. S. Military Academy, West Point, N. Y., for duty at that post.

Capt. Chas. B. Ewing, Asst. Surgeon U. S. A., will, in addition to his present duties as attending surgeon, and examiner of recruits in Baltimore, Md., report in person to the commanding officer, Ft. McHenry, Md., for duty as post surgeon, taking station there.

Capt. Guy L. Edie, Asst. Surgeon U. S. A., will proceed from New York City to Ft. Wadsworth, New York Harbor, and report to the post commander for temporary duty.

Capt. Louis W. Crampton, Asst. Surgeon U. S. A., now on leave of absence at Los Angeles, Cal., will report in person to the commanding General, Dept. of Arizona, for such temporary duty at Los Angeles, Cal., as may be required.

OFFICIAL LIST OF CHANGES in the Medical Corps of the U. S. Navy, for the Week Ending February 4, 1893.

Asst. Surgeon L. H. Stone, ordered to Naval Hospital, Brooklyn, N. Y.

P. A. Surgeon G. H. Barber, from Naval Hospital, Brooklyn, N. Y., and to the U. S. S. "Miantonomoh."

Asst. Surgeon N. J. Blackwood, from U. S. S. "Miantonomoh," and to the U. S. Navy Yard, Brooklyn, N. Y.

The Journal of the American Medical Association

No. 7.

ORIGINAL ARTICLES.

THE POSSIBILITY OF THE EARLY DIAGNOSIS OF LOCOMOTOR ATAXIA BY THE EYE-SYMPTOMS.

Read before the Philadelphia Neurological Society, Jan. 23, 1893.

BY HOWARD F. HANSELL, M.D.,

LECTURER ON OPHTHALMOLOGY, JEFFERSON COLLEGE.

A review of the voluminous literature on the subject of the eye symptoms in tabes will impress one with the overwhelming importance of a careful and thorough inspection of the extrinsic muscles, the pupils and accommodation, and the optic nerve in the diagnosis of that disease. And this is particularly true in its earliest stages. A well marked case in its second or third stage presents no difficulties. The symptoms are of such a pronounced and individual character and so frequently found in association that "he who runs may read." But in that variable and usually extended period before the spinal sclerosis has developed its distinctive features of altered locomotion, incoördination, perverted and increased sensibility and paralysis, when a diagnosis is of greater value to the patient, an investigation of the ocular apparatus will not infrequently furnish reliable data from which positive deductions concerning the distant future can be drawn.

I will take up, in this paper, eye symptoms of the first or pre-ataxic stage only. They include disturbances of,

First.—The Extrinsic Muscles.—Graefe,¹ in speaking of sclerosis of the posterior columns says, "paralysis of the eye-muscles may appear in a very early period of the disease, for we are bound to accept the conclusion that either independently of the disease process in the cord, or in connection with it, patches of degeneration analogous to those in the cord, form in the nerve nucleus or in the encephalic course of the fibres of the nerves supplying the muscles, and the paralysis can no more be attributed to the diseased patches in the cord than can the changes in the optic nerves which are found under similar conditions."

Schmeichler says² "the disturbance of the eye muscles in tabes consists in paresis of one or several. It begins, if it develops at all, almost always with the very first symptoms of the tabes, but at times it precedes the latter by many years."

E. Berger³ says, "in my cases (109) the far greater number of the ocular paralyzes was in the stradium preactacticum."

Gowers⁴ says "paralysis of the external ocular muscles is also common in tabes and occurs in several forms. 1. Transient weakness lasting a few days

or weeks, and then passing away. 2. Permanent paralysis, complete or incomplete, of a single nerve or part of a nerve. Either form may occur at any stage, but the first is more common in the early and the second in the later stages of the disease."

Swansy says⁵ "in the premonitory stages of tabes dorsalis ephemerical partial paralyzes affecting now one, and again another of the orbital muscles, may sometimes be observed."

Noves⁶ says, "in special cases the paralysis is likely to be incomplete and not to be permanent. No other sign of spinal cord disease may occur for a long time and this symptom, while unsupported by others, will remain of doubtful significance."

R.P. Howard⁷ details the history of a case from which I extract the following paragraph: "Patient, an educated man fifty-four years of age, was of studious and very temperate habits, and free from evidences of syphilis, the possibility of which disease he positively denied. He married at thirty-three and was the father of sixteen children, the youngest eight months old. About the beginning of August, 1883, he suffered from severe headache, which he regarded as migraine, having been afflicted with that neurosis in his youth; at the same time he became irascible. Toward the end of the month strabismus, diplopia, and slight ptosis on the left side supervened, but these gradually disappeared in about six weeks. Some five months later deviation of the right eye, with diplopia, set in, and in about two months was followed by ptosis, which like the other symptoms, developed gradually, but unlike them, has proved permanent." Among the reasons for making the diagnosis of tabes, he gives "the early disturbance of the external and internal ocular muscles."

Roberts⁸ says, "certain so-called premonitory symptoms are usually observed, which may last for months or years, but these are really the early symptoms of the disease." Among them he mentions slight strabismus or ptosis.

In an article by Dr. J.A. Jeffries⁹ are found the following statements: "In tabes, as has long been known, there has been frequently a history of transitory diplopia during the prodromal period." "The origin of these fugacious paralysis is not known, but their significance, when combined with previous syphilitic infection is gravely suggestive of tabes to follow." "An eye paralysis, however simple it may seem, is always a just cause for suspicion of trouble to come, and demands a prompt and thorough examination of the patient."

Alexander,¹⁰ in speaking of paralysis of single branches of the 3d nerve, says, "since the ptosis frequently disappears we must attribute to a transi-

¹⁰ Syphilis and Auge, p. 137.

tory disturbance of circulation, which sometimes precedes by years the development of tabes."

Cornwell¹¹ states that "in tabes dorsalis the paralysis (of the eye muscles) often precedes the other symptoms some months, and at times, years." Hughlings Jackson found in six out of nineteen cases, diplopia to be the first symptom. . . . After it has fully developed and remained stationary for a time, it is apt to disappear.

Moore¹² says, "we must not omit the paralysis of the external muscles of the eye, that are so commonly seen in tabes, usually either the abducens or the motor oculi, and rarely the fourth nerve, which gives rise to various symptoms of dizziness, diplopia and strabismus. Graefe has pointed out that tabetic patients show little disposition to fuse the images in binocular vision, and this is taken as a sign of the central origin of the affection. These muscular paralyses are frequent in the early stages¹³ of the disease; they are transient often in character, and this fact has not been very readily explained. Ptosis is also present when no other branch of the third nerve is involved."

Dr. Max Karger, of Berlin, in an analysis of 117 cases of locomotor ataxia, "finds at the commencement of the disease . . . slight and transitory paralysis of eye muscles."¹⁴

A sufficient number of authorities has been quoted to warrant the statement that ocular paralyses are among the earliest symptoms in the preatactic stage of tabes. The muscles affected are, in the order of their frequency, the external rectus, the levator palpebrarum, and finally other branches of the 3d nerve. Two features characterize early spinal paralysis and help to differentiate it from that and from other affections of the nervous system. 1. Its incompleteness: 2. Its transitoriness.

My first case was sent by Dr. Frank Woodbury, who kindly furnished the following history:

Case 1.—Mr. Blank, 61 years of age, of German parentage. Father died at about 60 years of age with catarrhal jaundice; mother died when he was a child. A sister older than himself died of phthisis; one brother died with pneumonia, the other with hepatic abscess after being afflicted with locomotor ataxia for several years. The patient is of highly nervous temperament and is excessive in his attention to himself and his health. As the result of a naturally good constitution and absence of all excesses, he has enjoyed remarkable immunity from sickness. He had croup as a child and had the other ordinary diseases of childhood; but his adult life has been exceptionally healthy. He has decided fondness for the pleasures of the table and as a result, has symptoms of chronic indigestion, constantly coated tongue, etc., which, however, causes him little annoyance. He has probably had some gastric catarrh for years and also post nasal catarrh, the latter having been cured by treatment. At one time he had middle ear inflammation, which permanently impaired auditory power in the right ear. Even previous to this time he had had tinnitus in this ear, which still persists, although the ears present no evidences of lesion. He has no vertigo; but on account of double vision is referred to Dr. Hansell for examination of the eyes.

Four months ago he noticed double vision. Examination revealed paresis ext. rect. of L., candle light 20' distance, exactly in front of face appeared double; images fused by prism varying, at different times, from 15° to 30°, base in; pupils contracted, L. more than R. and slightly irregular in outline. No synechiæ. Both contract on accommodation but not to light. Slight cortical capacity L. lens. Fundus of each normal excepting one vein in the left retina slightly tortuous. Nerves healthy in color and outlines distinct. Knee jerks exaggerated. No dizziness or ver-

tigo. Rombergs symptom absent. No incoördination, No disturbance in sensibility. No pains.

Second—The Pupil.—A consideration of the pupillary symptoms in the earliest stages of tabes involves a study of their size, their inequality, and their reaction to light and to convergence. Normal pupillary movements depend, in the absence of ocular disease, upon the sensitiveness of those fibres in the retina and optic nerve which convey impressions of degree of light; upon a healthy condition of the nuclei of the pupils in the floor of the fourth ventricle and intercommunicating fibres; upon the soundness of the pupillary branch of the 3d nerve, from its nucleus to the iris, and upon the cilio-spinal centre in the region of 1st and 2d dorsal vertebra and its communications with the cervical cavernous plexus, lenticular ganglion and the long ciliary nerves. Disease, therefore, of any one of these parts will cause abnormal contraction or dilatation, and will destroy reflex, consensual or associated action.

That such interference is found in the preataxic stage of tabes is shown by many authorities, and would probably be mentioned more frequently but that myosis may exist for years without attracting a patient's attention or bringing him to the notice of the neurologist, and no standard of size, under the same condition of light, seems to be accepted. It is, however, safe to assume that a pupil smaller than 2.5 mm. in diameter, in moderate intensity of light, is pathological.

Schmeichler (*loc. cit.*) relates the case of an "intelligent man who related to me that four year ago his attention had been directed to his narrow pupils; that he had followed their progressive narrowing since then before the mirror, and feared very much that he would become blind by their closure."

Berger found that six cases out of a total of 26 with myosis in stad. preatax. In the case of Mr. Blank, myosis is a conspicuous symptom. According to his own statement he has frequently had the size of his pupils brought to his attention during several years. A peculiarity noticed by Schmeichler of the tabetic pupil is the unusual length of time, after the instillation of a drop of atropine solution, before the pupil regains its previous size—from three to four times as long as in average normal eyes. I used one drop of an 8 grain solution of homatropine to dilate Mr. Blank's pupil to facilitate the examination of the fundus, and it was fully seven days before the pupil had returned to its previous size, five days more than is usually required. Again, the dilatation produced by a mydriatic is less in degree, rarely exceeding 4-5 mm. in width—a condition noticed under the homatropine mydriasis in Mr. Blank. A few writers speak of the inequality in the size of the two pupils in the early stages of tabes. Thus Berger says, "There is no marked difference in the relative frequency of inequality of the pupils in the different stages of tabes; it is but slightly more frequent in the initial stages."

Charcot¹⁵ has also called attention to this symptom.

Jessup¹⁶ says "unequal pupils are often found in cases of apoplexy, acute meningitis, chronic and acute alcoholism, general paralysis of the insane, locomotor ataxia."

Case 2.—Mrs. V., Dec., 1889. R. pupil contracted. L. normal,

¹¹ Am. Jour. Med. Sci., April, 1884

¹⁶ Oph. Review, July, 1888.

both respond to light and convergence. Dec., 1892. Had an attack of dizziness one month ago. Says she has rheumatic pain in feet. R. pupil contracted and does not respond to light, but contracts with convergence. L. pupil normal in size and reaction. Knee jerk on L. side almost absent. A positive diagnosis cannot be made, but the anisocoria, unilateral Argylle-Robertson pupil, limited color field with no diminution in the field for white, partial loss of knee jerk and fleeting pains in the feet would seem to point to a commencing sclerosis in the posterior columns of the cord. The Argylle-Robertson pupil is a well known symptom of tabes in all three stages. It is most common in the second, but exceeds in frequency even in the first stage, the normal. Good reaction of the pupil was retained until the paralytic stages in 109 cases studied by Berger, in only four. When that stage was reached all pupils were altered in their reactions.

The Argylle-Robertson pupil has been observed in progressive paralysis, in cerebral syphilis, and possibly in disseminated sclerosis but so rarely that its presence alone would almost warrant the assumption of a commencing post-sclerosis.

Third—The optic nerve.—The earliest sign of degenerative changes in the optic nerve is a diminution of the size of the color fields, then a loss of sensibility to green, with a relative decrease in the fields of other colors, a concentric limitation for white, and, finally, total loss of vision. In many cases it is quite impossible to recognize ophthalmoscopic changes until the field for white becomes limited. Hence the perimeter is more important than the ophthalmoscope in the early diagnosis of tabes. Perimetric measurements, to be accurate, must be conducted with great care, and often repeated with the same set of tests and under the same conditions of illumination. It must be remembered, too, that the ability to distinguish and perceive colors varies among different persons, and according to the method of examination. Ophthalmoscopically, the earliest stages of tabes may be suspected by the clear cut nerve with a pronounced excavation and distinctly seen lamina cribrosa and irregularly surrounded by pigment, loss of color, particularly on the nasal side, dilatation and tortuosity of one or two veins, perhaps limited to one and usually the lower segment of the retina (Schmeichler) otherwise vessels normal in calibre and unaccompanied by the white lines which indicate a thickening of their walls. Authorities differ as to whether the temporal or nasal half of the disc shows first the discoloration and hence we must conclude that it is sometimes one, sometimes the other, and frequently the color of the entire disc is normal. By far the greater portion of the cases shows the L. optic nerve to be the first implicated. That atrophy of the optic nerve may precede general symptoms of tabes is abundantly proven. In seven of Berger's cases it was the first symptom, spinal symptoms appearing later. He quotes Charcot, Förster, Graves and Michel in relation to the largest interval of time between the commencing "deterioration" of vision and the earliest and most common symptom of spinal irritation—lancinating pains—and states it to be from two to twenty years.

In case 1, left eye, examination on October 5 and 6, showed decided limitation for green. It was not recognized outside of a circle 5° from point of fixation. Two months later, after salivation and iodide of potassium in large doses the field for green became almost normal in extent. Again, a large retinal vein running down and in, was dilated and tortuous. After treatment it became normal in calibre and course.

Case 3.—Mrs. G. In September of 1883, complained that for 18 months she has not been able to see to go about alone at night, excepting in the moonlight, nor could she see to sew on any colored material. V. R., 20-100, L. 20-20. Both discs white. Fields for white limited on nasal side. Color fields not taken. Pupils very small but responsive to light and convergence. In November of the same year commencing tabes diagnosed by Dr. Chas. K. Mills, to whom I took her in consultation. "She now complains of sharp pains in the legs. Rhombert's symptom." (Extract from my note book). Five years later the disease ended fatally. While an investigation of the signs of spinal disease, had it been made during the 18 months prior to the first visit to me, might have revealed commencing degeneration of the cord, the first and only symptom complained of during that period, was deterioration of vision due to atrophy of the optic nerves, well advanced in the R. A diagnosis of tabes might safely have been made at this period (1883) from the eye symptoms. Myotic pupils, scarcely responsive, white discs and limitation of the fields for white and probably for colors (since she hesitated in matching colors—the only test to which she was subjected).

Pershing, in an instructive article "Pre-ataxic Tabes Dorsalis with Optic Nerve Atrophy" relates two cases, which I quote in part.

Case 1.—C. L., printer, 38 years old. His mother died of "neuralgia of the stomach." One of the mother's sisters was insane, and the patient's only sister is very nervous and excitable. . . . syphilitic history. . . . V. began to fail in the L. in April, 1889, and grew steadily worse until January, 1890, when V. in R. also became much impaired; L. seeming to improve. Transient ptosis on the left side was noticed several times. The knee jerks were found absent in November, 1889. Present condition November, 1890. Can barely see a hand close to face. Cannot count fingers. Pupils equal, moderately contracted; light reflex scarcely perceptible; accommodation reflex could not be tested. White atrophy of both optic discs. Knee jerks entirely absent even with Jendrassik's reinforcement. Plantar and cremasteric reflexes present; abdominal excessive. Station with eyes closed normal; stands on either foot. Walks backward perfectly well. No ataxia in arms or legs. . . .

Case 2.—E. P., 53, married. Mother died at 70, of softening of the brain. Father, brothers and sisters said to be very nervous. No syphilitic history. . . . Present condition Jan. 15, 1891. V. R. 5-6. L. 5-10. The fields are much contracted, both for white and colors, especially on the nasal side. Both optic papillæ are sharply defined and of a grayish tint. The R. pupil reacts well to light; the L. is contracted, irregular in contour, with light reaction barely perceptible. Both react well on convergence. The knee jerks are present, and are increased by reinforcement. . . . With eyes closed he can stand on either foot and walks well. There is no ataxia of arms or legs. (All other symptoms absent).

In determining the diagnosis, we must remember that the ocular symptoms illustrated by the cases recorded in the literature as well as my own three cases may be the result of other causes than posterior spinal sclerosis. The causes of ocular paralysis are traumatism, orbital disease, pressure upon the nerve in its course by gumma or other tumors, meningitis, dropsy of the third ventricle, nuclear disease, sclerosis of the brain, spinal disease, etc. Myosis may be medicinal (eserine, opium) irritative, in apoplexy, early stage of meningitis, inflammation of the eye, or paralytic, in affections of the lower cervical and upper dorsal spinal nerves, due to traumatism or disease. The Argylle-Robertson pupil is sometimes found in progressive paralysis but in the large proportion of cases it is a symptom of the first and second stages of tabes. Simple primary atrophy of the optic nerves (without signs of neuritis) is more frequently found in tabes than in all other organic nervous affections. To quote from Pershing's article, "Indeed primary bilateral atrophy alone makes the existence of tabes probable. Nettleship found that of 76 cases, 58 certainly and 10 more

probably were due to the same causes that give rise to degenerative changes in the spinal cord and brain. Peltesso found that of 98 cases of spinal or cerebrospinal atrophy occurring in Hirschberg's clinic, 78 were cases of tabes dorsalis." Among cerebral causes may be mentioned, hydrocephalus, tubercular masses pressing upon the chiasm, softening and sclerosis of brain tissue. V. Graefe attributes 30 per cent. of all optic nerve atrophy to spinal causes—degeneration of the posterior and lateral columns from sclerosis or chronic myelitis, idiopathic or traumatic.

Various and contradicting opinions are offered by investigators as explanatory of the ocular paralyses associated with tabes. We may, however, accept as probably true, that the paralysis of the extrinsic muscles is, when transient, the result of vaso-motor disturbance and when permanent, of peripheral neuritis, and rarely nuclear, excepting in the last stages, that the myosis and Argyll-Robertson pupil are symptoms of disease of the cilio-spinal centre and that the optic nerve atrophy is a true primary degeneration of the nerve in no way different from that of the cord but not dependent upon it.

My conclusions may be thus summarized:¹⁵

1. That a transient external paralysis, for example, a ptosis or esotropia, in the absence of known cause might be an indication of incipient tabes.

2. The spinal myosis, the reflex to light wanting but to convergence preserved, monocular or binocular would warrant a strong suspicion of incipient tabes.

3. "Idiopathic" optic nerve atrophy, non-inflammatory, of unequal degree, often precedes by months or years, the appearance of the spinal symptoms of tabes.

4. That pareses of one or two extrinsic muscles, spinal myosis and Argyll-Robertson pupil, and incipient optic nerve atrophy, coexistent in a person of from 30 to 60 years of age, with inherited neurotic tendencies are forerunners in the majority of cases of posterior spinal sclerosis.

HIP DISEASE.

BY JOHN RIDLON, M.A., M.D.,

LECTURER ON ORTHOPEDIC SURGERY IN THE NORTHWESTERN UNIVERSITY MEDICAL SCHOOL; PROFESSOR OF ORTHOPEDIC SURGERY IN THE POST GRADUATE MEDICAL SCHOOL, CHICAGO; SECRETARY OF THE AMERICAN ORTHOPEDIC ASSOCIATION;

AND ROBERT JONES, F.R.C.S.E.,

HONORARY SURGEON ROYAL SOUTHERN HOSPITAL, LIVERPOOL; CORRESPONDING MEMBER AMERICAN ORTHOPEDIC ASSOCIATION.

[Copyrighted by John Ridlon, M.D.]

The term hip disease is used for any chronic inflammation in the synovial membrane of the hip joint, in the acetabulum, in the head, neck, or great trochanter of the femur, or in the soft parts immediately surrounding these, which, if allowed to progress without treatment, would ultimately present the symptoms of a tubercular arthritis. From a clinical standpoint—the standpoint from which this article is written—it does not appear possible to the authors to accurately diagnose the situation of the primary lesion in more than a few cases; nor is it possible to differentiate between a small tubercular

focus in the acetabulum and one in the head or neck of the femur, and often it is not possible, for some time, to differentiate between a condition which will ultimately result in the separation of the head of the femur, and one in which will end in the separation of the great trochanter. Further, we are not able to point out the difference between tuberculosis immediately within the capsule and the same state of affairs immediately without that membrane. From a clinical standpoint we can only approximately locate a lesion, which, unrestricted, ulti-

FIG. 1.—Primary tubercular infection in the head of the femur. *a* Cheesey sequestrum; *b*, tubercular infiltration; *d*, pressure groove from resting against the upper rim of the acetabulum, the head being partly displaced from the cotyloid cavity.

mately involves all or nearly all of the neighboring tissues; which under treatment usually recovers, leaving us still in doubt as to its precise habitat, and which wherever be its origin demands one and the same treatment. This then in a routine way we characterize by the general term, hip disease.

Tuberculosis at the hip-joint usually commences as a primary (Fig. 1) or secondary (Fig. 2) osteitis, and more frequently in the femur than in the aceta-

FIG. 2.—Secondary tubercular infection; cone-shaped cheesey sequestrum; cartilage lifted up as a vesicle.

bulum. It may undoubtedly commence as a primary tubercular synovitis, but many cases of synovitis follow from a traumatic rather than from a tubercular origin. Peri-arthritis inflammation seems to derive its origin more frequently from the infectious fevers than from other causes. The favorite habitat of these lesions in the children of syphilitics is in the neighborhood of the epiphyseal line.

However the joint disease may commence, it is at the beginning, or very soon becomes tubercular. In the same way, wherever the lesion may be primarily found, if left untreated it goes progressively on,

¹⁵ If cases 1 and 2 should develop into unmistakable tabes, they will be illustrations of its earliest stages; if not, they must serve simply as examples of the eye symptoms common to that disease, and must be regarded as idiopathic or forerunners of some other central nerve affection than tabes. The conclusions are drawn from case 3, and those recorded in the literature.

extending from part or one tissue to another until all the structures composing the joint become involved (Fig. 3), and the result is a tubercular arthritis. It is, then, with a tubercular arthritis, more or less complete, that we have to deal in discussing the symptoms, prognosis, and treatment of hip disease.

difficult or impossible from the sensitiveness of the joint and its inability to sustain the weight of the body. Nevertheless the limp characteristic of hip

FIG. 3.—Cone-shaped sequestrum abutting against the cartilage, which is perforated with numerous holes and tilted away from the whole head of the bone.

Symptoms.—Almost invariably the first symptom noticed is a slight limp. This usually begins before there has been any complaint of pain, and it remains until a cure has been effected, and not infrequently it persists to the very end of life. In a few cases there may be one or more intervals of intermission during the early months of the disease. The limp

FIG. 5.—Early stage of hip disease. Flexion and abduction—false lengthening.

disease is not one of pain; it is rather one of impaired function.

FIG. 4.—Early stage of hip disease. Flexion of right leg without noticeable lateral deformity.

FIG. 6.—Disease of the right hip. Flexion and adduction.

is due to the inability of the patient to fully extend the thigh on the pelvis more than to any sensitiveness of the joint to weight-bearing; although in untreated cases, and in very many that are subjected to treatment, there comes a time when walking is

As a rule the patient very early in the disease becomes restless in sleep, and may cry out without fully awakening. The cry is peculiar, and consists in a sudden, sharp, frightened scream, occurring during the first hours of sleep. These night cries commonly precede and almost invariably accompany a period of pain. They have been considered as

characteristic of osteitis, though there can be no doubt of the presence of osteitis in certain cases where no night cries are heard; it is more probable that they are indicative of a rather rapid develop-

months, and often years before the joint is cured, and patients with non-suppurative, and at times with suppurative, hip disease, may never feel the least pain from the commencement of the limping

ment of a tubercular abscess under tension. The symptom is valuable, in the early stage of the disease, only as corroborative of other symptoms, and as a hint to the prognosis of abscess.

all through the three or four years' course of the disease to a cure, resulting perhaps in a perfectly archylosed joint. When pain is present it is usually complained of at the inner side of the anterior surface

FIG. 8.—Disease at the left hip. Untreated case. Flexion, adduction and outward rotation.

FIG. 9.—Disease of left hip. Marked flexion, outward rotation and adduction.

Pain is usually complained of at some time during the course of hip disease, but the fact must not be lost sight of that it is rarely complained of until long after limping has appeared. It disappears

of the knee, but it may be felt at any part of the hip or thigh; like the night cries it is a corroborative rather than a diagnostic symptom. It is indicative

of an osseous lesion, and, coming on or growing worse without assignable cause during the course of treatment, should be considered as pointing to the development of abscess.

FIG. 10.—Same case as Fig. 9. Hip splint on. Deformity reduced.

Inspection of a case of disease stripped for examination, reveals flexion of the thigh upon the pelvis (Fig. 4) with or without accompanying abduction or adduction. Most cases present one or the other lat-

Abduction when present usually accompanies the early stage of the disease (Fig. 5), and has been looked upon as indicative of effusion within the joint, but of this we do not feel certain. We have observed it late in the disease, and in cases where we have never been able to make out fluctuation. This position of abduction gives a false lengthening to the limb, and is the cause of the obliteration of the buttock fold.

Adduction usually succeeds abduction; and is always present late in the disease unless prevented by the nature of the treatment (Fig. 6). It is usually associated with flexion, although the treatment may have reduced, or prevented, flexion and the adduction

FIG. 12.—Flexing the well limb on the chest develops flexion in the affected member. The patient is unable to put the left limb down upon the table.

may remain. It is usually accompanied with some degree of inward rotation. In old and neglected cases outward rotation may accompany the flexion and adduction (Fig. 8). Outward rotation or eversion of the limb is usually associated with abduction, but the reverse may occur, as already pointed out, and inward rotation with adduction. The cause of these malpositions has not been absolutely determined; but it would seem probable that the position of the tubercular focus together with the assumed attitude of the patient determines the malposition. The patient assumes the attitude of greatest comfort whether lying, sitting or stand-

FIG. 11.—Testing the movements at the hip joint.

eral deformity, but the rule is not invariable, and some cases run their course and go on to a great degree of flexion without either abduction or adduction.

ing, and this strongly influences the deformity in the early stages of the affection. Later the malposition is determined by the unbalanced force existing between the opposing groups of muscles in their effort

to immobilize the joint, or between the muscular groups on the one hand, and the mechanical device employed in the treatment of the disease on the other hand.

Muscular shrinking, generally believed to be due to reflex influence, comes on early, is very constant, and may be regarded as a very valuable symptom. It has been claimed by careful observers that this muscular atrophy is due solely to disuse, inasmuch as it bears no constant relation to any other factor involved; but we have observed a case in which the limp had been present for only two weeks, and in which there had been no pain and no cessation from usual avocation, and yet in which there was found a circumferential measurement one inch less than that of the opposite thigh, a difference which went on

the diseased limb until all lordosis is corrected, and the pelvis is in a normal position. He applies a tape measure along the outer border of the limb in a line with the femur, commencing at the point where it diverges from the table. He measures the length to any point, and the length of a perpendicular from that point down to the table. The decimal fraction obtained by dividing the length of the perpendicular by the length measured along the limb will give what mathematicians call the sine of the angle. By consulting a book of mathematical tables the angle is found. G. L. Kingsley measures a constant length of twenty-four inches along the thigh, and then publishes a table showing the angle corresponding to the length of each perpendicular. For the convenience of readers we append Kingsley's tables.

FIG. 13.

FIG. 14.

FIG. 13.—Shows the normal arching of the spine in a healthy person, which can be voluntarily effaced, as shown in Fig. 14.

increasing at a less but at an unusually rapid rate during the succeeding fortnight before the application of apparatus. The fact that we did not know the relative sizes of the thighs before the limping commenced renders this case of no absolute value in controversial argument, but we are much inclined to believe that there is present in these cases a shrinking of the muscular masses over and above that due to disuse, or to the constricting effects of the dressings used. Muscular shrinking is so constant a symptom that it may be regarded as of great diagnostic value.

To measure for abduction and adduction the method of R. W. Lovett, of Boston, is the readiest and best.

KINGSLEY'S TABLE.

FIG. 15.—Thomas's flexion-test position: elbow hooked through the knee, and forearm carried across the chest. The affected left limb cannot be forced down upon the table.

Shortening may be either actual or practical. Actual shortening is due either to arrested growth, to actual bone destruction, or to partial or complete subluxation. None of these conditions are found early in the disease, but an accurate record should be kept, for in this way the prognosis as to the ultimate length of the limb can best be judged. Practical, or false, shortening is due to adduction or flexion, or both (Fig. 9). It is from the relation of the actual to the practical shortening that we conveniently compute the degree of adduction.

The extent of flexion caused by the deformity may be estimated in the following manner: Whilst the patient is on his back, on a table, the surgeon lifts

FIG. 16.—The diagnosis of hip disease in an infant. Disease in left hip. Lack of perfect flexion.

The patient is made to lie straight with the legs parallel. The surgeon now measures for real and for false shortening. Real shortening is found by measuring from the anterior superior spine of the ilium to the inner malleolus on either side and comparing them. False or practical shortening is estimated by comparing the distance between the umbilicus and the inner malleolus on either side. The difference in inches between the real and false shortenings is noted. We then measure the distance between the anterior superior spines of the ilia. Having obtained this information we turn to Lovett's table. If the line which represents the amount of difference in

inches between the real and apparent shortening is followed until it intersects the line which represents the pelvic breadth, the angle of deformity will be found in degrees, where they meet. *If the practical shortening is greater than the real shortening, the diseased leg is adducted; if less than the real shortening, it is abducted.* Take an example: length (from anterior superior spine) of right leg, 23; left leg, 22½; length (from umbilicus) of right leg, 25; left leg, 23; real shortening, ½ an inch; apparent shortening, 2 inches; difference between real and practical shortening, 1½ inches; pelvic measurement, 7 inches. If we follow the line for 1½ inches until it intersects the line for pelvic breadth of 7 inches, and we find 12° to be the angle of deformity, as the practical shortening is greater than the real, it is 12° of adduction of the left leg.

LOVETT'S TABLE.

FIG. 17.—Fitting of the pelvis giving false flexion of right thigh.

Actual lengthening of the diseased member rarely occurs, but we have observed it during the course of treatment by the long traction hip-splint. The importance of an accurate record of the angle of flexion and adduction, or abduction, is of the greatest importance. Upon it, and upon it alone at times depends the diagnosis of the disease; and upon it depends the diagnosis of a cure in all cases resulting in ankylosis. A joint in which the angle of deformity is changing is capable under proper treatment of gaining a still greater degree of usefulness. In a case destined to result in ankylosis a cure is not effected until the angle of deformity ceases to change.

The involuntary muscular spasm, which restricts the motion of the joint or absolutely limits it, is the diagnostic symptom of joint disease. It is the first symptom to appear and the last to disappear, and it is the only symptom upon which dependence can always be placed in making the diagnosis. It is believed to be of reflex character and to be due to the irritation of the nerves which supply the joint. It affects only the muscles which control the movements of the diseased joint, but it affects all of them. Upon this depend the diagnosis of the disease and the differential diagnosis from affections which

closely simulate the disease. Lack of normal extension and rotation is usually more noticeable in the first weeks of the disease than are restrictions to flexion and to lateral movements; but a careful comparison between the movements possible at the two hip joints will make the defect apparent to one who has become at all familiar with this peculiar symptom. To describe the nature of the spasm is scarcely possible; it is one of those things better learned by touch than by description. In attempting any of the normal passive motions at the joint (Fig. 11) it will be found that in most cases motion is quite free to a certain point; it is there checked, not with the slow elastic resistance of voluntary muscular opposition, nor with the sudden dead stop of fibrous adhesions, but suddenly and positively. Once felt, it is always to be recognized.

Abscesses occur in about half of all the cases in which treatment is not commenced very early. They may be present in any relation to the joint, but the most frequent position for the first abscess to appear is somewhat below and to the inner side of the anterior superior spine of the ilium. The abscess may appear early in the disease or at any time during its course. It is usually ushered in by a period of pain,

FIG. 18.—Hysterial hip, the left.

night cries, and increase of deformity; flexion is always present, and abduction is frequently found in early abscesses, while adduction is more frequently met with later in the disease. During the treatment of the disease any exacerbation of pain or tendency to deformity, unless there has been some well-recognized traumatism, is suggestive of the formation of abscess and warrants that prognosis. The first objective sign is a brawny feeling in front of the joint: this is or soon becomes tender to pressure, ultimately softens in its centre and fluctuation may be made out. The area of fluctuation extends, the extension usually being in the outward and downward direction, and at times fully two-thirds of the upper, outer, and anterior portion of the thigh is occupied with a fluctuating tumor. The abscess may, however, appear posterior to the great trochanter, or it may find its way through the acetabulum, and be made out within the iliac fossa, whence it rises up over the brim of the pelvis, following much the same course as a psoas abscess, and on reaching the thigh occupies its anterior and inner aspect. In some cases it simulates an anal abscess, and after spontaneous opening the

persistency of symptoms suggests a fistula in ano. Much care is required in differentiating it. The course of an abscess left untreated is to spontaneous opening and evacuation. If the abscess opens or is opened early, the pus is thick, yellow, and creamy in character; later on the solid contents separates itself from the fluid, and the abscess cavity is filled with a clear liquor, like whey, in which float large or small curds of fibrin. The abscess opening spontaneously at this time discharges at once the whey-like fluid, and the fibrinous curds come away later according to the size of the opening. If, however, the joint be treated by rest, very many cases do not go on to spontaneous opening; the abscess passes through the stages already indicated of a creamy pus succeeded by a thin serous fluid floating flakes of fibrin; when the fluid is absorbed and the fibrinous masses remain. Frequently, the sac containing these fibrinous curds will become cut off from the joint, and remain quiescent for months or even for years, then rapidly liquefy and empty itself spontaneously, or the contents may be absorbed, undergoing what is believed to be a fatty degeneration. Rarely, during the development of abscess, is there any especial fever or constitutional symptom except such as may be attributed to the pain; and the pain is felt only while the abscess is intra-capsular or is subperiosteal; when once the pus has escaped from the bone or joint, the suffering ceases and almost invariably the general health of the patient improves. The course of the sinuses, which remain after the spontaneous opening of the abscess of hip disease, is towards closure, at least when carious bone is no longer to be drained. A sinus leading to a cavity not connected with carious bone will usually close within a few weeks; one leading to carious bone will remain open until the bone is thrown off, or removed, or drained through some other channel. These spontaneous openings show a much greater tendency to closure than do the sinuses remaining after operative interference; especially is this true if the operative interference has been accompanied with the use of the rubber drainage-tube, the sinuses from which show very little tendency to closure. The course of these abscesses, treated by aspiration, depends entirely upon the nature of the contents, and whether or not they are connected with carious bone. The creamy abscess can generally be aspirated, but it is usually connected with carious bone, and almost invariably refills. The abscess containing the whey-like fluid and fibrinous curds can rarely be evacuated, even through a needle of trocar size, and these also usually refill when aspiration has been attempted. The course of abscess under treatment by incision also depends upon the nature of the abscess cavity; if all the tubercular material at the osseous focus can be removed, it may be expected that primary union will result, otherwise a sinus remains more subject to septic infection than the sinus resulting from spontaneous opening.

Diagnosis.—The diagnosis of hip disease is rendered comparatively easy by what is known as the Thomas flexion-test. This is founded upon our inability to extend an inflamed hip without producing lordosis. By lifting the sound knee until it touches the chest the pelvis is fixed and the spine is straightened (Fig. 12). If there be hip disease the patient is unable to extend the thigh on the diseased side and it remains at an

angle. If disease is absent the leg can quite easily be made straight. Few surgeons seem to have observed that if we take any healthy subject and lay him flat upon a table or other hard plane we can easily pass our hand under the lumbar vertebræ (Fig. 13), but if we ask the subject to touch the table with his back he is able to obliterate the hollow without lifting his limbs (Fig. 14). We have here therefore a very ready guide for the detection of deformity. In no case of hip disease is the patient able to straighten his spine, until art has stepped in and corrected the flexion deformity.

The application of the flexion test (Fig. 15) in the case of an infant requires considerable delicacy. A child of two or three years old is brought for examination. A vague history of irritability may be alone complained of, or pain may be occasioned while the child is washed. The surgeon is to find out in the first place whether there is an inflamed joint and if so, on which side. The child is gently put upon the table while the surgeon without exciting alarm holds a knee in either hand. The thighs are slowly flexed towards the chest, when it is observed that one easily yields to full flexion while the other becomes a little rigid (Fig. 16). The stiff hip is then gently allowed to fall while the sound one is fully flexed. It will then be perceived that the diseased limb remains at an angle and cannot be fully extended. Stress must be laid upon the necessity of not startling the child and in not using the slightest force; while care must be taken first, not to flex the pelvis upon the spine (Fig. 17), and secondly, to conduct the examination upon an even flat surface. Although this test is not absolutely diagnostic, if the hip be complained of and pelvic, vertebral, sacro-iliac and malignant disease be negatived, one can fairly infer the presence of coxitis.

Differential diagnosis.—Hip disease is perhaps more often confounded with Pott's disease at the lumbar spine than with any other one condition. In Pott's disease the only motions at the hip joint which are restricted are those in which the psoas muscle is put upon the stretch, namely, extension and inward rotation while in the fullest possible extension.

Sacro-iliac disease restricts the motions at the hip joint in precisely the same way as does Pott's disease, flexion, and rotation during flexion, being perfectly free.

The neuromimetic or hysterical hip (Fig. 18) is the most difficult of all to differentiate. All the subjective and many of the objective symptoms of true hip disease may be present. In untreated cases, however, muscular shrinking is rarely present; and the muscular resistance to attempted passive motion is somewhat different to the trained touch from that experienced in true disease. Furthermore hysterical condition are rarely present except in young women, and the history of repeated attacks together with the facial expression often gives a hint in the right direction.

Congenital dislocation and infantile paralysis have both been mistaken for hip disease, but a careful examination should exclude such a mistake. In both the range of motion is nearly normal, or greater than normal, in some or all directions; there is no muscular spasm and no history of pain or suffering.

Prognosis.—In considering the prognosis, the duration and the ultimate result as to life, the deformity, and the usefulness of the limb have to be taken into

account. Of cases of hip disease not subjected to operative interference, only about 8 per cent. die. Nearly all of these die from tubercular meningitis; a few die from waxy degeneration of the liver and kidneys following upon prolonged suppuration. Tubercular meningitis may attack a patient during the early months of the disease, during its later course, or when about cured, or even months after a cure has been effected. It does not seem to bear any relation to the development or course of the suppuration in unoperated cases, but it does seem to have a direct relation to those that have been subjected to the operation of incision and erosion, or scraping, of an abscess cavity. The patient attacked with tubercular meningitis, so far as we know, always succumbs to the disease.

The duration of hip disease under efficient mechanical treatment is from one to three years, although cases do sometimes continue for much longer periods. The ultimate result as to deformity depends upon the mechanical appliances used in the treatment, upon the care which the patient receives from the surgeon, and upon his home surroundings; few, if any, cases should be allowed to recover with other deformity than the shortening due to arrested growth and actual bone destruction, though as a matter of fact not a few cases to-day do recover with some degree of flexion and adduction. The amount of actual shortening depends upon the duration of the disease and the location of the tubercular focus more than upon the amount of suppuration. Some cases that have had several abscesses recover without shortening, while others that never have had abscesses recover with marked shortening. The shortening is rarely more than an inch in cases where subluxation has not occurred; but as time goes on and growth takes place after the cure has been effected, a few cases show an increased degree of difference in the lengths of the two legs, then as much as two or three inches difference may be found. If the joint be encylosed, or nearly stiff, and if there be some degree of flexion and adduction, shortening becomes a serious disability, but if the joint motion be of fair extent and if there be no flexion and a possibility of movement in the direction of abduction, compensatory lengthening takes place, and a real shortening of from one to three inches may not require any artificial lengthening of the member to render walking comfortable and graceful. A certain number of joints recover ankylosed, or with so little motion, that for the purpose of use the ankylosis might as well be complete; their number is uncertain, but the stiffness appears to depend upon the duration of the disease, the severity of the inflammation, and the inefficiency of the immobilization. Stiff joints do not result from immobilization, but from the lack of it, and suppuration is no indication that stiffness must result. We have seen cases that have had as many as six sinuses recover with normal motion, and on the other hand other cases in which no suppuration was ever made out recover with perfect stiff joints. Cases that never have been immobilized not infrequently recover with perfect ankylosis, while numerous cases perfectly immobilized for as long as six years have recovered with practically normal mobility. To attempt the prognosis of any individual case at the time of the first observation should not be attempted. It is not possible to tell how any case may turn out. Nothing

more than a guess can be formulated, and this must be founded upon the family history, the general physical condition of the patient, the duration of the symptoms, the existing condition of the joint, the surroundings of the patient, the care he is likely to receive, and the faithfulness, or the contrary, with which he may be expected to follow the directions given.

COMPARISON OF MARKET FLUID EXTRACTS AND THEIR RELATION TO FIFTY PER CENT. TINCTURES.

Read in the Section of Materia Medica and Pharmacy, at the Forty-third Annual Meeting of the American Medical Association, held at Detroit, Mich., June, 1892.

BY EDGAR L. PATCH, PH.G.,
OF BOSTON, MASS.

The question of the variability of fluid extracts as made from different lots of drug, by different manipulators, has often been discussed, and the suggestion has been made that if substituted by 50 per cent. tinctures, retail pharmacists could profitably make their own products.

It has even been asserted that 50 per cent. tinctures would average to be as strong as many market fluid extracts.

To arrive at an impartial verdict we have kept the record of 300 lots of fluid extract of dandelion U. S. P., and 250 lots of fluid extract of wild cherry U. S. P., made by as many operators from four uniform lots of drug.

The dry extractive from the dandelion was 26, 28, 30 and 35 per cent.

The range obtained by the 300 students was from 8.5 per cent. to 31 per cent.

The glycerin extractive from the wild cherry was 27, 28.8, 26.8 and 31 per cent.

The range obtained by the 250 students was from 14.4 to 31 per cent. Fifty-two different drugs were then selected, submitted to assay for extractive, alkaloid, etc., and made into fluid extracts by twelve members of the graduating class.

A similar line was made by one of my assistants and the assays made by a second assistant.

Two hundred and fifty market samples of fluid extracts were submitted to examination by the same parties.

A small line of 50 per cent. tinctures, made in duplicate, at different times, under the ordinary vicissitudes of store work, was made and examined by Mr. Newhall. The various results are embodied in the accompanying tables.

In considering these figures certain allowances should be made: First, some of the workers may have been more careful and obtained closer results than others; second, the moisture in the drugs was found to vary from 5.5 to 20 per cent., so that using the same menstruum with such drugs, there is variation by hydration. In one case a 45.5 per cent. alcohol becomes 43.22 per cent., and in the other 37.9 per cent.

A dry drug containing much gum or albuminous matter percolated with strong alcohol, may abstract water and increase the alcoholic strength by one or more per cent.

In all the tables where alcoholic strength of menstruum is referred to, per cent. in absolute alcohol by weight is indicated.

The alcohol strength of the fluid extracts was found by mixing 25 G. with 100 G. of water, distilling 100 G. in a properly sealed apparatus, taking sp. gr., finding alcohol weight strength of distillate by U. S. P. 1880 tables and multiplying by four. This gives the alcohol strength of the fluid extract.

To find the alcohol strength of the menstruum, the following method was employed:

As the extractive occupies the space of liquid, by subtracting the per cent. of extractive from 100, we have the weight of liquid in the fluid extract, and dividing the per cent. of alcohol in the fluid extract by the weight of liquid, gives the per cent. of alcoholic menstruum used.

A fluid extract gives 40 per cent. alcohol and 20 per cent. extractive; 100 G. less 20 G. leaves 80 G. of liquid; then 80: 100:: 40 per cent.: 50 per cent.

Third. Extractive is no positive criterion of the therapeutic value of a drug, but may furnish a method of determining exhaustion.

The quantity of extractive, the quality of the extractive, and physical incompatibilities of the fluid extract are, of course, entirely changed by slight variations in menstruum.

Extractives were determined by evaporating to near constant weight on a water bath. In extractives containing glycerin there is a constant, gradual loss from evaporation of glycerin.

Different lots of the same drug may vary 70 per cent., as from 14 to 24.

Fourth. Temperature alters the action of extraction. A range of 15° F. with same rate of flow at low temperatures, may make a difference of 10 per cent. more or less in the extractive from the same drug, by the same menstruum. That is, a range of 27 to 30 per cent., or 18 to 20 per cent.

Fifth. The relative amount of extractive obtained by exhausting 10 G. of drug with a menstruum may differ from that obtained from 10,000 G. of the same drug, owing to longer contact and greater alteration of the menstruum from its becoming a compound solvent.

Sixth. The therapeutic effect is affected by alcoholic strength.

NOTES.

Aromatic Powder.—A variation of over 300 per cent.

Belladonna Root.—Great variation in menstruum. The market samples with weak menstruum give a very dark-colored fluid extract whose high gravity is increased by glycerin. They will not make the U. S. P. lin. belladonna. The U. S. P. is a very light brown product.

Benzoin.—A variation of 400 per cent. One weaker than the U. S. P. tincture.

Benzoin Compound.—Tincture made from label directions varied from 9 to 19 per cent.

Buchu.—Market samples green in color and excessive in alcohol strength. U. S. P. 1880, olive brown. See 50 per cent. tinctures in comparison.

Cascara.—For therapeutic value of different constituents, effect of old and new bark and comparison of fluid extracts, see thesis by A. A. Burnham, Massachusetts College of Pharmacy. Another investigator claims to have found nux vomica in some specimens of fluid extract of cascara.

Cotton Root.—Notable variations.

Cramp Bark.—Variation of nearly 100 per cent. in extractive, 300 per cent. in alcohol.

Dog grass.—Made by U. S. P. method has a different flavor than when made by repercolation.

Ergot.—One sample only as weak as a 50 per cent. tincture.

Grindelia.—Variation in color is made by difference in alcohol strength.

Hydrastis.—Note variation in alcohol. In addition, samples of so-called aqueous goldenseal and samples of colorless were examined.

Ipecac.—Market samples were entirely different from U. S. P. in alcohol and resin. Evidently made by repercolation instead of the tedious U. S. P. method.

Marigold.—Very likely to gelatinize with weak alcoholic menstruum.

Quassia.—Variation of 150 per cent. in alcohol.

Sarsaparilla.—Variation of 200 per cent. in extractive and 120 per cent. in alcohol. Samples of compound fluid extract found to be made in some cases from oil of wintergreen and sassafras, without drug. So made, they mix freely with syrup, while U. S. P. will not.

Sculleap.—Made with U. S. P. menstruum will not remain clear.

Squill.—Variation of over 700 per cent. in extractive and 800 per cent. in alcohol. Made with weak menstruum has rich, deep color, having no resemblance to the U. S. P., in taste is much pleasanter, and mixes with syrup. U. S. P. is pale amber color and is bitter.

Wild Cherry U. S. P., represents all the astringent, sedative, tonic power of the drug, but cannot mix with syrup or aqueous vehicles. Market substitutes in no case represent the U. S. P.

H. A. Baker, class 1886, found fld. ext. U. S. P. 1880, made from virgin bark, to contain 3.06 drops of 2 per cent. hydrocyanic acid to a fluid dram. By repercolation, 3.32 drops. By 1870 method, 2.46 drops. 1860 method, 1.29 drops. Market sample, .84 drops. Syrups, .447 and .48 drops.

Page found in market samples 3 drops, 2.8 drops and 2 drops, but little bitter principle. All were made to mix with syrup.

It is seen that fluid extracts average much stronger than 50 per cent. tinctures.

REMOVAL OF THE GASSERIAN GANGLION.

A Clinical Lecture Delivered at Mercy Hospital.

BY EDMUND ANDREWS, M.D.,

OF CHICAGO, ILL.

On Saturday, January 7, Dr. Edmund Andrews performed for the fourth time, at Mercy Hospital, Chicago, his operation for the removal of the Gasserian ganglion. The patient was a woman and furnished typical indications for the operation, having suffered for years with a tic douloureux of the right side. She had previously undergone two operations, she said, presumably section and avulsion of the nerve, with the usual result, viz: a return of the agonizing pains in the course of about two months. When Dr. Andrews first conceived the idea of such an operation, he had satisfied himself that these obstinate trigeminal neuralgias usually have their origin in defective teeth which give rise to a neuritis involving first the inferior dental nerve and gradually progressing until the entire inferior maxillary branch of the fifth nerve is involved, that it ascends as far as the semilunar ganglion and stops there, not being transmitted beyond to the brain because of the difference in structure between the proximal and distal portions of the fifth nerve. His logical conclusion was that if the removal of the ganglion could be effected, the intolerable suffering of the patient would be relieved.

After a great deal of experimentation upon the cadaver, six different methods of procedure were devised for the accomplishment of the end in view, one of which Dr. Andrews now regards as the best and will be herein briefly described as the writer witnessed it last Saturday.

The field of operations was rendered as aseptic as possible, the right side of the scalp being shaved and the utmost pains being taken to guard against infection. Beginning near the external angular process a curved incision was made extending horizontally above the zygomatic arch, curving down in front of the ear and terminating near the angle of the jaw care being taken to avoid the pes anserinus. The flap thus made was turned down and stitched to the ala of the nose; the zygomatic arch was sawed through at each extremity and reflected down carrying with it the attached masseter muscle; the coronoid process of the lower jaw was then sawed off and turned up on to the temple, carrying with it the attachment of the temporal muscle, and was stitched to the scalp. Now some fat and connective tissue was exposed containing in it the internal maxillary artery, which was tied. Persistent oozing hæmorrhage had compromised each step of the operation and was particularly troublesome at this stage; the blood would well up into the wound almost as fast as an assistant could sponge it away, and owing to this masking of the parts involved, the operator had to literally feel his way in the dark. Search was now made for the inferior dental nerve which should serve as a guide to the foramen ovale, but it was not found, owing no doubt to the fact that it had been entirely torn away at one of the former operations. Therefore the finger of the operator felt for the posterior sharp edge of the external pterygoid plate of the sphenoid bone and passed it up to its base, near which the foramen is situated, and through which a probe was passed, the ganglion being transfixed thereby. Just external to the foramen ovale is a triangular free space on the under surface of the base of the skull and here a specially devised trephine with a long shank and a long center pin, was applied and the button of bone removed. The narrow isthmus of bone intervening between the trephine hole and the foramen ovale was bitten away with a pair of rongeur forceps and through the large opening thus made a surgical spoon was passed and the ganglion scraped away.

In closing up the wound Dr. Andrews advocates wiring together the bones sawed through, but in this particular case it became necessary to dispense with this procedure, owing to the manifestation by the patient of symptoms of collapse—due chiefly to the hæmorrhage, partly also to shock—from which however she rallied nicely after being put to bed, receiving hypodermic injections of digitalis and strychnine and the application of heat.

Time required for the operation was about two hours. To the bystander it seemed a formidable one—as it was a tedious one to the operator. But it must be remembered that the patients suffering with this trouble will invite almost any conditions whatever that will offer them escape and always say that if the operation wont bring them relief, they prefer not to awake from the anæsthetic.

As previously stated, this is the fourth time that Dr. Andrews has performed this operation. The first two, over a year ago, were followed by excellent

results, *i. e.*, complete relief up to the present date; the third died of shock from the operation: and it is said, to have been once successfully performed by Dr. Edward Kerr of Chattanooga, a time or two in Philadelphia, once unsuccessfully by Victor Horsley, an English Surgeon, and something like seven times by Dr. Rose, of King's College Hospital London, without a death. It is rather a remarkable coincidence that Drs. Andrews and Rose, one in England and one in America, entirely unknown to each other should have arrived at the same conclusions as to the advisability of removing the semilunar ganglion for the relief of facial neuralgia, and should have acted upon these conclusions at almost exactly the same time. These gentlemen since first hearing of the doings of each other, have been carrying on a personal correspondence exchanging views and plans and experiences relative to the fifth nerve. It would seem that to Dr. Andrews belongs the credit of first perfecting the operation and performing it on the cadaver, but, that Dr. Rose first undertook it upon the living subject.

Carl Stutsman, Chicago Med. Coll., Jan. 9, '93.

KNIFE CURETTE. ESPECIALLY ADAPTED FOR OPERATIONS ON THE BONES AND CARTILAGES.

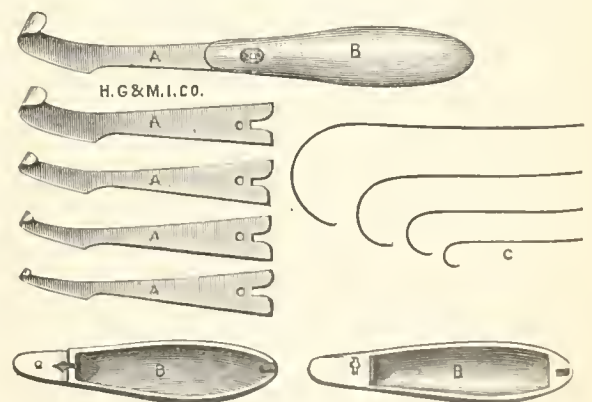

BY A. H. MEISENBACH, M.D.,

PROF. SURGERY IN THE MARION-SIMS COLLEGE OF MEDICINE, ST. LOUIS, MO.

This instrument is fashioned somewhat after the farrier's knife.

It consists of a blade (*a*) placed in a separable handle (*b*) as shown in the upper figure of the cut.

The cutting part of the blade is placed at an obtuse angle to the shaft: This gives a greater degree of leverage. The end of the blade is bent upon itself so as to form a loop or part of a circle. By means of this construction, the instrument has a round as well as a linear cutting edge.

The handle is made of metal in two separable parts, with a simple but effective lock and catch, as is seen in the lower figure of the cut. There are four blades of various sizes.

The figures are of one third actual size, with the exception of outline figures, (*c*) of the loops of cutting blade, which are actual size.

The various blades may also be attached to solid metal handles if so desired, and bulk is no objection.

With the separable handle the instruments can be more compactly placed in a small neat case; which

is especially desirable where different sizes of the instrument may be wanted at hand; for hospital work the solid handles, possibly may be of more satisfaction. The construction of the instrument is such that it is easily kept aseptic.

To the practical surgeon the many uses to which this instrument can be put will readily suggest itself.

In operations on the long bones as in osteomyelitis, superficial necrosis etc; on the joint surfaces in the removal of the tubercular masses and foci operations in the petro-mastoid region, and many other instances too numerous to mention. In many cases it may take the place of the chisel, if properly constructed and of right temper. The form of its construction makes it a peculiarly powerful instrument with which rapid and effective work can be done, and its advantages over the ordinary forms of curette especially in bone work can easily be appreciated. I believe this instrument will be a valuable addition to the armamentarium chirurgicum of the general surgeon.¹

DOMESTIC CORRESPONDENCE.

To the Editor of the JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION:

I am not willing to allow the statements in the editorial article on "Removal of the Ovaries as a Therapeutic Measure in Public Institutions for the Insane" in THE JOURNAL for February 4, to pass without question. I presume the statements are made on the authority of the distinguished chairman of the Lunacy Committee, of the Pennsylvania Board of Public Charities. Now, while I cheerfully concede Dr. Morton's distinction as a surgeon and teacher and acknowledge my obligations to his many valuable contributions to surgical literature, I cannot allow his sweeping assertions upon this question to pass without a mild protest.

Several years ago my attention was attracted by the statement frequently made in medical societies to the effect that many abdominal sections with removal of the uterine appendages had been done in American Insane Hospitals with a view of the curative effect of such operations upon various psychoses and neuroses. The assertion was perhaps still more frequently made that these operations had not only proven of no avail but also that insanity not rarely followed removal of the uterine appendages for other diseases. As I had no personal knowledge of any such cases, and could find no trustworthy accounts based upon facts, I determined to make a "collective investigation" of the subject and with this in view addressed a letter to every medical officer in charge of a public or private institution for the insane in the United States and British America. The officers so addressed responded courteously and I received detailed replies to my questions from 121 institutions. The results of an examination of these answers were reported to the American Medico-Psychological Association at its meeting in Washington last May. I found that only 39 such operations had been performed in the last ten years upon patients at the time in the care of these institutions. To these I could add, at that time 14 operations performed by myself in this hospital. Of these 53 cases operated upon seven have been mentally cured and discharged from the hospitals.

Twenty-six cases of insanity following operations upon the sexual organs were reported to me from these 121 institutions; but of these eight had recovered and been dis-

charged showing that the mental aberration following the operation had been only temporary; two were in an improved condition, four had died and twelve remained under treatment, showing indeed a very small proportion of persons insane enough to demand hospital or asylum restraint.

I am compelled therefore to disagree with the sweeping statement that these "experimental mutilations" (?) were either frequent or that their "ultimate success" is doubtful. More decidedly still do I disagree with the assertion that "many insane, epileptic and hysterio-epileptic women, who have been thus mutilated (?) have subsequently found their way into hospitals for the insane, and are heard of no more." If the hospital and asylum superintendents have made true reports to me, and I am sure they have, then the "many" women who have become insane after operations on the sexual organs do not exceed twenty-six in number. This is, I am sure a very small percentage of the total number of abdominal sections done in this country in the past ten years. I am now studying the question of the special causation of the post-operative insanity in these cases, and believe I shall be able soon to give a rational explanation for the same.

I venture to go a little more in detail into some of the results obtained in my own practice with removal of the appendages in insane women. In one of my cases a hysterio-epileptic mulatto woman, the patient had been an inmate of the hospital over seven years. Her convulsive attacks followed by violent maniacal outbreaks appeared to be closely connected with the menstrual periods. On these occasions she was wild and destructive; breaking, tearing, and fighting patients, attendants and physicians. She showed no tendency to improvement—rather the reverse. She was comparatively lucid in the intervals, anxious to get well, and asked to have the operation performed. She was discharged five months after the operation, apparently entirely restored and has since been earning her living as a domestic servant. She has had no recurrence of the convulsive or maniacal attacks.

Two cases were puerperal insanity; one in the second, the other in the third attack. Both of these women are now at home attending to household duties. In both there were lesions of the pelvic organs, sufficient in my opinion to justify the operation.

Another case of profound melancholia with onomatomania is sufficiently recovered to be at home assisting her mother in the household duties. In a letter written February 2, nearly four months after her discharge she reports herself as gaining mental strength and being almost free from the annoyance of the "inward voice" that formerly worried her so much.

Another case of melancholia with suicidal tendencies has recovered after repair of a badly lacerated cervix and has been discharged.

None of the cases upon whom I have operated have been made worse. I believe I shall soon be able to discharge others of those operated upon, as some show progressive improvement.

I deny then the assertion that the success of these operations in proper cases is "doubtful," "the distinguished chairman of the Lunacy Committee" of the Pennsylvania Board of Public Charities notwithstanding.

I do not know enough of jurisprudence to say whether the contention, of "the legal member of the Lunacy Committee" that neither an insane woman, nor her relatives can give legal consent to the performance of an operation upon her, is good law or not. I do not hesitate to say, and in this I am sure I will be supported by nine-tenths of American men and women, that it isn't common sense. If, however, it is true that neither the woman nor her guardians can give

¹ Holekamp, Grady & Moore, makers. St. Louis, Mo.

consent, then the responsibility rests entirely with the physician. No lawyer, no secretary or chairman of a Lunacy Committee, and no Board of Public Charities can relieve the physician of this responsibility, or prevent him from acting in accordance with the dictates of his conscience in this matter.

And so "the Committee on Lunacy of the Board of Public Charities" of the great State of Pennsylvania "has full authority under existing statutes to prohibit the performance of operations" upon and "to regulate the treatment of the insane." The medical officers of the Pennsylvania Hospitals for the insane must "take their orders" from the committee. These men and women, able, cultured, sympathetic, scientific laborers in the field of psychiatry must perforce, should the Committee see fit to demand it, that their patients committed to their charge not as their own professional experience demands, but as the Lunacy Committee directs! Lovely prospect for the asylum physician! If he or she thinks a patient requires a dose of morphine, he or she may find that the Lunacy Committee disapproves of this medication, because "it is the duty of this committee to regulate the treatment of the insane." That's what the "legal member" says. "It is brutal and inhuman, and not excusable on any reasonable ground" to endeavor to restore an insane woman's reason—unless it is done in accordance with the views of the Lunacy Committee. The gynecologists, those terrible fellows, want to invade the sanctity of the insane hospitals and rip open all the insane women in the State of Pennsylvania in order get an "added forward movement up the ladder of fame." At least, that's what the "legal member" says, and doubtless he knows. Of course, the gynecologists and those medical officers of hospitals who believe with them that mental derangement may be due to extra-cranial disease, cannot possibly be actuated by humane sentiments, or the desire to do more for the unfortunates placed in their care than has heretofore been done. They only want an "added forward movement up the ladder of fame!"

To say that the operation of oöphorectomy, so-called is brutal and inhuman, is to accuse the operator of brutality and inhumanity. In making the statement and inference the "legal member" of the Lunacy Committee utters a vile slander. His medical associates on that committee in giving publication to the statement and inference have endorsed the slander. Of this grave misdemeanor, perpetrated upon honorable men and women, I charge them before the bar of professional opinion. Are they willing to stand trial before that court? GEORGE H. ROBE.

Maryland Hospital for Insane.

Catonsville, Md., February 6, 1893.

Revision of the Code of Ethics.

To the Editor of the JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION:

Dear Sir:—In his letter to THE JOURNAL of Feb. 11, 1893 the writer examined only a few sentences, after reading the whole of the *News* editorial of Jan. 28. He will now give some attention to the remainder and analyze such sentence requiring special consideration. But before beginning this critical examination he will make a few general remarks.

1. There are several prominent features in both of the *News* editorials that require general revision; among them are assertions, opinions and assumptions. The first two can be of no value in argument unless based upon facts which are supported by incontrovertible proofs. The third, assumptions, are not generally regarded as logical deductions. The demands of the dissenters are in keeping with the features to which reference is made above, for they assert, opine and assume that the Code is objectionable

without offering any arguments as proofs to establish their claims. They should not forget that the burden of proof rests upon the aggressive side; the office of the defense being to controvert the testimony of the aggressors and to challenge them to furnish substantial facts in proof of their position. The author of the editorials says so much of what he regards as illogical that he may yet take advantage of the art of reasoning and perhaps construct a series of syllogisms to strengthen the position he occupies respecting the revision of the Code and the attitude of the dissenters.

2. The author of the editorials is apparently (inconsistently, however) in dread of that "formidable minority." How can he regard this minority as so ominous when, according to his own statement, it exists "principally" in one State? What is that unit to all the other States? What is that minority to the "general sense of the profession?" If that minority exists "principally" in one State, how insignificantly small it must be in the other States, where there seems to be general harmony! In an assembly of five hundred persons entitled to vote, a minority of two hundred and forty may be considered formidable and excite the apprehension of the small majority, which might in future become a "formidable minority." In many medical associations a majority of one often decides important questions, whilst other questions decides a two-thirds majority, particularly when it is proposed to alter their laws. It does not seem to have occurred to the author of the editorials that "the general sense of the profession" constitutes a "formidable" majority.

3. The writer suggested that it would be gracious for the minority to abide by the "general sense of the profession" and allow the Code to stand as it is. In reply, the author of the editorials said: "But the minority emphatically refuses to act in this gracious manner," and he has no reproof to make them for being ungracious! If the dissenters refuse to be gracious, kind, merciful, condescending and conciliating, but will assume a defiant, dictatorial, and malevolent spirit, how can they expect to be received in the fold of a benevolent confraternity? Repentance, with an avowal to endeavor to be just in future, is apparently their only hope. The author of the editorials seems to be at his wits' end because this "minority emphatically refuses" to be gracious, to be just, and to abide by the law. It is not improbable that the dissenters will be let alone severely, that they will be left in the moral and professional "background," unless they repent and, if they do, then the fatted calf will be killed and the prodigals shall feast and all shall rejoice. The American Association will thrive in spite of dissensions and can wait longer than contentious mortal members, then there will be no more threatening "formidable" minorities to disturb peace and harmony, for the schools will teach the history and philosophy of medicine.

4. The author of the editorials says: "It is not logical to assume that the sentiment which so divided the profession is confined to the State of New York." Is it logical to assume that the profession is divided in sentiment in other States than New York, since, as says the editorial of Jan. 28, "In the State of New York only has there been an expression of opinion on the Code?" Facts, well authenticated, and not bare opinions, or assumptions, are of value in argument. The defenders of the Code do not indulge in assumptions; they rely upon the logic of truth and justice.

5. The author makes an assertion to the effect that the old societies of New York are not represented in the American Medical Association; seemingly without being cognizant of the rules of the American Association. In accordance with these rules, when in one State, there are two State organizations, only one of these societies is entitled to representation. There are now two State organizations in New

York, only one of which adopts the laws of the American Association, and is thereby entitled to representation. This State Association from its large membership, is entitled to send seventy-five delegates yearly, and all of its members may become permanent members of the American Association. Before its defection, the old State Society could not send more than fifty delegates. The number of the author's elect seems to be diminishing, for he has retrenched the "able," leaving the "eminent," and, to keep these in countenance, he has substituted "valuable" for "honest." However, without assumption, it may be declared that eminent and valuable workers are all honest, just as all men are honest until convicted of dishonesty, therefore the adjective was superfluous and its suppression was wise.

6. Now this author indulges in severe reprobation of the advocates of the American Code (although he endorses its spirit), and reprehends what he styles "a blind adhesion to the Code as it stands," and further says that, "in view of the attitude of the minority, (it) is short of fanaticism, and is hardly less reprehensible than the extreme action of the advocates of the new code." After this and other terms of reproach, the advocates of the American Code may well exclaim, "Save us from a friend who uses such epithets against us, and who would have us surrender truth, principle, justice and honor, to his great bugbear of a "formidable minority!" The "eminent and valuable" workers also may well exclaim, Save us from the over-zealous friend whose advocacy is so hurtful to our cause! We have made a fatal mistake, but we are too proud to acknowledge our fault! We have rushed into evil ways, it is true; but, although conscience whispers, Ye are sinners, we shall not retrace our steps! Such are likely to be the reflections of the leaders. It is not improbable that the rank and file will say to these leaders: Ye have led us astray, but the light of truth is dawning upon us; we wish to be just; we repent, and must leave yours for the right path; we shall make known our fealty to the National organization; and many have already done so. The majority of the dissenters may tell the author that he was not empowered to say "they emphatically refuse" to be gracious, that he was not asked to plead for them, that they would not have selected him at counsel, still less as barrister, and that even as a friend of the court he would be injurious to the plaintiffs and of no use to the defendants. The author then proceeds to instruct the revision committee how they should frame a "newer code" that may or may not—most likely not—be acceptable to the dissenters who have so long endeavored to disprize an Association which, nevertheless, they wish to join, because from the point of view of this author, the "formidable minority" must rule the majority!

7. The author of the *News* editorials reproachfully says: "To assume that an overwhelming majority of the profession is opposed to any change in the Code is illogical and not in accordance with facts." The defenders of the Code have never assumed to be profound in logic or anything else; they have depended upon the simple logic of truth and justice. If the statement about the overwhelming majority be an assumption, it is the author's own assumption, for he has distinctly said that the "general sense of the profession" is favorable to the Code as it stands. Whether "Iowa's" statement, that nine-tenths of the profession favor the Code as it stands, is an assumption, the writer leaves to the editorial's author to prove. There is, however, in the quoted sentence one point which is clear; the author asserts, boldly and inconsistently, that a statement (which he assumes to be correct) is "not in accordance with facts," but he does not attempt to disprove this statement. What facts has he to show that the majority of the profession in the United States, or the smallest minority

outside of New York State, does oppose the Code and is in favor of the adoption of a "newer code?" and what evidence, as a seer, has he that in the event of the adoption of a "newer code," this may not lead to the "newest code," and so on without end? The assertion that a statement is not in accordance with facts is insufficient in any discussion. The aggressor must show what are the real facts, and prove his point, for the whole burden of proof rests upon him, whilst the defender controverts the assertions of this aggressor as well as he can.

8. If what follows be a specimen of the sort of evidence the author is to adduce in his disputations, it may be of interest to know what he generally regards as evidence. He says, in speaking of the New York State canvass: "Does not this showing indicate so considerable a dissatisfaction with the present Code as to call for serious consideration on the part of the central medical organization of the United States? The appointment of a committee of revision of the Code is conclusive evidence that such is the opinion of the American Medical Association." This "showing" does not appear to indicate anything more than the results of the New York State canvass, which are that out of 5,002 physicians, to whom were sent letters of inquiry respecting their views on the Code question, 2,547 favored the National code, 1,040 were for the "new code," 239 were for no code, 34 sent such indefinite replies that they could not be classified, and 1,142 failed to reply. So the real vote was 3,826, and of this number 2,547, or about two to one, were in favor of the National code, which may justly be considered as a "formidable" majority. To regard the appointment of the revision committee as "conclusive evidence" of anything like an expression of opinion, on the merits of the Code, by the Association, plainly indicates that the author needs to explain what his particular views of evidence may be. If he should happen to examine at leisure the subject of evidence he would be likely to withdraw his assertion concerning the "conclusive evidence" in question, and even to have misgivings of evidence furnished by any of the seven deluders; but fortunately he has added to his catalogue an eighth sense, *i. e.*, the "general sense of the profession," which he does not seem to consider as deluding. To emerge from the labyrinthine mazes of the controversy which he has allowed his too zealous self to enter, he may have followed the example of a well-known disputant and provided himself with "a genteel assortment of the best figures of rhetoric," so as to be able to show that a proposition should not be understood the way it is stated, but quite contrariwise; as, for instance, when he writes "conclusive" it should be understood to mean inconclusive. Then he may triumphantly exclaim that the figures of speech are the pillars of disputation! He should have known that the appointment of a committee is often only a concession to a few irritable, contentious members, and is not necessarily an expression of the assembly's opinion on the questions that may be examined by the committee, for the assembly does not take action on the subject until after the committee's report. The disaffected make persistent demands for the appointment of a committee, and the assembly, to be rid of tedious discussion and to prevent the waste of precious time, appoints the committee, but note the verbiage of the resolution: "Resolved, That the President appoint a committee of five to whom the Code of Ethics of this Association shall be referred for such changes or amendments as they may deem it wise to recommend, if they should decide that any change is required." The writer has failed to detect anything in this verbiage which may be construed as "conclusive evidence" that the Association was of opinion that the Code requires modification. The last clause of the resolution says distinctly, "if they (the committee) should decide

that any change is required." This surely does not indicate that the Association was of opinion that the Code needs to be modified, or that the hyperbolically "formidable minority" had given "conclusive evidence" of the necessity of such modification. How can all this be so regarded by the author after saying that the "general sense of the profession" is favorable to the Code as it stands? It is well known that the revision resolution was inspired by those who long since disfranchised themselves from the Association, and now insist upon being readmitted on their own terms. Is there any evidence that he who wrote and presented the resolution for the appointment of the revision committee was not, unconsciously perhaps, in the hands of the enemies of the Association?

9. Here is more of the inconsistency of the author who, having before said, substantially, that the public has nothing to do with the Code, now speaks of the provision "which has subjected the profession to criticism by the public on the grounds of intolerance and inhumanity." He reiterates that "the Code is for the profession and not for the public," and further says: "The public does not care for or read the Code; and as a rule, the few who have any knowledge of its provisions ignorantly regard it as intolerant, and in a certain sense inhuman." Whence his information that the public does not care for or read the Code, and in what particular sense is it inhuman? These are among the many examples of gratuitous assumptions by the author of the editorials. That the framers of the Code intended it for the public as well as the profession, is evidenced by the inserted article relating to the "obligations of the public to physicians," and these framers of the Code were far-seeing men whose ability, wisdom, scholarship, and motives have never been questioned. The author offers no testimony to show that "the public does not care for or read the Code." Here is another glaring inconsistency. Yet "the few who have any knowledge of its provisions ignorantly regard it as intolerant and in a certain sense inhuman." How do "the few" obtain this knowledge? A portion of the quoted sentence looks like calling a few members of the public bad names. May not the rest of the public, with propriety, resent the epithet ignorant? The American people has a fair stock of good sense, and is by no means grossly ignorant. The public may have been misinformed and very likely was intentionally misinformed by irregulars who are ever anxious to decoy the regular profession, and take special advantage of the existing dissensions to carry out their purposes. According to the author, the general public has not read the Code; this is not doubted, but may not this public have received, from designing persons, the impression that the Code teaches intolerance and inhumanity? Therefore would it not be proper to publish to the nation the whole Code together with the well known admirable commentaries appended thereto, and to await the decision of those who shall have read it with care, and then to ascertain how many consider it "intolerant and inhuman"! The public is dependent upon physicians for the cure of disease and for special and general sanitation, and physicians are dependent upon the public for their livelihood. This interdependence entitles physicians to know something of the laws governing the public, and entitles the public to know something of the laws governing physicians in their relations with each other and with this public. The Code was framed for the instruction and protection of the public as well as of physicians. It is astounding to hear any thinking being say that the public has nothing to do with the Code. Let the public have better opportunities to be acquainted with the provisions of the Code, and make no assertion that this public cares nothing for them unless a general opinion is expressed to that effect after careful perusal. Publish widely, in the

newspapers, the Code and commentaries, and let the public judge for itself.

10. The author of the editorials here makes a most strange disclaimer when he utters the following: "We do not discuss the question of revision of the Code in anything approaching a controversial spirit." The writer is forced to take issue with him also on this topic. The author disclaims a controversial spirit, and yet has turned against much of the matter and manner of the Code, though his opposition is not made by reasoning, by offering arguments to establish his position, and his statements are not generally in conformity with the customs of controversy. The editorial of January 28, manifests a strong spirit of controversy, while in it the letter of controversy is not in accord with custom, as already shown in several of the paragraphs which here give the results of its examination. The two editorials are therefore placed in evidence that their author is imbued with the spirit of controversy, but they give little evidence of the letter of controversy. The editorial in the *Medical News* of September 17, 1892, was the opening of the controversy, for at page 332 he says: "We throw out as tentative suggestions what seem to us the most important points, and invite full and free discussion of the various suggestions, *seriatim*." An author who invites full and free discussion need not expect all criticisms to be favorable to his productions, and should not be seriously grieved if some of the critics point out flaws in his statements and show why they cannot agree with his views. The writer challenged him to offer arguments and proofs in place of baseless assertions, bare opinions, and gratuitous assumptions. If he and those he supports are in the right, then the framers of the Code and the American Association have been wrong for forty-five years. If he cannot coolly and dispassionately discuss this question, or if he finds that he is in error, let him make a frank, open, and manly avowal that he is wrong, and he will probably rise to a great height in the estimation of the "eminent and valuable" workers as well as of the humble defenders of the American code. To acknowledge a wrong is always noble and never humiliating.

11. If, as says the author of the editorials, "it is not essential that a perusal of the Code should give pleasure as well as instruction," it may not be improper to ask if it is essential that such perusal should give neither pleasure nor instruction? If the Code failed to give pleasure coupled with instruction, it would seldom be read and would be of very little use. But there is no accounting for literary or any other taste. It seems to the writer that an essay composed in good manner and pregnant with useful matter should give pleasurable instruction to the reader, whilst a slovenly and obscurely written document which may contain some good ideas thus badly expressed, and which requires laborious perusal, would be likely to be cast aside, half read, by the majority, even of those who may be anxious to learn. It is scarcely fair to assume that all medical readers lack the refined discernment which seizes the beauties of a poem or of good prose, and distinguishes the perfect from the mediocre, the noble from the sublime, and finds for each its rightful place.

12. The writer once more declares that in this controversy he is actuated by the sole motive of defending what he believes to be a just cause. He will therefore spare no pains in endeavoring to find flaws in the statements of the opposition, he will use all legitimate means to defeat the opposition, but in a courteous manner and spirit, and will not employ unfair methods. If, however, in the heat of argument, he should make any utterance that may, in the least degree, be considered contrary to the customs of literary or scientific controversy, or if he should inadvertently make a misquotation, he humbly apologises in advance, and if ever

his attention is called to any utterance or misquotation he will cheerfully offer a special apology. The writer regrets that his occupations have not permitted a more complete and concise criticism of the two editorials. He has examined only the main features of these remarkable documents, and has left many things unsaid, otherwise too much of THE JOURNAL'S space would have been taken.

A CONSERVATIVE MEMBER.

To the Editor of the JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION:

I wish to suggest a method of dressing the cord in mid-wifery cases, which I think, will be an improvement over the ordinary way, as we know it. Thus, the cord is cleansed, and tied in the usual place, then a thick pad of aseptic lint with a hole in it is put on over it, then a small metallic plate of lead or zinc (par ex.) with a hole in it is put on

FIRST PAD

METALLIC PLATE

LAST PAD

close to the pad. The cord is secured to this plate by a rubber band or ligature around the legs (aa). If the rubber band is used, hitch a loop of it over one leg, tighten it around the cord and secure it to the other leg (a). Then, bend the legs down to the plate for fixing it. Now, carry the cord down in the long axis of the dressing and cover it

well with the other pad, which is perforated by, and held by bending down the legs (bb) on the lead plate, complete with the usual binder around the body. This gives a clean and fixed dressing, the metallic plate acting as a support in passive hernia. Truax Greene & Co. informs me that they can be made at a reasonable cost.

Evanston, Feb. 6, 1893.

JOHN H. BLACKBURN, M.D.

SOCIETY PROCEEDINGS.

American Electro-Therapeutic Association.

Second Annual Meeting, held in New York, October 4, 5 and 6, 1892.

WILLIAM J. MORTON, M.D., PRESIDENT.

FIRST DAY OCTOBER 4—AFTERNOON SESSION.

(Continued from page 160.)

ELECTRIC CATAPHORESIS; ITS USES IN GENERAL MEDICINE.

By William J. Morton, M.D., of New York City. Professor of Diseases of the Mind and Nervous System and Electro-therapeutics, New York Post-Graduate Medical School and Hospital.

Excluding from this section of our discussion reference to what would naturally fall to other participants and within the lines of introduction, physics, surgery, gynecology and nervous diseases, it would hardly seem at first glance as if much remained to be said in the section allotted to myself. And there may indeed, be danger of overlapping remarks. Yet, even in that case, such is the importance of cataphoresis in electro-therapeutics, and its interesting nature. I am sure the transgressor may hope for lenient judgment on the part of his hearers.

The part of this subject, most important from a medical point of view to elucidate, is the physics of cataphoresis, its nature, the laws which govern it—whether it is a simple mechanical transportation, whether it is incidental to or an actual part of electrolysis, its relations to chemical osmosis, and whether finally, it is not in reality a compound phenomenon consisting both of mechanical transport, and electrolysis, with, under certain conditions, the addition of chemical osmosis.

The existing confusion in this the most fundamental branch of our subject is apparent when we recall that according to Jurgenson fine solid particles suspended in the fluid traversed by the current flow in a direction opposite to its conventional direction while Quincke found that the particles flow in both directions; again methyl blue travels from positive to negative pole, while eosine travels from negative to positive, and an alcoholic solution of bromide of barium also travels from the negative to the positive pole. To the distinguished physicists who are with us to-day we look for light.

It has seemed to me that we may seek for an explanation of cataphoresis in the modern view of electricity which assumes that the electric energy resides in the medium outside of the conductor expending this energy upon conductor or non-conductor alike, the difference between the two being that the conductor dissipates the energy and thus becomes the seat of what is termed a current, while the nonconductor, though subjected to the same influence fails to dissipate it. In the former case the vibrating medium vibrates along the conductor by a succession of lapses or slips while in the latter case it vibrates against the non-conductor which becomes simply charged or electric. The former constitutes a current, the latter a charged body.

At this point, in cataphoresis, comes in the question of the electric resistance of the fluid conductor. If the fluid has little resistance, as in acidulated water, there is little

or no movement, but if the resistance of the fluid is increased, the rate of flow is increased and for a given resistance its flow will be proportional to the current strength. On the other hand, the resistance may be so increased that there is no cataphoresis, as in the case of oils, but there is also little or no current. May we not assume, to explain the transfer of fluids by cataphoresis that the action is mechanical, that the partially conducting molecules which constitute the electric resistance are borne along bodily, to use a rough comparison, like chaff before the wind—become in short, since the mass is fluid, a resistance which may be moved along, while the conducting molecules dissipate the energy they receive to form the current. We might designate this a theory of moveable resistance.

In support of a purely mechanical theory I would cite an experiment from Ganot's physics which is very easily repeated. A glass tube, say 1-16 of an inch in its internal diameter is filled with acidulated water and a globule of mercury nearly equalling the diameter is introduced. The glass tube is corked at each end, a wire is led in through each cork and the apparatus included in a galvanic circuit of from five to twenty cells. Upon allowing the current to flow the globule will promptly and invariably move from the positive to the negative pole even when the tube is so inclined that the mercury must be raised against gravity.

Again, in support of the same view, by making a paste of liquid glass and finely powdered graphite and smearing it over a positive carbon electrode I have caused, with 15 milliampères of current, the graphite to penetrate the hair follicles so deeply that they remain imbedded there for weeks in spite of efforts to remove them.¹

In this case since the graphite could not have been acted upon electrolytically it must have been forced into the follicles by the force of its flow.

Certainly, this question continuously arises, why do fluids of little resistance not suffer movement? The most likely answer would seem to me that where there is friction in a fluid there is movement, and where there is no friction there is no movement.

In the midst of so much uncertainty from a physical point of view fixed procedures of medical practice cannot in all instances be established.

But individual facts well sustained by experiment stand out from the confusion and lead to corresponding certainties in practical medicine.

It is certain,

a. That in a fluid and semi-fluid conductor like the human tissues there is a movement of fluid from the positive to the negative pole.

b. That extraneous fluids maintained in contact with the skin or mucus membrane and thus constituting continuity with the body fluids are transported from the positive toward the negative pole and that in this manner medicinal substances in solution may be caused to penetrate the skin and enter the tissues and the circulation.

c. And it is theoretically possible and demonstrated with tolerable certainty that medicinal substances in solution in the tissues may be removed from these tissues as well as introduced into them by the direction flow of the current from positive to negative pole.

Thus electric cataphoresis to-day presents itself to general medicine as well as to special, under two divisions, each one distinct from the other, viz.:

1. Cataphoresis or simple fluid transportation in the human body.

2. Cataphoric medication (and demedication).

It is difficult to say at present which of these two will in the end render most service in the treatment of disease.

1. Cataphoresis (irrespective of medication).

This has long been a recognized action of the continuous current. Named in the first instance by DuBois-Reymond, Remak later on included it in the *ensemble* of actions which he termed *katalytic*. But it is only in late years that it has received any worthy attention—an attention mainly the result of laboratory experiments upon the lower animals and upon dead animal tissue.

Among such experiments, almost unique and especially worthy of mention are those of G. N. Stewart, physiologist, in Owens College Physiological Laboratory. In all animal liquids when separated by a porous septum there was an immense transference of water from the positive to the negative compartment, also a distinct movement of pigments and proteids.

"For example, in an hour and a half, with a current of only five milliampères mean strength, the volume of a 3.6 per cent. hæmoglobin solution had diminished 40 per cent. in the positive compartment" and increased to a corresponding degree in the negative. Again, "In a two hours electrolysis of bile with a current of 65 milliampères, no less than 92 per cent. of the water had disappeared from the anodic compartment, which originally contained 10 c.c. of the liquid."

When 70 grams of rabbit's muscle with no porous septum was electrolyzed for thirty minutes by a current of 350 milliampères, the water in the cathodic half was found to exceed that in the anodic half in the proportion of 48 to 31 and the salts in the proportion of 48 to 23. Both electrolysis and cataphoresis contributed to this result.

In a living rabbit Stewart passed a hollow metallic electrode into the vagina; when this electrode was a cathode fluid was forced through it, while none appeared when it was an anode. In this case it might be queried if the flow was not due to increased secretion due to the stimulating effect of the cathode, but there was little doubt that cataphoresis was the main factor in its production.

These experiments are not cited to show the possibility of cataphoresis, for of this there is no doubt, but to show the very large amount of the transference of fluid which may take place in tissue. The fluid transfer also includes the removal of the substances dissolved in it, mainly salts. The importance of these latter to the maintenance of healthy nutrition is well known. Normally varying from one to two per cent. in muscle, nerve and other tissues, a decided change in the percentage produces a marked effect upon their vitality and their nutrition. The experiments of G. Weiss² upon the legs of living frogs show that the excitability of the untreated leg was for a long time twelve times greater than that of the electrolyzed leg, and that there were produced profound microscopical alterations in the structure of the muscle. Porret, in the phenomenon named after him, had already noted the cataphoric microscopical change in the muscle.

The importance of this fluid-conveying power and its concomitant deprivation of tissue of salts, both by cataphoric removal and by electrolysis, is scarcely yet appreciated. Its applications to general medicine are obvious, while it may explain well-known results thus far established empirically.

The gynecologists, under the leadership of Apostoli, have used currents of great current strength at the point of small metallic electrodes, and have thus arrived at distinguishing expressions relating to the action at either pole.

The hæmostatic and drying effect of the positive electrode may well be due to the removal of fluids, while the "liquefying" and "hæmorrhagic" effect at the negative pole is equally due to cataphoresis. Granting the softening effect

¹ New York Medical Journal, April 25, 1891.

² Technique d'Electro-physiologie, Paris, 1892, p. 125.

of the negative pole upon urethral stricture, is it not largely due to a liquefaction by the flow of fluids to it?

In a minor way it has long been noted that the eschar at the negative pole was soft and liquid while that at the positive pole was dry and hard, also that the negative needle in surgical electrolysis is loose and free in the tissue, while the positive needle, even though of unoxidizable material, was held firmly.

On a larger scale and in general, cataphoric accumulation of fluids at the negative pole is indicated in the resorption of tumors and of exudations. The application of the action to uterine fibroids and to inflammatory exudations is obvious. In the former case the great current density of the continuous current produces a contraction of the uterus and diminution of the vascular supply of the tumor with a loss of its salts. Its nutrition becomes impaired and a reduction in size is accomplished. In the latter the starvation of its salts alone is the most important element in causing absorption and dissipation. The cataphoric action of the current is also indicated in chronic rheumatic affections of joints and in thickening of synovial membranes about the sheaths of tendons.

In short, in determining upon what action of the current to appeal to to accomplish denutrition and absorption, cataphoresis comes saliently to the front.

2. Cataphoric medication and demedication.

The historical growth of the idea that medicine might be introduced through the skin is most interesting. This falls naturally under introductory remarks.

That medicinal substances do penetrate the skin is now beyond doubt. Personally, I have often ascertained the presence of iodide of potash in the urine after applying it to the positive electrode alone or to both electrodes, and have driven fine particles in suspension, like finely pulverized graphite, into the hair follicles, where they have remained firmly imbedded for weeks. Cocaine anæsthesia by electricity is a well established procedure.

To what extent this method of introducing medicine to the human system may become of practical utility in general medicine becomes an important question.

There are obvious reasons why the method cannot compete with the introduction of the same medicine into the stomach. To introduce it by the skin a battery is required; the amounts introduced are comparatively small, though large enough with certain powerful drugs; and it is difficult to measure the dose introduced with accuracy.

On the other hand there are advantages theoretical and practical which may be named, as for instance, when the tissue upon which it is required to have the drug act is superficial and local. This is often the case in diseases of the skin, in ulcerations, lupus and cancer, in superficially situated neoplasms like a syphilitic gumma.

Again, granting a part in the phenomenon of cataphoresis to electrolysis, it may be that remedies acting in their nascent state ought to be of especial efficacy.

To avoid the action of the fluids of the stomach upon medicines is also sometimes to be desired.

Comparatively very little in the way of the introduction of medicines in general medicine by this method has been done.

The medicines have been introduced by two systems; by electrodes of about the usual size modified to maintain the dissolved medicine in contact with the skin, and through the agency of electric baths.

By Electrodes.—The list is long of those who have introduced medicines or attempted to do so by this means. It would include the names of Pivati, Verati, Bianchi, Brigoli, Palma, Winkler, and many others of that time. Of Priestley Mangin, Guardana, Sigaud de la Fond, de Haen, Becquerel,

Davy, Fabr -Palaprat, Hassenstein. Of Beer, Clemens, von Bruns, Munk, Adamkiewrtz, Richardson, Wagner; of Erb, Larat, Bardet, and so on through a large bibliography to our own times.

To illustrate the present status of the subject in general medicine, and aside from experimental research, but few names can be or need be mentioned.

In April, 1889, Dr. F. Peterson's article on "Electric Cataphoresis as a Therapeutic Measure" awakened an entirely new interest in the subject on this side of the Atlantic.

In this same year, Mr. Newman Lawrence and Dr. A. Harris, both of London, separately and conjointly described the cataphoric method of medication, inventing if I am not mistaken the term "cataphoric medication" to describe it. Their paper was read before the Society of Arts.

In the same year also (November) Dr. Cagney, also of London, treated a variety of diseases by this method. Among other remedies he used Iodide of Potassium in cases of labyrinthine deafness, lead palsy, syphilitic gummata, etc. These English publications revived the interest in the subject on the other side of the water.

In later years some excellent and elaborate papers upon the same subject have been published in France though I cannot at this moment lay my hand upon the references. I recall at least the name of M. Danion in this connection.

At the International Congress held in Berlin, in August, 1890, a paper was read from Mr. Edison upon the employment of cataphoresis. After careful experimental work with solutions and porous septa the process was applied to two cases of gout.

The patient immersed his hands in jars of water. The one, the positive pole jar, containing a 5 per cent. solution of lithium chloride; the other, the negative jar, containing a solution of common salt. In the first case 5 ma. of current was used and lithium was detected in the urine.

A second case received 20 ma. On the whole the experiments were conclusive.

The writer published in April, 1891,³ an account of a new method of introducing medicines into local parts, like rheumatic joints and employed the lithium salts (carbonate chloride and bromide) placed in solution upon compounds suitably applied.

The method was termed anæmic cataphoresis, and on account of its practical relations should be mentioned here. As ordinarily introduced the drug quickly finds its way into the blood stream and its local effects are diminished or lost. In anæmic cataphoresis the blood stream is cut off by an Esmarch bandage or rubber rings and the drug acts directly continuously in *loco dolenti*.

Beginning at that time the treatment of rheumatism and gout by this method, the writer has continued it ever since with great advantage, especially in chronic cases. The solution of lithium salt is applied to large sponges bound upon each side of the joint, generally bloodless by an Esmarch bandage, and owing to the complex nature of cataphoric action the dissolved medicine is applied to both electrodes. The current strength bearable with electrodes four inches square was from 15 to 20 milliampères, duration of treatment 20 minutes.

In September, 1891, Dr. Imbert de la Touche, of Paris, read an extended paper upon the treatment of gout and rheumatism by cataphoric medication. The remedies in solution were applied by aid of a large sponge or absorbent cotton, and made to constitute a positive pole. Cases were carefully reported and the results most excellent.

(To be continued.)

³ Note on a new method of cataphoresis. N. Y. Jour. April 25, 1891.

THE
Journal of the American Medical Association
PUBLISHED WEEKLY.

SUBSCRIPTION PRICE, INCLUDING POSTAGE:
PER ANNUM, IN ADVANCE \$5.00
SINGLE COPIES 10 CENTS.

Subscriptions may begin at any time and be sent to

THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION,
NO. 68 WABASH AVE., CHICAGO, ILLINOIS.

All members of the Association should send their Annual Dues to the Treasurer, RICHARD J. DUNGLISON, M.D., Lock Box 1274, Philadelphia, Pa.

MEMBERSHIP IN THE AMERICAN MEDICAL ASSOCIATION.

This is obtainable, at any time, by a member of any State or local Medical Society which is entitled to send delegates to the Association. All that is necessary is for the applicant to write to the Treasurer of the Association, Dr. Richard J. Duglison, Lock Box 1274, Philadelphia, Pa., sending him a certificate or statement that he is in good standing in his own Society, signed by the President and Secretary of said Society, with five dollars for annual dues and subscription for THE JOURNAL. Attendance as a delegate at an annual meeting of the Association is not necessary to obtain membership. On receipt of the above amount the weekly JOURNAL of the Association will be forwarded regularly.

SATURDAY, FEBRUARY 18, 1893.

THE NECESSITY FOR TRAINED AND EDUCATED
HEALTH OFFICIALS.

There has probably been no time in the history of this country when trained, competent and efficient health-officers were needed so much as they are now. The average health-officer is appointed without any special training or qualification for the place; his tenure of office is so slight that very few feel warranted in qualifying themselves for such duties and in no other direction is there any special incentive to full preparation for the discharge of the responsibilities that devolve upon the holder of such office. Much has recently been said with regard to the manner in which cholera was managed in England during the last autumn, but nothing was said in regard to the special knowledge required of medical officers of health in that country, before they receive such appointments. No one is eligible to such appointment in Great Britain without special training and his qualification having been established by examination; his position is then assured and he is not subject to removal with change of administration. It ought to be axiomatic that no health-officer, no health-commissioners, no executive officer of a board of health, should anywhere be appointed, until after thorough examination, or training in a subordinate capacity, and until he had evinced special aptitude for and interest in that line of work. A great misfortune in this country is that whenever a change of administration is brought about, it is considered necessary to change officers of health and to appoint a new man without any reference to his special capability. Instances frequently occur, involving great responsi-

bility, where the appointee is wholly incompetent, and is dependent upon the subordinates in his office for information and advice; in short, is compelled to learn the duties incumbent upon him at the expense of the life and treasure of the public. Until a change is made in the mode of selection of these officers, and the tenure by which they hold their appointments is more stable, we cannot expect in this country efficient sanitary administration.

In all civilized countries, except the United States, there are some special qualifications required for this office, and just in proportion as they are exacted, in the same proportion is the community protected from preventable diseases; from unnecessary panics with the suffering incident thereto, and from the economic loss caused thereby. Unfortunately it is generally supposed that all medical men are sanitarians; this is not the case, as their education, training and work have not generally been in that direction. It is unfortunate that in the absence of epidemics or pestilence, too little attention is paid to the protection of the public health, and as a necessary consequence, to the selection of those whose duties require them to guard the public health. Laws should be passed in all the States defining the qualifications necessary for eligibility for appointment of health officers. This is in the direction of a civil service reform much needed.

Bills are now pending in a number of State Legislatures having for their purpose the enactment of efficient laws for the regulation of the practice of medicine by means of State examining boards. Wherever such boards have existed they have been of value not only to the State in affording protection to the people from charlatans and unqualified practitioners, but such boards have exercised a most valuable influence in elevating the educational standard of the medical profession.

We regret that in some instances, notably in the State of Illinois, bills have been introduced in the Legislature, which, if enacted into laws will practically annul or abrogate the efficiency of the present medical practice act.

The Chicago Medical Society and other similar organizations will do well to give this subject their practical attention.

PAPERS.—Those members of the American Medical Association who expect to read papers before the Sections should, as soon as possible, send the subject title to the Chairman or Secretary of the Section. See names and addresses on the title page of THE JOURNAL.

CRIPPLED CHILDREN.

A mass meeting was recently held in the Central Music Hall of this city for the avowed purpose of establishing a Home for crippled children. Many prominent clergymen and sagacious business men lent their presence or their names to aid the enterprise quite thoughtless, it would seem that it would be quite as reasonable to found a home for persons suffering from typhoid fever or disabled by fractured bones. The conclusion which these thoughts leads to is obvious. The prominent clergymen, the sagacious men of business, the charitable ladies, and the medical men who appear at the end of the procession are wholly unaware that it is possible to cure crippled children, rendering them self-supporting and useful members of society; that it is a hospital and not a home to which such patients should be sent, and that it is the trained surgeon and not the gentle physician upon whom the responsibility of their care and cure would fall.

In this number of THE JOURNAL, and the succeeding, we publish a paper upon hip disease, to which it would be well for those interested in a home for crippled children to read with some attention.

It is written by two gentlemen who have had unlimited opportunities for observation. There it will be learned that only about eight per cent. of all cases die; and of those that live all are curable without other deformity than a slight shortening of the limb or stiffness at the joint; that very many have normal length of the limb and normal motion at the joint; and that all have sound, strong and useful limbs.

Nearly as good results may be expected in POTT'S disease. The deformity of POTT'S disease may be prevented if diagnosis is made sufficiently early, *i.e.*, before the deformity has occurred; that in other cases, where the deformity has occurred, it can be reduced if treatment be commenced before consolidation has taken place and carried persistently forward; and that in the old and most inveterate cases all increase of deformity can be prevented, the duration of the disease shortened, and an improved attitude gained.

It is, then not a home with free food and clothing that the crippled children demand; it is a hospital for the correction of their deformities and the care of their diseases.

 THE CAUSES AND TREATMENT OF PREMATURE BALDNESS.

Under the above heading the *Medical News* discusses an article from the pen of SEEGER (*Wiener Klinik*, December, 1892). The fact that baldness is more common in men than in women at once suggests to the writer that the difference is to be found

in the care and covering of the hair in the two sexes. The same observations were made more than twenty-five years ago, and yet the number of bald-headed dermatologists to be seen in medical gatherings is steadily increasing. That baldness is much greater among men is an unquestioned proposition, and that it should be at once referred to differences in dress and manner of wearing the hair is most natural, *post hoc ergo propter hoc*. We are reminded in this connection of a celebrated gynecologist who observed in one of his clinical lectures that women with straight pubic hair were often sterile, when one of his students naively inquired if curling the pubic hair was not an indicated remedy in sterility?

One writer further finds that men wear heavy, rigid hats, that constrict the forehead, and discourage perspiration. The moisture and heat stimulate an abundant but unhealthy growth of hair. Among other causes it is noted that men wear their hair short. We are told that short hairs grow faster but do not possess so much vitality as long hairs, nor do they afford so much protection to the scalp. It is apparent that writers on this subject have fallen into the habit of mistaking mere association for cause and effect. Coincident phenomena are not necessarily causal in their connection. There is nothing in the above argument that would not apply to parietic dementia, it too is a disease more common in men than women, and the same want of ventilation and constricting hat bands, are coincident with the development of this disorder. Again, if these causes are so prolific in producing baldness, we must assume that the nutrition of the hair of the head is unlike that on any other portions of the body. Falling of the pudendal hairs is a very rare phenomenon, and yet they are peculiarly exposed to heat, moisture, and the accumulation of decomposing secretions. Again, the success of one of the older hernia operations was jeopardized by the growth of hair, and the accumulation of secretions in the invaginated portions of skin. Hairs grow abundantly in the nostrils, and persist there notwithstanding the heat and moisture. If frequent cutting of the hair is a cause of baldness, why is it that the beard survives the process of shaving, and that men who shave regularly have quite as heavy beards as those who allow them to grow?

The foregoing considerations are quite sufficient to show that we have not stated all, or indeed most, of the causes of baldness, especially when we consider that it is peculiarly a racial disease, some divisions of the human family being exempt from the disorder, notwithstanding the most unsanitary head covering. The fact is that premature baldness seems to affect males of the highest developed Aryan races, just as hysteria affects its females. Both are conditions due to heredity and racial peculiarities. Per-

haps we are losing our hair for the same reason that we are said to be losing our teeth; because they are no longer needed. The condition marks then but a step in the upward adjustment of the human form in advancing civilization. The early loss of the hair and teeth may yet be recognized as a sign of culture and refinement; and as was remarked some years ago in this JOURNAL, the escutcheon of the future will have for a ground a hairless scalp with a decayed tooth rampant.

THE MEDICAL SOCIETY OF THE STATE OF NEW YORK.

The President, DR. L. S. PILCHER, in his address delivered at the annual meeting in Albany, February 7, referred to the American Medical Association as follows:

The American Medical Association and State Representation.—I have the pleasure of presenting to this Society at this time a communication from Dr. William B. Atkinson, Permanent Secretary of the American Medical Association, transmitting a resolution adopted by that Association at its session held in Detroit, June, 1892, appointing a committee of five, instructed to meet a like committee from the State Medical Society of New York, and the State Medical Association of New York, for the purpose of adjusting all questions of eligibility of members of the State Medical Society of New York to membership in that Association, and notifying this Society that the committee had been appointed, consisting of Drs. N. S. Davis, of Illinois; John H. Rauch, of Illinois; William T. Briggs, of Tennessee; Dudley S. Reynolds, of Kentucky; and Willis P. King, of Missouri.

The evident intention of this resolution was to request that this Society appoint a similar committee to confer with the committee named, although the resolution as transmitted does not say so. It is difficult to see what purpose such a conference as is proposed could serve. The American Medical Association is very properly its own judge of what shall be the qualifications required of its members. It is a voluntary Association, responsible to no one, and may change its standard for admission at its will. At its session at St. Paul in June, 1882, it voted that the Medical Society of the State of New York was not entitled to representation in it, because the Code of Ethics adopted by that Society essentially differed from, and was in conflict with, the Code of Ethics of the American Medical Association. The status of affairs to-day differs in no respect from what prevailed in 1882, save that a year or two later the American Medical Association adopted an explanatory declaration which practically interpreted its own Code to mean the same as the Code already adopted by the Medical Society of the State of New York. It did not, however, rescind the vote of dis-fellowship adopted in 1862, but, on the contrary, at the recent meeting in Detroit, renewed it and extended it, to embrace not only this Society as an organization, but also all persons who affiliated with it. At this same meeting, also, it appointed a committee to report upon the revision of its own Code of Ethics. There is therefore no certainty as to

what the future Code of Ethics of the American Medical Association will be. It would be highly improper for the Medical Society of the State of New York to assume in any way to dictate to, or even suggest to, any organization not subordinate to it, what ethical standard, if any, such an organization should adopt. It must content itself with regulating its own standards, as it now does, suggesting in turn that it is equally indelicate for organizations which have no supervising relation to it to extend advice as to its internal affairs. Practically the relations of the Medical Society of the State of New York to the American Medical Association are the same as those which it sustains to the British Medical Association, the Canadian and Ontario Medical Associations, and to the Medical Societies of the various adjacent States to which it is in the habit of sending delegates annually, viz.: the relations of courtesy and comity. All these medical organizations named continue to receive with due honor and respect the delegates appointed by this Society, and doubtless whenever the American Medical Association shall signify its desire that this Society shall again send delegates to its meetings, such delegates will be sent. The Medical Society of the State of New York, however, must meanwhile be content to do its own work in its own way, awaiting the pleasure of the Association in question. Nevertheless, since a failure by this Society to appoint such a committee as is contemplated in the communication from the American Medical Association, would doubtless be construed by many, who are still ignorant of the real relations which exist between the two organizations, as displaying a factious and quarrelsome spirit, and as a matter of simple professional comity, I would advise that a committee of five be appointed by this Society to meet the committee of the American Medical Association as requested.

The Present Code of Ethics.—In the course of the discussions which have been provoked by the action of the American Medical Association just alluded to, it has come to the knowledge of your President that many of the physicians of this State are convinced that in view of the present state of general enlightenment prevailing throughout the State of New York, and the safeguards which by legal enactments are thrown about the entrance into the medical profession, it would comport more with the dignity of the medical profession, and would enhance the respect in which it is held by the general public if all specific rules of ethical conduct were elided from the by-laws of the State Medical Society, and if the regulation of such matters were hereafter left to the judgment of individual practitioners influenced by the well-known consensus of professional opinion and local custom in the places where the work of each is being carried on. Among a large number of representative physicians from all portions of the State with whom I have conferred on this point, I have found a singular unanimity of feeling on this subject. The only hesitancy which any have expressed has been as to whether it would be wise, since practically this is already the present status of the profession in this State, to make any movement looking to a formal revision of a Code from our by-laws, lest it should revive acrimonious discussion, and reawaken strife that would be detrimental to the higher interests of the profession in this State. By far the greater weight of the opinions which I have

been able to elicit has, however, been that no such result would follow; but that, on the contrary, such action would tend still more to heal old differences and bring together all the elements of medical profession in this State. Such is also my own mature opinion, and further, it has seemed to me that at present, where there is a general revival of interest in the matter of professional ethics, as is evidenced by the discussions which are now going on in the medical journals of the country, and when this question of Code is again unavoidably brought to the attention of this Society, that it is a specially favorable moment for taking this final step. At the present time the only allusion in the by-laws of this Society to a system of Medical Ethics is the very brief § 8 of Chapter VI., which merely says:

"The system of medical ethics adopted by this Society, February 7, 1882, shall be considered authoritative to govern the medical profession in the State of New York."

I would recommend that this section be dropped *in toto*. The effect of such action would be to leave this State Society without any formulated Code of Ethics, and to relegate the Code of 1862, together with that of 1847 and 1823, to the domain of history, though ever remaining of interest and value to the student of the development of ethical standards in the medical profession of this State.

Report of Committee on the President's Address.—DR. VANDER VEER read the report. It recommended the following:

That the Society reserves to itself the right to punish its members for any unprofessional conduct.

The determination of what shall be considered unprofessional conduct shall rest with the Society. If at any time charges are preferred against a member of the Society, these charges are referred to a committee which already exists for a similar purpose. This rule shall take the place of paragraph eight of chapter six of the by-laws, as well as the rules adopted by this Society in February, 1882.

Resolved, That the Society deems it unwise, at this time, to appoint any committee of conference with the American Medical Association upon the subject of medical ethics, as requested by that distinguished body; but the Society ventures to express the hope that the American Medical Association, at no distant day, will take such actions as will remove the merely technical obstacle to the most cordial coöperation between the two societies.

The *New York Medical Journal* refers to this action as follows:

At the meeting of the Medical Society of the State of New York held this week the general endorsement of the recommendations contained in the president's inaugural address was followed by specific action by which the society's Code of Ethics was extinguished. This, of course, freed the Society from any obligation to delegate a committee of conference to meet the American Medical Association's special committee appointed to consider ways and means of reëstablishing relations between the two organizations. The situation seems, therefore, to be somewhat improved; the State Society has no Code of Ethics, and consequently is less at variance with the American Medical Association than when it had a Code that positively clashed with the Association's code. It remains to be seen, however, whether other relations

between the two bodies than those of "comity" will again come into existence.

In this action of the New York State Medical Society there seems to be a rolling back and away of the clouds and mists that have obscured the relations of that organization with the American Medical Association.

We look hopefully to the committee appointed by the American Medical Association at its last meeting, to report for the approval of and adoption by that organization of a code of ethics, constitution and by-laws, that will be acceptable and provide an organic law that will make possible a unification and membership in one body of every practitioner of rational medicine in this country.

AN ARMY MEDICAL BOARD will be in session in New York City, N. Y., during April, 1893, for the examination of candidates for appointment to the Medical Corps of the United States Army, to fill existing vacancies.

Persons desiring to present themselves for examination by the Board will make application to the Secretary of War, before March 15, 1893, for the necessary invitation, stating the date and place of birth, the place and State of permanent residence, the fact of American citizenship, the name of the medical college from whence they were graduated, and a record of service in hospital, if any, from the authorities thereof. The application should be accompanied by certificates based on personal knowledge, from at least two physicians of repute, as to professional standing, character, and moral habits. The candidate must be between 21 and 28 years of age, and a graduate from a Regular Medical College, as evidence of which, his Diploma must be submitted to the Board.

Further information regarding the examinations may be obtained by addressing the Surgeon General U. S. Army, Washington, D. C.

C. SUTHERLAND,
Surgeon General U. S. Army.

BOOK REVIEWS.

INTERNATIONAL CLINICS: A QUARTERLY OF CLINICAL LECTURES ON MEDICINE, NEUROLOGY, PEDIATRICS, SURGERY, GENITO-URINARY SURGERY, GYNECOLOGY, OPHTHALMOLOGY, LARYNGOLOGY, OTOTOLOGY, AND DERMATOLOGY. By Professors and Lecturers in the leading Medical Colleges of the United States, Great Britain, and Canada: Edited by JOHN M. KEATING, R. D., Colorado Springs, Col., Fellow of the College of Physicians, Philadelphia, etc., JUDSON DALAND, M. D., Philadelphia, Instructor in Clinical Medicine, and Lecturer on Physical Diagnosis and Symptomatology in the University of Pennsylvania, etc., J. MITCHEL BRUN, M. D., F. R. C. P., London, England, Physician and Lecturer on Therapeutics at the Charing Cross Hospital, D. W. FIXLAY, M. D., F. R. C. P., Aberdeen, Scotland, Professor of Practice of Medicine in the University of Aberdeen, etc. Vol. III, Second Series, 1892. Philadelphia. J. B. Lippincott & Co.

There are 53 contributors to this volume on 77 subjects, filling 393 pages. The 24 plates are mostly well made, and there are 40 figures. The sections are apportioned as follows: medicine, 118 pages, surgery, 66, neurology, 60, gynecology and obstetrics, 58, ophthalmology and otology, each 19, pediatrics, 17, dermatology 15, laryngology and rhinology, 9, genito-urinary surgery 7.

The initiatory lecture is by Dr. Wm. Pepper, on eugenes-

tion of the kidneys, etc. He presented one case that illustrated the beneficial effects of injections of morphine in small doses to quiet the nervous system, secure rest, and increase the nerve power, which in turn acts favorably on the kidneys and induces a more active secretion. He does not ignore the fact that in organic disease of the kidneys, with greatly reduced secretion of urine, opium is a dangerous drug. Another case showed remarkable improvement following the exhibition of sulphate of sparteine.

Peritonitis and its treatment, by Dr. A. W. Mayo Robson, of England, is the subject of a lecture which places him on the same plane with many American surgeons in the treatment of abdominal diseases. On page 38 he says: "If relief does not occur from general treatment, advise abdominal section, when you will probably discover the cause, which may be remediable."

Dr. N. S. Davis, Jr., gives an excellent description of uræmia and its management. He believes that pilocarpine is contraindicated when the heart's action is weak, and he makes incisions instead of needle punctures about the ankles for anasarca. He recommends croton oil in minim doses; and morphine as well as chloroform and ether for the convulsions. The urine was much augmented by lactose.

Dr. Robert F. Wier reports a successful case of bone grafting. He operated on a tibia shortened by necrosis, fractured the fibula, and wired together the two corresponding ends of the bones above and below the seat of fracture. Union occurred and resulted in a useful, although shortened, limb.

Dr. Flemming Carrow describes his technique for cataract extraction. His patient was 90 years old. He was confined to bed 18 or 20 hours and then allowed to be in a moderately lighted room. The bandages were changed once in 24 hours, and the eye was opened on the fifth day.

Dr. David Webster has abandoned the actual cautery in large corneal ulcers and has returned to the old operation of paracentesis.

Dr. Thos. R. Pooley believes that cocaine used repeatedly endangers the integrity of the cornea.

Dr. J. Orme Green has rendered good service by directing attention to the frequent occurrence of inflammation of the middle ear in the acute infectious diseases. This common, but over-looked and neglected complication will be more readily recognized and appreciated if his lecture is widely read.

A striking example of the ungraceful and detrimental situations into which men fall when they attempt to teach outside of their customary lines of study, may be found on page 384. Dr. Beverly Robinson is lecturing on otology. In treating of otorrhœa he warns his hearers against doing anything to stop a purulent discharge further than to syringe the ear and to mop it out with cotton on a probe. He says: "If the discharge be very abundant, do not try to stop it too soon." As if one should say: "If your house is on fire, do not try to put it out too soon." If the discharge becomes fetid he allows some mild lotion, like a two grain solution of zinc sulphate. He thinks the discharge will be likely to diminish after a week or two, with little or no treatment. He mentions one class of cases in which he deems it important to stop the discharge, namely, tubercular. He objects to the use of such fine (ideal) powder as boric acid, but concludes that "scraping out the ear" might do good, and before he gets through with that ear he coolly knocks the most cherished props from under the favorite rules of practice of our most successful and accomplished otologists.

This is another illustration of the fact that one man cannot excel in all the branches of medicine, however clever he may be.

With the very large number of contributors to this work the subscriber may feel certain of acquiring in the series a veritable thesaurus, upon which he can draw for help in his difficult cases, with confidence. Many of the authors are well recognized authorities on both sides of the globe. A few are not known by their writings, but this opportunity may serve to induce brilliant, but hitherto hidden, lights to shine, and to illuminate many of the dark places that come in every practitioner's experience. It can be fairly said of these collections that their faults are few, and they are obscured by the great array of scientific facts that are marshaled in a masterly manner.

DISEASES OF THE RECTUM. By JOSEPH M. MATTHEWS, M.D., Professor of the Principles and Practice of Surgery and Diseases of the Rectum in the Kentucky School of Medicine. New York. Dr. Appleton & Co. (Illustrated by six chromo-lithographs.)

It is with pleasure that we announce the appearance of this classical work. As was to be expected from the pioneer in rectal surgery in America, Dr. Matthews has given us the best book extant on his special branch of surgery. The author has certainly shown that his pen is as gifted as his tongue. The preëminent qualifications of the work under consideration is its practicability and originality of method.

Dr. Matthews does not appear to have much faith in the efficacy and safety of the treatment of hemorrhoids by carbolic acid. It is a question in the mind of the writer, whether it is not the abuse, rather than the use of this method that is open to criticism. The operating surgeon is likely to despise all but operative methods. There are several specialists who operate only exceptionally, yet are doing most excellent work by local applications of astringent antiseptics and anodynes in cases that most surgeons would operate upon without delay. That itinerant quacks may misuse valuable methods is true, but this does not prove that all of their methods would be useless or dangerous in proper hands.

Taken all in all Matthews' work is one which no surgeon can afford to be without, and a large circulation is to be expected.

HAND-BOOK OF EMERGENCIES AND COMMON AILMENTS. Explaining the latest approved Treatment of Injuries, sudden and painful Attacks, Poisoning, and many common Diseases. By E. F. BRADFORD, A.B., M.D., (Harvard), Member of the American Medical Association, etc. Assisted by LOUIS LEWIS, M.D., Member of the Royal College of Surgeons, Eng.; one of the Editors of the *Medical Times and Register*, Philadelphia. Together with other Writers on special Subjects. Sold by Subscription only. Illustrated. Boston: B. B. Russell.

Here is a book that physicians can conscientiously advise their patients to read. It is full of common sense, and scientific facts made comprehensible to the reader of average intelligence. The uses of domestic remedies and of many new ones are taught. Proper precautions are given concerning the employment of these, and of illuminating oils, gas, etc. There are directions for resuscitating persons who are apparently drowned, asphyxiated, poisoned, etc. Tables of poisons and their antidotes, and the proper treatment, are given a conspicuous place. It may be thought that the people should not be taught to administer such remedies as laudanum and chloroform, but if they will keep them in the house and use them in the absence of medical advice, it is no doubt best that they should have such a guide as this book provides. If they do not deviate from the directions laid down, no harm will come.

Fortunately there is little to criticise. On page 87, in the article on insect bites, it is advised to bathe the face, neck, hair and all exposed parts "with a weak solution (50 per

cent. of carbolic acid" for mosquito bites. This is not a weak solution. It is strong enough to corrode tissues. Probably the author meant a 5 grain, instead of a 25 grain, solution.

The aim of the book is, not to make every person his own physician, but to teach everyone how to take care of himself when a physician is not really needed, and what to do while awaiting a physician's arrival, when it becomes necessary to summon one. Whenever a doubt exists as to the nature or cause of suffering, the reader is advised to consult a doctor. A good idea of the general tenor of the work is given on page 221. After giving a description of strangulated hernia, the paragraph on treatment begins thus: "What should be done? Send for a surgeon at once." Then follows a sensible course to be pursued until the surgeon arrives.

This little book will render important assistance to physicians, directly by reference to its pages, and indirectly by the more intelligent actions of patients and their friends. It contains a great deal of practical information not to be found in medical text-books. There ought to be at least one member of every family who should become familiar with its contents—the mother.

TWENTY-THIRD ANNUAL REPORT OF THE STATE BOARD OF HEALTH OF MASSACHUSETTS. Boston: 1892.

This is one of the most valuable contributions to the science of public hygiene. The examination of water and the study of typhoid are among the most valuable contributions to this subject made during the present year.

This book contains two valuable biological papers, one on the differentiation of the typhoid from other bacilli, by Geo. W. Fuller, the other on urogena, by Grey N. Calkins.

MISCELLANY.

AMERICAN ELECTRO-THERAPEUTIC ASSOCIATION—At the second annual meeting of the American Electro-Therapeutic Association, the following officers were elected for the ensuing year:

President, Dr. Augustin H. Goelet, 531 West 57th Street, N. Y.; First Vice-President, Dr. Wm. F. Hutchinson, Providence, R. I.; Second Vice-President, Dr. W. J. Herdman, Ann Arbor, Mich.; Secretary, Dr. Margaret A. Cleaves, 68 Madison Avenue, New York; Treasurer, R. J. Nunn, 119 York Street, Savannah, Ga.

The third annual meeting will be held in Chicago on Sept. 12, 13 and 14, 1893. A cordial invitation is extended to all members of the profession interested in electro-therapeutics. Arrangements for special rates on railways and at hotels are in progress.

The Committee of Arrangements will be obliged if those who intend being present at the meeting will send their names, the class and amount of accommodation required, titles of papers to be presented, applications for membership, etc., at as early a date as possible. Accommodation should be secured early on account of the crowded condition of the hotels, because of the World's Fair. All communications should be addressed to the Secretary.

The Committee will be glad to furnish any information in regard to the meeting upon application.

S. C. STANTON, *Secretary*.

FRANKLIN H. MARTIN, *Chairman*.

The Section on Laryngology and Rhinology of the Pan-American Medical Congress is now thoroughly organized with Secretaries in all the countries of South America as in the United States and Canada.

The President, Dr. E. Fletcher Ingalls, of Chicago, is making a thorough canvass to secure a large number of good papers for the Section, and aided as he will be by the able Secretaries, Drs. Murray and y Alonzo, and the corps of honorary Presidents he feels assured of the success of this department of the Congress. The honorary Presidents are:

Dr. Harrison Allen, Philadelphia; Dr. Frank H. Bosworth, New York; Dr. S. Solis Cohen, Philadelphia; Dr. D. Bryson Delavan, New York; Dr. J. F. Dixon, Portland, Oregon; Dr. Stephen Dodge, Halifax, Nova Scotia; Dr. W. C. Glasgow, St. Louis; Dr. Frederick J. Knight, Boston; Dr. Geo. M. Loefferts, New York; Dr. Alvaro Ledan, Villa Clara, Cuba; Dr. John N. MacKenzie, Baltimore; Dr. David Matto, Lima, Peru; Dr. P. Emelio Petit, Santiago, Chili; Dr. John O. Roe, Rochester, N. Y.; Dr. Federico Semeleder, City of Mexico, Mexico; Dr. Chas. E. Sajous, Paris, France.

The Secretaries for foreign countries are:

Dr. Ovejero, [Piedad 22] Buenos Ayres, Argentine Republic; Dr. Guedes De Mello, Rio de Janeiro, U. S. of Brazil; Dr. G. W. Major, Montreal, Canada. Dr. Felix Campuzano, [Virtudes 33], Havana, Cuba; Dr. Luis Fonnegra, [Calle 10, Número 263], Bogota, Republic of Columbia; Dr. Fabricio Uribe, Guatemala City, Guatemala; Dr. Henri Goulden McGrew, Honolulu, Hawaii; Dr. Angel Gavino, [Cocheros 15], City of Mexico, Mexico; Dr. J. Midence, Leon, Nicaragua; Dr. Eugenio Cassanello, [San José 119], Montevideo, Uruguay; Dr. Napoleón F. Cordero, Merida, Venezuela.

All physicians interested in this Section are requested to correspond with the secretaries for the United States. Dr. J. Maron y Alonso, (Spanish speaking,) Las Vegas, N. M.; Dr. T. Morris Murray, (English speaking,) Washington, D. C.

RAILWAY SURGEONS OF OHIO.—The Railway Surgeons of Ohio are called to meet in the amphitheater of the Ohio Medical University at Columbus, Ohio, on March 17, at 9 o'clock A.M., standard time, for the purpose of organizing an Ohio State Association of Railway Surgeons. It is hoped that all interested will make an effort to be present and take part. Those who expect to be present will please drop a line to the Secretary at Sandusky, that an estimate may be made and proper entertainment provided.

CHARLES H. MERZ, *Secretary*. S. S. THORNE, *President*.

THERE are thirty-three ophthalmologists located in Denver, and other specialists in proportionate numbers. Most of them attracted to that city by the salubrity of climate and their own physical ailments. Under such conditions there is not likely to be much of a rush of business for every one.

OFFICIAL LIST OF CHANGES in the Stations and Duties of Officers Serving in the Medical Department, U. S. Army, from February 4, 1893, to February 10, 1893.

Capt. Paul Shillock, Asst. Surgeon U. S. A., promoted as such, to date from January 31, 1893, in accordance with the Act of June 23, 1874.

Capt. Charles B. Ewing, Asst. Surgeon U. S. A., the order assigning him to duty as post surgeon, Ft. McHenry, Md., is suspended until June 1, 1893, when he will comply with the order. By direction of the Secretary of War.

Capt. Junius L. Powell, Asst. Surgeon U. S. A., leave of absence granted is hereby extended one month.

OFFICIAL LIST OF CHANGES of Stations and Duties of Medical Officers of the U. S. Marine-Hospital Service, for the four weeks ended February 4, 1893.

Surgeon F. W. Mead, to proceed to New London and New Haven, Conn., as Inspector, February 4, 1893.

Surgeon H. R. Carter, granted leave of absence for thirty days. February 3, 1893.

P. A. Surgeon J. B. Stoner, to assume command of Service at Portland, Ore. January 17, 1893.

Asst. Surgeon G. B. Young, when relieved, to proceed to Pittsburgh, Pa., for duty. January 17, 1893.

Asst. Surgeon L. E. Cofer, placed on waiting orders, January 23, 1893.

Asst. Surgeon J. M. Eager, to proceed to Cape Charles Quarantine for temporary duty, February 3, 1893.

Asst. Surgeon W. J. S. Stewart, to proceed to Norfolk, Va., for temporary duty, February 1, 1893.

DEATH.

P. A. Surgeon Spencer C. Devan, died February 1, 1893, at Philadelphia, Pa.

ORIGINAL ARTICLES.

RECENT JUDICIAL EVOLUTION AS TO CRIMINAL RESPONSIBILITY OF INEBRIATES.

Read in the Section of Neurology and Medical Jurisprudence, at the Forty-third Annual Meeting of the American Medical Association, held at Detroit, Mich., June, 1892.

BY CLARK BELL, ESQ.,

PRESIDENT AMERICAN INTERNATIONAL CONGRESS OF MEDICAL JURISPRUDENCE.

By the common law of England it was conceded the words "*non compos*" meant a total deprivation of reason. Lord Coke divided it into four parts or as he called them "manners."

1. The idiot or fool. 2. He who of good and sound memory at birth lost it by visitation of God. 3. Lunatics who have lucid intervals and sometimes of good sound memory and sometimes *non compos mentis*. 4. By his own act as a drunkard. So that drunkenness at and by common law, under certain circumstances, was a form or species of insanity. By the same common law it was held: 1. That the drunkard was responsible for all his acts criminally, even if the state of drunkenness was such as to make him insensible to his surroundings and unconscious of his acts. 2. That drunkenness instead of being any defense to a charge of crime committed while in a state of intoxication, was not only no defense but that it aggravated the act.

These doctrines were upheld by the English courts in *Damarees* case 15, St. Tr. 592; *Frost* case, 22 St. Tr. 472; *Rex v. Carroll* 7 c and p. 115; and these doctrines have been held likewise in nearly all the American States.

In Alabama, *State v. Bullock*, 13 Alabama 413; in California, *People v. King*, 27 California 507; in Connecticut, *State v. Johnson*, 40 Connecticut 106; in Delaware, *State v. McGonigal*, 5 Hartford 510; in Georgia *State v. Jones*, 20 Georgia 534; and in nearly every American State, similar decisions have been made.

The common law which would not uphold a deed, will, or contract, made by a drunken man in an unconscious state of intoxication, would hold the same man criminally liable for every act constituting a violation of the criminal law. To-day we are regarding those views as legal curios and relics of the past. The law should have its museums for the preservation of its antique anomalies. A silent unconscious change has been wrought in the law, not by legislation, but by the growth of ideas and the diffusion of knowledge. Insanity is now demonstrated to be a disease of the brain, of which it is itself an outward manifestation. Inebriety is also shown to be a disease of the man manifesting itself through brain indications, which demonstrate it to be a form of insanity wholly dominating the volition and beyond the power of the victim to control and it is now so

treated. The essential element of crime *intention* hardly fits into the acts of the unconscious inebriate, who while *blind* or *dead* drunk, kills an innocent victim, and the absence of motive like the absence of *intention*, are missing links in that chain, which the law exacts, in regard to all criminal action. It would be next to impossible now, to find a judge willing to charge a jury, that a crime committed by a man in a state of intoxication, in which the accused was unconscious of his act, or incapable of either reflection or memory should be placed on a par, with one fully comprehended and understood by the perpetrator.

Buswell says in speaking of the old doctrine of drunkenness being an aggravation of the offense "it is apprehended that this is the expression of an ethical rather than a legal truth." (*Buswell on Insanity*). Such considerations compel us to inquire: What is law? There are two schools of thought regarding it.

Webster, the great expounder of the American constitution is credited with saying, "Law is any principle successfully maintained in a court of Justice." This represents one school.

Richard Hooker in his ecclesiastical polity represents the other, he says of law: "There can be no less acknowledged, than that her seat is the bosom of God, her voice the harmony of the world, all things in heaven and earth do her homage, the very least as feeling her care, the greatest as not exempted from her power." The gulf intervening between these two extremes is as wide and deep as that which divided Abraham and Lazarus in the parable of our Lord.

The framers of the New York Penal Code, without the courage to hew down the error of the old doctrine, engrafted thereon a provision, that enables a jury now in that State, to pass on the *motive* and the *intention* of the unconscious and wholly insensible inebriate; so that by law now in New York since the Penal Code of that State, a conviction would in such a case be well nigh impossible.

How have the English judges met the question? In 1886, Mr. Justice Day in *Regina v. Baines* at the Lancaster assizes, charged a Lancaster jury: "That if a man was in such a state of intoxication that he did not know the nature of his act or that it was wrongful, he was insane in the eye of the law; and that it was perfectly immaterial whether the mental derangement resulting from such intoxication was permanent or temporary." In 1887, Chief Baron Pallett held that "if a person from any cause, say long watching, want of sleep, or deprivation of blood, was reduced to such a condition that a smaller quantity of stimulants would make him drunk, and that would produce such a state if he were in health; then neither law nor common sense could hold him responsible for his acts, inasmuch as they were not voluntary but produced by disease."

As long ago as 1865, in the case of *Watson* tried at Liverpool for the murder of his wife before Baron

Bramwell, the evidence showed that he was laboring under delirium tremens. After the act he grew calm and said that he knew perfectly well what he had done and that his wife was in league with men who were hidden in the walls. "Baron Bramwell, who favored hanging insane men who committed homicides when acting under an insane delusion, if of sufficient intelligence to understand the nature and quality of the act and its consequences, tried the case and charged the jury, "That there were two kinds of insanity by reason of which a prisoner was entitled to be acquitted; probably the jury would not be of opinion that the prisoner did not know the quality of his act, that it would kill and was wrong, but it was still open to them to acquit him, if they were of opinion that he was suffering from a delusion leading him to suppose that, which if true, would have justified him in the act; one more remark he would make, viz.: That drunkenness was no excuse and that a prisoner cannot by drinking qualify himself for the perpetration of crime, but if through drink his mind had become substantially impaired, a ground of acquittal would then fairly arise.

The prisoner was acquitted. Under the English law, there is no right of appeal to the convicted homicide as in the American States, and so it is difficult to find the decision of English higher courts on the questions involved in the discussion.

In the American States no person is executed except on the decision of the highest court of the State if the accused desires it and appeals; in England the appeal does not lie as a matter of right and so the opinion and dicta of the English trial judges form the real body of the law of England upon these questions.

Baron Bramwell undoubtedly regarded Watson as entitled to an acquittal, and the case shows a remarkable result in this respect; had he been insane and committed the homicide under delusions which dominated his will and controlled his action, he would have been convicted if he had sufficient intelligence to understand the nature and the quality of the act, but the drunkenness which had caused the attack which resulted in delirium tremens with a diseased condition of the brain also resulted in a delusion, which controlled his mental powers, so as to render him irresponsible at law.

In 1888, Baron Pollock held, that the law was the same where insane predisposition and not physical weakness was the proximate cause of the intoxication." The English Home Secretary, Mr. Matthews is one of the ablest men connected with the English Government.

Under the English system he has the power to commute or modify the sentence of the courts in criminal cases, and he exercises it with as much effect and more in many cases than would the reversal of the Appellate court, if the right of appeal existed.

No eye in Great Britain sees more clearly or more intelligently the action of the criminal courts than his. It is his province to correct errors and redress grievances and abuses, if such exist or occur in the criminal jurisprudence of Great Britain. He has recently named a commission composed of Mr. J. S. Wharton, Chairman, Sir Guyer Hunter, II. P. Mr. E. Leigh Pemberton, Assistant under Secretary of the Home Department; Mr. Daniel Nickolson, Super-

intendent of the Broad Moor Criminal Lunatic Asylum, and Mr. C. S. Murdock head of the Criminal department, to inquire into the best mode of treatment and punishment for habitual drunkards.

Mr. Matthews says regarding the appointment of this committee, "Great difference of opinion has arisen as to what kind and degree of punishment for offenses committed by habitual drunkards would be the most effectual, both as a deterrent and with a view to the reformation of such offenders; it appears to me that advantage would result from an inquiry being made into the subject." It may be fairly claimed so far as the British Islands are concerned that the old common law rule no longer is enforced there, and that inebriety as a disease is now not only recognized as an existing fact, but that the jurisprudence of that country is receiving such modifications as are necessary to fit it, for the advance made by scientific research.

We are doubtless near similar results in the American States.

ON CHOREA, VIEWED FROM THE STAND-POINT OF COMPARATIVE PATHOLOGY.

WITH AN ENTIRELY NOVEL THEORY AS TO THE CAUSE OF THE MUSCULAR TREMOR AND INCOÖRDINATION, AND A NEW THERAPEUTICS.

Part of a Clinical Lecture delivered February 3, 1893.

BY HORATIO C. WOOD, M.D., LL.D.,

PROFESSOR OF MATERIA MEDICA, PHARMACY AND GENERAL THERAPEUTICS, AND CLINICAL PROFESSOR OF NERVOUS DISEASES, IN THE MEDICAL DEPARTMENT OF THE UNIVERSITY OF PENNSYLVANIA, ETC.

[Stenographically reported for THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION.]

Gentlemen:—I am going to occupy your attention this morning with the discussion of a subject which is of great scientific interest, and which may prove to be a discovery of considerable practical importance. Some years ago, as you know, I gave much attention to the subject of the physiology of the choreic movements. At that time, I made a number of experiments upon the lower animals, especially upon dogs, and succeeded in demonstrating, in the dog, that these movements had their origin in the spinal cord. I found that in the choreic dog, after dividing the spinal cord in the dorsal region, the movements continued in the posterior extremities just the same as before, save that, after the division of the cord, the muscular movements in the fore-limbs and hind-limbs were no longer synchronous; that is to say, rhythm did not agree as before.

On coming to apply these observations to man, I must tell you that we have in the human subject two varieties of choreic movements: in one form, they correspond with those in the lower animals. This is the variety known as "St. Vitus' dance," which is rare in adults but common in children, and undoubtedly affects the spinal cord, as I shall presently explain. The second form is common among adults but rare in children. In it the movements are more violent and even convulsive. These have their origin in the cortex of the brain, from minor lesions in the motor areas; but there may be widespread and destructive lesions in the motor regions of the cortex. I may illustrate this by a case that I saw several weeks ago. It was that of a boy, who was found in an out-house, unconscious, pulseless, appar-

ently dying, and, indeed, at first, was thought to be dead by those who found him in this condition. He was suffering from poisoning by inhaling coal gas. He was carried into his home and resuscitated; but it was found, after regaining consciousness, that he had violent, apparently purposive movements of the arms and legs, which he could not control. The limbs were thrown about by irregular, muscular contractions, and he was kept in bed with difficulty; in other words, he had a furious attack of acute, cerebral chorea. I attributed the chorea to multiple cortical embolism, the result of the arrest of circulation during the period of suspended animation, and I said that the case would die. The patient did die a few days afterward, but the choreic movements never ceased until death. Owing to some misunderstanding, I was not at the autopsy, and no parts of the brain were saved. It was found intensely congested, but there was no careful microscopical examination of the cortical regions of the brain, such as would be required to establish my diagnosis. This is to be regretted, but cannot now be helped.

Returning now to the form of chorea first mentioned, which usually occurs among children, I have arrived at the conclusion that the cause of the choreic movements is a paralysis, or depression, of the inhibitory function of the cells of the spinal cord. You know, from your studies in physiology, that there are in the spinal centres, as elsewhere in the brain, motor cells, and others which inhibit or arrest the discharge of motor impulses. It has been denied that inhibition exists; but I think the researches of Gaskell have demonstrated that in the heart (and as I believe, everywhere in the body), there is a period of functional excitement with discharge of force and destruction of tissue, and a period of functional quiet with repair of tissue. The accelerator nerve stimulates to functional activity; the inhibitory nerve to functional rest and reparative activity.

Now, it has occurred to me that the choreic movements in the form under consideration, as they occur in the child, are due to loss of inhibition. If you will observe a choreic child attempt to pick up an object such as a piece of paper from a table, you will see that the muscular movements are exaggerated so that the hand moves through a much wider range of motion than in health, the result being that the child will be obliged to make several attempts before the object is attained. The wider range of motion in this case is evidently due to a failure to arrest the motor impulse at the proper period. There has been a failure of the inhibitory function of the spinal cord to arrest the movement at the proper time. This explains the causation of the peculiar muscular movements in this form of chorea. I believe that it is based upon a new observation in the physiology of the spinal cord; it is new, at least, as far as my reading goes.

For some time I have had this in my mind, and have been casting my thoughts around endeavoring to find out how to confirm this theory. It finally occurred to me that I had been teaching you, in my lectures on therapeutics, for many years, that quinine has the property of exciting the action of the spinal inhibitory cells. You recall Chaperon's experiments, which established the fact that in small doses quinine causes in frogs a lessening of reflex activity, which, however, is restored by section of the medulla, thus showing the independent action

of the spinal cord when relieved from the inhibition coming from above. This led to the discovery of the inhibitory centres of the medulla by Setschenow and the location of Setschenow's centre. Small doses of quinine stimulate Setschenow's centre, and lessen reflex activity; but large doses cause permanent paralysis of reflex activity. It is evident that the larger doses act upon the spinal motor cells in the same manner that the small doses affect the higher centres. There are many other facts which demonstrate the existence of spinal inhibition; but their discussion would lead us too far afield, especially since they do not bear directly upon the subject under consideration to-day.

Some years since Ringer and Murrell brought forward the theory that atropine is a paralyzer of inhibition. You remember the experiments of Fraser. He had killed some frogs with atropine, as he thought, and threw their bodies at night on the laboratory floor; but the next morning, on coming into the room, to his surprise he found all the frogs alive and in active convulsions. The only plausible explanation of this is that atropine, in the proper dose, paralyzes both spinal motion and motor inhibition, and that the effect of inhibition passes off and allows excessive motor discharge, and this produces violent muscular movements, not because of motor excitement, but because the restraining force of inhibition has been lifted off from them.

Sedgwick, of London, some time ago, objected to the theory of spinal inhibition, because of his discovery that atropine prevented the primary loss of reflex movements from being produced by quinine, which I referred to a few moments ago, as demonstrated by Chaperon. I think, however, that this fact cited by Sedgwick is really in favor of the theory, rather than in opposition to it, as he supposed. Quinine stimulates inhibition and atropine paralyzes it, therefore atropine would naturally set aside the physiological action of quinine. Does it not become apparent to you that Ringer and Murrell are correct in explaining the action of atropine? Can it be otherwise than that atropine and quinine oppose each other in their action upon the spinal cord?

In casting around for some means of testing my theory of the production of choreic movements, I first obtained some choreic dogs, to try the therapeutic experiment upon. I will first call your attention to this long roll of blackened paper upon which you observe this kymographic tracing, the register of the dog's choreic movements. Here you notice the continuous and rhythmical contractions of the muscle indicated by the needle upon the paper as it revolved upon the drum of the instrument. At this point where the movements begin to increase in their range, the animal had a hypodermic injection of atropine. These injections were repeated until two and a half grains (Gr. 0.15) had been given. Coincident with the administration of atropine the tracings show increase of amplitude, until they are increased fourfold. This increase seems to be attributable to the effect of the injections and, thus far, the results are exactly in accord with previous reasoning. The animal at this point, had an injection of six grains (grams., 4) of quinine, and immediately the movements declined and, in the course of from twenty to thirty seconds, entirely ceased. This is beautifully shown by the tracing. The amplitude of the excursions of the needle rapidly diminishes until they

cease absolutely. Now as to this action of quinine there can be no possibility of doubt. The atropine I have only experimented with once in a case of chorea; but the quinine I have used in a number of dogs and am positive that the quinine arrests the choreic movements in dogs, so that, as far as this goes, it carries out my theory.

My next line of investigation was to study the condition of the reflexes, such as the knee-jerk, in chorea. *A priori*, what would we expect to find in regard to the knee-jerk, in chorea? The motor-cells of the cord are in a state of weakness in a case of chorea; but the inhibitory cells are in a state of greater weakness. This would lead us to expect that in the first place, the reflexes would be less than normal. When, however, a voluntary movement is made, on account of the failure of inhibition, the motor impulses from neighboring cells would overflow, and reinforce the motor impulses beyond the normal amount and the reflexes would be increased. (Explanation of reinforcement, illustrated by drawing a diagram of spinal cord with motor and inhibitory cells, upon the blackboard.) In the normal condition, this overflow would be checked by the inhibitory cells, but when these are weakened experimentally, or by disease, it is not so checked and the reflexes are extraordinarily increased. I wrote to Dr. Wharton Sinkler requesting him to communicate to me his observation as to the condition of the reflexes in chorea. He replied that the phenomena are different from what might be expected, the reflexes are diminished in all cases of chorea; but that he had observed the curious fact that the knee-jerk in chorea is greatly increased by reinforcement. That is to say that, at the time the knee-jerk is tested, if some other muscular movement be performed, like extending the arms or tightly clenching the fists, the knee-jerk is greatly exaggerated. This I explain by the weakening of inhibition and the consequent overflow of motor impulse as already mentioned.

So far this is of scientific importance only. It appears to me as if, in the practical study of chorea, we have hitherto overlooked the phenomenon of inhibition. The phenomena of chorea, like those of hysteria, are not phenomena of increased excitement of motor centres; but of paralysis of inhibition. The conjunction of increased muscular and nervous discharge with evident weakness of the spinal centres is explained by the fact that the motor cells are weak; but the inhibitory cells are weaker still. Sometimes in chorea in the child, as commonly in the dog, the movements are rhythmical, and although they are constant the child does not get tired. No one in health could continue this motion for half an hour without fatigue. How can this be explained? In the anatomical rooms, you have learned to refer anomalies to a reversion to a lower type. You have seen how a stump is produced by evolution to a certain point for a certain purpose in the case of the animal, and that is altered by higher evolution in man. Now, I believe, that we may have a physiological reversion as well as an anatomical reversion, and applying this to the spinal cord, we may have a reversion of the function of the motor cells to those of the lowest type of nerve-cell in which the discharge of force is rhythmically continuous. Just as the beating of the heart never ceases during life, so it is the function of the primitive nerve-cell to unceasingly give off force. The strange phenomenon

of lack of tire in choreic movements, then may, in this way, be explained on the principle of reversion,

Applying these investigations to cases of chorea, it occurred to me to give quinine a trial. I may say, that it has been only during the last ten days that I have thought of this subject from the clinical standpoint. I have thus far had the opportunity of employing it in only one case in the human subject. It was a child with well marked chorea, brought by her mother to the Out-patient Department. She was ordered full doses of quinine, and was brought back in four days with the report that she was very much improved. I spoke to Dr. Pearson, of the Veterinary Department, and asked him to try the alkaloid in choreic dogs. He told me in the first place that he had never found anything that would do choreic dogs any good; his experience is that chorea in dogs is incurable. Here is an English setter dog suffering with chorea. One week ago he could not stand upon his feet, owing to violent choreic movements. He had quinine given freely by the mouth and within twenty-four hours, the movements decreased; he now walks about and is apparently almost well; at least, he has very little left of his chorea. So far as practical results go, it therefore looks as if the theory would stand the test of experience; but whether our present prospect is simply a mirage or not, time alone can tell.

I now bring before you two children suffering with chorea. The first one is seven years of age, and small and poorly developed for her age. The second is ten years of age and appears to be in a better nourished condition; but in the second, the chorea is more marked and of shorter duration than the first, in which, according to the mother, it has existed more or less for four years. I will put both of these patients upon the quinine treatment and will report the result at our next meeting.

ADVANCEMENT OF SURGERY.

A Paper Read before the Vigo County Medical Society, April 1890.

BY JOHN E. LINK, M.D.,
OF TERRE HAUTE, IND.

Why I should have been selected to read a paper to the Society on the "Advancement of Surgery" is incomprehensible to my mind, unless it was for the purpose of inducing me to post myself more thoroughly upon the literature of the subject. Sure it is, that I, probably of all the members, have paid less attention to the serial productions, as published in our overloaded journalism, than any other member here. And I think it is a well understood fact, that I read less of our periodical literature, as well as our secular papers, than any other member of this community. What has stood the test of ten years' popular favor becomes a part of our texts; and compared to-day with what has been introduced as novel and good, not one-tenth part bears the test of the decade. For this reason I have declined to place any of my thoughts or methods into the hands of publishers, and only a few of the things that presented themselves as original, from observation or thought, have found their way into print through the pen of others more ambitious to write. And I say to you to-night that I had far rather have come here before you, presenting a patient with oral explanation, than to attempt to write. It is generally understood that the only way for a man to bring himself into prominence

is to write, but a man's good works live after him in spite of silence. James R. Wood wrote little or nothing, yet his name stands out prominently as an original thinker and tireless worker. And so, if I criticise some of the newly accepted theories and practices, as appear in our medical journals, in surgery, adversely, I hope you will not lay the disappointment you realize in this paper at my door, but to the source—the appointing power.

Taking up the recent text-books of to-day and comparing them with those of the last fifty years, the enthusiastic student of journalistic surgery will surely be surprised, especially in the more common and frequent cases that the surgeon is called upon to treat.

From what I have said it might be inferred that I am a non-believer in progression in our science—in evolution. Such is not the case, I assure you. I believe not only in mind evolution, but in all organic-living, process-evolution—that all things that live a true and healthful life add something to the process of such existence, that for every healthful spear of grass that grows the element that produces it is made richer for the production of others of its kind, providing each has the advantage of improvement. For the advanced speed in training, the possibility of the next horse to improve is greater. Mr. Beecher, in a sermon preached in Plymouth Church, said, as one horse makes a given advanced record on the track, the whole herd comes up to it, and so another and another, attributing it to the will of the trainer. I attribute it to the cultivation of a process in nature—a cultivation of the soil of speed, as it were, and to me, as tangible as the fertilizer of the agriculturist and horticulturist.

I appear, therefore, before you to-night to present in conscientiousness sake my views of what truly constitutes the advancement of surgery, and to protest, in some instances, against what I believe to be the fallacies of, and detrimental to our science and practice. To enable us to overcome the obstacles in our way and to reach our destination, it sometimes becomes necessary, like the school boy, who as an excuse for tardiness, said “the ice was so slick that for every step he made forward he slipped two back,” and when the teacher reminded him that if such had been the case he never would have reached there, said, “Oh, but I turned around and went the other way.” So to-night I ask your indulgence in the experiment of turning back in our efforts to advancement.

The fundamental principle of the practice of surgery and medicine is anatomy and physiology. This, of course, all will admit. The sun, Emerson says, shines in the eye of the man, but into the soul of the child. As we grow older in our science I fear the beauties of the underlying and overarching principles of our profession are overlooked in too many cases, and only the poet, the enthusiast in nature, stops to see, as Emerson again puts it, the “beauty in a corpse.”

I was surprised to notice recently in one of our daily papers the faults and disadvantages of too much newspaper reading. How I should like to see the same good sense and frankness appear in some of our medical journals. I take but one—THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION. I think it is to their interest, and that they have the judgment necessary to select from among them all the best. I glance over each number, and at the end of the year

I again run over the index and select and read upon such topics as have presented themselves to my mind as of interest. I do not hold myself, or my methods, up before you as infallible or necessary to success. What one conscientiously believes to be right, one conscientiously desires others to know of and have the privilege of following.

I attended one full, and parts of two courses of lectures, devoting my whole time, outside of listening to didactic teaching, to the dissecting room, and never attended a dozen clinics in the hospital. I loved the study, though hard, that gave me the grounds for future thought and observation in after years of practice, and never, either in my military experiences in hospital or in civil practice, did I allow a winter to pass, for fifteen years, without a careful and thorough dissection of one or more human subjects. I believed then, and can now say that I am convinced, that with a clear insight into the human organism, a sure foundation for reflection and action is laid. I never now feel the least timidity as to myself, and never approach a patient without assurance and sympathy. The engineer who knows, as is often said, every bolt and screw of his engine, not only handles it well but loves it with a tenderness—else how should he have studied it so. And now the greatest regret I have is that opportunity has not made it possible for me, or more easy for me, to have continued my investigations and to have kept my memory fresh in the minutiae of anatomy. One of the first advantages, and consequent advancement in surgery as well as practice, is the facility afforded by our State, and many of the others, in obtaining material for dissection. The new beginner can have the unclaimed dead galore for filling in his leisure hours in improvement, and the gratification of his increasing taste for knowledge. When a thorough knowledge and familiarity with the dead subject is attained, whether in the practice of medicine or of surgery, the practitioner can, with good judgment, approach the sufferer confidently, without undue assurance. Therefore, I have seen fit recently, in the view of too much “antiseptic surgery,” to designate most of my practice, “physiological antiseptic surgery, *versus* germicidal antiseptic surgery.” Antisepsis has its place, I admit, but he who anchors his faith in it alone, or in most part, follows the shadow instead of the substance. What has been done by the leading minds in advancing the theory and careful methodical practice of antiseptic surgery is well: and careful, systematic work and thought is improvement. He who is unusually careful of the little things cannot well neglect the more important. All intelligence, all knowledge on any scientific and practical subject is advancement—is improvement. Anatomy is the great ocean of intelligence upon which the true physician must sail. Bacteriology is but one little harbor—with its present boom. All credit to the men who by days and nights of study, have unearthed the little fellows and made them visible to the eyes of all through the microscope, but pity to him and his patients who sees only through the lens of the microscope, neglecting the greater, seeable with the eye and tangible to the brain. That these microbes are the causes of disease, *per se*, is not proven, and that we should accept them as such, there is no more reason than that the maggot in the dead horse should be held responsible for his death, or that the wiggle-tail in the rain barrel should be

taken as cause for the turbid and generally changed condition of the water. A few years ago it was the popular belief that "bots killed the horse." I remember my first post-mortem. It was in the case of a fine three-year-old, which died after an illness of two or three days. I, then aged about fourteen, followed his remains with sharpened butcher knives to the woods over against the cliff, and made a kind of barn or trap door opening into his belly, where I found the contents of stomach promiscuously distributed. What at first looked like a spider's web, proved to be the shreddy perforated remains of a stomach. At the small remaining swallow, or œsophageal end, I found a mass, probably a pint or more of grubs—a living mass of bots. That settled it: the horse had died of bots. Then next, what will kill them? My father, the hired man, and a number of neighbors, began the experiment, first with lard and turpentine, the accepted treatment for bots. In this they lived and moved and had a being—yes, even in *pure* turpentine. Nothing, as I recollect it, seemed to be instant death, excepting pure nitric acid—that settled them. And so we, in our wisdom, in the ocular appearance of things, decided that for bots there was no cure. Now, need I say, we know all horses in perfect health have living bots in their stomachs, living happily with the horse as their friend, they even, the farrier, may tell you, his benefactors. When disease disturbs the secretion of the glands and they are starving, they take hold of the little glands, eating them for their nourishment, and after death destroy the organ—not before.

That bacteria are the cause of disease to my mind there is no proof. That they are scavengers, I take such data as above, for proof, together with my clinical experience and observation to the contrary, extending over twenty-five years, with at least a part of the time, as good opportunity to observe as any man living. My only sin of omission, punishable in ridicule by an ungenerous profession, is my living in a small city instead of London or New York. Antiseptic surgery, so-called, had its origin in Listerism, which was the carbolic spray, though now we are told that Lister does not now advise the spray, but other methods and appliances. To express myself plainly, in brief, everything that is cleansing is claimed as Listerism. That "cleanliness is next to godliness" I have never heard attributed to him, and yet we all accept it. But knowledge is godliness, and has no better exemplification to me now than in physiological surgery.

In the treatment of simple fracture and dislocation, there has been no marked advancement, excepting in appliances—each having a peculiar method of his own selection, but the text-books give us about the same—in fractural appliances Buck, Hamilton, and others more or less ancient.

Commerce has done much for us in the way of convenience. The rubber bandage, accredited to Esmarch—the rubber drainage tube—but little better than the old tent—which, had it been as universally applied, would have done much good in this line. The enthusiasm of men in advertising these things has caused a more general application of the principle and are an advantage in surgical practice.

The first thing that strikes me in the comparison of the old and new text-books of the last fifty years, is the illustrations; the artist having done a great part, commerce filling in the supply of conveniences;

the rubber coil for cold application to the head, the inhaler for chloroform and ether—largely the devices of Esmarch and a few others, whose names add to their popularity. Esmarch's bloodless operation is an innovation, and worthy of the name of advancement, though taking the place in principle, to some extent, of the old tourniquet. Surely this method of controlling the arteries high up in the extremities, the axillary in shoulder joint operations, the common iliac and abdominal aorta, are a great convenience to the profession, an improvement over the pressure by hand, entrusted to an assistant, as in my early experience.

Abdominal surgery has made wonderful strides in practice since the war; and we can only wonder at the blundering of our former negligence and oversight, the result of a kind of superstition as to sacredness in invasion, rather than any proof to the contrary. Antiseptic surgery too often gets the credit, though McDowell, in his successes, did not know or practice it. And to-day Tait is notorious for his ignoring it, though one of our most successful gynecologists.

But to traumatic surgery I wish to call your attention, more particularly to penetrating wounds of the abdomen. In relation to the thought as to the hinderance in superstition, I wish to call your attention to the unreasonableness of the argument used a few years ago—and even now for all I know—that women bore these operations—abdominal sections—better than men, maybe from the thought of the difference of the pelvic organs, in contradistinction to the higher viscera. I heard this argument advocated three years ago at the meeting of the International Congress, at Washington. I only now wish to say that it is absurd and will not bear the test of clinical experience any further than that woman's resolution often serves her a better part, in trying times, than man's.

If I were asked to name the part in surgical practice the most fully typifying the advancement of the profession, I should unhesitatingly say, the localization of certain centers of cerebrum enabling us to locate pus cavities within the cranial cavity. This is of far more scientific importance, requiring a much more exact knowledge of the part than the abdominal viscera. In the latter, the novice may venture with but a cursory knowledge of anatomy. The antiseptic fad is here barred by necessity of a knowledge of exact science, not coverable by the cloak of ignorant assurance. The ambition of notoriety here stands halt, with cap in hand, doing reverence to the truly learned.

I have held in all my work before medical associations that there is little or no special knowledge of anatomy required to do abdominal surgery; and that promptness in action, in case of injury to the abdominal viscera—requiring surgical interference—was the great desideratum; that the general practitioner should be held responsible for prompt action in opening up the cavity, in cases of penetrating wounds, stopping hæmorrhage and sewing up the perforated bowels; that neither anatomical knowledge or surgical skill is required. The farmer does as much, with impunity and little loss of life, spaying pigs. With a butcher's knife he eviscerates the slaughtered animal, seldom or never cutting a gut. As for the ligating of a fold of mesentery or omentum containing bleeding vessels, one with skill to serve in sewing

a button on his trousers is sufficient. And in the sewing up of a wound in the bowel, the interrupted suture or any other, as well as the continuous, will do the work of preventing leakage, and any material for suture answers the purpose almost as well as the catgut or silk. Nature in her endowment, with resources to meet demands in the exudation of lymph with omentum for patch will cover effectually whip cord, if necessary, and sloughing finds its way in natural process into the cavity of the bowel.

I could cite instances of the remarkable tolerance of the tissues of the peritoneal cavity in wounds, that must have paralyzed the antiseptic surgeon of a few years ago. The case, more or less familiar to us all, of the man who attempted suicide by abdominal section in the pine woods of Michigan, is notable. But time requires that I must hasten, and one instance must suffice. A case in my practice occurred a few years ago of penetrating wound and recovery, where promptness in operating, not antiseptic surgery, saved the life of a little boy of this city. The case, as reported by me, has been published in several medical journals, and can be found in the transactions of the Ninth International Medical Congress, Vol 1, page 543. The central idea involved was, as above, that the surgical section of the Association should teach to operate in all cases of penetrating wounds, immediately.

You will, I hope, pardon me for having dwelt at some length upon the surgery of the cranium and abdomen; and yet much more needs to be said of our advanced knowledge of the tolerance of these parts, especially of the brain. But our recent text-books speak of these. So I will pass to one other subject as coming under my observation since the time of my attending lectures in 1861—the successful accomplishment of the ligation of the arteria innominate. The operation had been performed unsuccessfully by Valentine Mott, and others. Mott had left it as a legacy to the profession that it could be done successfully. Daniel Brainard, of Chicago, declared his faith in the judgment of Mott, and so it proved. In about the year 1863 or 1864, Dr. Smith, of New Orleans, performed the operation with success. The patient entirely recovered and lived for some years, but subsequently dying of disease, a post-mortem examination proved the accuracy of Dr. Smith's work, and the profoundness of an opinion based upon anatomical knowledge.

The processes of repair in the breach of continuity of bone substance was for many years a conjecture, more or less, and up to the time of 1876 and 1877 the theory, pro and con, as to the possibility of reunion in simple fractures without shortening, occupied a considerable part of the time of the deliberations of the Surgical Sections at the meetings of the American Medical Association. It had been long taught that no reformation of bone could obtain in cases of loss of substance where the periosteum was destroyed. I have always held to the contrary. As early as 1861, at the time of my attending lectures under Brainard's teaching, it was held that in the removal of diseased bone there could be new bone formed if the periosteum was saved. I argued that if bone would reform where the original periosteum was conserved, it would also be possible for it to reform without it, basing my opinion upon anatomical data, and I so declared myself at a meeting of the American Medical Association in Chicago, in

1877. It was published as a part of the discussion before the Surgical Section in the *Cincinnati Clinic* for June, I think, of that year. I then stated, and am still convinced of the fact, that bone will reform where the original track of the shaft is kept open, providing the surrounding soft parts are healthy, with regard to their usual blood supply, independent of periosteal conservation. Cell proliferation from the medullary substance will fill the space and calcification will, by natural habit, be supplied by the centering arteries. The periosteum having no osteoplastic rôle specific to its organization, constituted only of blood-vessels and connective tissue. I have removed as much as five inches of the tibia in one instance, and three or four inches in quite a number of cases, where there was no periosteum remaining, and have had perfect union with little, or no, shortening. As to what the opinion is now, or what work has been done in this line in the last ten years, I am not informed. I think antiseptic surgery has so completely absorbed the minds of surgeons and occupied the time of the deliberations of societies, that there has been no recent advanced thought in this most practical branch. Bone grafting held a prominent place in the favor of our journalistic literature a few years ago, but it has never had the backing of anatomical or physiological reason nor practical sense. As no notice appears, to my knowledge, in our recent text-books, I infer that it has been relegated to the antiquities of sheer nonsense and buncombe. Of skin grafting, I am happy to be able to testify to its physiological claims and practicable application. I have had some charming results, and observed others in the practice of other surgeons, that leave no doubt as to its having become a part of our practical business, in the great work of alleviating suffering and correcting deformities: and it is of recent date, having had its birth and growth within the time of my experience in practice.

Among the notable failures and absurdities, in claims to originality and advancement, I will call your attention to the hazardous practice of opening the knee joint and wiring the fragments of the patella. This was, I well remember, advertised as one of the triumphs of antiseptic surgery but a few years ago. It is an operation uncalled for and hazardous in the extreme, and universally I think, as it should be, discarded.

For the purpose of reaching the true Mecca of learning, let us turn back upon the slippery way for a little while, to look upon one of the oldest means, by far too little understood, even by those who practice it in surgery—bandaging. What does that practice involve as it is done in this day of antiseptic surgery—so-called? How many physicians recognize it as one of, if not the very most potent, means of antiseptic precautions and remedies? Has it ever been taught by the fathers and promoters of antiseptic surgery that it was the greatest of "microbe-killers" on earth? And yet I stand before you to-night to bear earnest and truthful testimony, that never in a four years' army surgical experience—a greater part of the time in hospital wards, where erysipelas was of common occurrence in gunshot wounds—never have I seen a case occur beneath a carefully applied bandage—a physiologically applied bandage—the bandage of even and easy support. And more than this, I have applied the roller bandage in many—in all—cases, when applicable, that I have

treated, both in military and civil practice, since 1863, and never saw a case resist such treatment for three days. The redness and swelling of the part subsides, and the patient's general condition improves, from the very first application. And therefore, from the antiseptic surgeon's standpoint, the roller bandage must necessarily be a microbe preventer and killer, worthy of no small amount of consideration. Dr. Dudley was probably the greatest advocate and most successful applier of the roller bandage. It has been said, though, of his students, that they did much harm. This was their fault, but no detraction from the principle involved.

Of all the appliances and devices in surgery the bandage is the most potent, and if I were reduced to the extremity of giving up all others or it, I should unhesitatingly select the bandage alone. With it I can give perfect anatomical adjustment in fractures of the extremities, and physiological rest to diseased structures; not only of the extremities, but of the abdomen and chest. Even in pneumonia the most charming results have been obtained in my practice; and in gunshot penetrating wounds of the lungs, life and comfort at once have come back to the sufferer. I have seen the rigid muscles of the face, expressive of pain, gradually relax as layer after layer was laid gently around the chest; and the patient, grateful for the sweet comfort of relief, would say, "Doctor, I feel so much better," and gently fall asleep, with rapid recovery. As to the answer of my belief here in the bacteria theory—"you must read your answer in the stars." There are no humbings there.

I will call your attention to the repair of lost structure, the healing of wounds, for the most part open wounds. Union by the first intention, requires no discussion here, as the process is unattended by any pathological process, and the question as to antiseptic treatment is not involved. To typify the healing process with necessary treatment in one class of cases, I think, will be sufficient for them all.

Early in 1863 I began the treatment of stumps openly. After the limb had been amputated by the circular method, in the usual way, I bandage well down to the edge of the wound, in such a way as to give perfect support to all the tissues involved in the trauma, extending the bandage up on to the limb, so as to embrace all the muscles involved in the cut; thus giving uniform support and quiet to the tissues. This is rest without restraint, which absolutely fulfils all the indications in physiological surgery. Within from five to ten days the slough, consisting of blood and clot, wounded tissue from the knife, etc., is thrown off, and healthy granulations obtain. For the first few hours there is a free discharge of bloody serum; then a small quantity of pus, just sufficient to flood off the foreign substance. From this time on, there is absolutely no pus discharge, providing—as I am able to do—no dressing other than water comes in contact with the wound. I say no other than water: I do sometimes use a slightly stimulating wash consisting of nitric acid, one drachm to the quart of rain, or other distilled water. The hollow, cone-shaped wound enables me to do this easily by merely throwing a damp cloth over the mouth of the wound. Here is a brief description of what I know to be a novel method of procedure. What seems the most startling to the profession, I claim there is absolutely no pain, no discharge, during the healing, and that these stumps usually close by

the process of granulation in two or three weeks, leaving only a small centrally depressed cicatrix, not larger than a five cent silver piece. Of over three hundred amputations so treated, not one has died from secondary causes. The bandage is seldom changed from the time of the operation and first dressing until the wound is healed. Others are applied over the first, so as to keep up the uniform support necessary in the contraction from shrinkage of the stump. This principle of permanent, undisturbed dressing, is as old as Larrey's practice. What is novel is the detail, I may say. The same processes and treatment are involved in the treatment of compound fractures, with loss of bone substance. The limb is maintained in its normal length, the track of the bone shaft left open to fill in by granulation.

Now can any of you see in this treatment Listerism? I have been told that the absolute drainage and consequent cleanliness of these open wounds is antiseptic surgery. This, truly, is evident from the results obtained. But is it Listerism—I being its originator? Frank Hamilton said to me that he told Lister that "we have a surgeon in Indiana whose wounds are antiseptic in their nature." At a meeting of the American Medical Association in Chicago in 1877 he (Hamilton) was acting as chairman of the Surgical Section, and after I had presented the case of a little negro boy, whose leg I had amputated five weeks before, bore testimony to having seen my cases in the army, and he stated that he had tested my method in Bellevue Hospital, and admitted that he was unable to account for the wonderful results.

Dr. Moore, of Rochester, says in an article read before the Section of Surgery, in the American Medical Association at a meeting in 1878, and published in the Transactions, entitled, "Prophylaxis of Septicæmia in Surgery": "This principle of outflow seems to me to be the explanation of the excellent results of the method of Prof. Link, of Indiana. The stump is the end of the limb, and the compression not only keeps the muscles quiet, but procures a constant outflow, and arrests septicæmia by arresting endosmosis. I have always employed his method since I heard his admirable paper at Louisville."

Again, in an address on surgery entitled, "A Sketch of the Progress of Surgery," delivered in the Section of Surgery in 1888, he says:

"Surgeons at different periods changed their methods, and open wounds were proclaimed as far more successful than those that were closed. But the term "open wound," as generally employed, is a misnomer. The wounded surfaces, it is true, are not pressed into contact, and provision is made for the drainage of the purulent matter, but these surfaces were still more or less in contact with each other. I do not hesitate to say that one of our own members, who made the first declaration of his method in the Surgical Section of this Association, has placed the question of the management of open wounds upon a perfect basis. It has usually been my custom to employ it since its announcement, and never with regret. There have been no failures, and little or no constitutional disturbances. I refer to Prof. Link's method, by which the bandage restraining the swelling causes the edge of the wound, which should be circular, to rise like an erectile tissue and stand up open to the air, thus making the only genuine air dressing that I know of."

I have never conceived for one moment that these

wounds with their soiled dressings were free from bacteria; believing, as I have from the first, that these microbes are only scavengers and common, or liable to exist, in all cases of death, decomposition and degeneracy of tissue. Consequently, I sent a sample of such bandages, removed from a compound fracture of the leg, of six weeks' standing, to Dr. Marcy, of Boston, for examination. The specimen was removed and at once placed in sealed bottles, some dry, others in alcohol and glycerine. The doctor wrote me—and I have the letter now before me—“These dressings literally swarm with bacteria.”

The patient, Mr. Johnson, of Otter Creek township, suffered a compound fracture of the leg, middle and lower thirds, with the loss of the shaft of the tibia of $3\frac{1}{2}$ inches. I dressed the wound, or limb, with bandages stayed with the shavings used in packing buckets and tubs for shipping. The wound was left open. Whisky dressing and hot water was the treatment from first to last. In fourteen weeks the wound had closed entirely and bony union obtained with little or no shortening. No unfavorable symptoms of septic poisoning or traumatic fever supervened. Yet, as Dr. Marcy reports, bacteria literally swarmed around the wound in the dressings. Is this the cleanliness of Listerism—the outpouring of Dr. Moore—or is it the physiological treatment of support, making the conditions antagonistic to diseased action—the shutting out of disease? As in the case of erysipelas, did the bandage act as a germicide?

The contagion of germicidal pathology, I think, reached its climax when the fellow (I do not remember his name or where I saw an account of it) claimed in an article published in one of our journals, that “where the skin is not broken, and diseased action of a septic character is taken on, the germs must necessarily have gotten in at the back door, as it were.” Yet it seems that, where the physiological indications of support are met, the “germs” stay out, though the front door is left open.

In the early stages of the wound Dr. Moore's reasoning might hold good, as to the flooding off by the serous discharge, but in a little while, and before the slough is removed or any pus formed, there is no such outpouring; the wound is comparatively dry excepting as moistened from time to time by the damp cloth, or water that may be poured over it.

Dr. Moore said that my showing that wounds, so treated, do not discharge pus, completely revolutionizes former ideas as to the healing process. Looking into one of those rapidly healing wounds with its masses of granulation processes, rolling together like scrolls; cicatrization so rapid that the surface shrinks to nothing in a few days; one notices first, within a few hours after injury, the swelling out of medullary substance, like new granulation tissue—as Virchow claims it is—bone tissue held in reserve; then following in a few days the soft parts exterior to the bone; the whole blending, presents a pinkish hue, more or less variegated in tinting like a rose bud: at places almost blood red; the new vessels easily discernible through the thin film of covering with an ordinary lense. One sees at once what Virchow, Cohnheim, Billroth and their contemporaries have taught of the identity of white corpuscle—the final cell—and their identity with the pus corpuscle; and in the cultivated mind's eye, easily learned by the every day student in what he may see through the lense of a microscope, in the web of a frog's foot, or the bat's

wing—like diligent workers climbing the ladder to the top of the wall, or, like busy ants repairing the breach in their home—come crowding upon each other through the delicate avenues of capillary new formation, the white cell to be laid like the brick in the wall, with mortar; cells and inter-cellular substance, all dumped to the great builder, Nature; each selected to its part. The white blood corpuscle making new tissue, rapidly coming in excess, not needed here, in pns. as ordinarily in the battle of fighting some offending substance, lays itself into the wall in repair, locking firmly in each other's embrace: they form new tissue, contracting as they solidify into the connective. This process being even, the surface contracts alike: not only puckering the edge of the skin towards the bone, but depressing the center, leaving the cicatrix well embanked around with original skin. We can have no tender stumps.

The thought that lies nearest all this is the part taken by the bandage—the only seemingly universal auxiliary, as all other treatment is incident to necessities as they may arise. First the stiffening of the skin covering; second, rest, as above; third, the uniform pressure that it exerts upon every vessel of the pathological tissue, preventing blood stasis (and venous absorption)—no swelling—no pain. The swelling is the result of congestion and exudate; pain of inflammation, the result of nerve tension or stretching in the tissues from swelling. The pressure exerted by the bandage, together with the free exit of serum, prevents congestion and infiltration. Later comes the other stage: inflammation cut short by other conditions, and only obtaining, in so far as a kind of inflammation process is necessary to the healing of the wound, not necessarily sufficient to result in suppuration. In these cases the white blood corpuscles are not called upon to act as pus to flood off the offending substance and are, therefore, utilized as tissue makers.

The ultimatum of surgery is not in the size of the Catlin knife, or the sharpness of the scalpel in dexterous fingers. The transcendentalism of surgical science is the footing on the pinnacle of the spire, that has its foundation in bone, nerve and artery, finished in capillary cells, molecule and protoplasm; the skilled hand and trained mind reaching out into the infinite of these materialisms.

In conclusion upon this subject, I wish to say that the roller bandage, slightly enforced, meets all the indications in the treatment of fractures of the extremities; putting the muscle to sleep, as it were; with flexion of the lower extremities, the limb rotated outward and laid level upon the bed: we have a perfect adjustment of the bone, with no spasms of the muscles or tendency to displacement: the patient rests easy and comfortable, bacteriology to the contrary notwithstanding.

The rubber bandage, as usurped by Martin, on its elaboration to the use of treatment of varicose veins and synovitis, is a little better than none, and only advantageous to the laity in its easy application by them.

The flannel bandage meets the true scientific requirements of physiological action, and is to be much preferred by the skilled in the use of scientific means for the relief of all chronic troubles.

It is a common principle in nature to resist any obstacles to its tendencies, even unhealthy ones. Apply the bandage for the above chronic condition.

and the first effect is irritation and a tendency to increased congestion. But nature, finding the environments unsurmountable, takes the only remaining course for relief; diminished congestion, and absorption, obtain, until the shrinkage leaves the parts loose and free. Consequently the rubber bandage is wrong, and Martin admitted that in arthritis it should not be used. Nature here finds no point of rest in the following up of the pressure of the elastic bandage; the irritation is continuous. But with the fixed bandage of flannel or old, well worn domestic, it is different. The thought that suggests itself to the "thinking"—which we seldom do until the necessity to account for facts pushes us to it—that the more seldom the dressings are changed the more rapid the recovery. So Larrey taught nearly a hundred years ago, and we, to-day, are forced to go back and admit a homicide and burial of one of our nearest and dearest, though commonplace friends, in the neglect in ambition of seeking the mysterious. Thus we are constantly stumbling over practical things lying around and near us in the blindness of egotistical-far-seeing-ambition. There is no more notable instance of this, than in the case of chloroform and sulphuric ether as anæsthetics, so called. Alcohol is to-day their superior, having this true principle more fully marked, as its very first effect is anæsthetic when given in large doses, and it meets all the practical necessities in far the greater proportion of capital operations, as I have frequently demonstrated.

Anæsthesia can be produced by the rapid administration of whiskey in less than one hour, and with far less general physiological disturbance than by chloroform or ether. The most serious disturbance is that probably of congestion or hyperæmia of the medulla oblongata; and this is counteracted by the loss of blood, mental impression and nerve shock incidental to all surgical operations. Whilst whiskey increases the blood supply to the base of the brain, chloroform diminishes it. The two used in conjunction—the one by the mouth, the other by inhalation—act in harmony anæsthetically; the one counteracting the unhealthy or dangerous tendency of the other, they should be used jointly. But with choice between the two—the one to the exclusion of the other—I should unhesitatingly select alcohol, as I am convinced that anæsthesia can be made complete, with less than one tenth part the death rate of volatile anæsthesia.

Therefore, I am in the habit of administering frequent doses of whiskey followed by small quantities of chloroform. A few inspirations is sufficient to quiet the patient. After which a prolonged operation can be practiced, the physiological conditions remaining through the severe trials of a capital operation nearly, to all appearances, normal. The florid or normal color of the surface, especially the countenance, respiration, heart-beat, pulse-wave, all leading to a feeling of assurance of minimum danger from anæsthetic causes.

LATER—November, 1892.—H. C. Wood's tests as reported to the Int. Med. Congress at Berlin, 1890, were correctly made and deduction proper. But the administration of alcohol hypodermically after profound anæsthesia by chloroform with failure to reinstate is liable to be misleading. Alcohol will prevent, under its primary influence, shock, mental depression and collapse, but will not restore from them, if at all profound.

SPECIFICS FOR THE CURE OF INEBRIETY.

BY T. D. CROTHERS, M.D.,
OF HARTFORD, CONN.

When any great truth begins to receive public recognition it is always first welcomed by the credulous and visionary enthusiast, who surrounds it with the most extravagant expectations. This brings out the charlatan and empiric who studies to turn all such facts and conditions to his own personal profit. In this way the credulity of the one and the charlatanism of the other envelop the truth with a confusion and mystery that often conceal it for a long time. Only the student and the scientist realize that behind this glamor and illusion there is a uniform evolutionary movement along different lines from that suggested to the popular mind.

The growth of the truth is through separate periods and stages. The first stage is that of indifference, neglect, and denial. Then follows the credulous period, in which the truth is partially recognized and accepted, with extravagant conceptions, associated with wild empirical efforts to incorporate it into practical life. Finally, it is fully understood, studied, and accepted, and becomes a part of the world's great possessions. This is the natural history of every new fact of science and every new discovery concerning the evolution of humanity. Often these stages extend over long periods of time and are unrecognized except by a few persons; or they follow each other rapidly, but always along the same lines.

The dawning truth that the drink evil is a disease, and curable as other diseases are, has passed the first period of neglect, indifference, and denial, and has come to the second stage of partial recognition and acceptance. The same army of the credulous, the enthusiasts, and marvel-hunters are welcoming this fact, and the same wild expectations of its practical possibilities fill the air. This is followed by the same old charlatanism and empiric efforts to make personal profit out of these truths by the use of the same old quackish means and methods.

These efforts are prominent by the same assumption of superior knowledge of discovery of new facts, of new remedies, and new methods, all of which are concealed. Then follow claims of extraordinary cures under extraordinary conditions, the proof of which depends alone on the statements of the cured.

Then comes the old story of persecution by physicians and scientists, and of posing as martyrs, public benefactors, and pioneer discoverers, with indirect appeals for sympathy from the broad and liberal minded. Back of all this is a pecuniary field actively tilled which yields rich harvests, and altogether it is the same old familiar history of empiricism, which is always to be found on the advancing frontiers of science. Within two years a large number of charlatans have appeared, claiming to have found remedies and specifics for the certain and permanent cure of the drink disease. A great variety of means and drugs are offered, each one claiming to be superior to all others. Recently one of these empiric specific cures has led all the others in boldness and prominence. Starting from an obscure Western village, it has spread out into many branches, all organized and conducted on one general plan, and federated together. Physicians have been enlisted to conduct each branch, companies have been organized, houses hired, and elaborated arrangements

made for the work. Special papers have been established to defend its interests, and the pulpit and press have indorsed and freely praised these efforts. Every possible avenue to attract public attention has been industriously cultivated to keep the subject before the people.

Large numbers of persons who claim to be cured have organized into clubs, and display hysterical enthusiasm to prove the reality of their cure and the greatness of the projector.

It is assumed that the inventor of this specific was the first to urge the theory of disease in modern times; also that he has made a great discovery of a new remedy the nature of which he carefully conceals from the rest of the world. The most wonderful and complete cures of the most incurable cases are accomplished in two or three weeks on some unknown physiological principle. These assertions are sustained by certificates of clergymen, reformed men, and others, and are accepted as facts without question or other evidence. Dogmatic statements and bold assertions, coupled with savage criticism of those who dare to doubt, together with half-truths and wild theories, mark all the literature of this specific. The commercial side of this remedy is equally startling and Napoleonic as a business success. It is a curious fact that this particular cure is very closely followed in all its details and claims by a number of imitators, who have made equally wonderful discoveries in precisely the same way, but all are concealed for the same pretended reasons. It is equally curious to note the absence of novelty and originality of methods compared with the means and efforts used to make popular and create a sale for most of the proprietary articles on the market to-day. All these specifics for the cure of inebriety are without any practical interest except as phases of the psychology of the drink disease. It is very evident that they could not attract attention on their merits, and the means and appliances used to bring them into notice. Their existence depends on a psychological subsoil, which would favor the growth and culture of any remedy involved in mystery, and promising marvelous cures in a brief time. This subsoil is simply the expectant credulity of a large number of persons, who recognize the possibility of disease in inebriety. Without this all specifics, no matter how wisely and shrewdly presented, would fail. The conditions are all ripe for such empiricism, and its growth, life, and death are governed by causes unknown to and beyond the control of its boastful authors.

Every temperance revival movement depends on some psychological subsoil of expectant credulity, and is followed by the same dogmatic empiricism and the same wonderful cures, and, hysterical confidence of permanent results. Certificates of cure, and enthusiastic praise of means and methods of far greater magnitude than that which follows any specifics, could be gathered and noted after every temperance revival.

The specific cures of inebriety to-day have appeared many times before in the history of the past. Often the empiricism associated with it has been entirely moral and ethical, and at other times it has been pecuniary and selfish. The old Washingtonian movement was a good illustration of a great specific cure, bound up with a great tide of moral empiricism, which for years created intense interest.

The presidential campaign of 1840 was notorious for the excessive use of hard cider, whisky, and rum. Every political meeting was marked by the free use of these spirits, and as the excitement of the struggle increased, temperance men drank, moderate drinkers became drunk and delirious, and never before or since has the excitement of politics been so intimately associated with inebriety in all its forms.

At the close of the campaign it was estimated that over half a million voters were practically inebriates, or had been repeatedly intoxicated during the excitement and excesses of the campaign.

Newspapers and court records showed clearly that a high tidal wave of drunkenness and moderate drinking existed at that period. Then followed the inevitable reaction, and at this moment the Washingtonians appeared. A few months before, a small drinking club in Baltimore changed to a temperance society, and called themselves Washingtonians. Its members were reformed men, and its leader, John Hawkins, was an enthusiastic, passionate orator, who urged the pledge as a remedy for drunkenness with intense earnestness. The excitement of the political campaign and its drink excesses had prepared the public mind for this great emotional remedy—the pledge. John Hawkins' infectious earnestness animated his followers, and roused up an army of lecturers which scattered to every town and hamlet all over the country. The campaign excitement of 1840 appeared again in a great temperance reform wave, which steadily grew in number and enthusiasm up to 1847, when a high tidal point was reached and reaction begun. Over a million persons signed the pledge, and the evils of drinking and alcohol were discussed in almost every neighborhood in the country. Never before had any reform movement been prosecuted with such terrible earnestness and contagious enthusiasm. All selfish motives and personal interests seemed to disappear in the one great purpose to pledge the victim and inspire him to avoid spirits and lead a temperate life. The spirit of the old crusaders seemed to have reappeared again. This was literally a psychological storm-wave, the reaction in part of the campaign of 1840, and the outgrowth of obscure psychological conditions, which had been prepared for a long time before. It crossed the continent and was felt everywhere, and a few years later was only known in the history of the past. While a number of inebriates were restored, its real work and value were in a different direction, not yet fully realized. It seemed to be a great force that fused and mobilized a tide of oncoming truth, and was literally a forerunner, indicating new and clearer conceptions of inebriety. It not only broke up old theories, but opened up new ranges of work, and gave glimpses of more effectual methods for cure.

The first inebriate asylum in the world grew out of this movement, and all the various temperance organizations date from the same source. Even the Prohibition party is the outgrowth of this reform-wave.

It was the first great psychological evolution of the drink question, giving an impetus and inspiration to its study, above all moral and political considerations. It was also a great empirical epidemic which assumed that the drink evil was the result of a feeble will, the remedy for which was the pledge, supported by personal sympathy in organized societies

It was a moral and ethical empiricism, based on the purest and highest motives; had it been founded on truth, would have lived as a great power in the upward movement of the race. In this connection it will be of interest to trace another great wave of empiricism, that created interest for a time. Unlike the Washingtonians, it was thoroughly mercenary, and, like the present specifics for inebriety, it was born in mystery and sustained by credulity and dogmatism.

The experiments of Galvani in 1785, attracted great attention. The most extravagant expectation of the practical galvanism in curing disease may gradually spread among non-experts all over the scientific world. Various empiries appeared claiming remarkable results based on this new force. Finally, in 1796, Dr. Perkins, of Connecticut, announced that he had discovered two metals which, combined in a secret way, possessed marvelous powers of galvanism, which he called tractors, or pullers-out of disease. These tractors resembled a piece of gold and silver fitted together, about four inches long, and were used by being moved up and down over the part affected, to draw out the disease and restore the vital forces. Almost every disorder known was cured or relieved by this means. The discoverer challenged the world of science everywhere, and invited criticism, and pointed to the persons cured for irrefutable evidence. The psychological soil was prepared, and the army of credulous enthusiasts were all ready to welcome him. In two years these tractors attained great popularity in this country. They were literally recommended and indorsed by the faculties of the three medical colleges, and vast numbers of clergymen, members of Congress, and public officials. A special patent was issued, and signed by George Washington, as a slight token of the great service the inventor had rendered the world. Pamphlets, sermons, lectures, papers, and even books were written and scattered everywhere, giving the theories and results following the use of these tractors. In 1798 Perkins went to London. His boldness and dogmatism immediately commanded popularity. After a time a hospital was established, called the Perkinson Institute, offered by the nobility, with Lord Revois as president. Large sums of money were given for the treatment of the poor by this method. Free dispensaries were opened, and trained assistants used these tractors for all cases, with boasted success. Lectures were given on the philosophy of this method, and students were instructed and sent out to open branch institutes. The rich purchased these tractors and became their own doctors, and the poor were obliged to accept treatment from others. With empiric shrewdness, certificates of cure were gathered, which exceeded ten thousand in number, and were signed by princes, ministers of state, bishops, clergymen, professors, physicians, and wealthy laymen. The inventor was recognized as a great public benefactor and pioneer, also one of the few mortals who would live down the ages. Perkinsism seemed to have won a place in the scientific history of the world. By and by this gilded cloud of popularity burst, and the charm was dissolved. Two physicians made tractors of wood and sold them as the original, producing the same results and the same crop of certificates of cure. After making a respectable sum of money, they published their experience, together with the thanks and public prayers for the great

blessing conferred on the world by these means. Like the "South Sea bubble," Perkinsism dissolved and was no more. The branch institutes for treatment by the tractors closed for want of patients, and the tractors disappeared. Behind all this tremendous enthusiasm for the good of science and humanity appeared a commercial spirit that was startling.

These tractors were claimed to be gold and silver, and sold at from ten to twenty dollars each. In reality they were made of brass and polished steel, at a cost of about twelve cents each, in an obscure Connecticut village, from which they were shipped to the inventor, who sent them all over the world. Of course, Perkins made a fortune, which compensated in a measure for his sudden fall from greatness.

While this was a great empirical epidemic with a mercenary object, based on a few half-defined truths, it materially furthered the growth and evolution of this subject. Many of the wild theories which gathered about Perkinsism suggested clearer conceptions to later observers. Like the specific inebriety epidemic, it began as an assumed discovery of some new power, claimed from metal (not used), with some new physiological action by some new process, enveloped in mystery and only known to the discoverer. The tractors were patented, and only made by Perkins, and the certificates and statements of those cured furnished all the evidence. Literally, the effects were entirely mental, depending on the credulity and expectancy of those who claimed to be helped.

The present epidemic wave for the cure of inebriety is hardly up to the average of former empiric efforts in adroit manipulation of the credulous public.

The successful charlatan of modern times has always exhibited some psychological skill in the display of assumed truth and the concealment of his real motives. In these inebriety cures there is a coarseness of methods, with brazen assumptions and display of pecuniary motives, that quickly repel all except the unthinking. The circulars, statements, and appeals to the public are overdone, and sadly lacking in psychological skill. A certain crankiness, with strange combinations of rashness and caution, stupidity and cunning, suggests that inebriate intellects are the guiding spirits in the management of these cures.

On the other hand, the very spirit and hurry of the movement suggests a full recognition of the brevity of the work and the need of active labor before the "night cometh when no man can work." In this the highest commercial and psychological skill appears. Dependence for popularity of the cure on the emotional enthusiasm of reformed inebriates also suggests a short life and early oblivion, of which every temperance and church movement for this end furnishes many illustrations.

There can be no doubt of the fact that a certain number of inebriates are restored by each and all these various methods of cure, and a certain other number, always in the great majority, are made worse and more incurable and degenerate by the failure of such means. But, above the mere curing of a certain number of cases, a great psychological movement is stimulated, and a wider conception of the evil follows of permanent value. The inebriety specifics are epidemics of empiricism that will pass away soon, but they will rouse public sentiment and

bring out the facts more prominently as to the disease of inebriety and its curability. This second stage of this truth resembles the "squatter period" of every new Territory—a stage of occupation by squatters, fortune-hunters, and irregulars of every description, who rouse great expectations, build canvass towns, making a show of permanent settlement, and attract crowds of credulous followers, only to prey on them. These persons disappear when the real settlers come. They never develop any lands or discover any new resources, but prepare the way and concentrate public attention for the final occupation. The specific vaunter of to-day is the squatter settler, who will soon disappear, and be followed by the real settler and the scientists.

Inebriety, its causes and possible remedies, are a vast, unknown territory, the boundary lines of which have been scarcely crossed. The facts are so numerous and complex, and governed by conditions that are so largely unknown, that dogmatism is ignorance and positive assertions childishness.

The recognition of disease is only recently confirmed by the accumulation of scientific facts, although asserted and defended for a thousand years as a theory. The realm of causation is still invested with moral theories, and moral remedies have been used in the same way for a thousand years. While science has pointed out a few facts and possible laws of causation, and indicated certain general lines of treatment, it gives no support to the possibility of any specific remedy that will act on an unknown condition in some unknown way. Inebriety is literally an insanity of the border-line type, and a general condition of central brain defect, unknown, and clearly beyond the power of any combination of drugs. To the scientists, all this confusion of theory and empiricism hides the real movement, and is in itself unmistakable evidence that somewhere in the future the entire subject will be known, not as a statement or theory, but as scientific truths established on scientific evidence beyond all doubt.

The specific epidemic delusions for the cure of inebriety will quickly disappear, as others have done before, and its real value to science and the world will appear from future psychological studies.

ALCOHOLIC INSANITY AS ILLUSTRATED BY THE CASE OF JOHN REDMOND.

Read before the Chicago Academy of Medicine, October, 1892.

BY HAROLD N. MOYER, M.D.,

ADJUNCT PROFESSOR OF MEDICINE, RUSH MEDICAL COLLEGE; NEUROLOGIST TO THE CENTRAL FREE DISPENSARY.

An etiological classification of insanity has proved quite as fallacious as in other departments of medicine. While at first it appeals to the reason as an admirable means of dividing diseases, and as often giving a hint of their chief indications for treatment, in actual practice it results in grouping together incongruous and widely separated conditions. It is needless to refer at this time to the contentions and useless polemicalizing that has been indulged in the discussion of disorders laboring under an etiological terminology. We need mention but one, spinal concussion. The same difficulty attaches to the term alcoholic insanity; by some it is used to denote any mental change due to alcohol, by others it is restricted to the more permanent mental states resulting from the prolonged ingestion of alcohol. In the same loose

manner various other terms have been employed to designate different phases of the effects of alcohol upon the brain, such as acute alcoholism, delirium tremens, chronic alcoholism, mania à potu, dipsomania, etc. While these terms are descriptive of fairly well marked clinical groups, yet they have been so carelessly applied by medical writers that it is impossible in many cases to accurately define them.

Leaving out of consideration the more evanescent effect of acute alcoholic intoxication, we begin the study of the action of the prolonged ingestion of alcohol upon the mind. It is apparent from even superficial observation that the chronic inebriate is in an abnormal mental condition. If the grosser phenomena of insanity, such as delusion and hallucination, are not present, there is the enfeeblement of the will, impairment of memory, perversion of the moral sense and a general letting down of the mental tone. This condition is, however, not insanity in the strict sense of the term. In this mental condition of the inebriate, which is but an expression of the nutritional disturbance in the brain, and in which all the other organs share, we have a fruitful field for the development of the psychoses. It is to be remembered that alcohol may stand as a predisposing or exciting factor in the development of several forms of insanity. Thus it may initiate an attack of melancholia or mania, and the course, duration and termination of these disorders will not be different from that observed in cases presenting the most diverse etiology. These should not be classed under the head of alcoholic insanity. The importance of alcohol in the production of parietic dementia is admitted by all, and yet the clinical history and termination of these cases is not different from those in which there was entire freedom from the alcohol habit.

It will be seen from the foregoing that many, perhaps the majority, of all patients tracing their derangement to the misuse of spirits, do not suffer from alcoholic insanity. It may well be asked wherein is the justification of the term. Is there a well marked psychosis having its origin in the prolonged use of alcohol that can be clinically differentiated from other groups, and presenting sufficiently marked characteristics to enable us to affirm a probable alcoholic etiology in cases where the previous history is unknown? This question can, we think, be answered affirmatively.

As Spitzka so aptly puts it, the phenomena of alcoholic insanity develop upon the peculiar mental condition of the inebriate, such as hysterical and epileptic insanity is superadded to the mental conditions always found in these neuroses. The early stages of alcoholic insanity are marked by hallucinations, generally of vision, in this we note a close resemblance to the acute alcoholic delirium. These aberrations in the sensory sphere soon give rise to persecutory delusions of a fixed character. They usually relate to the sexual organs, the sexual relations and to poisoning. So constant is this association of delusions in this form of insanity that Spitzka says where this relation is found it comes as near demonstrating the existence of alcoholic insanity as any one group of symptoms in mental pathology can prove anything. Alcoholic insanity has a closer resemblance to paranoia or monomania than to any other psychosis, as is shown by the chronic and persistent

nature of the trouble, the fixedness of the delusions, their persecutory character and absence of emotional disturbance. The resemblance of paranoia and alcoholic insanity is clinical only and relates to the more apparent symptoms; pathologically it is closely allied to parietic dementia as essentially a degenerating psychosis. While the delusions are fixed they are not logically supported as in paranoia, they lack the systematized and organized quality found in the latter disease. Krafft-Ebing pointed out that the delusions of alcoholic insanity take their origin in preëxisting hallucinations while in paranoia this is never the case. Another differential point that we have noted in our cases is that the paranoiac correlates the hallucination with his delusions. That is the delusion furnishes an explanation for the hallucination. This we think is the foundation of the fact noted by Spitzka that the acts of insane inebriates are not consistently regulated by their delusions. The emotions are but little involved. What there is is usually shown by depression that can be readily explained by the distressing hallucinations and delusions of persecution. The prognosis is always grave, the patients even when confined in an asylum and denied all alcohol, invariably progressing toward dementia, that does not differ from the terminal states of other psychoses.

With these preliminary considerations we will pass directly to a consideration of the case of John Redmond. He was admitted to the Eastern Insane Hospital Jan. 11, 1889. The history which accompanied him at that time stated that he was 35 years old and that there was no special neurotic heredity, that his mother had lived to be 70 and his father 85 years of age. That he had used alcohol and tobacco excessively for the past two years, ever since the abduction of one of his children. There is evidence to the effect that he had been a free user of liquor long before the time named in this history. The duration of the disease was given as six months. It was first shown by irritability which soon passed to delusions of persecution, marital infidelity and poisoning. He was said in the commitment to be homicidal and that he carried a revolver, on one occasion firing through the floor. On January 17, it is noted that he was improving though his face was flushed and he was easily excited, particularly when discussing the subject of his detention in the hospital, which he regarded as unjust and as belonging to the same class of persecution to which he had been subjected at home, when tricks had been played on him with telephones, and by suspending his bed with ropes and swinging it around rapidly. February 1, he conducted himself rationally though his earlier delusions persisted. February 8, he was sent home with an attendant for a day. April 30, he was discharged improved though it was noted that his delusions, while less insistent, were still present. After his return he resumed to some extent his drinking habits, with the effect of accentuating his delusions though it is not certain that at any time he was as bad as when he was sent to the asylum.

One day he sent a message for Dr. F. M. Wilder, who had been his family physician, to call and see one of his children; he met the doctor at the door, fired several shots at him, killing him instantly. Some months after this, just preceding his trial, the writer examined Redmond in the county jail. At that time he was in fair physical condition, conver-

sation was coherent, and on most topics there did not seem to be any special impairment of the mental faculties. Serious lacuna were noted in the memory. There was decided uncertainty in the movements the hands which at times would suggest tremor. As soon as the killing and his marital relations was broached he immediately became excited, walked nervously up and down the room, and started in with a tirade of abuse against Dr. Wilder, stating that the doctor had attempted to destroy his home and debauch his wife. That on one occasion Wilder had given him medicine that had caused his head to burst open, and more than a quart of water ran out. While he was in this condition the doctor attempted to persuade Mrs. Redmond to retire alone with him to an adjoining room, saying "do not stay with this dead man," or "he will soon be dead, let him alone." It will be seen from the foregoing history that Redmond was continuously insane from about July, 1888, to the time of his trial, a period of four years. During all that time he had persistent delusions of persecution, of marital infidelity and of poisoning, and that these directly related to Dr. Wilder. They were sufficient to establish clearly the diagnosis of alcoholic insanity.

The jury brought in a verdict of guilty and fixed the penalty at imprisonment for life.

The law regarding the relation of alcoholism to crime is by no means fixed. In a general way it may be stated that drunkenness is not considered as an excuse for crime, and that intoxication cannot be pleaded in mitigation of punishment, excepting in those cases in which the degree of the crime is affected by motive. In the cases where the crime is committed while the accused is laboring under delirium tremens, or the more evanescent mental disturbances of acute alcoholism, it is held that he is responsible and punishable. It is manifest that under such a rule the intoxication is punished, and not the crime for which the person is upon trial. A third condition which is almost universally admitted to absolve from responsibility is when the chronic ingestion of alcohol has resulted in the development of insanity of a permanent type. These cases are to be judged the same as insanity having its origin in other causes, than the abuse of alcohol. It is apparent that Redmond comes under this latter class. The theory adopted by the prosecution and supported by expert testimony was that he had so far recovered that he was able to abstain from the use of liquor, and so the crime being the outgrowth of an acute intoxication, would come under the second class. This view does not appear tenable to us as it leaves out the dominating effect of chronic mental disease and assumes on the part of these patients a degree of self control, often not possessed by persons unaffected by mental disease. Such a partial view does not take into account the fact that the delusion regarding Dr. Wilder developed more than two years before the killing, and there is no evidence to show that there had been anything more than a partial restoration of health, in that time. My view is that the crime was the outgrowth of a delusion, having its origin in a diseased condition of the brain, for which the accused was not criminally responsible. In a measure, this view was reflected in the verdict of the jury, as had they fully believed in the sanity of Redmond they would have sentenced him to death as the crime was clearly premeditated.

In conclusion, I fear that the medico-legal relations of crime growing out of alcoholic intoxication will ever remain an obscure chapter, in jurisprudence. On the one hand will be the fear that too liberal rulings will result in the escape of great criminals, while on the other hand, the misfortunes of the alcoholic lunatic will be accounted in some degree at least, of his own making. Perhaps some of these difficulties can be met by needed modifications of our statutes by which dangerous and incurable criminal lunatics may be incarcerated for life in an asylum for insane criminals.

834 Chicago Opera House.

SOCIETY PROCEEDINGS.

The Medico-Legal Society of Chicago.

Regular Meeting, December 3, 1892.

JUDGE OLIVER H. HORTON, PRESIDENT.

E. J. Doering, M.D., President Chicago Gynecological Society, read the following paper

THE BASTARDY LAW OF ILLINOIS.

Mr. President, Ladies and Gentlemen:—The subject to be briefly submitted to your consideration to-night is strictly speaking, a legal rather than a medico-legal topic. On the other hand, it is a subject in which we, as physicians, are more interested than any other class of society, for it falls to our lot to witness the mental suffering, the physical agony of the unfortunate mother, it is our duty to usher into the world the most unwelcome of all visitors—the bastard child. On the statute books of the State of Illinois you will find the following laws relating to bastardy, which have been in force for 20 years, since July 1, 1872:

After the usual phraseology relating to complaints, warrants, trial, etc., we read as follows in paragraph viii: In case the issue be found against the defendant or reputed father, or whenever he shall, in open court have confessed, the truth of the order and judgment of the court to pay a sum of money not exceeding one hundred dollars for the first year after the birth of such child, and a sum not exceeding fifty dollars yearly for nine years succeeding said first year, for the support, maintenance and education of such child, and shall moreover be adjudged to pay all the costs of the prosecution, for which cost execution shall issue as in other cases. And the said reputed father shall be required by said Court to give bond with sufficient security to be approved by the judge of said Court, for the payment of such sum of money as shall be ordered by said court, as aforesaid, which said bond shall be made payable to the People of the State of Illinois, and conditioned for the due and faithful payment of said yearly sum, in equal quarterly installments, and the clerk of said Court, which bond shall be filed and preserved by the clerk of said Court. Paragraph xv, provides: If the mother of any bastard child and the reputed father, shall at any time after its birth, intermarry, the said child shall in all respects, be deemed and held legitimate, and the bond aforesaid be void. Paragraph xvi further provides: No prosecution under this Act shall be brought after two years from the birth of the bastard child.

Now first of all I desire you to notice that process under this Act is a *civil*, not a criminal proceeding. It means in other words simply a civil suit for damages to support the child, without in the least reflecting on the defendant in any manner whatsoever. This is all the redress the law permits to the unfortunate plaintiff. And this is called justice.

Now I presume no one will seriously question the statement that in ninety-nine if not one hundred per cent. of all cases of bastardy, the male has been the aggressive party, nor that the vast majority of cases of this kind are simply cases of seduction under the verbal promise of marriage. But the State of Illinois says officially to the male citizens, such an offense is not criminal and places the damages for degrading womanhood, for cursing innocent childhood, for producing untold misery, anguish and torment at the uniform price of five hundred and fifty dollars. On the other hand when a wretched woman, driven to despair by the outrage committed on her, kills her seducer and father of her unborn child, she is promptly acquitted by the uniform verdict of the jury "not guilty." What inconsistency! Murder justified when the State of Illinois says a fine of five hundred and fifty dollars would have been ample punishment!

Such infamous perversion of justice as expressed by the bastardy law of this State, bears of course legitimate fruit. Under its fostering care the number of illegitimate births are constantly increasing, the business of the abortionist becoming more flourishing, houses of prostitution filled with the victims of the seducer, all, thanks to their partner in crime, the State of Illinois.

Now Mr. President, we have in this Society repeatedly expressed our indignation at the laws relating to the insane, would it not be well to pay some attention to the insane laws relating to the same? Now consider this Bastardy-act of Illinois. If you hold that the woman in question has forfeited all claims, no matter how her ruin has been accomplished, by what authority do you condemn her innocent offspring? Is it just, is it humane, is it Christian to curse the whole life of an innocent being, by damning it from birth until death, by stamping on its brow indelibly the word "bastard?" If you strangle such an infant at birth, you are guilty of murder, but strangling it would be an act of mercy, rather than the existence to which you are pleased to condemn it. The statutes provide that if any time after its birth the father marry the mother, said child becomes legitimate. Is it right, is it just to leave to the choice of the guilty parent the happiness or wretchedness of two immortal lives? Leave it to the seducer's *choice* whether to condemn a suffering broken-hearted mother to be a social outcast, her innocent offspring to be a bastard? Do you call this justice? Mr. President, I care not for ancient, I care not for modern law, I care not for precedents in such matters I recognize a higher—a moral law—and I hold sir, that cohabitation with resulting pregnancy constitutes marriage in its truest sense, and justice is but a mockery, until the statutes declare it also to be such in a legal sense. Not until then sir, has the State done its first duty—justice to all—justice to the man, justice to the woman, justice to the child—that is equality—now it is tyranny.

If you raise the objection that the parent might be already a married man, I answer, apply to him the criminal code relating to bigamy and permit his victim to assume his name, and constitute the child an heir at law. Vice versa, if the mother be already married, punish her for bigamy and permit the child to assume the name of its father with all the rights pertaining thereto.

Where the question of parentage cannot be decided as in the case of a prostitute, often such child should be a ward of the State, whose duty it should be to provide for its adoption among the farming population with a suitable compensation to its foster parents. Minors should be treated as adults. It would teach the parents the necessity to impress upon their children when arriving at the proper age, the sacredness of the marital relations, instead of leaving them as now to get all information on sexual matters from lewd

books and evil companions. Finally if you raise the objection that rich men and rich men's sons might fall prey to designing women, I ask what of it? Think of the millions of poor women who have been made the victims of designing men and ever will be! I sincerely hope that some of the legal members of this Society will become sufficiently interested in this matter to prepare a Bill in accordance with the views so briefly uttered, and I will gladly attend to the details necessary to submit it to the Legislature at the coming session. While radical action may not be hoped for till women have a right to vote, it is still within the range of possibilities to change the Bastardy act into a criminal procedure, and one important advance towards justice will have been gained.

Our social fabric is full of imperfections, crying evils abound everywhere which sooner or later may produce an upheaval of stupendous proportions, but to mind the greatest outrage of all committed by legal sanction, is the crushing of two lives, the damning of two souls for life and of eternity, the violation of all divine law—the Bastardy act of Illinois.

Discussion.

Dr. Sarah Hackett Stevenson.—There are only a few things I have to say in regard to this law and they have already been well said by the writer of the paper. As has been stated, the complaint of bastardy is not a criminal charge, it is quasi-criminal and quasi-civil. Upon investigation I find it is a county court proceeding, not considered in the light of redressing a wrong to the mother, but is designed only to protect the county from the support of paupers. I think this is a point we should consider in our discussion. The penalty upon a conviction on this charge is "to pay a sum of money not exceeding one hundred dollars for the first year and not to exceed fifty dollars yearly for the nine years succeeding, for the support, maintenance and education of such child, and he shall pay the costs of prosecution." I call your attention to the fact that no account is taken of compensation to the mother in this proceeding, although there is an alternative; if the man has property she has a remedy in a civil suit for damages. It is my opinion that the law is entirely inadequate, there is no good reason why judgment in such cases should not be rendered for double and treble the sum now allowed. The man who is father of an illegitimate child should pay as much, if not more for its support, than the father of a legitimate child is obliged to pay for the support of his child. The illegitimate child certainly needs more protection from the law than the child born into a family with family protection; if any difference is made it should be made in favor of the unprotected innocent child, the victim. And furthermore, there should be an additional penalty, what is known as "exemplary damages" to the mother. Not a mere reimbursement of pecuniary loss, but a compensation for the injuries sustained. These are the points I should make in a discussion of this subject, viz: That it is not a criminal proceeding; and the damages are inadequate. They are simply what it would cost the county to maintain the child. We know a mother, with a child must be at a greater expense in taking care of that child, than the county could possibly be. In the first place her own earning capacity is almost ruined, and the cost which falls upon her in its maintenance is much more than the cost to the county in taking care of that child should it become a pauper. As I understand it, the monetary basis is upon the question of the cost to the county in taking care of this child if it becomes a pauper. But if we encourage the mother to take care of her child, which all people of good morals are endeavoring to do, the cost of maintaining it is much more than it would

be to the county, because the county places these children in institutions where they can be taken care of at the lowest possible rate.

Dr. C. D. Wescott.—It seems to me that no argument is necessary to make us all feel as Dr. Doering and Dr. Stevenson do in this matter. A mere statement of the law is sufficient to convince us that it is not only inadequate, but wrong, that the woman is not considered at all. The best point in the doctor's paper, however, is that the act which has given origin to new life should constitute legal marriage, as it certainly does actual marriage. The law should make every man feel that if he is an actual father, he owes it both to the mother and to the child to be as much a father to that child as the mother will allow him. If she does not want to live with the man who has deceived and wronged her, she certainly has a right to claim everything else that the father of that child should do for it and for her. If it is possible for this Society to do anything to influence legislation in that direction we should do it. We should certainly give Dr. Doering hearty thanks and approve the paper in a public way.

Mr. Joseph W. Errant.—I have been brought in contact, from the lawyer's side, with a good many of these cases, and speaking from that standpoint I heartily approve of what has been said here this evening. Every word the speaker of the evening has said in regard to the bastardy laws of the State of Illinois is true, and if he had spoken stronger he could not have gone far astray. It is simply another illustration of the fact that many of us meet with in considering the laws of the State of Illinois, that whereas in material prosperity we claim to be one of the first States of this Union, yet so far as our legal system is concerned we are in the dark ages. This is only one of a thousand instances that might be brought up to show the weakness in our practice and in our laws, and this brings home to us this thought: What we need in the State of Illinois is a commission of men learned in the law, who have had wide experience and will devote five or ten years of their lives, by the consent of the people, to investigating this subject and devising for us a legal system under which this great community may go forward in the future. Three-fourths of the States of this Union have laws making seduction a criminal offense. The great State of Illinois by this bastardy act gives a license to any man to seduce any woman in this community that he may see fit to follow. A license, that's what it is, and nothing else. Yet, when it was proposed some four years ago to place a law on the statute books of this State making seduction a criminal offense, the men in the committee said, "it is all very well to protect your daughters, but we must also protect our sons; what will become of the poor boys if we place such a law as this upon the statute books of this State?" That is the way they looked at it. So back of this law there must be public opinion. There must be a social opinion which will demand a different order of things, which will look at mothers from a different point of view. Back of such legislation as you call for, there must be a social opinion among women which will not trample upon any woman who is placed in the position you have described to-night, and which has come under my observation, not once, but a hundred times, not the social opinion of the mother, for instance, who when her son has done a wrong act passes it over and gladly welcomes him back to the home, but shuts the door to the daughter who has possibly made a misstep. So in addition to what Dr. Doering has said I would impress upon you the fact that this question is a very large one indeed, that it is not merely a question of legislation and law, but also a question which has very much to do with the social opinion of men and women.

It is an absurdity to assume that a woman can bring up a child on the pittance which this law provides. Further than that there is no provision made under this law for the long period of inability to work which may precede the birth of the child; and if the child does not live there is no payment at all. It is purely a question of support. This law is simply one evidence of many absurdities on our statute books, all of which ought to be done away with and better provisions made. We face the fact that there is not sufficient public opinion in this community to demand even the law which I have described, and which provides that seduction shall be made a criminal offense, whereas in three-fourths of the States such a law exists. We have furthermore to develop a social opinion which will consider this question from a larger point of view. It is a social question, and it is also a legal question.

Mr. David J. Wile:—Inasmuch as the proceedings of this meeting are to be published to the world, it is but proper that exactness should characterize statements concerning the bastardy statutes of Illinois. Interesting as is Dr. Doering's paper, it has not given an accurate statement of the law as it stands to-day. In addition to what has been stated, the statute provides, that after a defendant has been adjudged the father of the bastard child—in case he refuses or neglects to give such security as may be ordered by the Court—he shall be committed to the jail of the county, there to remain until he shall comply with such order, or until otherwise discharged by due course of law. *Any person so committed shall be discharged for insolvency or inability to give bond; provided, such discharge shall not be made within six months after commitment.*

The statute further provides: The mother of a bastard child, before or after its birth, may release the reputed father of such child from all legal liability on account of such bastardy, upon such terms as may be consented to in writing by the judge of the County Court of the county in which such mother resides: Provided, a release obtained from such mother in consideration of a payment to her of a sum of money less than four hundred dollars, in the absence of the written consent of the county judge, shall not be a bar to a suit for bastardy against such father, but if, after such release is obtained, suit be instituted against such father, and the issue be found against him, he shall be entitled to a set-off for the amount so paid, and it shall be accented to him as of the first payment or payments: And provided, further, that such father may compromise all his legal liability on account of such bastard child, with the mother thereof, without the written consent of the county judge, by paying to her any sum not less than four hundred dollars.

I do not regard Dr. Doering's proposition of *ipso facto* marriage as a practicable remedy. In its very essence, marriage in the first instance is purely matter of contract, not enforceable against the will of either party. The action for breach of a promise to marry is one to recover damages for breach of a *contract*, not for the commission of a *tort*. An enforced marriage does not mean support.

The law provides for the recovery of mere money damages in cases of seduction. The ability to enforce payment depends upon a defendant's financial condition. Strange as it may seem in these days of moral enlightenment, Illinois lags far behind her sister States by failure to treat real seduction as a heavily punishable crime. There is reason to hope that the next Legislature will remedy this defect in the law.

The real truth is, that illegitimate births occur principally among those classes of our population where pecuniary redress is practically impossible, because of poverty. In the so-called "higher classes of society," other means seem

to be accessible, whereby the responsibilities of paternity and maternity may be evaded. That those means come within already existent criminal inhibition, quite as worthy of consideration as the subject discussed this evening, may be safely admitted.

It occurs to me, however, that many of the shortcomings of the present bastardy law might be remedied if the jurisdiction of Courts of Chancery were enlarged so far as to permit the prosecution of a bill for separate maintenance for the benefit of the innocent child, under provisions similar to those which now exist in favor of wives who, without their fault, live separate and apart from their husbands.

The broader and deeper question involved cannot be settled by enacted laws or judicial decrees.

Dr. J. B. Hamilton:—In regard to one point suggested by the last speaker there is a fact bearing on this which is a precedent: In the Legislature of Washington Territory some years ago they enacted a law in regard to white men living with Indian women, that all such as were found and reported to the court should be recorded as legally married and the children should be declared legitimate. That was carried into effect, and hundreds of persons who had gone into Washington Territory at an early day and lived with squaws, were obliged to take care of children under the act cited. I cannot give its exact date, but I think it was 1875. That carried into effect the suggestion of Dr. Doering, and I never heard that there was any legal objection to it on the part of anybody.

Mr. L. Kistler:—It is perhaps difficult for any one to suggest just exactly what would be the proper line to take. It is true that a man who is responsible for the existence of an innocent being should be held responsible for the support, not only for a certain number of years, but as long as it may be necessary. It seems to me an ordinary rational view would demand that a man should be held responsible by society for his acts. In my practice I have prosecuted one bastardy case, and that set me to thinking. I cannot repeat my language, but the defendant got so angry that he got up and shook his fist in my face, and of course the result was he was convicted. However, he made amends by marrying the girl subsequently. I am inclined to think that our law is simply the outgrowth in a measure of the average public sentiment. We may hold advanced views, but as a rule no thoughts or views culminate in the law, because law is simply a crystallization of the average common sentiment of society. I sometimes am discouraged, but recently I had occasion to examine the jurisprudence of the State of Rhode Island, and I found that it is about two hundred years behind the times; so I came back to the State of Illinois feeling that we have made considerable advancement.

In regard to this Bastardy act, it could be improved. As it stands it is simply an attempt to provide for the support of the innocent child, irrespective of the effect it may have upon the mother or upon the father, but it fails to do this under the existing state of society. There should be abundant provision for the child until it is able to take care of itself. I would feel inclined to go so far as to make the father thoroughly responsible for the child. As to the mother, of course the bastardy act goes upon the basis that one is as guilty as the other and is not for it to say which it is. I think, however that in most instances the man is the responsible party, although there seem to be, in the condition of society as it is, some exceptions. But in any case I would go as far as suggested by the speaker before me, that there should be more abundant provision by legislation that the innocent one should be provided for, and the father be held responsible just the same as if the child had been born in wedlock.

Judge Horton:—It would not be an easy matter to those who have had any experience to say just how you would

defend a man, guilty or innocent of this charge. I have never known a man to be acquitted when he was charged with it, and a lawyer who could try such a case before the average jury and get the man free when the woman accuses him, would have a successful practice in Chicago.

As to the topic of legislation, I do not know whether Dr. Doering knew what he was assuming when he offered to take charge of this, but I had a little experience some years ago when I sent down to the Legislature an amendment to the divorce law. It was supported by every paper in Chicago. The *Tribune* got the views of nearly all the judges in the State of Illinois, and published column after column recommending it. It passed the House but failed in the Senate, and some wag suggested to me that the reason it failed was that every one of those fellows knew that his wife had good reasons for a divorce, and did not approve of enlarging the subject.

American Electro-Therapeutic Association.

Second Annual Meeting, held in New York, October 4, 5 and 6, 1892.

WILLIAM J. MORTON, M.D., PREST.

FIRST DAY—OCTOBER 4—AFTERNOON SESSION.

(Continued from page 188.)

I am not aware of any further literature relating to general treatment by means of electrodes.

I may remark here in passing that I have found that the cataphoric power of electricity is not confined to galvanic currents alone. With the aid of the "Static induced" current first developed by me from an influence machine and using block tin electrodes and blotting paper to retain solutions, I have caused cocaine anesthesia, and introduced iodine and many other medicines through the skin. Using tincture of iodine as described, over the spinal cervical centres, I have arrested completely a case of progressive muscular atrophy in which the disease had already invaded and was successively invading the muscles of the upper extremity.

I have also devised and used a cataphoric mouth electrode, by means of which solutions of medicines held in the mouth are caused to enter the circulation by the mucous membrane of the mouth, thus avoiding the fluids of the stomach, and a similar electrode which performs the same function per rectum.

Electric Baths.—The electric bath itself, has long been regarded as not a little *ex cathedra* even to the liberal minded medical "electrician," and much more so the "medicated" electric bath.

A careful study of the physics and physiology of the subject will convince even the most skeptical of the fact that medicine can be practically introduced through the unbroken skin by immersing the patient in a fluid electrode which in fact such a bath constitutes. Edison's experiment of causing the patient to immerse the hands in fluid was in reality a limited electric bath, and now that we have his authority as well as that of Mr. A. E. Kennelly, who personally superintended the experiments, we may accept without shrinking the principle of the "medicated" electric bath. Moreover, high scientific approval of this method is not wanting in the careful work of Gärtner, Cagney, Steavenson and many others.

Cataphoric D. medication.—It is scarcely probable that anything more than extraordinary circumstances would call for the elimination of medicinal substances from the body by means of electricity, since it is probably impossible to prevent their natural elimination, and since again other simple means of elimination are available, as for instance the administration of iodide of potash in lead poisoning.

Still the occasion may arise as in ulcers due to direct poisoning of metallic salts employed in electro-plating. Such was the occasion, I believe, which first gave rise to the method. About 1855, a Mr. Vergnès, an electro-plater of Havana, Cuba, found that he had an incurable ulcer due to frequently plunging his hands into solutions of cyanide and nitrate of silver and gold. One day, accidentally immersing his hands into the bath already prepared for plating he found that the negative element had received a metallic coating. The hint was acted upon and a number of similar treatments resulted in the rapid cure of the ulcer.

From this incident sprung the Vergnès "electro-chemical bath" as it was named, and practiced by a Mr. Royal in New York City. Its vogue seems to have depended largely on a rampant idea that mercury clung to the system of many unfortunates and should be eliminated by this method. The bath tub was of copper and insulated from the earth, the patient was also insulated from the tub by sitting on a wooden-seat. The water, in case gold, silver or mercury was to be eliminated was acidulated with nitric or hydrochloric acid; if lead was to be removed, with sulphuric acid. The positive pole of a thirty cell galvanic battery was held in the hands while the negative pole was connected to the copper bath tub. A porcelain tub in which is immersed a copper plate will do equally well. In the same year M. Poey made this method the subject of a communication to the French Academy.^{4,5}

Vergnès also reversed the current in his bath and claimed to introduce medicinal substances, notably phosphate of iron in a solution to which nitric acid was added, and also quinine. The patient sat in a bath containing the solution of the medicine holding the negative pole in the hands. No physician could consent to put in practice a method as inexact as the above outlined, unless advantages not obtainable by stomach or by hypodermatic administrations can be demonstrated.

Experiments could be easily made which would determine the accuracy of these claims. The question of resistance comes to the fore, if this is too much reduced by acids and inorganic salts the conveying power is also diminished.

Gärtner and Ehrmann⁶ have already practically to a large extent answered this objection in their published experiments of introducing corrosive sublimate by the medicated bath method in the treatment of syphilis. Four to six grams of corrosive sublimate were put into the water; the current strength was 100 ma.; the duration of treatment 15 to 20 minutes; at the end of four days there was still to be found in the urine of 24 hours, 0.7, 0.3, and 1.3 mgr. of mercury. Kronfeld has corroborated Gärtner's results in Prof. Lang's clinic in Vienna.

In conclusion, while we must grant the solidity of the physical facts we yet need much clinical experience and, the time has not yet come for a judicial expression as to the value of these methods in general medicine.

NOTES UPON THE CHEMISTRY OF CATAPHORESIS.

By W. H. Wailing, M.D., Philadelphia Pa.

Before entering upon the discussion of the subject-proper let us glance at the tissues and cells of the human body, and briefly consider the effects of the electric current upon them.

A condensed classification of the tissues of the adult is as follows:

1. *Epithelial tissues.*—The primitive surface tissues of the inner and outer germ layers, which are variously modified for several distinct duties.

⁴ See Medical Electricity, Steavenson & Jones, Philadelphia, 1892.

⁵ See A Treatise on Medical Electricity, by Julius Althaus, Philadelphia, 1873.

⁶ Lewandowski, Electro Diagnostik and Electro-therapeutie. Wien and Leipzig, 1892.

2. *Nerve tissues.*—Springing from the former and conducting, controlling and distributing impressions.

3. *Muscles.*—Or contractile tissues in close relation to both of the previous groups.

4. *Connective tissues.*—The materials used in the general body architecture. Bone and cartilage, modifications of connective tissue, we need not consider. The blood vessels are chiefly made up of connective tissue, and even the blood itself may be considered as an outcome of this fourth group since the cells of the blood are first formed in the mesoblast and later from the connective tissue corpuscles.

The various secreting organs are made up of epithelial cells, held together by connective tissue, and in close relation to blood-vessels and nerves.

All these tissues have their origin in the primitive material which we term *protoplasm*. This protoplasm has certain movements which characterize its life and these movements are affected by mechanical, chemical and electrical stimulation, differing in character. That if slight excitation by the induced or faradic current, increases the rapidity of the movements, stronger ones cause tetanic contractions, and numerous and powerful ones cause coagulation. In this connection, I enter my protest against the use of strong faradic currents given by the street-fakir, or the so-called testing machines found in public places. Such experiments are dangerous, and should be prohibited by law.

The galvanic current causes dilatation and contraction of the blood-vessels by direct stimulation of their muscular fibers, acting in like manner upon the lymphatics, "causing more ready circulation of the blood and nutritive fluids; increased power of imbibition of the tissues; increased osmotic processes; changes in the disassimilation and nutrition of the nerves on account of their stimulation or sedation; changes in the molecular arrangement of the tissues, caused by electrolytic processes; and finally the consequences of the mechanical transport of fluids from one pole to the other." (Erb.)

The current exerts a more or less direct influence upon the trophic centres in the anterior cornua of the spinal cord. Its action on the brain, we will not consider in this paper.

Under powerful shocks from a dynamo, the red blood corpuscles are immediately disintegrated and destroyed, producing instant somatic death. Very strong currents from a galvanic series will also disintegrate the living cell in the interpolar region. Under moderate currents, interpolar effects and changes are scarcely noticeable, yet they take place in a proportionate degree. These changes in the vital processes, and the consequent good results obtained by the use of electricity alone, are often greatly increased by the timely and judicious combination and application of the galvanic current and certain drugs and chemicals. This method I have styled anodal and cathodal diffusion. It is also called cataphoresis. I need not go into the history of the subject, it being somewhat familiar to most of you. I wish more particularly to call your attention to the chemistry of the poles of the galvanic series, and the corresponding chemistry of the substances to be used with them in cataphoresis.

First as to suitable electrodes. Tin has been quite extensively used as it oxydizes slowly, and the resulting compound is harmless. Gold and platinum are better, but too expensive. In place of either of the above metals I use carbon. The disc which is about one and one-quarter inches in diameter is shaped with a file so as to receive an insulating ring of hard rubber, which projects about one eighth of an inch forming a shallow cup with the carbon as the bottom. Before the rubber is permanently adjusted, the carbon is submitted to a bath of hot paraffine and fully saturated with

it. This renders the electrode impervious to all liquids, while not interfering, practically, with its conductivity. The rubber ring being adjusted, and a suitable attachment made, the diffusion electrode is ready for use. As a vehicle for the medicament, absorbent cotton or white blotting paper discs may be used. In some cases where the whole limb or a joint is to be treated, my bandage, made of tin foil, is to be used over the wetted bandage. This latter method may be used to advantage with the lithium salts in gouty joints. The current intensity to be used is determined to some extent by the sensations of the patient. I am in the habit of using from five to ten or fifteen milliampères, with sittings lasting from five to ten or fifteen minutes, the drugs thus used being morphine sulphate, cocaine hydrochlorate, mercury bichloride, potassium iodide, lithium citrate and aconitine, in solution, and tincture of iodine and chloroform. Other substances have been mentioned and used by prominent operators, notably helleborine, onabain, strophanthin, menthol, carbolic acid, etc., by Dr. Frederick Peterson.

Does electrolysis take place during cataphoresis, and what are the reactions? The law of chemical affinity is an electrical one, and "polarity" determines the formation of all crystallizable bodies. Some substances are always electro-positive in their affinities, and some are always electro-negative. For instance, hydrogen is always electro-positive and oxygen is always electro-negative. Some elements, on the contrary, are variable. Copper is electro-positive when coupled in a galvanic pair with mercury, tin, iron, nickel, zinc, lead and some others, but electro-negative if thus coupled with silver or platinum. Silver is electro-negative towards lead in a solution of dilute nitric acid, but electro-positive toward the same metal in a solution of cyanide of potassium.

Regarding electrolysis, which I think takes place in all our cataphoric applications, with possibly a few exceptions, Prof. Rhoc says: "It seems clearly established by numerous experiments that galvanic conductions through liquids is always electrolytic; in other words, there can be no conduction of an electric current through a liquid without that molecular re-arrangement in the fluid through which the current passes, and that molecular disintegration at the surfaces of the electrodes which we know as electrolysis; that the various processes supposed to go on in the body under the influence of an electric current, and termed by different authors absorptions, electrical osmosis, and electro-catalysis, will properly be ranged under the single conception of electrolysis.

"It is held by some that there is an actual transfer of ions from one pole to the other. By others that there is a polarization of the molecules, so that the electro-negative element is forced towards the anode, and the electro-positive element towards the cathode, where the terminals appear as ions.

"It must be remembered that electro-negative bodies may acquire electro-positive polarity, and vice versa, the polarity of the elements depending upon their relations to other elements in a compound, rather than upon any intrinsic property. This will account for some otherwise anomalous changes in electrolysis."

Whilst this latter statement is true, there are many elements that are constant in their chemical affinities.

We will now consider some of the substances used in cataphoresis in their relations to the anode and cathode. I have already referred to hydrogen and oxygen. The law of polarity will be found in full force here. The hydrochlorate of cocaine has the chemical formula of $C_{17}H_{19}NO_4$, HCl. Used upon the anode, the acids being electro-negative would collect at the anode, while the base, cocaine, being

electro-positive, would be repelled and driven into the tissues. The fact that this salt, used upon the cathode, does not produce anæsthesia, proves this clinically.

Chloroform, having the chemical composition CHCl_3 , and which may be considered to be the chloride of the trivalent radical formyl, would also, theoretically, be used on the anode, although it is denied by some that electrolysis takes place in this substance, with the weak currents used. I have never used it with the cathode.

With morphine sulphate, mercury bichloride, lithium citrate and aconitine, the anodal pole is used, and for the same reason; the base being electro-positive is driven into the tissues. If, however, we wish to introduce the benzoic acid in benzoate of sodium, we should use it with the cathode.

Iodine and iodide of potassium. It has been the custom with all operators to use these substances with the anode. Now iodine is an electro-negative always, either when alone, or in combination with potassium, and when acted upon by the galvanic current, will be repelled by the negative, and attracted by the positive pole. This is easily demonstrated by wetting a piece of absorbent cotton with a strong solution of iodide of potassium, place it upon the cathode and a thin piece of coagulated egg albumen upon that, wrap the anode in absorbent cotton and wet it in plain water. Place the anode upon the albumen, turn on about thirty ma. of current, and you will soon perceive free iodine on the anode, it having been freed from its combination by electrolysis and forced through the albumen. Reverse the current, when instantly free iodine appears at the lower pole wetted with the solution of potassium iodide, and gradually disappears from the upper electrode, where it had before collected. The iodine does not appear in the interpolar region, but we must remember that we are now dealing with dead animal tissue, and not with the living cell capable of absorption and assimilation.

Repeat the experiment, using the tincture of iodine, and a piece of chicken skin in place of the albumen. (Of course fresh cotton is also used.) Place the skin on the cotton wet with the iodine, it being on the cathode, the flesh side uppermost. Wet the other pole in plain water as before, turn on a current of five milliamperes for five minutes, and the iodine will appear at the anode. Take fresh material all around, and repeat the experiment with the poles reversed. No iodine will appear at the cathode, which is now on top. As before stated, iodine is always electro-negative, consequently is always repelled by that pole.

A prominent operator and writer reported a case some time since in which he used the tincture of iodine on a goitre with the anode, and claimed wonderful success therefrom. That there was an increased absorption by reason of the stimulation and increased vascularity as a later result, I am ready to admit, but am not willing to concede direct penetration of the substance due to the direct action of the current. Had he used the cathode, there would have been all three, increase of stimulation and absorption, and a direct introduction of the substance into the tissues.

In certain skin affections, especially those of a parasitic origin, I have used mercury bichloride on the anode with most happy effect, when other remedies have failed. This method is safe, pleasant and sure. In herpes circinatus, ringworm of the scalp, etc., a 1-1000 solution of the bichloride on the anode, using a current suitable to the case, will soon result in a cure.

To recapitulate: Use with the anode, all substances the base of which, being an electro-negative body, you wish to introduce into the system, and with the cathode such as are electro-positive in character, or when it is the substance taking the place of an acid, as in potassium iodide.

I was the first to call the attention of the profession to

the *chemistry of cataphoresis*. This was done before the Philadelphia Electro-Therapeutic Society, February 12, 1891,¹ and again before the Alumni Association of the Medico-Chirurgical College, March 20, 1891.²

I shall continue my investigations in this interesting field with still other substances, and report results at some future time.

1606 Green St.

CATAPHORESIS IN GYNECOLOGY.

by Dr. A. H. Goelet, of New York City.

Unfortunately, or perhaps fortunately for my hearers, there is little to be said upon cataphoresis in gynecology. So far as I am able to judge from my own experience cataphoresis has a limited usefulness in gynecology. Perhaps others have pushed their investigations further and have formed a different opinion, and for this reason I would prefer to listen rather than endeavor to impart any information, but I have consented to respond hoping that the little I may be able to contribute may possibly suggest more extended investigation in this direction. If I have not done this myself it is because I believe I have been able to accomplish the desired end more readily in some other way.

Some years ago I did considerable work with cocaine upon the positive pole in the vagina for the relief of pelvic pain and congestion of the pelvic organs, and believe I succeeded in affording relief in many instances where, at that time, I was unable to relieve so readily by other means. Subsequently morphia was employed for the same purpose and I must say with some satisfaction. But afterwards my attention was directed to the tension faradic current which was found more serviceable, and cataphoresis for this purpose was abandoned.

Now the only use I find for cataphoresis is to produce anæsthesia of the vaginal wall, which renders puncture more tolerable to the patient. With a 4 or 8 per cent. solution on the positive pole, with 10 or 15 m. used for five or six minutes the vagina can be rendered so insensitive that the needle can be introduced without the patient being conscious of what is being done, and in nervous, highly sensitive patients this is a great advantage. Unless the tumor, or mass punctured, is unusually hyperæsthetic the pain sometimes experienced while the current is in force is very much diminished also by applying this drug in this manner before hand, and the aching which sometimes follows immediately after puncture is materially lessened.

I have made some experiments with ergot and iodine introduced through the vagina by this means but cannot say that the results so far have been encouraging. I have discovered however, that the vagina can be very thoroughly blistered with these remedies, if the current is too strong, in fact with a comparatively mild current. Dr. Hunter McGuire has, I believe, obtained some satisfactory results from the use of iodine in this manner in fibroid conditions.

By means of this process it is possible to introduce drugs into the interior of the uterus and as this is an excellent absorbing surface no doubt something may be accomplished in this direction. A novel method of application has been suggested recently by a gentleman in this city whose name I cannot now recall. He employs plaster of Paris moulded around a platinum wire and saturates the plaster with the drug to be employed.

The use of iodide of potassium has been mentioned as a remedy to be used by cataphoresis. As I understand it, this is not strictly cataphoresis, since the solution is decomposed, but it is rather electro-chemical decomposition and not electric cataphoresis.

¹ See Times and Register, March 21, 1891.

² Ibid., April 9, 1891.

As I have said, I would prefer to hear from some one who has made more extended investigations.

THE USES OF ANODAL DIFFUSION IN NEUROLOGY.

By F. Peterson, M.D., of New York.

In discussing this question of the employment of electric cataphoresis in nervous diseases I can hardly do better than quote from one of my former papers the main points at issue.

"I was led myself into making a study of electric cataphoresis by my own work in a neurological line, and my first experiments were conducted with a view to relieving pain. I received the suggestion after vainly endeavoring to combat severe supraorbital neuralgias in several patients. All known appliances and agents of the healing art had been ineffectual, blistering, electricity, aconitia, and the progressive series of narcotics and anodynes, which generally terminate with the morphine habit. One of the patients had suffered from morphine inebriety for a year, but had recovered from that with her supraorbital anguish unassuaged. I found that ten to twenty per cent. solutions of cocaine on the anode gave absolute relief in these cases for from four to ten or eleven hours, and without constitutional effects of any kind. A deep analgesia was produced in the area covered by the anode. No doubt constitutional effects would ultimately result by indefinite continuance of the application.

Since that time I have made it a point always to use the cocaine solution in any sort of superficial pain in which I think the anode to be of advantage. The method does not mitigate neuralgic pains which owe their origin to lesions far back of the point to which the electrode is applied, as in disease of the Gasserian ganglion, or the idiopathic neuralgias of central origin; and it is here that cocaine cataphoresis has actual diagnostic significance. If the pain is relieved by the treatment, the lesion is in the immediate neighborhood, or peripheral to the anesthetized area, and this would furthermore suggest the possibility of permanent cure by neurectomy. This idea of the diagnostic value of cocaine cataphoresis is Dr. Starr's, and it has some sort of corroboration in a case of intense supraorbital neuralgia which I lately saw with him. A 20 per cent. solution of cocaine used with a strong current for a considerable period of time did not diminish the paroxysms of pain in the least. A few days afterward neurectomy was performed, and this also had no effect upon the neuralgia.

Cocaine employed in this way does not cure neuralgias of peripheral origin. All that is claimed for it is that it gives relief without producing constitutional effects, and is, therefore, superior to any narcotic given internally, and to any other local application.

Other local anesthetics are chloroform, aconitia, ouabain, strophanthin (Arnaud's), helleborin, menthol, and carbolic acid.

Chloroform causes a dermatitis, and should be used only when counter-irritation is desired in conjunction with a transitory anesthesia. I have employed chloroform cataphoresis in one case of cervical neuralgia with good effect. Helleborin and aconitia I have also used successfully, but the latter, while it gives rise to a deep analgesia, also causes painful burning and smarting, unless combined with a cocaine solution.

While my experience with the method has been chiefly in neuralgias of superficial nerves, I have not failed to give it a trial in other conditions where it seemed to be expedient. I have been using cocaine and helleborin with the anode in two cases of tic convulsif of late, placing the electrode over the trunk of the facial or one of its branches. Whatever may be the explanation of its effect, these cases certainly

show very great improvement, and a remarkable diminution of the spasm after each application, such as was not obtained from the employment of the electric current alone. In a case of blepharospasm, cocaine cataphoresis practised near the outer angle of the eye produced a very marked change in the extent and frequency of the movement. I have no doubt, however, that the results would be better still if we had some drug to use with the anode which would act upon motor nerves in the same way as the local anesthetics act upon sensory nerves; if, in other words, we had some trustworthy local paralytic. Atropia and curarin do not seem to answer the purpose.

There can be no doubt that the effects of the galvanic current upon nutrition are in part due to the cataphoretic transfer of molecules of protoplasm and liquid from one cell to another, or from a cell to a capillary vessel in the path of the anodal stream, and since the diffusion takes place more readily and more quickly in direct proportion to the current strength it behooves us to employ as many milliampères as feasible in our galvanization of the atrophied and paralyzed extremities of poliomyelitis, chronic neuritis, and peripheral nerve trauma. Moreover, there would seem to be a possible advantage in the use of nutritive emollients in conjunction with the labile application of the anode to the atrophied member, just as they have been combined from time immemorial in the exercise of the aliptic art (massage)."

General Discussion.

Dr. Massey had made use of this method in connection with cocaine applied on cotton to the vagina and to the uterus. The anesthesia was not marked in the vagina, and he attributed this to the fact that the upper portion of the vagina is normally insensitive. A more positive anesthetic effect had been noticed from the positive pole in the uterus. The method is chiefly of service in producing very superficial anesthesia, and is, therefore, not very useful in gynecology.

He had tried cataphoresis in connection with iodide of potassium in the treatment of enlarged glands in the neck, but he thought it objectionable for strong currents cannot be employed on account of the great irritation of the skin which they produce. The glands were considerably swollen for some days after each treatment. Better results were observed by using his favorite soap electrode, and a current of sixty milliampères.

In making a vaginal application he usually employed a zinc electrode, insulated with rubber, and wound tightly with cotton, and he had experienced considerable difficulty in keeping the cotton sufficiently moist. When the cotton became so dry as to offer undue resistance to the passage of the current, he reversed the direction of the current, making it negative. This would cause the cotton to become moist again, and allow the current to pass more easily. The method was a good illustration of electro-convection.

As an example of electric elimination, he referred to a practical use which he had made of it. While removing hair from the face, with an iron needle, he had accidentally made this needle positive, with the result of immediately producing a metallic stain in the skin. By reversing the current, and using a clean needle, the metal was in a few minutes re-deposited upon the needle, and this too, without greatly increasing the irritation. It had not infrequently happened that without our knowledge we had made use of cataphoresis to impregnate our patients with the metal from the positive electrode. He had employed iron on the supposition that this metal was not a foreign substance in the human system.

Dr. Hutchinson thought the effect was about the same

whether the solution was applied on one or the other pole? Cataphoresis at present occupies about the position of the phonograph, and its practical value has not yet been determined. With the exception of a few observers—notably our own members, Drs. Peterson and Morton—most of us had not accomplished any very definite results with it.

The President said that he wished to be placed on record as a firm believer in cataphoric phenomena, and he thought simple cataphoresis would prove to be one of the most important branches of our subject.

Dr. F. von Raitz, of New York, said that there seemed to be confusion concerning this subject, some observers claiming that there was only anodal diffusion, others, that there was only cathodal diffusion, while still others, believed that the diffusion occurred at both poles; yet these widely different views are held by men all of whom had had large clinical experience. The speaker said that in the paper which he read before the Association at their last meeting, he stated that as it has been generally admitted that acids are found at the positive pole, and alkalis at the negative, it must also be admitted that certain chemicals are more easily diffused from one or the other pole, and others again, from both.

Dr. Nunn said that the reference had been made to Verrier's experiments in 1855. He had repeated these, and had published the results. So far as mercurial de-medication was concerned, these results were entirely negative, and also as regards Verrier's experiments and claims. He had recently experimented with cocaine and other substances in connection with extirpation of urethral caruncles, and had found the method quite useful. He had also followed the experiments of Hunter McGuire, and like the President, he had applied the iodide of potassium to *both* poles. He did this because he thought this would favor the interchange of the elements, and he believed that he had seen benefit from it. It was bad policy to use iron needles in removing hairs; the delicate point of a gold needle will pass into the skin with the utmost ease if a mild negative current is first turned on. For twenty years, he had used the same two gold needles, and he had made extensive use of this method of epilation, removing six thousand hairs from one patient alone.

Dr. E. V. Agramonté, of New York, by irritation, said that he had witnessed the effect of cataphoresis in his own person, as he had presented himself as a subject for experimentation at the time when Dr. Peterson first presented his paper on cataphoresis before the New York Academy of Medicine. Five minutes after introducing the cocaine into his hand by the current, the hand felt entirely anæsthetic over an area of two inches in diameter, and the skin which is quite thick, could be pierced very deeply with a needle without his feeling it. We all know that we cannot apply a 10 per cent. solution of cocaine to the unbroken skin of the hand without the aid of electricity, and obtain any such result. If he recollected correctly, the anæsthesia remained more or less pronounced for several hours, and the application produced no untoward effect excepting a redness of the part which lasted for a day or two. He thought this report was due to Dr. Peterson, and he offered it as a personal testimony to the passage of a solution through the epidermis, which we know is an impassable barrier to endosmosis.

Dr. E. L. H. McGinnis of New York, said that his experience with cataphoresis had been limited to three or four cases, and in these no definite results were obtained. He had tried it with cocaine on the positive pole, and applied to the vaginal vault, and to the skin. No effect had been produced on the latter, and a slight action was observed in the former case, which was attributed by him to the cocaine itself, irrespective of the action of the current.

Dr. Massey quoted the experiment of moistening the negative pole with a solution of iodide of potassium, and placing it on the back of an individual, and passing a current while the positive pole was placed to the breast, and so making the iodine transverse the body, just as it would a bowl of water. He was inclined to think we were mixing up electrolysis with mere cataphoresis.

The President remarked that this was the famous experiment made as far back as 1833, and repeated hundreds of times since then without success. He had himself repeated the experiment, but could not obtain any iodine at the positive pole. Undoubtedly, free iodine would be eliminated through the kidneys, and could be easily detected in the urine, but this was a very different matter.

Professor Houston, in closing the discussion, said that he had not known before that electro-therapeutists looked upon the ordinary action of the current as a cataphoric action, as he had never seen it so stated in any standard medical work. It is a well established fact, that there is a normal, and abnormal cataphoresis, and on this account, he was surprised that every now and then there should a discussion as to the difficulty of estimating the resistance of the human body; for, if cataphoric action takes place, the resistance must vary with the strength of the current upon which the cataphoric action depends, and moreover, it will be symmetrical. There is also a variation in the resistance due to electrical polarization, but this is asymmetrical. He had been asked if there was any peculiar effects existing in the intra-polar region at the surface of the membranous sacs in the human body. The current must necessarily cause an engorgement of some tissues, and a depletion of others. He could not agree with the president, that osmosis might be neglected in the study of the physics of electro-osmosis. The fact that in osmosis there is an unequal mixing, shows that there must be unquestionably a transportation of material from the negative to the positive pole, as well as from the positive to the negative, and for this reason, there does not seem to be any occasion for placing the material on both electrodes. He was not aware that any one had claimed to produce free iodine in the manner described by Dr. Massey, although this might be expected as all the phenomena of cataphoresis are dual phenomena. The fact that an electric current reverses the action of cataphoresis is no proof that the transportation is purely a mechanical one; indeed, he thought this fact showed how intimately electrical phenomena are associated with those of ordinary osmosis. The current produced by ordinary osmosis does not tend to help but rather to retard the passage of a liquid from the positive to the negative pole. It does not, therefore, seem possible to consider cataphoresis independently of osmosis, for apparently no osmotic current is produced without the development of an electric current.

FIRST DAY—OCT. 4.—EVENING SESSION.

STABLE ELECTRODE, OLD MATERIALS NEWLY ARRANGED.

By R. J. Nunn, M.D., 119 York St., Savannah, Ga.

The ingenuity of the students of electro-therapeutics has been so thoroughly exercised in looking for new materials for use as stable electrodes, that it would seem that a limit has been wellnigh reached and no new substance is likely to be proposed for that purpose. For that very reason, however, suggestions for the modification of some of the older forms, perchance for improvements in the methods of using old materials, may not be without profit and advantage.

Excluding from this discussion all forms of cauterizing electrodes, it will be observed that the one quality common to all electrodes used for conveying currents of high potentiality is moisture, and this is true of every variety from

clay to punk. It follows then that the true electrode is water.

From this it may reasonably be argued that the arrangement which will bring the largest amount of water in closest contact with the skin, and which is most convenient to handle, will be the form which will commend itself most to the working electro-therapeutist.

Without stopping to canvass the merits and demerits of many varieties (both of form and material), which from time to time have claimed the attention of the profession, let me here say that the simplest, handiest, most convenient and withal the most efficient material which has presented itself to me is cotton or linen cloth.

Of course this has been used by every operator, but it may not have been used in the manner about to be suggested.

Assuming that the quantity of fluid interposed between the surface of the body and the metal electrode has much to do with the distribution of the current over a large surface, it is my habit to employ such a number of pieces of the material used as will make a pad of an inch to an inch and a half in thickness when wet. If lint is used forty or fifty pieces will usually be found sufficient. Less will do with patients who are not very sensitive, but sometimes more may be used to advantage. It is hardly necessary to say that the pad may be a single mass or may be compounded of pads of different thicknesses.

The construction of this pad is simplicity itself.

A number of pieces of material—say lint—are cut of the size desired. These are sewed together by a single loose stitch in the center which keeps them in place. The stitch must not be tight or an indentation will be made in the pad, which is not desirable.

This pad may be used with or without a piece of chamois leather to insure closer contact with the skin.

Assuming the chamois to be employed, the first step will be to thoroughly moisten it and carefully apply it, avoiding wrinkles and air bubbles.

Over the chamois so applied a few layers of well wetted lint should be smoothly applied, and the remainder of the thickness desired is made up of moist lint.

It is well to have the first layer wringing wet, as more perfect contact is thereby assured.

If the pad is all in one it should be laid out flat, then soaked with hot water, the excess of water pressed (not wrung) out, and the contact surface sprinkled with sufficient water to make it quite wet. It is then applied to the part.

After the pad has been placed in position the metallic conductor is placed upon it, and the electrode is complete.

It may not be amiss to mention the well known fact that the size of the metallic plate has much to do with the distribution of the current. The plate should be pliable, so as to adapt itself uniformly to the pad, which, as is already well known, is a necessary condition if you would have the current evenly distributed over the surface.

Of whatever material the electrode is made, however carefully applied, it is, according to my experience, almost impossible to make perfect contact over large surfaces without recourse to additional pressure, and for this purpose it is my habit to use by preference a bandage. By its use and by firm pressure a much higher ampèreage can be borne than when the pressure is not employed.

The novel features which it is here desired to emphasize are:

1. The recognition of the fact that water is the true electrode.
2. The use of sufficient thickness of cotton or linen cloth to permit the even distribution of the current.

3. The thorough saturation of the layers of cloth in contact with the cuticle for the purpose of ensuring the best possible contact.

4. The employment of an animal membrane under the pad, designed to minimize the local action upon the cutaneous surface.

5. The use of pressure to obtain more perfect contact over the whole surface, and thus permit of using a greater ampèreage.

Discussion.

Dr. Massey said he had not yet found an electrode equal to clay, which, when properly wetted, adapts itself thoroughly to the surface to which it is applied, and requires no pressure to keep it closely in contact with that surface. If fine, white China clay be employed, it enters into the very crevices of the skin. Clay being alkaline, lessens the resistance of the electrode itself, even when of considerable thickness, and the alkalinity may be of possible utility in helping to saponify the oil contained in the cuticle. To be at its best, the clay should be made over fresh at least every morning, and more often if many cases are to be treated. The speaker said he had also obtained excellent results from the use of pads made of thin cheese-cloth with some elastic material, like cotton wool. Instead of a metal plate, he prefers a flat spiral of wire, the turns of which are about half an inch apart. This arrangement adapts itself to the electrode much more perfectly than any metal plate can possibly do. The most important point, is the use of soap on any electrode, and no matter how good the electrode, there will be less discomfort when it is covered with a good lather.

Dr. Mosher, of Brooklyn, said she wished once more to call attention to her Indian meal poultice electrode. The softer variety of meal is cooked, and then placed in a double cheese-cloth bag of the size of the metal plate to be used, and the meal, while quite warm, is placed on the abdomen, and allowed to remain there for several minutes before beginning the treatment, in order that the warmth and moisture may have time to act upon the skin, and render it a better conductor. The metal plate is then laid upon the back of the meal, and if more pressure is desired, this can conveniently be obtained by the use of a small sand-bag. Very high currents can be passed through this electrode with very little discomfort to the patient. When lighter currents only are used, she employed a pad of from four to ten layers of cotton flannel, placed evenly over the surface. The meal poultice applies itself even more closely than the clay to the surface, and patients who have both forms of electrode used on them, express a very decided preference for the meal electrode.

Dr. Anna Galbraith, of New York, said that a stable electrode similar to the one described in the paper had been in use for sometime past at the New York Orthopedic Dispensary. She preferred to wrap the wire gauze electrode in a number of pieces of linen, and this was pressed against the surface by means of a band of tennis belting, buckled tightly to the person. This belting was superior to chamois leather, as the latter shrunk, and became uneven. For the negative pole, she used cotton wrapped over the metal, and then covered with lint. The clay electrode while admirable in itself, was found not suited to dispensary practice.

Dr. Goelet thought he had solved the problem of furnishing a satisfactory clay electrode. The clay when the consistency of putty is first rolled into a flat cake, then covered with "lintine," which is compressed absorbent cotton, then covered with gauze, and backed with rubber. By thus covering the clay with cotton it does not soil the surface to which it is applied as does the unprotected clay. The neutral

plate, which consists of wire gauze, is placed on the back of the clay cake and the binding post penetrates its several layers of coating. After being thoroughly wetted, this pad is placed on a zinc vessel containing warm water. It can be easily cleansed by washing with soap, or if the covering becomes stained, it can be bleached with a solution of the peroxide of hydrogen.

Dr. Robinson, of Albany, preferred wire gauze, as it was neither too stiff, nor too flexible for easy manipulation. The wire gauze can be nickel-plated, and then kept in sheets ready for use. When wanted, it is covered with three or four thicknesses of flannel, and for strong currents, with cotton batting or "lintine." It was certainly the best electrode he had ever used where currents of moderate intensity only were required.

Dr. Roekwell said that after trying many kinds of electrodes, he had finally adopted the plan of keeping a large quantity of clay in a dish. The middle of the mass of clay was scooped out, and the hole filled with water. When an electrode is wanted, a sufficient quantity of clay is removed from the mass, and wrapped in a towel to remove superfluous moisture, after which, it is rolled to the proper size. With this electrode, he could always use a current of 75-100 milliamperes without causing pain. For still stronger currents, the clay should be enclosed in gauze or tarlatan, and in winter, it is desirable to keep the electrode on a warming pan, as suggested by Dr. Goelet.

Professor Houston asked if anyone had tried increasing the conductivity of the clay by mixing it with graphite.

Dr. W. T. Bishop said that the main object was to secure proper conductivity, and this was done by having the electrode moist; but it must be evenly moist, and of uniform thickness. As prepared by many operators, it varied greatly in thickness and consistency. Unless the metal plate is made to cover the entire surface there must be some points where the current is more dense than at others, and to that extent the efficiency of the electrode was destroyed. A thoroughly moist electrode consisting of clay mixed with graphite would probably cause the best diffusion of the current. Dr. Mosher's suggestion was also an admirable one.

Dr. Massey was not favorably impressed with the suggestion to add graphite, first, because it would make the electrode very dirty, and secondly, and more important, because one of the objects of a conducting joint between the metal and the skin is to modulate the passage of the current. Probably the most perfect electrode would be a piece of fresh meat, as we wish to transfer the current from the metal to the skin without too sudden a change in the resistance. The preparation of his clay electrode was delegated to the office nurse, who carefully kneaded the clay with her hands before making it into a pad of the required size. Mosquito netting was placed under the clay, and sometimes he placed on the top of the clay, instead of the spiral, a lead plate, cut in the shape of a Maltese cross. Where there are scratch-marks, or pimples on the skin that portion of the plate over there is raised a little.

Dr. Mosher said that she protected such sensitive spots, and very often, the navel also, by slipping a glass microscope slide underneath this part of the plate.

Dr. Dickson described an electrode which he was endeavoring to construct in such a way as to be free from the disadvantages connected with other electrodes. His idea was to use a large rubber cup filled with absorbent cotton moistened with some saline solution, and to make metallic connection by means of tin or lead cut in various shapes.

The President said that in the construction of an electrode it was important to remember that the removal of the point of metallic conduction from that of electrolytic con-

duction, diminishes the pain: A piece of fresh meat was probably the ideal electrode, as regards conductivity.

Professor Houston remarked that Dr. Dickson could easily have a metallic coating deposited on his flexible diaphragm.

Dr. Massey said this would be quickly destroyed when used as the external positive pole, and the metal would be carried into the patient's body. At one time, when experimenting with flexible plates, he had used a piece of Turkish toweling, thoroughly wetted, on which was placed a lead plate. This was used as a dorsal electrode on a case of alcoholic paralysis which he was treating at that time, and it was his custom to keep one such electrode for each patient. After some months of treatment, he was surprised to find that this electrode had been greatly diminished in size. Of course, a good deal of the metal was caught in the towel, but it was probable that an appreciable portion also found its way into the patient.

Dr. Nunn in closing the discussion, said that the sole object of his paper was to elicit a discussion on this important subject. He had found the electrode described in his paper, very well adapted for rapid office work. After trying various animal membranes, he had found chamois leather the best. The unhandiness of the clay, and the difficulty of getting it evenly mixed, had been well brought out in the discussion. Dr. Mosher's meal poultice was a capital idea. Electrodes of clay mixed with graphite had at one time been in the market, but he could not recall by whom they were manufactured. To protect scratch-marks, and other sensitive spots, he applied small bits of rubber tissue. The hollow electrode described by Dr. Dickson, is very similar to the one devised by Dr. Franklin Martin.

(To be continued.)

DOMESTIC CORRESPONDENCE.

The Code of Ethics.

To the Editor of the JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION:

For more than forty years the writer, from frequent perusal and constant familiarity with the "Code of Ethics" as originated by Percival and amended by the American Medical Association, has been led to regard it as the embodiment of the wisdom of the profession touching their relations to themselves and to their fellowmen; and he cannot but feel profound misgivings at the proposition now under discussion to abolish that time-honored instrument and to substitute therefore a so-called modernized code, adapted, it is alleged, to the assured needs of the profession, and conformed to the requirements of precision and brevity. Conciseness in a rule of action for the guidance and government of the busy multitude is a desideratum to be had at any cost short of obscurity, and this is especially true when the law is upheld by the authority of legislative enactment; but when its sanction rests solely on the consent of the governed, the *raison d'être* should be distinctly stated and not promulgated in the tone of autocratic dictation.

There are few men competent to form an opinion on the literary merits of a paper who, after careful and impartial reading of the Code, would not admit that as a specimen of English "pure and undefiled" it does honor to the scholarship of its authors. Its style is perspicuous without dogmatism, copious without redundancy and elegant without pedantry. Its tenets have no flavor of magisterial assumption but are formulated in reason and justice, so plainly set forth that the "wayfaring man, tho' a fool, need not err therein." The writer desires only to express his hearty approval and unqualified endorsement of "Conservative" in the ground he has so admirably maintained, in his contributions to THE JOURNAL of Dec. 10, 1892, and January 14, 1893.

A. N. TALLEY, M.D.

THE
Journal of the American Medical Association
PUBLISHED WEEKLY.

SUBSCRIPTION PRICE, INCLUDING POSTAGE:
PER ANNUM, IN ADVANCE \$5.00
SINGLE COPIES 10 CENTS.

Subscriptions may begin at any time and be sent to

THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION,
No. 68 WABASH AVE., CHICAGO, ILLINOIS.

All members of the Association should send their Annual Dues to the Treasurer, RICHARD J. DUNGLISON, M.D., Lock Box 1274, Philadelphia, Pa.

MEMBERSHIP IN THE AMERICAN MEDICAL ASSOCIATION.

This is obtainable, at any time, by a member of any State or local Medical Society which is entitled to send delegates to the Association. All that is necessary is for the applicant to write to the Treasurer of the Association, Dr. Richard J. Dunglison, Lock Box 1274, Philadelphia, Pa., sending him a certificate or statement that he is in good standing in his own Society, signed by the President and Secretary of said Society, with five dollars for annual dues and subscription for THE JOURNAL. Attendance as a delegate at an annual meeting of the Association is not necessary to obtain membership. On receipt of the above amount the weekly JOURNAL of the Association will be forwarded regularly.

SATURDAY, FEBRUARY 25, 1893.

TUBERCULOSIS OF THE FEMALE GENERATIVE
ORGANS.

The Johns Hopkins Hospital Reports, Vol. III, Nos. 1, 2, 3, contains an article by DR. J. WHITRIDGE WILLIAMS, in which the subject of tuberculosis of the generative organs of woman is presented in its entirety. There are many points of interest to all physicians brought out by this thorough study and among them we would refer especially to the undoubted frequency of genital tuberculosis which appears to be far greater than was ever suspected and the disease consequently deserves more practical attention on the part of the gynecologists. DR. WILLIAMS found genital tuberculosis seven times in ninety-one cases in which the tubes and ovaries were removed for purulent process or for adhesions; in other words, genital tuberculosis may be expected to occur in about one out of every twelve operations for the removal of tubes and ovaries the seat of past or present inflammatory disease; in only two out of the seven cases was the disease recognized at the time of the operation, so that in 70 per cent. of these cases the disease would have escaped observation were it not for the routine examination practised with the microscope; it will consequently become evident that up to this time most of the statements as to the frequency of genital tuberculosis represent only one quarter of the actual number of cases, the other three quarters having previously escaped attention. The order of frequency for the various portions of the genital tract is as follows: tubes, uterus, ovaries, vagina, cervix, and vulva; for obvious reasons a definite, numerical statement as to the actual comparative frequency in these various parts cannot yet be made.

There are also certain points in the etiology of female genital tuberculosis to which the observations and literary researches of DR. WILLIAMS call particular and emphatic attention. He shows that generally speaking tubercle bacilli may gain entrance to the

genital tract in three ways: 1. From areas of tuberculosis already existing in the patient; 2. from the outer world by direct infection; and 3. by bacilli from the excretions of tuberculous patients invading the genital tract as in cases of tuberculosis of the urinary organs or intestines. With reference to the first mode of infection mentioned, the following general statement summarizes fairly well what is said on that point: The majority of cases of female genital tuberculosis are secondary to tuberculosis elsewhere in the body, and are due either to infection from the blood or from neighboring organs.

The question as to direct infection from the outer world is one of great interest. Tubercle bacilli are universally distributed and they may gain access into the vagina in a multitude of ways: by the examining finger, the use of dirty instruments, of foul syringes, of unclean linen, and in many other ways, but particularly by coitus with men affected with various forms of uro-genital tuberculosis. The frequency of this disease in all parts of the genito-urinary tract in men suggests opportunity for infection; and from the investigations of JANÉ we have a right to believe that in some instances phthisical men might introduce bacilli into the vagina without any tubercular lesions of their genitals. In spite of numerous reported cases of suspected infection by coitus, its occurrence cannot as yet be considered as proven by scientific methods, and scientific proof is manifestly very difficult to bring forward in this instance because the possibility of infection from the blood can never be positively excluded. Owing to the resistant structure of the healthy vagina and the cervix, and to the periodical menstrual exfoliation of the uterine mucosa, we would naturally not expect the disease to develop in these parts as readily as it would in the tubes, to which the bacilli might be carried by the lymphatics from vaginal abrasions or directly through the uterus. Such reasoning as this would serve to explain why the tubes are so much more frequently affected than the uterus, even in primary cases. The occurrence of infection by coitus, though not conclusively demonstrated as yet, is nevertheless very probable, and, of course, if infection in this way holds good for women, it also applies to men, and the family physician should consequently prohibit coitus between persons, one of whom has genito-urinary tuberculosis. DR. WILLIAMS also considers fully the clinical history, the diagnosis, and the treatment of tuberculosis of the female genital organs, and we feel sure that his excellent presentation of this interesting subject in all its aspects will do much good because it will rescue the study of female genital tuberculosis from the neglect at the hands of gynecologists, writers, and teachers into which it appears to have fallen on account of the supposed rarity of its occurrence.

RITUALISTIC CIRCUMCISION.

At a meeting of the Berlin Dermatological Society in 1892, DR. LEWIN spoke on the subject of ritualistic circumcision and its therapeutic indications. He stated that the prepuce is not a very favorable ground for infection, being thick, elastic, and not easily torn; as it contains parallel muscular and some elastic fibres, it is mobile and extensible to double its volume. It has neither sudoriparous glands or hair, and its sebaceous glands serve to maintain the suppleness of the skin. Being of inconsiderable volume, ulcers do not penetrate it deeply, and it is rarely the seat of a gangrene for which it need be amputated, and any mode of treatment may be employed for its diseases.

The other portions of the penis are less favorably formed for treatment; the glans, containing few elastic fibres, is neither mobile or extensible, and ulcers occurring therein are prone to pursue a destructive course. The retro-glandular furrow is easily torn or fissured, the numerous sebaceous glands opening therein form reservoirs for the retention of the secretion, and sixty per cent. of the cases of ulcer that are situated on this portion of the penis are followed by buboes. The frenum is less favorable for the development of ulcers, but it is easily torn.

If the prepuce is amputated the glands of TYSON dry up, the fat of the internal surface is lost and a resistant cicatrix remains.

In no part of the Bible is circumcision referred to as a sanitary procedure, nor was that suggestion of its desirability made until a much later epoch than that of the writing of the Scriptures. In the beginning, circumcision was nothing more than a legacy from the heathen cult of Moloch.

In a thousand cases of ulcer of penis treated by LEWIN at the Berlin Charité, almost fifty per cent. were on the prepuce, nineteen per cent. on the glans, fifteen per cent. on the corona, nine per cent. at the meatus, and the remainder on various portions of the penis.

DR. SAALFIELD believed that LEWIN'S statistics showed that the prepuce was a *locus minoris resistentiæ*; besides erosions thereon, the accumulation of smegma favored balanitis, and both these predisposed to infection.

DR. ROSENTHAL remarked that as in erection the prepuce was retracted and everted, the other portions of the penis being uncovered as well, the least resistant portions would be affected. It would therefore be interesting to know what proportion of venereal ulcers occurred on the internal surface of the prepuce.

To these criticisms LEWIN replied that the internal surface was often affected because it projected somewhat during erection; but the reason that the prepuce was so often the seat of venereal ulcers was because

infection occurred during coitus from lesions most frequently located on the labia majora and minora and not on the cervix uteri. The statistics he gives seem to show that the prepuce is a rather favorable ground for infection, though if evidence could be obtained regarding the site of lesions in an equal number of circumcised and uncircumcised persons, it would be possible to judge more definitely regarding the value of circumcision as a prophylactic operation.

From a religious standpoint it is a relic of barbarism, and from a medical standpoint PROFESSOR MASTIN has shown the unfortunate anatomical changes it induces, while the physician must remember that for him to recommend it from a prophylactic standpoint is tantamount to advising illicit and promiscuous sexual relations.

CHOREA.

The *questio revata* as to the pathology of chorea appears to receive a satisfactory solution in the admirable clinical lecture of PROFESSOR H. C. WOOD, of Philadelphia, appearing in another column, which has been reported exclusively for THE JOURNAL; and which we do not doubt will be fully appreciated by our readers. Hitherto, the important physiological function of inhibition, which BROWN-SEQUARD cited so effectually in support of his theory of the causation of cerebral convulsions and paralysis, has been entirely overlooked in studying the pathology of spinal affections. This is the more remarkable since the fact of the independent action of the spinal cord as a reflex centre has been known since the days of MAGENDIE and JOHN HUNTER. Up to the present time, however, DR. WOOD'S theory is the first application of this well known physiological observation to explain the phenomena of functional nervous disease. As DR. WOOD has pointed out, this explanation will apply in hysteria as well as in chorea, neither of which is attended by increased motorial excitement in reality, but by decreased inhibition. The form of chorea due to disease of the cortical motor centres in the brain, of which the lecturer gives a good illustration, is, properly speaking, no chorea at all, but is merely a symptom of cerebral disease, and is analogous as a symptom to the muscular motions of paralysis agitans or post-paralytic tremor. The disease known as chorea, or St. Vitus' dance, appears to be spinal in its origin, and therefore may be, and very probably is, due to deficient inhibition and overflow of motor impulses. If time shall confirm this theory, which is certainly logical, and so far has been supported both by experiment and clinical observation, we shall have to congratulate PROFESSOR WOOD upon his valuable discovery, and our readers upon receiving its first public announcement in medical literature.

THE AMŒBA COLI: ITS RELATION TO DYSENTERY AND TROPICAL SUPPURATIVE HEPATITIS.

In the *Indian Medical Gazette*, for November, 1892. SURGEON-CAPTAIN PATRICK HEHIR, of Hyderabad, gives the results of some of his studies on the organisms found in tropical dysentery and hepatic abscess. He is particularly fortunate in being located in a region in which these affections are very prevalent. As causes of the epidemic of dysentery which he observed he mentions 1. The amœba coli; 2. Malaria; 3. Exposure to sudden vicissitudes of temperature; 4. Putrefaction of animal matter, especially that of human ordure; 5. Infection from other cases of dysentery; 6. Mechanical and other engorgement; and 8. *Bacillus dysentericus*. In the evacuation of dysenteric patients the amœba coli was found frequently, but not invariably; and it was also found in other bowel affections, as the mucus enteritis of infants, simple diarrhœa, and in some cases of catarrhal inflammation of the rectum, due to engorgement. The *bacillus dysentericus* found by HEHIR, and considered pathogenic, was found associated with the amœba coli, and is described as a short, straight bacillus, usually of a length about equal to one-third the diameter of a red blood corpuscle, with rounded ends sometimes jointed, rarely curved. These bacilli were sometimes present in vast numbers. They were sometimes found in the substance of an amœba coli, and when lying in the vacuoles of the amœba they could be easily seen. They stained well with methyl blue. No culture experiments with this microbe are recorded. This bacilli was often found in the pus of liver abscesses; but in four cases in which he was able to demonstrate the amœba coli in aspirated peritoneal fluid, HEHIR failed to find his *bacillus dysentericus*.

Since he has succeeded in demonstrating the amœba coli in the peritoneal effusion of suppurative hepatitis following dysentery; HEHIR is strongly in favor of the views of COUNCILMAN, who maintains that one mode of liver infection from dysentery is brought about by the amœba passing through the walls of the diseased bowel, and across the peritoneal cavity to the liver. In fact, he believes that this direct infection is the chief importance in the production of liver abscess of amoebic dysentery, rather than the infection by means of emboli along the blood or lymph streams.

THE PERSONNEL OF STATE MEDICAL EXAMINING BOARDS.

It is with pleasure that we notice the attempt at medical legislation in the different States and that the excellent Minnesota law is taken as the basis, as it has proven itself exceptionally effective.

Several legislatures have before them bills closely following the lines mapped out in Minnesota. We

read with regret however, that there is much opposition in certain quarters in reference to the composition of the board. After much thoughtful consideration, at the time of the passage of the Minnesota statute, it was deemed expedient to make the board entirely free from the influence of any medical school. It, therefore, made any member of a medical faculty ineligible to membership on the Board of Medical Examiners. Time has proven the wisdom of the framers of the law, in insisting on this provision. We would strongly urge that this provision be included in all the statutes, and trust that in further reflection the opposition to this proviso will cease.

It is undeniable that a board with no member of any medical faculty should be non-partisan. There can be no reason for a bias in favor of any school. Such a board will also have less occasion for friction. The profession at large will have more confidence in such a board and last but not least the general public will have less occasion for twitting us with attempting class legislation if they can be assured that it is wholly non-partisan.

The membership of these boards is of vital importance to the successful working of the law, secondary only to the provisions of the law itself. It should be a matter of profound regret, if, after success in the passage of a law, its provisions should be partially nullified by a non-harmonious board.

A wholly disinterested board except as to the personal qualifications of each candidate—a board which has no interest in the record made by the graduates of any particular school or medical college—such a board, we maintain is a desideratum. A board constituted in any other manner, we fear, will jeopardize success. The more one studies the question, the more confident one becomes, that the greatest factor in the successful execution of these medical laws is the entire divorcing of Examining Boards from any and all medical schools.

PAN-AMERICAN MEDICAL CONGRESS, SECTION OF MILITARY MEDICINE AND SURGERY.—The following gentlemen have been duly appointed members of the Advisory Council of this Section: Col. Louis Read, M.D., Surgeon-General N. G., Pa.; Newton L. Bates, M.D., Medical Director U. S. N.; J. H. Tryon, M.D., Medical Inspector U. S. N.; Lieut.-Col. Eustathius Chancellor, M.D., Medical Director N. G., Mo.; Bryt Lieut.-Col. A. A. Woodhull, M.D., Surgeon U. S. A.; Major Jos. H. Corson, M.D., Surgeon U. S. A.; Major Geo. Henderson, M.D., Medical Director N. G., D. C.; C. N. Hoagland, M.D., Ex-Surgeon Ohio Vols.; Bedford Brown, M.D., Ex-Surgeon C. S. A.; H. C. Goodman, M.D., Ex-Surgeon U. S. Vols.; Melancthon Storrs, M.D., Ex-Surgeon Conn. Vols.; O. D. Ball, M.D., Pension Ex-Surgeon, Albany, N. Y.; Capt. H. O. Perley, M.D., Asst. Surgeon U. S. A.

GEO. M. STERNBERG,

Deputy Surgeon-General U. S. A., Pres. of Section.

A BOARD of officers will be convened at Washington, March 30, 1893, for the purpose of examining applicants for admission to the grade of Assistant Surgeon in the U. S. Marine-Hospital Service.

Candidates must be between twenty-one and thirty years of age, graduates of a respectable medical college, and must furnish testimonials from responsible persons as to character.

The following is the usual order of the examination: 1, physical; 2, written; 3, oral; 4, clinical.

In addition to the physical examination candidates are required to certify that they believe themselves free from any ailment which would disqualify them for service in any climate.

The examinations are chiefly in writing, and begin with a short autobiography by the candidate. The remainder of the written exercise consists in examination on the various branches of medicine, surgery and hygiene.

The oral examination includes subjects of preliminary education, history, literature, and natural sciences.

The clinical examination is conducted at a hospital, and where practicable candidates are required to perform surgical operations on the cadaver.

Successful candidates will be numbered according to their attainments on examination, and will be commissioned in the same order, as vacancies occur.

Upon appointment the young officers are as a rule first assigned to duty at one of the large marine-hospitals, as at Boston, New York, New Orleans, Chicago or San Francisco.

After four years' service, Assistant Surgeons are entitled to examination for promotion to the grade of Passed Assistant Surgeon.

Promotion to the grade of Surgeon is made according to seniority, and after due examination as vacancies occur in that grade. Assistant Surgeons receive sixteen hundred dollars, Passed Assistant Surgeons eighteen hundred dollars, and Surgeons twenty-five hundred dollars a year. When quarters are not provided, commutation at the rate of thirty, forty, or fifty dollars a month, according to grade, is allowed.

All grades above that of Assistant Surgeon receive longevity pay, 10 per centum in addition to the regular salary for every five years' service up to 40 per centum after twenty years' service.

The tenure of office is permanent. Officers traveling under orders are allowed actual expenses. For further information, or for invitation to appear before the board of examiners, address:

WALTER WYMAN,
Supervising Surgeon-General,

U. S. Marine-Hospital Service, Washington, D. C.

GERMANY AND THE PAN-AMERICAN MEDICAL CONGRESS.

AN OPEN LETTER FROM PROFESSOR CZERNY, OF HEIDELBERG, AND REPLY BY SECRETARY-GENERAL REED.

(Translated from *Deutsche Medicinische Wochenschrift*, Jan. 12, 1893, p. 47.)

AN OPEN LETTER

TO CLAUDIUS H. MASTIN, M.D., LL.D., Mobile, Ala., President of the American Surgical Association, in reference to the Pan-American Medical Congress:

Honored Sir and Colleague.—You were kind enough to extend to me, December 3, 1892, a personal invitation to attend the Pan-American Medical Congress, to be held at Washington, September 5 to 8, 1893. According to the preliminary announcement, and to your communications, the Congress, in connection with the Columbian exposition at Chicago, will offer so many attractions that I exceedingly regret not to be able to accept so amiable an invitation extended to me by one of the most prominent members of the body of American physicians.

As the reasons which prevent me from attending might be of interest to the German physicians, you will certainly pardon my desire to make these reasons more generally known in this manner.

At the first glance, one might have been impressed with the idea that the Pan-American Congress was intended to be a rival to the long-prepared International Medical Congress, which is to be held at Rome, from September 24 to October 1, 1893. However, as at the former international expositions, almost always contemporary medical and scientific congresses took place, it appears but just that the American physicians should also avail themselves of the opportunity of meeting on their own continent. But since the physicians of all civilized countries are united in the humane endeavor to rather mitigate than to increase difficulties between nations and continents, where such exist, I, therefore, think any intention to injure the International Congress by the Pan-American, must be entirely excluded.

Perhaps the meeting of the International Congress might be postponed eight days, which, for several reasons, would be more desirable. With earnest intentions and favorable weather, it ought to be possible to make the trip, with the modern fast steamers, from Washington to Rome, from September 9 to September 23. *It would not be a bad idea if those members who desire to make the journey would do so jointly, directly from Washington to Rome, on a steamer chartered expressly for that purpose, in order to bring the greetings of the rising capital of the promising West to the old Metropolis of European civilization.*

A more serious consideration to visit the Pan-American Congress is entertained by me regarding the question of languages. In section 9 of your programme it says: "The language of the Congress shall be Spanish, French, Portuguese and English." The German language is probably excluded because it is nowhere official language in America. If this consideration should have prevailed, then the Dutch and Danish languages ought to have been permitted, since these languages are in official use in America. Be this as it may, *I do not think that the physicians of Germany can take part in the proceedings of the Pan-American Medical Congress, if they are not permitted to read their papers in German, while any other language but the English is admitted at the Congress. It must be remembered that also at the International Congress "Remarks are permitted in any other language, if any of the members are willing to translate them into one of the four official languages."*

I shall not mention the work done continually for the science of medicine in the German language, but I desire to refer to the great number of prominent American physicians who have received the best part of their education in German schools; and to the numerous German physicians who practice with success in America, and who have added so much to the great reputation in which American medical literature is at present held in the whole world. Indeed, I am inclined to believe that North and South American physicians will frequently be able to communicate with each other in the German language, learned by them in our universities. If I am not mistaken in this, I certainly think that the Executive Committee of the Pan-American Medical Congress should pass a resolution which would enable German physicians to visit the Congress, provided a participation on our part is at all desired.

I shall be exceedingly gratified if my suggestions should find favor on the other side of the ocean; and if I should be thus enabled, dear Sir and colleague, to personally enter into friendly relations with you in Washington.

With best wishes and compliments of the season, I am,

Yours respectfully,
DR. CZERNY,

Honorary Member of the American Surgical Association,
HEIDELBERG, December 28, 1892.

(REPLY.)

THE PAN-AMERICAN MEDICAL CONGRESS,
Office of the Secretary-General,
311 Elm Street.

CINCINNATI, February 14, 1893.

PROFESSOR V. CZERNY, Heidelberg:

My Dear Doctor.—My distinguished colleague, Dr. C. H. Mastin, has referred to me for official reply your open letter addressed to him and published in the *Deutsche Medicinische Wochenschrift*, for January 12, of this year.

A careful reading of your valued communication leads me to the conclusion that you in common with other distinguished German *savants*, hesitate in accepting an invitation to attend the Pan-American Congress I, because the

German profession is not officially invited by the Executive Committee to become a constituent part of the Congress; 2, because the German language is not one of the official languages of the Congress, and 3, because a general participation on the part of yourself and conferees might be construed into disloyalty to the International Medical Congress which is to meet in Rome, in the same month.

In reply I beg to state, that the occasion for holding a medical Congress in the United States in 1893, is the fact that a large number of physicians will be in this country in attendance upon the World's Columbian Exposition. This attendance will be largely, although not by any means exclusively, from the countries of the Western Hemisphere. It would have been very desirable indeed, to have arranged an organization which would have embraced all the countries of the world. The medical profession of the United States, however, acknowledges allegiance to the World's International Congress which is to meet in Rome. To have attempted an organization in Germany or any other European countries in the interest of the American meeting, would have been in violation of our loyalty to the International Congress, while an official invitation to the government and medical societies of Germany and other European countries to send delegates to the Washington meeting would have been almost inimical to the interests of the Rome Congress. It was, therefore, resolved that the organization should be limited to the American countries, and that while it was desirable to secure the attendance of our distinguished conferees from Europe as guests, invitations to that end should be strictly personal in character, and should be issued by the general officers and presidents of sections, at their discretion.

The languages chiefly spoken by the various constituent countries of the Congress are Spanish, Portuguese, and English, and these were accordingly selected by the Committee as the official languages of the Congress. French, which the language of important colonies and communities, was subsequently added, at the instance of our conferees in Brazil, who employ it largely in scientific communication, as, indeed, do a large proportion of the physicians of both the English and Spanish-speaking countries. Danish and Dutch are not included, simply for the reason that it is extremely, indeed, practically impossible, to deal with them satisfactorily in a literary way in this country. It was hoped that delegates from countries and colonies speaking other than Spanish, Portuguese, English and French, would furnish their remarks on papers in one of the official languages. This was so thoroughly understood by the committee and has become such a well established usage at international congresses, that it was not deemed necessary to state it explicitly; but I shall communicate the suggestion which you kindly make to the Executive Committee, when I have no doubt it will be made definite in the By-Laws.

As early as December, 1891, I opened correspondence by telegraph with the President of the XI International Congress, and subsequently with Professor Maragliano, of Genoa, the Secretary-General, asking that the date of the Rome meeting be arranged so as to permit us to send delegates from Washington. The date of the International Congress was accordingly changed from the 17th to the 24th of September, which will give us sixteen days in which to go from Washington to Rome. Arrangements were begun in February of last year for a special sailing of a steamer September 9th, direct to Italy, by way of the Azores and Gibraltar to take those desiring to attend the Rome meeting, a special reduced rate being accorded for the occasion. My present correspondence indicates that a large number will avail themselves of this privilege. It is highly gratifying to note that the expediency of this plan has occurred quite independently to one so conversant with affairs as yourself.

Permit me to say in conclusion that our European conferees who may honor the Pan-American Medical Congress with their presence will be accorded every linguistic privilege, that arrangements have already been made for their return to Italy in time for the International Congress, and that in the event of their coming they will be greeted with a most cordial American welcome.

Very sincerely yours,

CHARLES A. L. REED,
Secretary-General P. A. M. C.

Approved:

WILLIAM PEPPER, President.

CLAUDIUS H. MASTIN, Member of the Board of Trustees.

NECROLOGY.

W. W. Dawson, M. D.

It is our mournful duty to record the death in Cincinnati, Feb. 16, of Dr. William W. Dawson, a Trustee of and Ex-president of the American Medical Association.

Born in Berkeley County, Virginia, Dec. 19, 1828. While a child his parents moved to Green Co., Ohio, where he received a good classical education. Later he became a student of medicine in the office of an elder brother, the late Dr. John Dawson, and attended lectures in the Medical College of Ohio, where he graduated in 1850. He served one year in the Commercial Hospital as an interne, and two years after leaving the hospital was chosen professor of Anatomy in the Cincinnati College of Medicine and Surgery, holding this position for three years. From 1860 to 1864 inclusive, he occupied the chair of Anatomy in the Medical College of Ohio. From 1864 to 1870, he as a member of the surgical staff lectured on clinical surgery in the Cincinnati Hospital, and in 1870, was chosen professor of surgery in the Medical College of Ohio, lecturing there until 1884, when he resigned the didactic part of his professorship, and continued his clinical lectures until the beginning of his fatal illness.

In 1869, Dr. Dawson was elected president of the Cincinnati Academy of Medicine, and two years later president of the Ohio State Medical Society. In 1871, he was appointed surgeon to the Good Samaritan Hospital. During all his professional life he enjoyed a large and remunerative practice, and in 1888, as a crowning glory of his professional career, he was elected president of the American Medical Association. The succeeding winter he suffered from a severe attack of the gripe, and had a number of relapses. Those who were present at the Newport meeting of The American Medical Association will remember his affliction at that time, and when those who were intimate with him prognosticated the fatal termination which has just taken place.

Dr. Dawson was much more than a good surgical operator, his diagnostic ability and knowledge of pathology was not excelled in his day. His loving kindness to those who sought his services will never be forgotten. His generosity and open hearted hospitality was without bounds. While on all occasions he was the highest type of nobility in his profession. Courteous to all and the very soul of honor. No man ever feared professional poaching or unfair treatment from Dr. W. W. Dawson. His personal friends were almost as numerous as the inhabitants of his city. He was truly one of Nature's most loveable noblemen. We ne'er shall see or know his like again.

Dr. James Bell.

Dr. James Bell, an ex-president of the Kansas Medical Society, member of the American Medical Association and of the Ninth International Congress, died at his home in Olathe, Kansas, Jan. 13, 1893.

Dr. Bell was born in Washington, Pa., in 1826, of Scotch-Irish ancestors. In his early life his parents moved on a farm in Mahoning Co., Ohio, where, while yet a youth, his mother was left a widow with 18 children. With the pluck of his race he assisted in raising the family, obtained a fair education, and when 28 years old graduated at the medical department of the Western Reserve University, and commenced practice at New Concord, O., where he continued until 1869, meanwhile spending a winter in Philadelphia and graduating from Jefferson in 1864.

In 1869 he moved to Olathe, Kansas, where he remained in practice to the time of his death. He was twice married

and leaves a widow and four children. The doctor was a Scotch Presbyterian and sufficiently tenacious of his views, both medical and religious, to become a martyr or to make martyrs, but during his last illness, which was quite prolonged, from yellow atrophy of the liver, he adopted that broader charity that forgives as it would be forgiven, and accords to others what it reserves to itself, the right of individual belief, and died at peace with God and man, and in the hope of a glorious immortality.

DR. WILLIAM B. DAVIS, of Cincinnati, died at his home in that city February 16. The cause of death being a heart lesion superinduced by an attack of grippe two years ago. Dr. Davis was born in Cincinnati July 2, 1832, his academic education was obtained at Woodward and Delaware Colleges, and his professional courses were taken at the Miami and Ohio Medical Colleges. During the War he served for a brief period as surgeon of the 137th, O. V. I. Reg., after which he spent some time in Europe. On his return he was elected Professor of Materia Medica in the Miami Medical College. This chair he held for a number of years.

Dr. Davis was the author of many papers which were read before the local medical societies, the Ohio State Medical and the American Medical Association. His two last contributions were read at late meetings of the latter body and on the subject of albuminuria in its relation to renal affections, attracting unusual attention.

Dr. Davis was a man of much public spirit, serving his city as a member of the Board of Education, as one of the founders of the Public Library and Director of the Cincinnati University. From its organization he was one of the Medical Directors of the Union Central Life Insurance Company. From childhood he was an active member of the Methodist Episcopal Church, and to which he contributed largely of his means. Dr. Davis was a highly esteemed and influential citizen, a cherished and true friend, a beloved physician, and typical Christian gentleman.

BOOK REVIEWS.

THE MODERN ANTIPYRETICS; THEIR ACTION IN HEALTH AND DISEASE. By ISAAC OTT, M.D. Second Edition. Paper. Easton, Pa.: E. D. Vogel. 1892.

The large amount of valuable information incorporated in this little volume of 125 pages deserves a better dress than is afforded in its present unpretentious and modest form.

The author's contributions to this branch of pharmacological investigation are well known, and give increased importance to his views. The work is subdivided under the heads: Heat, Thermotaxic Apparatus, Cortical Thermotaxic Centers, Heat Production in Normal and Febrile State, Fever, Physiological and Pathological Action (of antipyretics), Chemistry and Therapeutics of the Modern Antipyretics, with a closing chapter on the Value of Antithermics in Typhoid Fever. It will here be seen that the subject is discussed in a scientific and logical manner, and with the author's rich experience as an experimental physiologist, the work assumes a very practical character.

Now that so many new antipyretic agents become available, it certainly behoves the thoughtful physician to inquire into the chemistry and pharmacology of his favorite antithermic drug. He will find a concise and practical summary of the subject in this little book. Then too, the experimental physiologist and pharmacologist will find much valuable data between the unassuming covers of Dr. Ott's work.

MISCELLANY.

THE GOVERNMENT OF VENEZUELA AND THE PAN-AMERICAN MEDICAL CONGRESS.—Señor P. Ezequiel Rojas, the Venezuelan Minister of Foreign Affairs, has forwarded on behalf of his government through the U. S. *Chargé d'Affaires* at Caracas, a formal acceptance of the invitation issued pursuant to the joint resolution of the United States Congress to the various governments of the Western Hemisphere to send official delegates to the Pan-American Medical Congress. The selection of delegates has not yet been made, but the names will be forwarded at the earliest possible moment.

COMMENCEMENT OF THE MEHARRY COLLEGE.—The seventeenth annual commencement of the Meharry Medical Department, of Central Tennessee College, Nashville, Tenn., was held at the Gospel Tabernacle, Feb. 7, in the presence of an audience of more than three thousand people. There were thirty-six graduates in Medicine, two in Dentistry, and six in Pharmacy.

During the past session one hundred and twenty students in medicine, seven in dentistry and twenty-one in pharmacy were enrolled.

About one-half of the educated colored physicians of the Southern States are graduates of this institution.

THE forty-second annual session of the Iowa State Medical Society will be held at Burlington, Iowa, Wednesday, Thursday and Friday, May 17, 18 and 19, 1893.

OFFICIAL LIST OF CHANGES in the Stations and Duties of Officers Serving in the Medical Department, U. S. Army, from February 11, 1893, to February 17, 1893.

First Lieut. Isaac P. Ware, Asst. Surgeon U. S. A., is granted leave of absence for one month.

Col. Joseph Smith, Asst. Surgeon-General U. S. A., is granted two months' leave, with permission to leave the United States.

Major J. V. D. Middleton, Surgeon, will in addition to present duties as post surgeon of the Presidio of San Francisco, Cal., perform the duties of Medical Director Dept. of California, during the absence of Col. Joseph R. Smith, Asst. Surgeon-General U. S. A.

First Lieut. Frederick P. Reynolds, Asst. Surgeon, is relieved from duty at Ft. Monroe, Va., and assigned to duty at West Point, N. Y. Par. 1, 2 and 4 of S. O. 34, A. G. O., February 14, 1893.

Capt. Eugene L. Swift, Asst. Surgeon U. S. A., the suspension of the order assigning him to Ft. Yates, N. Dak., is removed.

A board of medical officers, to consist of Col. Charles H. Alden, Asst. Surgeon-General U. S. A.; Lieut.-Col. George M. Sternberg, Deputy Surgeon-General U. S. A.; Major John Van R. Hoff, Surgeon U. S. A.; Capt. Guy L. Edie, Asst. Surgeon U. S. A., is constituted to meet in New York City on the 27th day of March, 1893, or as soon thereafter as practicable, for the examination of candidates for admission to the Medical Corps of the Army, and for such other business as may be brought before it.

First Lieut. Charles Willeox, Asst. Surgeon, is granted leave of absence for one month, with permission to apply for an extension of one month.

OFFICIAL LIST OF CHANGES in the Medical Corps of the U. S. Navy, for the Week Ending February 11, 1893.

Asst. Surgeon B. R. Ward, ordered to training ship "Richmond."

Surgeon George F. Winslow, ordered to the U. S. S. "Monterey."

P. A. Surgeon W. F. Arnold, ordered to the U. S. S. "Monterey."

Asst. Surgeon L. L. von Wedekind, ordered to examination preliminary to promotion.

Asst. Surgeon Geo. A. Lung, ordered to examination preliminary to promotion.

ORIGINAL ARTICLES.

EXPERIMENTAL UNION OF THE URETER AFTER TRANSVERSE DIVISION.

BY WELLER VAN HOOK, A.B., M.D.,
OF CHICAGO.

[*Preliminary Contribution.*]

Hitherto experimental surgery has not supplied the practitioner with a method by which the continuity of the ureter, when completely divided by transverse injury, could be restored. The brilliant case reported recently in full by Kuester,¹ in which the upper end of the ureter—the infundibuliform

versely divided ureter when that injury occurs below the infundibulum. The experiments of Th. Tuffier,² who endeavored to accomplish this object by the application of sutures, are discouraging in the extreme. For even when union took place, the resulting scar contraction of course obliterated the lumen of the duct.

To obviate the necessity of making a line of sutures around so narrow a tube, the writer put in practice the following plan: The ureter of a medium-sized dog having been exposed and isolated at a point one inch above the entrance of the ureter into the bladder, the duct was cut across with scissors, and one-half inch of its extent cut out and discarded. The free end of the lower portion of the ureter was then closed by a ligature near the point of severance. Next a longitudinal slit about three-eighths of an inch long was made in the side of this portion of the

FIG. 1.

portion—was excised to relieve obstruction, has been exceeded in ingenuity of conception by the work of Prof. Christian Fenger, in two cases reported at the meeting of the Chicago Medical Society held February 6, 1893. But these cases offer no suggestions to aid in the effort to unite the ends of the trans-

FIG. 2.

verse, about one-fourth of an inch below the ligature. A suture was passed through the wall of the upper fragment of the ureter, the opening of which had been enlarged slightly with the scissors. The point of the needle with which the suture was armed was passed through the slit in the lower portion of the ureter, and carried down the lumen of the tube for a half inch, then pushed through its wall. By gentle traction the upper piece of the ureter was then invaginated into the lower portion, and held there by fastening the suture to the outer layer of the wall of the tube. Two delicate sutures were then passed at the ends of the slit in the wall of the lower portion, to favor rapid union, and the whole site of operation upon the ureter was carefully covered by a fold of the abundant omentum.

¹ Langenbeck's Arch., Bd. 44, S. 850.

² Étude Experimentales sur la Chirurgie du Rein, Paris, 1889.

The dog recovered with no ill effects whatever, and was killed twenty-six days afterward. There were no adhesions in the peritoneal cavity, except where the omentum had been sewed down. There was complete permeability of both ureters, as shown by the probe passing in Figure 1, through the ureters into the bladder. Upon laying open the right ureter, which had been the subject of operation, the mucous membrane was seen to be continuous, perfectly healed at the point of junction, and presenting no diminution of caliber. This lack of stricture formation was to be expected from the fact that the line of primary union was necessarily an oval, not a circle, corresponding to the shape of the slit as distended by the invaginating end of the ureter. The line of scar tissue must thus necessarily be long enough to more than accommodate the lumen of the ureter. The fact that one portion of the tube must enter the lumen of the other tube, does not constitute an objection to the method, since the lumen of the tube can be enormously increased by stretching, without prejudice to the integrity of its walls.

Figure 2 shows the right ureter laid open from a point one inch above the line of union to the cystic end of the ureter. Around the ureter is the piece of omentum used as a covering to the wounded surfaces. The left ureter appears smaller, because somewhat dried at the time the photograph was made.

As the method has been successful in the dog, it is to be expected that in man it will be more easy of application, since in the human subject the ureters are larger and more easy of access.

HIP DISEASE.

BY JOHN RIDLON, M.A., M.D.,

LECTURER ON ORTHOPEDIC SURGERY IN THE NORTHWESTERN UNIVERSITY MEDICAL SCHOOL; PROFESSOR OF ORTHOPEDIC SURGERY IN THE POST-GRADUATE MEDICAL SCHOOL, CHICAGO; SECRETARY OF THE AMERICAN ORTHOPEDIC ASSOCIATION; ATTENDING ORTHOPEDIC SURGEON TO ST. LUKE'S FREE HOSPITAL, CHICAGO,

AND ROBERT JONES, F. R. C. S., E.,

HONORARY SURGEON ROYAL SOUTHERN HOSPITAL, LIVERPOOL; CORRESPONDING MEMBER AMERICAN ORTHOPEDIC ASSOCIATION.

[Copyrighted by John Ridlon, M.D.]

Treatment:—It is the function of a normal hip joint to permit of motion in several directions and to sustain the weight of the body, both during walking and while standing at rest, without injury to its structure. When a joint becomes diseased these functions become restricted or abolished, motion is no longer possible, or possible to only a limited degree, and the joint refuses to sustain the superincumbent weight for any prolonged period.

If we study the clinical evidences presenting at a hip joint, as it passes from health to disease and back to health again, we find them to be somewhat as follows: all the muscles, whose functions it is to move the thigh on the pelvis, gradually become more and more rigid from involuntary muscular spasm until all motion at the joint is abolished. The thigh becomes gradually flexed on the pelvis, and usually at first abducted (Fig. 5); later on as flexion increases it becomes adducted (Fig. 6), but in either case the position is such that in walking the full weight is not thrown upon the diseased member for more than a brief time at each step, and prolonged weight bearing, while standing at rest, is not possible.

The joint becomes more and more sensitive to the vibration of locomotion, weight bearing is no longer tolerated, and the patient takes to his bed. The leg in any case assumes the position of greatest comfort and the muscular spasm protects the joint which by this means becomes locked. As the patient drops asleep the muscular spasm relaxes somewhat, and, if the limb does not lie securely fixed, motion takes place at the joint, injury is inflicted, the patient screams with pain, and the muscles are again on guard. Long continued malposition results in structural shortening of the tissues on the side of the flexion and finally immobilization of the joint is maintained with but little muscular effort. When the joint has been freed from motion and weight bearing for a certain time the tenderness passes off, and the patient is able to move about his bed without suffering and ultimately arises and walks, often bearing his whole weight upon the affected member without pain. Nevertheless muscular spasm and

Fig. 19.—The Davis hip splint.

Fig. 20.—The Sayre short hip splint.

rigidity are maintained for a very considerable time. When the disease has terminated the spasm disappears, but the structural shortening of the soft parts remains, and yields gradually to use during the subsequent months and years; but if the disease has been of a severe type, it always remains to some extent.

The result of this cure by the natural process is usually a limb flexed and adducted, with true or false shortening, and a joint which lacks the normal range of motion. These defects appear to be due to the prolonged course of the disease, which hinders the growth of the limb and renders more rigid the shortened muscles; to the position of deformity in which the leg rests while structural shortening takes place, giving rise to permanent flexion and adduction and to their result, false shortening; and finally to the exaggerated bone erosion and consequent true shortening brought about by nature's unaided imperfect immobilization and protection.

The efforts of nature to effect a cure may be supplemented by art. The means which art adopts are: to protect from deformity, or, if it has already appeared, to correct it, and thus it robs the muscular contracture of its deforming power; to immobilize the joint, and thus relieve the muscles from a state of spasm and subsequent contracture; to relieve pain and prevent the bone destruction due to both

attrition and pressure; to relieve the joint from weight-bearing, and the pressure arising therefrom; and finally, to diminish all these by shortening the course of the disease. The all essential element of treatment, beyond the correction of any existing deformity, may be summed up in one word—rest. The ideal treatment would be *perfect rest* of the joint from active and passive motion, from the jarring incident to all locomotion, and from intra-articular pressure due either to muscular spasm or to weight-bearing. Such an ideal treatment we do not think has ever been attained.

The fathers in surgery treated hip disease by rest in bed and by more or less successful attempts at immobilization. Deeros, in the *Gazette des Hospitaux* of June 30, 1835, published a case of hip disease in which traction was employed. In 1839, J. H. James, of Exeter, England, presented at the Provin-

intended to give elastic traction and counter-traction at the hip joint, without restriction of the normal motions of that articulation, the attempt being to separate the articular surfaces and to thus obtain "motion without friction" at the joint (Fig. 19). Another radical change in principle was that the apparatus was to be employed while the patient walked, it being expected to furnish ample protection to the joint from the traumatism of locomotion. These principles of an ambulatory apparatus, which permitted motion at the joint and protected it by elastic traction and counter-traction, were at once adopted by Dr. Lewis A. Sayre, Dr. Charles Fayette Taylor, and others, and the treatment, which was believed to allow "motion without friction," became known as the American plan of treatment (Fig. 20).

It is perhaps, unnecessary to say that the principles upon which this treatment was based have been

Fig. 21.—The Taylor hip splint.

Fig. 22.—Judson's hip splint.

Fig. 23.—The Sayre long hip splint.

Fig. 21.—Shaffer's hip splint.

cial Medical and Surgical Association, at Liverpool, a plan of immobilization for the treatment of fractures of the thigh, by the use of traction in the axis of the shaft of the femur. In the same year William Harris, of Philadelphia, published a series of four cases of hip disease in the *Medical Examiner*, January 19, treated by traction and counter-traction combined with Hagedorn's apparatus for fractured thigh. The first of these cases was four months after Deeros' paper.

The first portable traction hip splint was devised by Ferdinand Martin and is illustrated in Bonnet's "Therapeutics of Articular Disease," Paris, 1853.

Following these, traction was used by various surgeons with weight and pulley and other devices, as a means of immobilization in the treatment of hip disease. In 1859, Henry G. Davis, then a resident of New York City, presented a plan of treatment essentially different in principle from any that had been previously employed. It consisted of a mechanical device,

entirely abandoned by the profession. Traction obtained by a mechanical device, known as the long traction hip splint, is still used both during recumbency and during locomotion, but it is no longer used with the idea that "motion without friction" is a mechanical possibility. Perhaps the best commentary upon the use of the long traction hip (Fig. 21) splint is found in the fact that in the city of New York three of the veterans in the profession use practically the same splint in the same way for the accomplishment of three different ends—namely, Dr. Judson (Fig. 22) uses the splint for the fixation it gives, Dr. Sayre (Fig. 23) uses it for the motion which it permits, while Dr. Shaffer believes the beneficial effect chiefly rests in the traction which it exercises (Fig. 24).

We would not be understood as denying that inelastic uninterrupted traction is an effective, though by no means the most effective, means of obtaining fixation during recumbency; but traction applied by means of any apparatus upon which the patient

walks, not only fails in immobilizing, or in being a useful immobilizing adjunct to any other apparatus, but it actually increases motion, tremor, and irritation at the articulation. This was pointed out so long ago as 1879, by the late Joseph C. Hutchinson, of Brooklyn. It is only necessary to observe a child walking upon a long traction hip splint to recognize this fact. The hip splint is applied whilst the patient is recumbent, with a traction of eight or ten pounds. The weight of the splint is from four to six pounds. When the patient stands upon the healthy extremity

Fig. 26.—Ridlon's long traction hip splint, with friction body piece. This splint is no longer made use of by the authors.

and lifts the affected member and splint the traction upon the joint is from twelve to sixteen pounds. □

In taking the first step the splint is placed upon the ground and the sound limb lifted, when the whole weight of the patient, from fifty to one hundred and fifty pounds, is thrown upon the perineal supports. They yield somewhat, the splint

Fig. 27.—The Thomas hip splint.

bends a little and the traction force is entirely relaxed, as shown by the straps bagging at the ankle; with the next step, when the splint is raised from the ground, fifteen pounds of traction is again in force. We have thus an alternate traction of fifteen pounds and a relaxation which allows almost the full force of the muscular spasm to drive the bone upward into the diseased socket. This push-and-pull or pumping

action at the joint goes on with each step at the rate of at least three thousand strokes an hour as the child runs about in his ordinary play. It would appear then, that the traction splint used during locomotion is an excellent means for increasing motion at the joint, and that there is no excuse for those surgeons who use this device as a means of immobilization, or with the idea that it gives continuous traction. Traction may add to effective immobilization, and in convalescent cases may be used without serious harm, provided the patient uses crutches and has a patten on the foot of the sound side sufficiently high to effectually prevent during locomotion the apparatus

Fig. 27.

Fig. 28.

Fig. 27 showing adduction wing.

Fig. 28 showing abduction wing.

from coming in contact with the ground. We do not advocate this plan of treatment, because we think that so long as it is thought a patient can find any relief or benefit from the use of traction, he should be confined to the recumbent posture. When the joint has sufficiently recovered to warrant locomotion, traction is unnecessary. In the case of the hip it is especially so. Surgeons advocate it on the plea that it diminishes intra-articular pressure. In early coxitis it can only induce pressure upon the lower and inner aspect of acetabulum and the corresponding portion of the femur. In the late stage it can only viciously pull upon the soft structures helping

to form the joint. Apparatuses devised to give traction during locomotion are expensive, difficult of application, easily misplaced, require frequent attention, are harmful if used during the stage of pain and useless after it has passed. We have used the long traction hip splint (Fig. 25) in many hundred cases of hip disease, and we have abandoned its use because it does not, at best, readily overcome deformity; it permits the development of a marked degree of flexion with abduction or adduction, in cases where no deformity at first existed; because under its use patients suffer again and again from exacerbations

Fig. 29.—Outlines of the main stem of the Thomas hip splint. A, For stout patient. B, For thin patient. C, For thin patient.

of pain and increase of deformity which always force them to bed for a longer or shorter period; and because under its use the period of treatment is exceedingly long and the results far from perfect. Nearly all cases, when cured, present the deformity of flexion and adduction and the false shortening arising therefrom; they present a great rigidity and considerable real shortening, and not a few of them a functionless flail joint at the knee from the indefinitely prolonged pull. All that is necessary for the safe conduct of the joint may be obtained by the use of an apparatus simple of construction, slight of cost, easy of appli-

Fig. 30.—Schematic showing of the relation of the main stem to chest, thigh and leg.

Fig. 31.—Twisting the stem.

cation, not readily misplaced, rarely requiring attention, more effective to overcome deformity, to prevent the development of deformity, and to allay muscular spasm and pain, than any traction apparatus with which we are familiar.

We do not describe any apparatus of the many in general demand, except that which we ourselves have in constant use in all our cases. This apparatus is known to the profession as the Thomas hip splint (Fig. 26), known so deservedly, because it was first used by the late Hugh Owen Thomas, of Liverpool, as a means of immobilization by antero-posterior leverage in the treatment of hip disease; but it is to the principles upon which this splint is used, rather than to its general form, that the name of

Thomas should be applied, for unless the splint be used upon these principles, it may be a wholly worthless incumbrance.

Before the time of Mr. Thomas a somewhat similar device was used by Mr. Hilton to overcome deformity, and since the time Mr. Thomas first gave the splint to the profession others have used apparatuses looking somewhat like his splint, but wholly ineffective, either because of their shape or flexibility, or rendered useless by the addition of traction forces applied either in a lateral or longitudinal direction. *The Thomas splint is intended to immobilize the hip*

Fig. 32.—Wrench for bending and fitting the Thomas hip splint.

joint by a direct antero-posterior leverage action. By this action it reduces the deformity, or opposes a tendency to deformity. By its weight and rigidity it steadies the inflamed articulation and quickly relieves muscular tremor.

The Thomas Hip Splint.—The Thomas hip splint consists of a main stem, a chest band, a thigh band, and a calf band, and occasionally of an abduction or adduction wing passing round the flank (Figs. 27 and 28). The splint is constructed of the softest and

Fig. 33.—Bandage over outer wing of thigh band, and wings of chest band drawn up or down.

toughest iron. Annealed steel is not the material to be used, inasmuch as sufficient rigidity cannot be obtained without rendering the parts too difficult to easily mould to the contour of the patient.

Most serious results accrue from making splints too light, and the following practical instructions may be useful: For an adult of about six feet the upright should measure $1\frac{1}{2} \times \frac{1}{4}$ inch; for an adult of about five feet six inches the upright should measure $1\frac{1}{2} \times \frac{3}{16}$ inch; in a boy of ten the upright should measure $\frac{3}{4} \times \frac{3}{16}$ inch; for a child of five the upright should measure $\frac{1}{2} \times \frac{3}{16}$ inch; for an infant of two the upright should measure $\frac{1}{2} \times \frac{1}{4}$ inch.

In length it reaches from the lower angle of the scapula to the junction of the middle and lower third of the leg, passing down posteriorly to the hip joint. In growing children it is customary to make that portion below the joint somewhat longer than that above, but nothing is gained in immobilization by making one part longer than the other, taking the hip joint as the middle point. The upright stem is bent in two places, one opposite the fold of the buttock, the other just above the joint, so that the leg portion and body portion follow parallel lines distant from each other from one-half to two inches, this distance depending upon the size and stoutness of the patient (Fig. 29).

As a rule, the stouter the patient the nearer do these parallel lines approach each other. In a case where the trochanter is enormously hypertrophied the buttock bend may be entirely dispensed with, and

in that case the body and thigh portions of the upright form a straight line. The bends referred to should be rather rounded than angular, as may be seen in the illustration. The leg portion from the fold of the buttock to the lower end is perfectly straight, as is the portion from the bend opposite the joint to the upper end. The stem is usually twisted somewhat in its longitudinal axis, so that the body portion lies slightly to the side and flat against the curved outline of the chest, while the leg portion lies directly posterior to the middle line of the leg (Fig. 30). The buttock portion lies between the great trochanter and the ischial tuberosity. The twist varies according to certain conditions, which will be hereafter referred to in describing the adjustment of

length being due to the greater distance it has to travel. The relative length of these wings may be determined by measuring from the lower angle of the scapula around each side to the front, where it is intended that they should terminate. There is no special advantage in having these wings to end opposite each other, although it may perhaps make a somewhat neater looking apparatus. The upper end of the main stem is forged flat and bent over the chest band, and the two are made fast by a single rivet. In each end of the chest band a hole, three-quarters of an inch in diameter, is forged for the fastening of the shoulder straps; or, what is less convenient, holes are drilled for the attachment of buckles, or bandage. The thigh band is made of flat bar iron, $\frac{1}{16} \times \frac{3}{4}$ inch, and, being placed on the surface of the main stem next to the patient, is joined to it by one rivet at a point about an inch below the lower bend. If the splint is to be made reversible the wings of this band should be made of equal length: if it is intended for one side only the inner wing is made an inch or two longer than the outer. The calf-band is also made of flat bar-iron, $\frac{1}{16} \times \frac{3}{4}$ inch, and is joined to the lower end of the stem by a single rivet in the same manner and with the same rel-

Fig. 34.—Left wing of chest band drawn down to adduct the right limb.

the splint. The chest band is also made of flat bar iron, which varies in width and thickness in proportion to the size of the patient—usually from $\frac{1}{2}$ to $1\frac{1}{4}$ inch wide by $\frac{3}{8}$ inch thick. It should be long enough to encircle the chest to within an inch or two. If the splint be made reversible, so that it may be applied to either leg, as is customary in hospital work, it is joined at its middle to the upper end of the stem, whereas if it is to be used only in a certain individual case, it is joined from one or two inches to one side of its middle, so that one wing will be longer than the other. The longer wing encircles the chest opposite to the diseased side, its greater

Fig. 35.—Showing possible lordosis in correcting a case of marked flexion.

ative lengths of wings as the thigh-band. When an abduction or adduction wing is required it is made from the same sized iron as the thigh-band. This should be placed at such a point that it will pass around the flank midway between the crest of the ilium and the ribs. This point is usually about midway between the buttock bend and the chest-band. The wings or bands are bent approximately to fit the imaginary patient, and the surface of the entire splint next the patient is covered with felt, either harness-makers felt, or what is better, ordinary boiler felting of one-fourth inch thickness. The whole is then covered with that kind of sheep-skin known to the trade as bazil leather, or "tan sheep." This should be put on wet and snugly stitched into place, so that as it dries the shrinking will prevent any slipping upon the iron. The stitching of this leather is of course done on the surface of the splint away from the patient; it may be done with the so-called ball-stitch, or, what is more ser-

viceable but less neat, the two edges of the leather may be drawn up together and sewed through after the manner of the harness-maker with a double waxed end; the redundant portion of the leather is then trimmed off.

The splint is then applied while the patient rests upon his back, the wings upon the side away from the deformity being opened out sufficiently to slide the splint under the patient from the affected side without unnecessary jar or movement. When the main stem rests in place, the leg portion will be directly behind the middle line of the thigh and leg, the part between the bends directly at the back of hip joint, and the body portion somewhat to the outer side of this line, the whole lying flat against the chest,

Fig. 36.

Fig. 37.

Fig. 36.—Nurse. Fig. 37.—Nurse attached having an abduction wing.

thigh and leg. This fitting may be done approximately by the hands, but better by wrenches (Fig. 31) hereafter to be described. The wings to the inner side of leg and thigh and the wing of the chest-band on the same side, namely those on the side away from the diseased articulation, are drawn more closely than those on the affected side (Fig. 30). The reason for this is that the splint tends somewhat to the affected side of the patient and to draw the leg into abduction.

Particular attention must be paid to the bending of the body wings. As the chest is not circular it is necessary that the body wings should not be made

circular, else intolerable soreness will result. By closely examining Fig. 30 this will be seen. The part between A and B upon which the patient lies is but very slightly curved and this allows the body to rest comfortably and travel easily towards the diseased side B, which is of great advantage.

Another very simple expedient consists in making a small hole in the bandage and passing it over the outer of the thigh wings and rolling it under splint and thigh and round the limb, so that the appliance is pulled in the opposite direction to that which it tends to travel. When satisfactorily fitted a short piece of bandage is wrapped around the splint and leg at the lower extremity and pinned securely, and another wrapped around the thigh above the knee, or, what serves in some cases more satisfactorily, a single piece is wrapped around the knee in the figure-of-eight fashion and pinned with a large pin directly through the covering at the back of the splint, so that the bandage cannot slip upon the splint, and any tendency of the splint to slip downward is avoided.

Fig. 38.—Changing the skin under the splint.

If the splint be found too large, or when the patient grows, too small, it may be necessary to modify or increase its length. This is quite simply done. If it be too large draw both body wings towards the abdomen; if too short draw them towards the neck. The dotted lines (Fig. 33) will explain this. A strip of broad bandage is then looped around the upper end of the stem below the chest-band, and having been twisted two or three times so that the ends will separate high upon the back (Fig. 38), each end is carried over a shoulder and brought down to the hole in the end of the chest-band like a pair of braces (Fig. 27); here each is tied securely, crossed to the hole at the opposite side and again tied, when the ends are tied together. The final knot should be secured either with a long pin driven through it and twisted at its end, or with a bit of adhesive plaster. The splint should be applied without bending it from the shape already described if it is possible to force the leg at the knee reasonably near the splint. The lumbar spine readily curves when there is flexion at the hip suffi-

ciently to allow the limb to be brought down to the splint when there is as much deformity as fifty degrees; but if the deformity be very great, as much, perhaps, as nineteen degrees, it may be necessary to bend the splint just enough to get the limb in contact with it when the fullest possible lordosis has been obtained (Fig. 35). In these cases the bending is done at the upper bend of the main stem, directly at the back of the hip joint. In practice, however, this will rarely be found necessary, and has its disadvantages.

leather. Lead foil plaster is alone placed around the body wings and stem. If the splint has been accurately fitted no sore or excoriation results.

If it is desired to prevent a patient from walking, a strip of iron is screwed to the lower end of the splint, and may be bent to pass free of the heel, and carried ten or twelve inches below the foot, so that standing or walking is quite impossible. This piece is called a "nurse," and will be found, when children are restless, a safe precaution during the period of recumbency (Figs. 36 and 37). If severe leverage be

Fig. 39.—Lifting a patient in the splint.

If there exists any considerable degree of abduction a wing should be attached as already directed, passing around the flank on the side opposite to the disease. If there be any considerable adduction the wing is attached to the same point, but passed around the flank on the side where the disease is located. Care should be taken to draw these wings well in between the ilium and ribs, since pressure is

brought to bear over the buttock in order to reduce a marked and rigid deformity, care should be taken to shift the skin about twice a day where it presses with most force on the stem (Fig. 38), and to see that all parts about the hips are kept clean, dry, and well-powdered, otherwise pressure sores may result.

If the splint has been bent to fit the deformity, it must be straightened as soon as possible, sufficient

Fig. 40.—The patten.

not tolerated over these bony points. At other times these body wings are drawn down into the position taken by abduction or adduction wings when one cannot conveniently procure the additional wings. In case of the very poor the hip splint is often applied by one of the authors without padding or

opiate being given to quiet the pain during the few hours or days of the reduction of the deformity. During this time, of course, the patient must remain in bed, and recumbency should be maintained until all pain and intense muscular spasm has subsided. When the deformity has been reduced the leg should scarcely at all interfered with, the splint should

Fig. 41.

not be removed, motion should not be tested, even the bandage at the knee should not be changed except they become slack or soiled. The most abso-

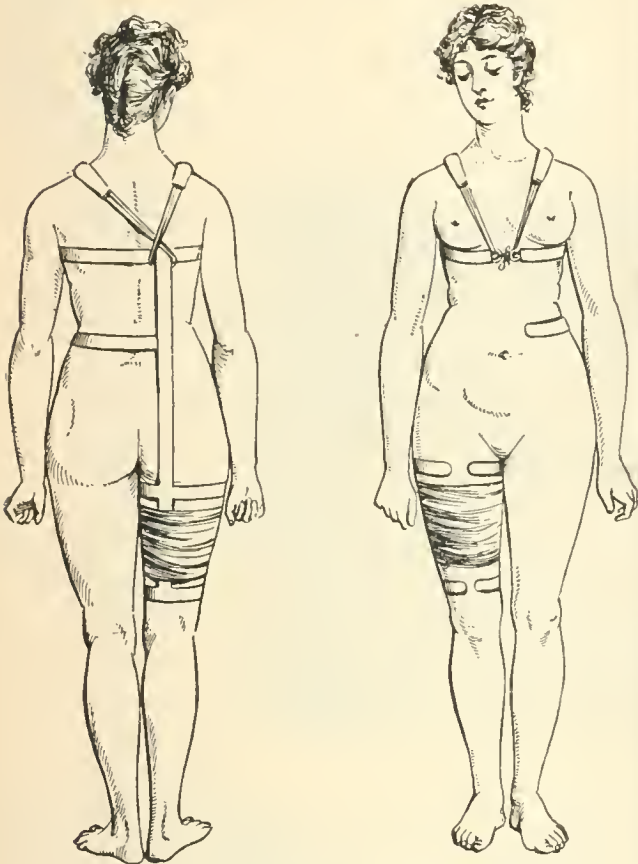

Fig. 42.—The short, or walking brace used during convalescence.

lute quiet to the joint and to the patient must be enjoined, and the necessities of nature should be

hand under the splint just below the knee, while with the other she lifts the chest band (Fig. 39). When all pain, tenderness, and muscular spasm have been quiescent for some weeks, and when no sign of fluctuation can be made out about the joint, the patient may be allowed to arise and get about on crutches, aided by a patten on the sound limb.

The patten consists of an iron ring with two uprights, the ring resting on the ground and the uprights rising from the front and back, reaching to the shoe and fastening to the heel and sole (Fig. 40). The ring is oval shaped and is made of square bar-iron not less than three-eighths of an inch thick. It reaches from the ball of the foot to the middle of the heel and its width is slightly more than that of the sole of the shoe. The uprights are of round bar-iron

Fig. 43.—The Thomas flexion test position.

set at right angles to the plane of the oval ring, and should at their lower ends be welded to it, their upper ends are forged flat, pierced with three holes and bent forward. If the patten is to be attached to a thin-soled shoe it will be better to rivet these flattened ends to a metal plate shaped to fit the sole of the shoe and screwed to it. The height of the patten depends upon the size of the patient and should be from four to six inches, high enough to prevent the patient from reaching the ground with the toe of the affected side. This with the ordinary axillary crutches completes the walking outfit (Fig. 41).

For the most perfect result the patient should be kept recumbent until all pain, tenderness and mus-

Fig. 44.—Sinus healed. Good position.

attended to by gently lifting both lower extremities and inserting the bed pan. This can be done without causing pain in even the most sensitive joint. The good limb is placed gently across the diseased one, and the nurse lifts the patient by placing one

cular spasm have subsided. He may then walk about on crutches and patten until all the soft tissues about the joint are well atrophied and all trace of the disease has disappeared.

The patten may be then dispensed with and the

crutches shortened, and in this manner he may go about for two or three months. If there be no evident return of the disease the crutches may now be thrown aside and the joint further tested by two or three months' use. All still going well, the splint is now cut off at the knee so as to permit of flexion there, a band being attached at the lower end after the same manner as the calf band (Fig. 42).

experienced by a patient recovering from articular disease cannot be very reliable under the masking influence of a splint. The test comes on removal of restraint, and a very critical time it is unless the surgeon has grasped the knowledge whereby such a test becomes reliable. No surgical text-books give any allusion beyond vague generalities to the means of knowing the right moment to discard treatment.

Fig. 45.—Flexion of thigh. Sinues open.

This short walking splint having been worn for two or three months, and there being no return of the symptoms of the disease the splint is removed at night for a month or two. If the joint remains well

There is no more danger of relapse in cured joint disease, than there is of disease in a healthy articulation. But if a joint be pronounced fit for use when the remnants of inflammation have not gone, it is

Fig. 46.—Same case as fig. 45; flexion reduced and sinues closed.

the splint is removed for certain hours during the day and then altogether, and the joint finally tested for perfect cure.

The joint should be imprisoned long after the appearance of disease has gone and after all subjective symptoms have disappeared, for the sensations

easy to understand the very frequent references to relapse which meets us everywhere. The law may be again laid down. *A joint is cured of disease where the range of movement does not diminish by use, or in those cases resulting in ankylosis a cure may be pronounced where the angle does not change after use.*

All patients should be examined at the commencement of treatment for the purpose of diagnosis and record, and again at the close of treatment for a comparative record and for the diagnosis of a cure. In each instance the patient should if it is practicable, be entirely stripped of all clothing the attitude should be noted in standing, walking, and lying, the amount of motion at the articulation compared with that of the sound side, the member measured for both real and false shortening, for abduction, adduction, flexion and atrophy.

It is our effort to encourage rather than otherwise the production of abduction in the cure of hip disease. It diminishes the amount of practical shortening caused by displacement, erosion or arrest of growth. By recognizing this we are sometimes able, where there is perhaps two inches actual shortening, to slant the pelvis sufficiently to render the apparent or practical measurement equal on either side.

To render the pelvis flat in a definite position it is customary for us to put the patient in what is known as Thomas's "flexion test" position (Fig. 43). This consists in flexion of the thigh of the sound side upon the trunk, so far that the elbow of that side can be hooked into the flexure at the knee and the forearm carried across the body. This gives a sufficiently definite position to render meas-

from side to side as the patient lies upon the table, or the patient may sit with his legs dangling over the side of the table and the foot may be swung from side to side. The patient then is placed prone, and, if the degree of deformity will admit it, the leg is flexed on the thigh at a right angle, the ankle is grasped by one hand, the pelvis steadied by the other hand resting on the sacrum, rotation is tested by moving the foot from side to side, and also by lifting the whole limb from the table. The parts about the joint should be palpated for tenderness, induration and fluctuation. The presence and size of abscesses should be noted, the location of sinuses and their character, and the nature of the discharge. The advent of an abscess is usually first made by increased pain, muscular spasm and tendency to deformity. Tenderness may often be made out on palpation, and sooner or later, induration or a boggy feeling is manifest. This usually is first felt directly in front of the joint, although it may appear posterior to the greater trochanter, or in fact at any point in the neighbourhood. As the abscess increases in size it usually extends downward and may come to spontaneous opening within a few weeks, or not until after many months.

It does not appear to us that anything is to be gained, and often much may be lost, by early opera-

Fig. 17.—Fixation traction after excision of the hip joint.

urement, made at different times by the same or different surgeons, comparatively accurate, although unless the surgeon be careful, flexion to the Thomas position in some cases tilts the pelvis upwards and renders the record of deformity not only that of the existing flexion but also that of the amount of normal extension.

These deformities may, perhaps, be more accurately measured with the goniometer, but the measurement with the tape is generally more convenient, and is sufficiently accurate. The amount of muscular atrophy of both thigh and calf should also be recorded. The degree to which motion is possible in the antero-posterior direction may be ascertained in the same way as deformities are measured. The deformity having been measured and recorded, the presence or absence of involuntary muscular spasms, limiting the motion of the joint, should be tested. To make this test it is convenient to first test the leg of the sound side. The pelvis is steadied by one hand, placed over the spines of the ilium, while the other grasps the leg just below the flexed knee; flexion, abduction, adduction, and rotation are then tested. The affected limb is then tested in the same manner. In timid patients or very sensitive joints it may be as well to test rotation by rolling the leg

tive measures upon the abscess of hip disease, provided there are no constitutional symptoms of septic infection. An abscess opened early invariably conduces to carious bone, and generally to a joint extensively diseased. Rarely can all the tubercular material be removed without a complete excision of the upper portion of the femur and of the acetabulum. Unless all diseased tissues be removed, a sinus is likely to remain which may subject the patient to septic infection. An abscess left unopened for some months often descends a considerable distance and becomes cut off from the site of the original focus. In such a case careful operative measures without drainage should result in immediate closure and primary union, but it is not easy to tell when the abscess is no longer connected with diseased bone or joint, and the surgeon who interferes takes a very serious responsibility. He should not, in our opinion, open such an abscess unless he can be reasonably sure of removing all tubercular material, and of closing the wound without drainage. The use of a draining tube leads to the formation of a tuberculous sinus, which is exceedingly difficult to heal, far more difficult than a sinus resulting from spontaneous opening. When operative measures are undertaken we believe that the tubercular tissues, whether sac of

abscess, wall of sinus, synovial membrane, cartilage, or bone, should be removed by cutting with a knife or chisel, instead of the scratching and scraping to which such tissues are usually subjected by the so-called sharp spoon. There can be no question

Fig. 48.—The double hip splint.

that the risk of general infection is greater from a cutting operation than where none is done, but the risk is much increased by the scraping process. In considering the treatment of these abscesses it should be remembered that a very considerable number of

ing from its presence. We would make the same rule regarding other operative procedures, such as the removal of the focus of disease within the bone, excision of the joint, and amputation. If any case in the recumbent posture should grow progressively worse under efficient immobilization of the joint and the best obtainable hygienic surroundings, operation for the removal of the disease would be indicated; but we have not seen such a case unless it had been allowed to go on to an exceedingly advanced stage without any treatment whatever. The preservation of the patient's life, then, we would make the only indication for an excision of the hip joint, or for an amputation. The operations for excision, or for amputation, need not be described here, since they are found in all works on general surgery; but if excision be performed, thorough mechanical treatment following the operation is indicated and should be the same as in the treatment of an unsound articulation. This after-treatment we think is often neglected by the general surgeon, and may account for some of the relapses which have been reported. The mechanical treatment of these cases, consisting of immobilization and protection to the joint, should be continued until every evidence of unsoundness has been absent for a very considerable time. The hip-splint, used after an excision, should be supplemented by the addition of fixative traction as is done in some cases of fracture of the upper portion of the femur (Fig. 47).

A strip of adhesive plaster is applied to each side of the limb from the upper portion of the thigh to the neighbourhood of the calf-band of the splint, the lower ends of these strips are then carried around the wings of this band, so as to secure the necessary traction, and fastened securely, and the splint is adjusted without the usual shoulder straps. While the patient, without shoulder straps, is lying in bed the splint tends to work downward sufficiently to overcome the muscular contracture which would produce unnecessary shortening. At times old and neglected cases will present themselves for treatment with a serious deformity, and the question as to whether any operative measures are demanded. If

Fig. 49.—Side bar to correct or prevent knock-knee from spasm of the adductor muscles.

them, if left to themselves, the joint being put at complete rest, never go on to an opening, but gradually dry up and disappear without any apparent ill-effects to the health of the patient (Figs. 44, 45, 46).

If it were certain that every abscess would come ultimately to the surface, or if there were any reason for believing that the health of the patient suffered from allowing them to remain unopened, or from their being reabsorbed, operative measures would be justified in all cases; but as there is no way of knowing what is to be the course of any given abscess, we believe that the indications for operative interference should be made to depend upon the general health of the patient, and that no abscess should be opened unless the patient's health be unquestionably suffer-

muscular spasm be evident on attempting motion at the joint even if there be no possible motion, or if an apparently sound joint possesses a certain degree of motion, the deformity can be corrected in a comparatively short time by the leverage action of the splint; or the deformity may be corrected at once, or nearly so, by anesthetizing the patient and placing the limb in the best possible position. In these cases we do not recommend section of the tendons, fasciæ or other contracted tissues, although there may be no very serious risk in their division. To this subject however, we will return again. We think it safer to divide the femur with the chisel either through the neck or in the neighbourhood of the lesser trochanter than to attempt a fracture by manipu-

lation. The after-treatment of either of these operations is the same as indicated after an excision of the joint. The patient should remain in bed until union is sound, when the splint may be removed and he may remain in bed, an equal time, without immobilization, or in place of recumbency, in certain cases, the splint may be cut off at the knee and the patient allowed to go about with splint and crutches, without the patten, for a period equal to that which was required for the union of the bone.

Cases occasionally appear with abscesses or sinuses so placed that the pressure cannot be born from the main stem; it is then customary to immobilize by the double hip splint with a longer or shorter section of the main stem on the affected side removed. The double hip splint, which is used in all cases of hip

Fig. 50.—Attachment for knee joint disease in conjunction with hip disease.

(Fig. 48) disease affecting both joints at the same time, and in some cases of young children where the joint sensitiveness in single hip mischief is extreme, consists of the chest band already described, from which two main stems pass at a point opposite the lower angle of each scapula downward, posterior to each hip joint and down the back of each limb, and separate at the bottom by a distance from four to eight inches. The lower ends of the main stems are joined by a straight bar of iron, the inner wings of the thigh bands are usually omitted, and we gener-

ally add a lateral wing to each side. Upon this splint the patient can be moved from bed to a couch or to a carriage with very little inconvenience or pain. Cases of double hip disease are not so very infrequent, occurring perhaps in the ratio of one to one hundred of single hip disease. The disease rarely begins in both joints at the same time, and it occasionally develops in the second joint while the patient is lying recumbent and protected from all traumatism during treatment of the first joint. Under these circumstances it frequently occurs that the joint last attacked recovers first, though not invariably with the greatest amount of motion. Partial or complete ankylosis of both hip joints resulting from double disease is not so very serious if the lumbar spine be sound and flexible, and provided the limbs be in relatively normal position. Patients are able to walk and to climb stairs, to sit, and to perform most of the ordinary movements of life fairly well. The results of double hip disease, treated by the Thomas double hip splint, appear to be somewhat better than the results of disease in single joints. The nature of the affliction is such, that prolonged recumbency is necessitated, and walking is impossible before recovery has become practically complete.

In hospital practice and among the very poor and ignorant, it will often be found impossible to keep the patients in bed with single hip disease as long as we have indicated to be desirable, and it will also be found impossible in all young children and in many older ones to compel the use of the high patten and crutches. Parents will permit these children to walk and bear their weight upon the diseased limb. As a matter of fact these cases do better than we might expect. We have observed many such, and find that some recover without flexion, rarely with adduction, and with very little, and sometimes no, shortening. The number that have partially stiff joints is greater than among those where treatment has been carried out in accordance with correct theories.

Now and again during the development of abscess a case will present so intense a degree of spasm of the adductor muscles that, if the patient remains fixed in the ordinary splint, knock-knee will result from adduction of the thigh, the lower portion of the leg being held by the lower part of the splint. This complication is prevented or corrected by passing a light bar of iron from the thigh band to the calf band, along the outer side of the leg, and bandaging the knee to this band as well as to the main stem (Fig. 49).

In cases where disease at the knee-joint appear at the same time with disease at the hip, the knee may be immobilized by joining the knee and hip-splint together, or by adding to the hip-splint a light band of iron passing down each side of the leg and around somewhat below the foot, and rivetted to both inner and outer wings of the thigh and calf bands (Fig. 50).

In cases of spondylitis of the lumbar region, occurring at the same time as the disease at the hip, the back may be protected by a stout sling of leather, passing from one main stem to the other of the double hip-splint, or the main stem with its thigh and calf bands may be attached to a spinal support.

ADDRESS ON DIETETICS.—MEDICAL FOOD ETHICS NOW AND TO COME.

Delivered before the Section of Physiology and Dietetics of the American Medical Association, at its Forty-third Annual Meeting held at Detroit, Mich., June, 1892.

BY EPHRAIM CUTTER, M.D., LL.D.,
OF NEW YORK CITY.

SECRETARY OF THE SECTION.

There is no doubt in my mind that most of the common diseases depend upon food for cause and cure save those from wounds, injuries, contagion and infection.

Foods are substances, organic and inorganic, which, taken into the human body become normally changed into the normal tissues of that body and which sustain normal life. On this definition, air is food, water is food, common salt is food, all belonging to the mineral kingdom. It is clear that life cannot exist without air food, for example; cut off all air food from the sick and you cut off the sick from their life and disease.

To put this more clearly take the Sections of this Association, in the order given by the Secretary in THE JOURNAL:

Obstetrics and Diseases of Women.—If I can judge from experience, difficult labors and gynecic diseases are largely due to bad feeding before and after labor; I know a case where a woman had four successive very difficult labors which were deemed so perilous that her physicians advised her not to have any more children for fear of death—yet this woman after being dieted had a fifth labor that was so easy that her child was born with only one pain and a half hour before any physician could reach her. I have known puerperal convulsions which is one outcome of fatty degeneration by feeding on carbo-hydrates in excess—to be cured by medication and nitrogenous food and two successive labors to be normal.¹

Section of Surgery and Anatomy.—A great many of the physical lesions for which surgery is used come from bad feeding—among which are tumors, diseases of the eye, stricture of intestines, empyema, to name no more. If a body is otherwise healthy from good feeding such bodies respond the best to surgical means used for relief, especially in cases of wounds, contusions, fractures.²

State Medicine.—Read the discussion on Senator Paddocks' Pure Food and Drug Bill and the diplomatic reports of our ministers to France, Germany and Italy on the hog.

Ophthalmology.—Oculists have told me that a large part of the diseases of the eye came from bad feeding. Drs. B. W. Richardson and S. Weir Mitchell years ago showed the production of cataract in ten minutes time by the hypodermatic injection of one teaspoonful of a saturated watery solution of sugar under the skin of a guinea pig or a frog.

Laryngology and Otology.—One reason why I am now an advocate of food treatment of disease is that I found I could not cure throat cases satisfactorily unless I paid attention to the diet. Pharyngitis sicca

for example thus becomes very curable. The delicate structure of the ears are much affected by bad feeding, which was seen when men were fed on oat-meal alone, being troubled with noises and later deafness.³

Diseases of Children.—It is notorious that one-half of all children die before five years of age and the greatest cause of this mortality is bad feeding. Cholera infantum is par excellence a food disease and my grand-children did not have it as they were fed on wheat, milk and meat.

Oral and Dental Surgery.—A dental friend once fed three youths, from ten to fifteen years on animal food and fresh air food in the woods of Maine; in three months the texture of their teeth was changed from chalky and friable to the firm normal fibrous texture of health—all which tends to show that decayed teeth come from bad feeding. I know a man about sixty years of age who expected to lose all his teeth before the age of thirty, but by giving his teeth better soluble mineral food he retains most of them in fairly good order; this was a case of consumption of the bowels in early youth. Feed man as well as dogs are fed and you will have as good teeth, but the teeth must have hard things to chew as Prof. E. A. Wood, of Pittsburg, has shown. In the London Zoological gardens a number of years ago some lion cubs were born with cleft palate which on investigation was found to be due to the fact that their mothers had not been fed on their usual supply of animal food during gestation.

Neurology and Medical Jurisprudence.—At a late medical meeting, alienists showed casts of defective jaws and teeth of aliens. I have seen a good many such in the mouths of people. I have met them in traveling (to say nothing of those encountered and examined in practice) who were not aliens. I think the bony defects came from bad feeding. Stunted trees are found to be due to sterile soils and high altitudes, i.e. from a limited supply of air and earth food. Unless the nervous system is well fed insanity and nervousness cannot be kept out. I think that divorce comes somewhat from bad feeding producing dyspepsia and nervousness which make constant quarrelling, conflicts and clashing more easy.

Of the urine of one hundred male aliens (asylum) I found catarrh (protoplasmic) of the genital organs in 80 per cent.; this catarrh is a fruitful cause of neurasthenia amounting some times to insanity and it is produced by bad feeding and also cured by good feeding mainly. (This statement is based on more than ten years of recognition of this catarrh as a cause of neurasthenia in private practice). I know that doctors would have clearer heads if they fed their brains rightly, and their patients would have leveler heads if fed rightly and perhaps there would be fewer suits for mal-praxis.⁴

Dermatology and Syphilography.—I have seen diseases of the skin held in abeyance by good feeding and return with bad feeding. As to syphilis I believe it is a germ disease communicated by contact and is not wholly in this category—but good feeding goes a long way towards relieving and curing the terrible devastations of syphilis which occur in those who are poorly fed and weakened by drink. A case

of syphilis of ten years' duration, remarked that the periodic skin troubles he had could be kept down only by following the course of diet laid down for him and using his ointments; if the diet was not maintained as ordered, local applications were worthless.⁵

Materia Medica and Pharmacy.—As things now go the efforts of this Section in the food line are largely on manufactured dietetic preparations. One preparation of invalids' food has gone so far as to define a mechanical separation to be an extract. Indeed the medical profession has been and is now in the receipt of more instruction on food from this Section than any other.

Physiology and Dietetics.—This is a food division without any doubt.

Practice of Medicine.—Here is an abundant field for food in the handling of acute and chronic diseases—of the latter note consumption of the lungs and bowels, bronchitis, hay-fever, asthma, rheumatism and all affections of the alimentary tract, to name no more.

This brief statement shows how close the subject of food comes to our Association and leads us to discuss

MEDICAL FOOD ETHICS AT PRESENT.

Judging from the reluctance of physicians here and abroad to furnish papers for this Section it would seem as if the profession was in an apparently helpless condition as to food with the exception of pharmacists who so freely publish instructions as to foods and the treatment of disease by foods. Often it is the food they prepare that they recommend and offer as a clear guide to the perplexed physician out of his dilemma. The most positive directions for surest relief come from those who are not even pharmacists nor apothecaries and then if the words of these food vendors are to be relied on there is no need of any physician studying up the subject of alimentation nor hence any necessity for the Section of Physiology and Dietetics.

We should always be grateful for any useful information as to foods no matter whence it comes, but it does seem that the absence of any chairs in our medical colleges especially on the subject of foods is one cause of the present failure of food ethics.

Another trouble is the difficulty in carrying out any regime of food. Patients, cooks and almost all the laity are not willing to deny their appetites and had rather eat and die than eat to live. They will not give up what they like to eat on the principle that the French now lay down and Count Rumford laid down, that any agreeable food was nutritious. This difficulty in the army and navy is overcome by the discipline, and we have the privilege of hearing from these arms of our service where the men must eat what the surgeons direct, according to law.

Among the curiosities of medical food ethics are: 1. the fact that physicians have stood up for their rights to study foods, but a cold shoulder has been turned to them as a rule, their dieta disobeyed, while the dieta of unprofessional people, non-medical experts and pharmacists are received as law and gospel no matter if these dieta proved clinically to be

untrue and fallacious, while curiously, some physicians recommend a food which chemically and morphologically has been shown to be common flour worth perhaps five cents per pound but which advertised as a food sells for one dollar a pound and set forth with steel engravings. Surely this attitude of medical men against their fellows and in favor of out-siders is very queer ethics.

COOKS USURP THE PLACE OF DOCTORS.

Menus are made by cooks who are nameless and know little of food save as to their preparation. Generally cooks are uneducated with some noble exceptions as Count Rumford and the present German Ambassador to France. It is a singular state of ethics that the medical profession are not called in to make out the menus for tables and banquets just as they do for the Army, Navy and Hospital Marine. Many a time has a physician's good work been upset by a Delmonico dinner eaten without any regard to its physiological, pathological, chemical, kinetic, potential or physical relations! To be sure the aesthetics of taste, smell, sight and touch are allowed by the cooks full sway as to food in these cases—but the point is that medical knowledge is not invoked so that the dinner will round out into its full proportions of efficiency in all directions of good health. If more medical supervision was exercised there would be much less bad cooking and less occasion for the remark that "God made good steaks but that Satan spoilt them in cooking!" It may be because cooking is considered a drudgery that the present state of medical ethics towards it exists. But after what has been said here as to the etiology of food diseases it certainly is a matter of the greatest importance for medical men to look out for the interests of their patients as to cooking. I have known one badly cooked beefsteak to restore the haze of albumen, casts and fatty epithelia to urine which had become clear after fourteen days of hard strict watching and care. I have no doubt physicians now get the reverse of praises because their good work has been undone by badly cooked food.⁶

FASHIONS IN FOOD.

While it is the fashion not to have any children, or having them in spite of fashion, lot to *suckle*, of course artificial foods are in demand and normal lactation is at a discount, no matter what the medical profession teaches to the contrary. Just as women will environ themselves with strait jackets (corsets) no matter what doctors say and no matter if they fall dead as one did lately in New York at a ball, killed by tight lacing and probably the fatty degeneration that came from a languid and impeded circulation caused by tight lacing.

A debt of gratitude is due to those who prepare good food substitutes for such a deficiency caused by following the fashions. Some time ago some vendors of infant foods claimed that their wares were better for babes than the normal breast milk, but this claim is withdrawn now. (If mothers would live on a diet of two-thirds animal and one-third vegetable, they would have milk enough, as I have found from my personal experience).

There are some artificial foods which do not

⁵ Morphology of syphilitic blood, Am. Jour. Dental sciences, Oct. 1879. —Throat syphilis and tubercle according to Salisbury, Arch. of Laryng. N. Y., Dec. 1880.—Blood changes in syphilis treated by the McDade Fluid Extract Stillingia, Gaillard's Med. Jour. Feb. 1881.—Crypta syphilitica, Monographia syphilitica, Sept. 1888.

⁶ Food as an aesthetic, chemie, physiologic, pathologic and therapeutic, Am. Jour. Med. science, Jan. and Feb. 1880. Baked Beans, a serio-humorous medical paper, Alb. Med. Annual, Feb. 1887.

verify their claims, and all claim to be the best for monetary if not monopoly reasons. It is the fashion to reach every physician in the land with food advertisements; the more money made on the food the better the advertisements. The tone of these advertisements is humiliating to the medical profession, as they take it for granted that no one knows anything about these foods but those who write the advertisements. They even instruct almost every other department of medicine and assume a superiority of medical knowledge over those who it may be have studied medicine longer than the self-styled instructor has lived. One such in my own office, a lad of eighteen years assured me that sugar in large excess was of no harm in medicine. But I had learned that it would return albumen to the urine and yeast to the blood whence it had taken time and care to eliminate them by stopping off sugar and kindred hydro-carbons. There is this to be said: So long as the medical profession refuse to study the action of common foods on the body till thoroughly understood, just so long dietetics will be a terra incognita, and I do not see how any medical man can be blamed for doing what he can to enlighten the darkness of so important a subject and to wake up fashion to take a sensible view of food.

Once it was the fashion for women to wear thin-soled shoes and many were supposed to get ill from this exposure, but now happily it is the fashion for women to wear thick soles; I heard a man say before the fashion changed that if women were weaker than men, they ought to wear thicker shoes than men. A sensible view to take, and shows sensible fashion.

Would that it might be the fashion for wives so to feed that lactation could be possible for two years. They do this better in Japan. The Japanese minister to this country in 1886, Hon. R. Kuki, told me that it was not rare to see Japanese children suckled to the age of ten years! Rameses II, the Pharaoh of Moses time in an intaglio, is depicted as suckling the breast of the goddess, Isis. His figure is of a youth of seventeen years standing and sucking the left breast while the goddess with her right hand embraces him! Pharaoh wished to show his descent from the gods—but as this symbolical picture at the age of seventeen months would have answered just as well as at seventeen years it seems as if it was the custom for the Egyptians to suckle children to the age of seventeen years. To us the intaglio seems impossible, but a patent nursing bottle and a child of seven months would come near the ideal of conventional suckling of to-day which too many doctors recommend.

AMERICA IS OR SHOULD NOT BE BEHIND IN COOKING.

It is often truly said that America has means of cooking to excel other countries: 1. As to things to cook, and 2. as to things to cook with.

1. Nature has lavished on America a splendid soil and cultivation, and Congress has appointed a department of Agriculture in the President's Cabinet to look after food production and these wise national provisions have already redounded to an abundance of food products not elsewhere seen. America is the granary of the world and its store-house of cattle. One feels proud of what has been done and all medical men should sustain the Agricultural bureau of our government. The subject of American food products has lately been a matter of great diplomatic discussion and legation management with the nations

of Europe, and European people live better because of our agricultural harvests.

2. I often think that Count Rumford's heart would leap for joy if he could see the modern appliances for cooking used in America, and that he would be displeased with his successors for not awarding his prizes to manufacturers of all sorts of cooking implements such as are everywhere seen in America; the modern cooking stove for example is a marvel of fine iron casting and of a skillful application of the principles of heat. The oil stoves—the steam cooking apparatuses, the common closed baking pans where high steam is used, the bilateral cooking of beefsteak, the cooking by gas are very worthy of commendation. But with all these advantages it must be owned that there is too much bad cooking in our fair land. In place of good coffee, bad coffee is common, spoilt in the preparation; steaks are fried to become like leather, and so on through the list. I have labored so long in this field and with seemingly but little good result that I believe the ethics of bad cooking cannot be changed unless physicians organize and continue to work to promote a healthy public opinion as to this most important matter. The American Medical Association should endorse the sentiment that bad cooking results in physiological sin and is a crime against the very woof and warp of society, by cheating it of its inalienable rights, just as dear as those were that our Revolutionary fathers fought, bled and died to secure from King George III. How much use is it to have free citizens if they are condemned to eat badly cooked food which causes weakness, sickness and disease!

The ethics practiced towards Dr. Sylvester Graham who years ago advocated facts about wheat bread which are now accepted show the slow and conservative ways in which things are sometimes done. I remember as a boy how much he was talked against and persecuted. But now that all the actors have passed away it remains for some one to give him due credit and justice.

The physiological and pathological effects of food used exclusively and singly, on the blood, sputum, feces, on the nervous system and the alimentary canal have not been studied by physicians enough on man; a few have done it well, but their reports are not received by the profession in general and are often scouted mostly on personal grounds which should not enter into scientific investigations. It is far better to simply repeat such work and see if it is correct, giving the phenomena free chance and scope; then if the facts are not sustained, controvert and condemn; but in this age words and arguments not based on facts are worthless. As one has truly said, the present age has a very strong magnifying glass and applies it too for the bringing out of truth, which stands all tests.

Ethics of food based on facts will stand the test of time and prove of lasting value. Hence it is our duty to change all *our* false ethics and act in accord with truth and justice and then shall we truly honor our profession and add new lustre and glory by its beneficent acts.

A Throat Specialist's Opinion.—Lately writing he says: "I do not know any food to cause or cure diseases of the throat." Now I know that oat-meal will cause sore throat, and a lay-man once told me he would not eat oat-meal because it made his throat sore. *I know also that some coughs depend mainly upon the irritation produced by gravelly deposits*

in the expectoration made up of crystalline matters such as are found in the urine and feces, the natural exits of these saline deposits. These deposits are caused by living on too much food from the vegetable kingdom so that the natural channels of elimination are not able to expel them. Asthmatic coughs come under this head. *Pharyngitis sicca* I have seen relieved at once by a liberal diet of hot water and animal food. To my mind such facts as these are sufficient reasons for connecting the cause and cure of throat affections with food. Perhaps my opinion in laryngology as to food is not authoritative; however, it is now thirty-four years since Alvan Clark made for me a laryngoscope and twenty-six years since I first did thyrotomy without tracheotomy for the removal of intra-laryngeal growths, and while my practice has not been limited to laryngology or gynecology, or the chest, or making diagnoses with the microscope, I have endeavored to do what might be called an all round work and thus my labor with the microscope and on foods has demonstrated to me clinically that intra-laryngeal growths are amenable to food treatment.⁷ We forget often that nature is all the time trying to cure lesions in the throat (which never rests) as well as in other parts of the body, and if she has the right food to do it with she more often succeeds than when the bad food cause is kept going all the time.

The ethics of medical agnostics are sometimes amusing despite the serious consequences they often produce. A noted statesman lay seriously sick; eminent medical men examined him and finally after consultation told him he could live but a few hours; he asked them to leave him alone, but they replied, "You are dying and need us!" "Why do I need you if I am dying; leave me alone and let me die in peace;" the medical men went, the old man took a big pull of brandy and lived several years. It is no uncommon thing to see in the daily press notes of Blank's serious illness, that all hope had been given up by his physicians two or three of whom were constantly at his bedside. (It is no wonder a man does die when he has several doctors constantly attending him, presaging death.) But some of these cases live several days longer than the time allotted for them by their medical advisors and as in the case noted, sometimes they get well in spite of the doctors. These medical jackals are a drag on the profession; if one tries to enthuse hope in a seriously sick chronic case and with hard work, patient labor and much anxiety endeavors to start the patient toward health, such will do all they can to hurt and hinder; these are harsh words but they are true and need to be spoken in such an address as this.

"Eat what she pleases."—"Doctor, what shall I give my girl to eat" was lately asked by a mother whose daughter aged 14 had a lesion of the spinal column and whose breakfast was made up of a cup of coffee and a little toast, and who immediately went off to attend school all day. The answer, "eat what she pleases." Now I suppose this is a typical answer and fitly represents the state of medical action, if not opinion, at the present time among a large class. It was honest no doubt as the physician believed what he said sincerely. But as one can be sincerely

wrong or right, sincerity does not cover the ground of this action. Under the present medical ethics I do not see how the busy practitioner can come to any other decision. To be sure there are writings enough about food but there is a great lack of writings to show how foods do act on the system as verified by chemical, morphological, physiological, pathological, culinary qualitative and quantitative tests, on man as a race.

For example take *quantity*. Water hot or cold taken in moderate quantities as food is essential to human life. But put a tube down a man's throat and attach the outside end to a hogshead of water and turn the water on and the result would be disastrous. Quantity should be normal.

Quality.—Some mushrooms are edible; other mushrooms are inedible. The quality of beef makes the greatest difference. Quality should be good.

Cooking.—Bad cooking is notorious for its bad effects. Good cooking is celebrated for its good effects. It should be good.

Pathological tests.—Carbo-hydrates in excess will put yeast in the blood, albumen in the urine, cataract in the eyes, to name no more.

Physiological tests.—The diaphoresis, diuresis, peristalsis downwards, the thinning of the blood, the solution of salts by drinking hot water is an example. The tests should show normality.

Morphological tests.—These include the normal morphologies of blood, urine, sputum, feces, skin, which vary to abnormal when improper food is eaten. These should be normal.

Chemical tests.—Albuminuria, glycosuria, oxaluria, etc., are removed by excluding certain foods and brought back by a resort to those foods again.

The standard of healthy secretions, I prefer, is found in a healthy babe suckling a healthy mother's breast.

These are the tests the writer approves of, and which he thinks the profession should employ in dietetics.

MEDICAL FOOD ETHICS TO COME.

These will be given by public opinion unless the profession does. People are finding out that medical men must care for the food question. Hon. Chauncey M. Depew, LL.D., the noted after dinner speaker on both hemispheres, the orator on great national and collegiate occasions has his popularity based on gracefully voicing public sentiments, and what he says reaches such a large number of people that his utterances may be taken for a fair index of popular thought on almost any subject he desires to discuss. He lately said that soon physicians will prescribe what people should eat at banquets and all other occasions. It will not be the first time that public opinion has compelled physicians to take up neglected departments of their art. The late Dr. Benjamin Cutter, my father, told me that in Massachusetts about one hundred years ago there were so many wives dying in child-birth under uneducated mid-wives that Governor Brooks and other men of influence, made a determined effort and compelled the physicians to become obstetricians with the result of lessening the mortality and changing the fashion from female to male obstetricians.

The air is full of the food question. All classes of people are interested in it, that is, if one can judge from observation and when the people rise to the height of compelling physicians to treat diseases by

⁷ On the laryngoscope and rhinoscope, Boston Med. and Surg. Jour., 1861, 1866, 1867. Case of aphonia cured by extirpation of a neoplasm on the vocal cords by laryngotomy, Am. Jour. Med. Science, Oct. 1866. Sequel to a case of laryngotomy, thyrotomy, Arch. of Laryng. Oct. 1882. Laryngological contributions, Journal Am. Med. Assoc., 1889.

food and make medicines secondary matters, there will be not so much difficulty in getting papers for this section as there is now.

Experiments.—Experiments in feeding are going to be carried out on a large scale so that we shall know if the experiments that have been made are correct and on a broad basis, and if not correct to right them so that the physician shall know just what to prescribe. Such experiments will lead to *Chairs of instruction on foods in our medical colleges.*

Physicians (not pharmacists, who are not educated to be clinicians) are to be the teachers and authorities on foods. I do not attack pharmacists for the work they are doing on foods, but instead the idea that clinicians have neglected their duties in this line; I believe that possibly my letter published in THE JOURNAL Dec. 19, 1887, started the movement that resulted in the Section of Materia Medica and Pharmacy in our Association. I am truly a friend of pharmacists.

Possibly the need of physicians will be lessened, as lives will be lengthened and the sum of human weal increased, but the legitimate business will be work enough for scientific clinicians who will cure disease by preventing it, and such work will be better paid than now.

Character of the Food Work.—It will probably be national as the nation which is best fed will, other things being equal, be the one to conquer the others in war. Nations will evolve by good feeding and devolute by bad feeding. Beef has made Britain great in war. Diseases will be treated by prevention rather than by cure, by removing *prime* causes rather than by removing results of these causes or the secondary cause. The relation of germ diseases to food will be understood to depend mainly upon a weakening of the dynamic forces of the body systemic by bad feeding thus rendering it a prey to parasites. When medical men will be able and willing to do their duties as to food, so that their wards are in good health by avoiding the causes of ill health and sustaining the body systemic in a normal condition, the heights to which intellectual, moral, scientific and religious culture will go are simply beyond the conception of thought.

The Bible tells us that the fall of man came by eating forbidden things; the words health, hale, holiness, all come from the same root. I believe there is such a thing as physiological sin, and that if we had sound minds in sound bodies there would be less sin and crime than now. The late Dr. West of Princeton, Mass., suggested that the great use of tobacco might partly be explained by people living on flour deprived of its normal mineral constituents; hence the starved nerves "cry out" for more food and men stifle these persistent neurotic cries for proper food by narcotizing themselves with tobacco! I think it may be so, for I have heard of drunkenness being cured by eating beefsteak when the desire for drink came. In my opinion the present great prevalence of diseased nerves, eyes, ears, teeth, hair, bones, the asthenic type of disease—the decline of the normal increase of our native population, the prevalence of tuberculous diseases—to name no more—come from the too exclusive use of carbo-hydrates so popular in fashionable and unfashionable life—and that common flour is one great food at fault, because society demands that bread should be *white*, and hence impoverished of its phosphorous bearing gluten and mineral soluble salts.

CONCLUSIONS.

It has rarely been the fault of the medical profession to stand in the way of the best means of treating disease. Indeed, as public opinion governs all things, so is the profession held back from its legitimate work by a lazy public opinion, so a little earnest thought by the great mass of people on their relations to medical men would be of great assistance to us. I think medical men do not comprehend their real power in the community, and if on these food questions after thorough examination an opinion is given and concurred in by the profession, public opinion will wake up to the full importance of the subject.

All I ask now is that before condemning or endorsing the views here put forth, the honored and honorable members of our Christ-like profession will examine for themselves the truth. If they have not done so already, they should experiment on animals (themselves the best animals to employ) by living on single articles of food and study the blood, feces and urine and see if the standard of perfect health is kept up. Those who will not do this on animals must keep silence when their opinions clash with the facts already given.

Dr. Sims, a late President of this Association, once told me to give details whenever I presented any subject—so I will try to follow his directions, *i. e.*

Medical Food Ethics to come in the Sections of the American Medical Association will, according to my best knowledge and belief be somewhat as follows, provided general experience coincides with the experience of some American physicians.

The Section of Obstetrics and Diseases of Women will use its influence to have food in motherhood beginning with the erection of the family altar and kept up till the children have outgrown the family home by feeding on a diet of two-thirds animal and one-third vegetable food,⁸ and thus many difficult labors will be avoided, I think even those from contraction of the pelvis, convulsions from fatty degeneration, flooding from want of tonicity. There will be plenty of breast milk so that it will be unnecessary to use artificial foods. Children thus fed before and after birth will have good constitutions, other things being equal, which is a great thing to have in such a world as this.

As to *Diseases of Women.*—Should this Section adopt the views which the writer thinks are correct, to-wit—that a great deal of gynec disease can be best handled by prophylactic and post-phylactic feeding as a foundation, then will their ethics include a regulation of the diet of women even before their birth.

The writer knows of cases of uterine fibroids cured by diet. He believes that in cases of ante-flexion where the uterus has been kept in place by a topographically correct pessary, if a proper diet is enforced that the relaxed and stretched ligaments will by nature's own processes be restored to normal length. The stretched ligaments will become shorter and the shortened ligaments become longer; the vaginal muscular tissues will resume their normal tone and contraction, and with these results the uterus will stay in place (normal) after the artificial support has been withdrawn. He speaks from experience.

When a case of laparotomy is in good order from

⁸ Food in Motherhood, London, D. Stott, Pub'r, 370 Oxford St.

feeding, the progress of the case is very satisfactory. An extra-mural fibroid was once removed from the fundus of the womb by one of the great American gynecists; the case had been under diet for its removal, but not satisfied with the slowness, the knife was resorted to, over fifteen years ago, with perfect success and the delight of all concerned.

The writer has reported a few of his cases of fibroids treated by food, and in a table appended here gives more case histories with those of patients sick with what was called cancer. It has been my experience and that of others to find in every case of cancer that came under our observation a history of great loss of nerve force from shame, poverty, grief, excessive worry, over hard work and improper feeding, and hence my definition given in 1887 of cancer being "tissue under mob law."

The Section of Surgery and Anatomy in my opinion will be decided in its utterances as to the food of their subjects. A late case is in point: A man was on diet for syphilis; in exposure in a boat off the Massachusetts coast, with hard rowing in rather cold weather, unused to work, he had a bone felon in the palm of his right hand, took cold in it and he went to a local surgical sanitarium in Boston. The writer, as the patient said, made quite a mental commotion in the institution by ordering porter-house steaks to be freely eaten; the orders were obeyed, and the attending surgeon said he had not seen a like case do so well.

Again, diet is better than surgery, sometimes, and if more largely practiced, would be many times. A case of empyema of long standing was brought to me, a man of about sixty-five years; he had been advised by the surgical staff of the Massachusetts General Hospital to have an ex-section of a part of a rib, though, with all due respect to their learned opinion, I never could see how removing a section of the rib was going to bring about a normal condition of the pleura. I told the patient that if he would live on beef and beef alone (N.B.—I never did and never do prescribe raw beef), I thought that nature would cure him. He followed the advice and was reported as cured in less than a year. It is said that prize-fighters after training, which includes dieting, sustain injuries in fights which look very serious, but which heal up with little or no trouble. When a subject of any surgical operation is filled up with gasses from fermenting food, or more or less undergoing a fatty degeneration from languid and impeded circulation from paralyzing foods, when he is half starved on improper food, depressed by food that is hard to digest, from bad quality, quantity or cooking, to name no more, he is less liable to make a good recovery than if he was in line with dietetic normality. This is on the principle of not wasting force on abnormal environments, and thus having it to use in the repair of the lesions left by the surgeon. Oftentimes surgical operations are upset by colds. Now, patients fed rightly are not apt to take cold, as the blood corpuscles are not huddled or stuck together, the fibrin filaments are of normal fineness, there are no skeins of fibrin, nor blood crystals, all which make active factors in the apparently simple process of taking cold; the blood driven from the surface of the body by the application of cold congests the weakest internal organ and stays there because of the abnormal physical features named above and which can be removed by good feeding. This is an age of germicides in surgery; now, there

is nothing better to resist germs, than healthy tissues made so by good feeding. We are all of the time surrounded by the germs of disease which do not infest us if our health is good and normal. Depress that health, and the germs will be more apt to take root and grow. Peach blight is a result, not a cause.

Food relations to the Surgeon.—If dyspeptic clergymen will write dyspeptic sermons, then dyspeptic surgeons will be apt to do dyspeptic surgery. A surgeon needs a clear, level head, a keen eye, an educated touch, a strong heart, a velvet, but firm and steady hand, and withal an executive ability that is ready for emergencies and for the unexpected, which is sure to happen. But how can these requisites be had if he live on baked beans or other foods which are difficult to digest, cloud the mind and take away his nerve and verve? Nor do I think that surgeons who drink liquor or are soaked in tobacco, which some almost eat, can do the best work, for their hands will shake under fire.

Pathological Anatomy is built on bad feeding which is the strongest agent in the production of diseased structures.

Section of State Medicine.—The food ethics of this Section relate to the alimentation of the army, navy, marine hospital services and the people in general. It could well embrace the duties of our Section of Dietetics. It should have more to do with State and National laws about food. No matter what else is valuable in a State, healthy citizens are the articles of highest value. They cannot be healthy citizens without proper food.

The subject of diet for travellers is of State importance. Certainly if articles of food, like hogs and cattle for example, are matters of governmental care as shown by the Quarantine inspection for trichinosis, and the cattle pest, and the ethics of transportation, to name no more, the proper manner of serving up of these articles of food on the rail or boat, at stations or hotels even, are matters worth the solution of State Medicine. This position is one argument in favor of having a Secretary of Public Health in the President's Cabinet, an event greatly to be desired.

Section of Ophthalmology.—If it is true that sugar affects the eyes as aforesaid, certainly this Section has something to do with food. If it is true, as one ophthalmologist asserted, that nine-tenths of eye diseases were due to deficient or improper feeding, I think the position is correct. Inattention to the food question by this Section is an ignoring of the rational treatment of all diseases, to-wit—removing prime causes. The writer wishes this Section would heed these words and teach these specialists who cannot begin to meet the demand for their services caused by love of sweets in foods.

Section of Laryngology and Otology.—From what has been said above, this Section cannot afford to ignore food. Besides topical applications, such as iodoform, iron, nitrate of silver, etc., as Dr. Louis Elsberg used to say, act mainly by stirring up things in the hope that they would settle down in a normal condition, as the atmosphere does after a thunder storm. In other words, nature is the healer, and the more the recuperative powers of nature are, the more successfully will things settle down. In no way does nature get more force for the human body than from proper feeding. I have known laryngeal growths so voluminous as to cause aphonia, disappear without

any but nature's treatment. And as I have known large fibroids to disappear under diet, it seems fair to infer that in the constant laying down and taking up of body tissues, normal structures can replace throat growths when nature is fully supported by good feeding. I have known enlarged tonsils, flabby throats, pharyngitis sicca and catarrhs to disappear under diet. When coughs are caused by gravel in the sputum, gases in the alimentary tract from hard digesting foods, or foods in excess, from fibrous hypertrophies, to name no more, I know there is nothing like the food treatment to remove these prime causes.

(To be concluded.)

SOCIETY PROCEEDINGS.

The Medical Society of the County of New York.

Stated Meeting, Monday, January 23, 1893.

DR. CHAS. CARROLL LEE, PRESIDENT, IN THE CHAIR.

Dr. Simon Baruch read a paper on

PRACTICAL DATA ON THE APPLICATION OF WATER IN SOME INTRACTABLE DISEASES.

The recent revival of hydrotherapy is an interesting phase of therapeutics in this country. Three years ago the first paper, giving a general review of the uses of water external and internal, by lavage, irrigation, baths, etc., was read before this Society. Therefore the history of this subject is closely bound up with the history of this Society. Articles on this subject have now become numerous. A new journal has appeared on balneology, and a department in that magnificent specimen of American journalism, the *Annual of the Universal Medical Sciences*, chronicles the advances in this therapeutic specialty. Indeed, a recent letter from Dr. Winternitz, Professor of Hydrotherapy in the University of Vienna, refers to the fact that more is now done in this country for hydrotherapy than in Germany, its birthplace. For this reason I venture to offer some practical remarks on this subject.

The chief, though not the only aim of hydrotherapy, is to stimulate or give tone to the nerve centers. Since all vital energy emanates from the latter; since the proper performance of all the organic functions depends upon their activity, it is fair to deduce important therapeutic results from this agency, which influences it so potently. The main question is, does the application of water to the cutaneous surface stimulate the nerve centers? That this is a trite physiological fact, is daily observed in the effect of a dash of cold water in reviving a case of syncope. Here we have a brief shock to the sensory peripheral nerves, followed by reaction, whose effect is transmitted to the central nervous system and thence to the respiration, deepening it and the circulation, restoring the falling pulse; thus the temporarily dormant vital powers receive a stimulus whose appreciation must convince the most skeptical by its very simplicity. At this time I do not propose to dwell upon the various modifications which change in the temperature of the water applied to the cutaneous surfaces may produce, nor the remarkable difference of effect resulting from the increase of the pressure under which it strikes the skin, nor the valuable results of changes in the duration of the procedure. Suffice it to say that we have in the external use of water a therapeutic agent so flexible that it may be adapted to the most varying types and forms of disease.

The following brief outlines of cases are presented in order to enable you to obtain a view of the practical application of hydrotherapy to some intractable chronic diseases, to demonstrate its flexibility and to point out the methods of adapting it to varying conditions.

Intense Chlorosis.—Miss H., *et.* 20, ill two years; under constant treatment by gynecologists in Harrisburg, Baltimore and Philadelphia, was brought as a last resort to Dr. T. G. Thomas to be placed in his sanatorium. Dr. Thomas discovered no uterine trouble, and referred her on June 8, 1892, for hydratic treatment, with a diagnosis of chlorosis of aggravated type. Local medical and institution treatment, iron, arsenic, diet and massage, and change of air had been tried in vain. Although the patient was plump, a more pallid creature could not be imagined. The slightest exertion produced difficult breathing and rapid heart action. Menstrual flow was regular, but scant and very pale. Blood examined by Fleischl's hæmometer registered 31 per cent.

June 10. Preparatory treatment by hot air baths and douches, to educate the patient's reactive capacity, was ordered. Fainting in the hot air bath, she was removed, a spray douche of two seconds at 64°, with 20 lbs. pressure, was rapidly passed over her, in a sitting posture. She again fainted. Friction produced no reaction.

On the following day a milder course was pursued. She was gently wrapped in a long-haired woolen blanket for forty-five minutes. Parts of the body were successively uncovered and splashed with water at 60°, thrown with some force from the hollow hand of the attendant. This was followed by friction, and continued until the whole body had received the ablution and friction. The same treatment was continued on the 11th and 12th, when she fainted twice. This was repeated without fainting until the 16th of June. She was again placed in a hot bath (167°) with a cold compress around the head, and given frequent sips of ice-water. The head not being subjected to the heat, the patient was enabled to breathe the cool air which permeated the room. When the cutaneous vessels became turgid she was seated in a tub containing eighteen inches of water at 100°, thoroughly rubbed for three minutes. This was followed by an ablution at 60°, good friction drying and general massage for fifteen minutes. She fainted twice during these procedures.

July 8. The last treatment had been continued, reducing temperature of the spray douche daily one degree; to-day she had an air bath (160° F.) followed by spray douche under 30 lbs. pressure for five seconds, beginning at 80° and rapidly reduced to 50°, followed by fifteen minutes' general massage. She reacted well and felt comfortable.

July 14. Same treatment has been continued. To-day she had a hot air bath (175°) followed by rain bath thirty seconds, at 94° reduced to 69°, then spray douche ten seconds 79° to 54°, and general massage. Reaction good.

July 30. This treatment has been continued until to-day she took a jet douche at 45° without flinching. Being absent in Long Branch, I wired Dr. S. T. Armstrong to examine her for me. Dr. A. reports: Miss H. looks quite well, eats and sleeps well, and is certainly improved since I last saw her. The comparison test indicates about 100 per cent. hæmoglobin.

August 1. Miss H. left for her home in Pennsylvania. This case certainly illustrates:

1. The effect of the douche in improving the nutrition.
2. That hæmatosis may be enhanced by the stimulus conveyed from the periphery to the nerve centers and thus reflected upon the blood-making functions (as has been well shown by Winternitz, Thermes and others).
3. That the most feebly reacting patient may by perse-

See "The Uses of Water in Modern Medicine," by Simon Baruch, D. Detroit: Geo. S. Davis.

verance and proper adaptation of the hydiatic procedure, become accustomed to this treatment. The danger of shock from cold water is proven to be chimerical by this case.

If this fragile and sensitive young woman could be accustomed to the douche by beginning with mild procedures, no chronic case that is not *in extremis*, could fail to respond to it.

Nervous Dyspepsia—Anæmia.—Mrs. O., æt. 28, resident of Florida, consulted me May 5, 1892, for "catarrh of the stomach." Because of agonizing pains after meals, she has been living on mush and milk, and has had medical treatment for several years, with diminution but not disappearance of the pains.

She is emaciated, her voice is feeble; she is depressed and hopeless. Her wan face and prematurely old appearance bear evidence of a life of constant physical suffering. There is not the particle of the hysteric element in this case. Ordered at 12:30 P.M., a full test meal at Delmonico's, which she reluctantly accepted, because of dreaded increase of pain. Returning to my office at 5:30, the stomach was washed out without difficulty. To her surprise my prediction that her dinner would be digested was verified, a little tomato peeling being the only remnant visible.

The diagnosis of a gastric neurosis being thus confirmed, she was ordered a mixed diet, chiefly consisting of hot milk and stale bread and hominy for breakfast, adding eggs (soft boiled later) same with fish or oysters for luncheon, and steamed rice and roast beef for dinner. Dessert and salads forbidden. The general invigoration of the entire system being the chief therapeutic element in this case she was at once placed upon daily hydiatic measures as follows:

May 6. Hot air bath at 169° for six minutes filled the cutaneous vessels of her pallid skin and produced free perspiration. This was followed by a tub bath of water at 98°, for five minutes and a rain bath of 95° reduced to 90° for ½ minute at 20 lbs. pressure for the purpose of increasing cutaneous action. A tonic procedure by the spray douche at 90° for five seconds, with friction, closed the first treatment and resulted in good reaction.

On the following day she remained in a hot air bath at 164° only long enough to render the cutaneous vessels turgid to promote reaction from the rain bath for 30 seconds at 90° reduced to 80° and a spray douche at 70°. Reaction very fair.

May 11. Temperature of rain bath was reduced to 75°, and a jet douche at 65° was added. Reaction good.

May 23. Same treatment with jet douche to back at 60°.

May 25. Complained of sciatic pains on right side. The Scotch douche was applied to the gluteal region for 30 seconds followed by jet douche of one second at 59°.

May 31. On account of menstruation treatment had been omitted for six days. Sciatic pain is relieved. Treatment of May 11 resumed.

June 12. Temperature of rain bath reduced to 70°; patient has been steadily improving in flesh and spirits, being free from pain until to-day. The addition of cauliflower to her diet reproduced pains. Stomach was washed out and some mucus found in it.

Temperature of jet douche was raised to 60° as patient was excited by it.

June 19. Jet douche suspended; hot air bath 180° followed for 40 seconds by rain bath of 75° reduced to 65°. Stomach was washed out again.

June 20. Pain returning, the constant current 12 milliamperes was applied by a large flat sponge electrode over epigastric and a small one over lumbar region.

June 27. Temperature of baths having been higher, were now reduced, patient being again depressed. The jet douche was given at 50° for 3 seconds. Reaction good.

July 9. Electricity having been unavailing and there being fermenting material found in the stomach, the Scotch douche has been applied to epigastric region for 30 seconds after the rain bath 70° to 45° daily, and followed by jet douche at 50° or 3 seconds. Patient now feels sufficiently restored to go to Buffalo to her parents.

Under date of November 26, 1892, she writes that she has gained fifteen pounds in weight and is much stronger, etc., has continued the diet prescribed, because, like most of these neurotics, she "feared her stomach was not equal to much of a change." Most of the time she is entirely free from pain, she has slight distress every now and then, but expresses the warmest gratitude for the help given.

This case is similar in many respects to the case of Dr. H. reported in "The Uses of Water" pg. 85 Vol. 1 and 3, demonstrating the value of hydrotherapy in improving the nutrition and thus furnishing better blood to the stomach nerves, which are calling for it through pain.

Diabetes and Obesity.—Failure of Diet.—Success of Hydrotherapy.—On March 7, 1892, I was consulted by Mrs. S., wife of a prominent police official, æt. 63. She had been suffering from lassitude, loss of appetite and depression of spirits for several months; had been relieved of muscular rheumatism by wet packs and massage a year ago.

Examination of urine reveal 6 per cent. sugar by fermentation test, spi. gr. 1040, quantity in 24 hours 51 ozs. She was languid and indisposed to exercise, weighing without clothing 252¼ lbs. on the 21st of March. An antidiabetic diet was ordered and systematic walking exercise. The former was rigidly adhered to for four weeks without effect, the latter could not be accomplished because walking two blocks "put her out of breath," and exhausted her. Acting upon the well known physiological fact that next to the liver the skeletal muscles hold most glucose, and that sugar is by exercise of these muscles best utilized for the benefit of the organism, I regard systematic exercise of quite as much importance as diet. I have the record of six cases in which these two combined entirely and permanently removed the sugar from the urine. A strict diet having failed in this case, it was important that some therapeutic method be adopted to enhance the patient's capacity for muscular exercise. It was determined to reduce her weight and invigorate the nervous system by a carefully regulated hot air bath until free perspiration ensued, once a week, followed by the spray douche at 90° for ½ minute, and at 80° for ten seconds, this succeeded by active massage. Five times a week she received a tonic hydiatic procedure beginning on the 28th of March with the dry pack for ½ hour to fill the cutaneous vessels, followed by a general abluition at 70° and good friction. Patient attended daily, coming from her home on West 152nd street in a carriage, as she was unable to walk.

On April 15, she had lost 61 lbs. and felt able to walk six blocks twice a day.

April 22. Urine showed spi. gr. 1035, sugar 5¼ per cent. Wet packs 45 minutes, sheet wrung out of water at 50°, followed by hot air bath 10 minutes at 85°. Sponge abluition on back at 70° with active friction in tub—massage 15 minutes. The object of this treatment was to increase tissue change and improve the circulation in the muscular tissues. This was continued until the 6th of June, the jet douche at 75° being added as a tonic and for contracting the muscles. The result of these procedures was ability to walk more every day until she was not fatigued by four miles per diem. The diet being rigidly adhered to, a rapid decrease of sugar was evident every week from the date of the first half mile walk.

Since July 1, she has been entirely free from sugar until the present time; frequent analyses having been made until the 1st of December, 1892. In this case the diet alone

pursued for five weeks made no impression, but as soon as the patient was able to oxidize her sugar by means of muscular exercise, improvement became pronounced. No medicinal agent could have accomplished this change in the nervous, muscular and vascular structures in so brief a time, if at all. Of this I am convinced by other cases similarly treated.

Diabetes mellitus cured by Diet and Hydrotherapy.—Mrs. Dr. B., æt. 65, applied for treatment for a severe herpes zoster on the left part of the back below the scapula. On the evening of April 4, 1890, I was hastily summoned, after I had treated her for herpes on the preceding afternoon. She was absolutely comatose without any reflexes, etc. Drawing some urine by catheter I found no albumen, but decided evidence of sugar, this being its first discovery. Towards morning she became conscious spontaneously and began to improve. On the following evening she was seen in consultation by Dr. A. J. Loomis. She continued under the treatment, chiefly dietetic and codeia and constant current for severe neuralgic pains at former seat of herpes. Sugar has been almost constantly present in small quantities one-half to one per cent. During the winter of 1892-93 she decided to take a thorough course of hydrotherapy, encouraged by the patient whose history is given above and who lives near her. The same treatment had not the slightest effect on the urinary sugar. But she regarded herself to be so much invigorated and capacitated for work and exercise, that she voluntarily takes the treatment twice a week as a tonic agent.

Sexual Hypochondriasis.—Failure of Hydrotherapy.—M., æt. 47, was referred on June 5, 1892, to the Institute by Dr. J. Weir Mitchell, of Philadelphia, with the following history (here abbreviated): Patient complains of impotence and a sensation of water trickling down front of thighs. Habits good, had three children all dead; two died at birth. Three years ago when his wife was absent he first discovered the trickling sensation. On her return he found sexual desire present but was incapable. Emission occurred and still occurs in sleep. Had two strictures cut without relief. After being in the mountains a year ago he had two successful connections and again in November, 1891; more frequent emissions and firmer erections during sleep. These are rare now. Present state—stout man abdominal pannus; uro-genitals, cremaster reflex absent; paræsthesia along anterior crural nerve; electrical examination negative; sleeps well; appetite good, no sperm in urine.

Dr. De Schweinitz pronounces eyes normal. Dr. Mitchell regarded patient as suffering from some slight, but distinct trouble of the lumbar or dorso lumbar cord, dread of sexual failure is probably emotional; full recovery of power is probably not to be looked for. Advises electricity (detailed) also douches alternating warm and spinal column.

Treatment at Institute June 5.—The patient's peripheral circulation being feeble, skin flabby and inelastic, pulse compressible and a general aspect of mental and physical depression being present it was thought advisable to give him tonic treatment as follows: A hot air bath (170°) for twelve minutes having warmed him up, a rain bath of 100° reduced to 80° during 45 seconds was given under 30 pounds pressure. General massage was given for fifteen minutes. Reaction was poor.

June 6.—Hot air bath (178°) 10 minutes; rain bath 95° reduced to 70° during one minute, was followed by Scotch douche (alternating hot and cold stream) to spine. Reaction poor.

June 11.—Same treatment was continued reducing temperature of douche daily one or two degrees and increasing pressure. Reaction is now good and patient looks brighter.

The perineal douche (jet) of 60° for one minute is now added for psychic effect.

June 12.—Patient dissatisfied, does not think he can improve by having a little cold water sprinkled on him and insists upon more active measures.

June 16.—The psychrophore of Winternitz (a small rubber or skin bladder secured to a double current straight rectal tube attached to an irrigator) is applied for five minutes with water flowing at 45°.

June 19.—Patient looks brighter, but insists that, without any test, his sexual power has not improved. He leaves for Chicago to-morrow and tells me that without my knowledge he had been under local treatment by Dr. E. L. Keys while he was under my care.

The other two cases of sexual hypochondriasis, of a milder form and in younger men, were successfully overcome by the treatment here outlined.

Sexual Neurasthenia.—Recovery under Hydrotherapy.—In a man aged 25, the tonic treatment by hot air baths followed by rain baths and jet douche to spine, gradually lowered to 35° was positively efficient in establishing a satisfactory condition. This gentleman applied for treatment for general debility. He was not a sexual hypochondriac, because he incidentally mentioned that he had been married six weeks, and did not experience the feelings that he had anticipated from sexual congress, to which he had been an entire stranger before marriage.

After two months treatment he volunteered the statement that he was entirely satisfied with the results.

Angina Pectoris.—Mr. D., aged 40, of robust appearance gives a history on the 24th of September, 1892, of having suffered for several months from agonizing pain in the præcordial region whenever he attempted to exercise much. He was disabled from business and much depressed, all functions normal. Dr. Kenne, his attendant, called Dr. Janeway as consultant; diagnosed angina pectoris. Another consultant diagnosed aneurism of the aorta, advising rest and the usual treatment. Mr. D. presented a decidedly gouty diathesis, urine loaded with uric acid, etc. He was put upon a non-meat diet, and a daily wet pack for one hour, and a continuous wet compress around left side of chest; gave glonoin and strychnia; after three months treatment, during which pain diminished in frequency and intensity, he was allowed to take a trip to Chicago. On his return he was placed upon a diet of chopped beef, preceded by hot water, for breakfast and dinner; oysters and hot milk for lunch. Compresses have been discontinued. Wet packs daily, sheet wrung out of water at 50° and followed by an affusion with water at 70°. He always sleeps soundly during the packs.

January 1.—Reports himself entirely free from pain although he has done more work than ever in his life, and passed through the excitement of seeing his factory burned down and reconstructing it.

The soothing effect of the wet pack and its effect in promoting tissue change are well exemplified in this case.

Incipient Phthisis.—Mr. S., from Kentucky, æt. 26, merchant, consulted me at Long Branch on July 29, 1892. Looks pale, emaciated, states that he has been losing flesh and coughing seven months, is constipated, has no appetite. Caught cold during a fire. No hereditary element. Temperature 101°, pulse 120. Physical signs, percussion dull over left supraclavicular space, respiratory murmur in left apex harsh, respiration prolonged. Ordered calomel, 6 grs., and absolute rest. July 31, feels better. Temp. 99°. Ordered to go to the Hydriatric Institute for treatment. Here he was weighed (nude), 106½ lbs., and received a hot air bath until warm, to enhance his reactive powers; this was followed by a rain bath of 95° reduced gradually to 80° for forty seconds

under 10 lbs. pressure, gradually increased; then spray douche at 15 lbs. pressure, gradually increased to 30 lbs. for four seconds, at 70°. This was repeated daily. He reported again at Long Branch ten days later looking better, appetite improved and with a gain of 1½ lb. He says a friend advised him to have his sputum examined, the latter was found to contain bacilli. He was urged by his friend to see Dr. E. G. Janeway, who after prolonged examination pronounced him phthisical, and advised him to leave the city at once and ordered creosote. As he was improving under hydrotherapy and disliked to leave, I regarded his departure with disfavor and advised continuance.

September 8. The hot air bath, followed by rain bath 80° to 70° and spray douche 70° to 40°, have been continued; until to-day patient weighs 114 lbs., a gain of 7½ lbs. in five weeks, appetite is excellent, cough still troublesome; is very hoarse, temp. 101°. Benzin inhalation and ¼ gr. codeia every four hours improved cough in two days, during which the hydratic treatment had been discontinued. It was now resumed.

September 12. Temp. is 90°, cough reduced to a minimum, appetite excellent. Weight 113½ lbs. Has been taking 6 drops creosote t. i. d., which sickens him and is discontinued. Ordered maltine with peptones t. i. d. in milk.

September 17. Hot air bath (170°) three minutes, rain bath 80° reduced to 60°, from which he reacted well. Cough troublesome. A spirometer test shows 190° before and 260° after treatment, which is 20° above the average for his height.

September 20. Dr. J. S. Ely reports tubercle bacilli in small numbers.

December 30. With occasional interruptions and loss of weight, patient has progressed well, and to-day weighs 121½ lbs., looks well, coughs but little, no temperature, and is anxious to go home. Dr. Freudenthal, who treats his throat, writes January 12, 1893, after detailing from his case records the physical signs he found on July 27 and again on November 11, 1892: "Patient looks and feels much better and has gained 10 lbs. in weight. Ulceration of the ligamentum glosso-epiglottiticum and of the vocal cords, which have healed under lactic acid and menthol oil (20 per cent.)."

"Although I am not as optimistic as you are regarding water treatment, I must acknowledge, that the improvement in this case is remarkable!"

January 21, 1893. Patient is to-day almost free from cough, has good appetite and digestion, weighs 123½ lbs. (a gain of 16 lbs.), and five lbs. in excess of his average weight in health. Dr. Van Gresen reports that no tubercle bacilli could be found after examination of seven slides.

REMARKS.—There having been no change made in the patient's diet, mode of life and treatment, this case is a clear illustration of the utility of judicious hydrotherapy in improving nutrition in cases that usually thwart us. Clinical evidence of its value in phthisis is accumulating so rapidly that I need only refer here to a few of the cases I reported to the State Medical Society last February. One of these, *et.* 33, of one and one-half year's duration, beginning with pulmonary hæmorrhage, gained 24 lbs. in three months, and coughed so little that no specimen of sputum could be furnished; another 36 years old, ill two and one-half years, beginning with hæmorrhages, gained 21 lbs. and lost all bacilli from sputum, and returned to work; another *et.* 31, ill one year with repeated hæmorrhages, night sweats, etc., who was discharged after one year's treatment with 20 lbs. gain in weight, without bacilli, and slight physical signs, and able to go to work (*Transactions New York State Medical Society, 1892, p. 382*). Such stubborn facts should make us pause ere we condemn these sufferers to exile from home. A more methodical management, as indicated in the

above quoted, offers a reasonable prospect of success for home treatment. Witness the case of H. B. (*p. 383*), who after emigrating to Minnesota and improving there for six years, came to this city with a cavity and the most desperate general condition, and was sent home so much improved that he is able to attend to business.

Clinical proof abounds that phthisis offers, next to nervous diseases, the most fruitful field for hydrotherapy.

Advanced Bright's Disease with Albuminuric Retinitis. Remarkable Results from the Hot Blanket Pack.—Mr. J., *et.* 60, a foreman at a lead trap factory, came under my care by request of his benevolent employer, on the 4th day of May, 1891. I had attended him several years ago for lead colic and severe headaches, from which he recovered. I now found pronounced swelling of feet and ankles, breathlessness on exertion, morning nausea, headache, double vision and vertigo; urine showed a large proportion of albumin, abundance of hyaline casts, *sp. grav.* 1020.

Patient received 10 grains of calomel, was put on bitartrate potas-lemonade, and was ordered one minim of 1 per cent. solution glonoin every three hours until flushed. He also received hot blanket packs of one hour, morning and evening. The quantity of urine having been reduced to 22 ozs., this treatment continued active until May 28. Dr. Edward S. Peck examined his vision to-day, and diagnosed homonymous diplopia, amblyopia and albuminuric retinitis. Dr. Peck examined urine on the 29th, and found it to "contain albumin in large reduction." There being some improvement in the symptoms, the same medicinal and dietetic treatment was continued. The hot blanket packs were given once a day, by means of a blanket thoroughly wrung out of hot water, laid upon another blanket; patient was snugly tucked into the hot blanket and afterwards covered by other blankets. He remained in this one hour or more, until he perspired very freely—successive parts of the body were now gradually uncovered and thoroughly dried. General friction closed the procedure.

June 30.—Examination of urine made from time to time revealed gradual improvement, in quantity and constituents. He went to the country on the first of July, 1891. On the 9th of September he called at my office. His urine presented but a trace of albumin, he was free from all unpleasant symptoms, was strong and had resumed his duties at the factory for the past week.

October 4, 1891.—I could find no trace of albumin nor casts in his urine. He worked without interruption during the entire winter, until August, 1892, when he was obliged to discontinue by a severe diarrhoea, for which I was not called. He went to Hackensack, N. J., and was there attacked on the 16th day of August by apoplexy and hemiplegia, from which he died, after remaining unconscious six days.

Dr. St. John, his attendant, states that prior to this illness he had examined the urine, finding no casts and but a small per cent. of albumin. There was no oedema. This case illustrates the value of the hot pack in restoring the failing function of the kidneys. It is to be regretted that the patient did not remain under observation. These points however, cannot be disputed; that he was utterly disabled by pronounced uræmia and albuminuric retinitis. He recovered from these so as to work steadily for a whole year. His work demanded precision and good sight, both of which he possessed during this period.

Dr. William McLaury, who attended other members of the family saw him during and after the illness.

Cases like this should give us confidence in the value of hydrotherapy in milder cases of Bright's disease.

In the Montefiore Home such cases are not infrequent. In the report for 1891, Drs. Ettinger and Rosenthal says:

"Two cases of chronic Bright's disease owe marked improvement to the systematic application of hydrotherapy." Both had been treated for several months elsewhere, without benefit. Both suffered from extensive dropsy of abdomen and legs. Eight quarts of fluid were removed from one of these on the day of admission and the other had been repeatedly tapped. The dropsy has progressively disappeared, until now it is entirely gone in both cases."

Subute Nephritis.—Intense Catarrhal Jaundice.—Mrs. S. consulted me on June 29, 1892, being pregnant eight months. Albumin and granular casts in urine indicated nephritis of pregnancy. Two days later she was attacked by convulsions, during which she was delivered of a child which has continued to thrive. She remained comatose twenty-four hours, the urine being reduced to six ounces. Calomel, hot blanket packs and nitroglycerin "unlocked" the kidneys. The urine remained albuminous and scant for several weeks. Her recovery has been slow but steady under a non-meat diet, digitalis, nitroglycerin, etc. Urine was still albuminous when I was compelled to leave her on the 5th of September. She was now kindly cared for by Dr. A. H. Smith, who sent her to me on the 26th of September with the following (here abbreviated) history. "For some time after you left Mrs. S. did very well. The urine was abundant and the amount of albumin very small. I allowed her meat once a day. Appetite improved and kidneys remained satisfactory until her menstrual period, when there was an abrupt fall in the amount of the secretion to 30 ounces or less with increase of albumin to 5 or 6 per cent. I then put her back on digitalis and added potas acetate. This failed to increase the urine and the hands and feet became a little swollen. I then ordered nitroglycerin and in twenty-four hours, the amount was doubled. The specific gravity kept about 1015 to 1020. Diet, mostly milk. About a week ago, when the quantity of urine was smaller, she developed an intense itching of the surface without any eruption. Increase of urine was not followed by improvement in this respect.

It appears to me to be a case well adapted for hydrotherapy and I am glad she is under your observation for this reason especially. The itching is very distressing.

Bicarbonate soda has little effect. Hyosciamin gave her sleep. I sincerely hope you will be able to do something for her relief, etc." Having returned to the city on the 27th of September, I found Mrs. S. in a most distressing condition from constant itching of the entire surface; her eyes and skin had a yellowish tinge, bowels constipated, stools clay colored; no appetite; urine 30 to 36 ounces daily by careful measurement and decidedly albuminous. All sorts of local applications failed except a warm bran bath, the success of which was temporary. She was now ordered a daily wet pack for three quarters of an hour, sheet wrung out of water at 70°, reduced daily two degrees, followed by rapid ablu-tion with water at 60°, reduced daily one degree; also an enema of 1½ quarts of water every day at 80°, reduced daily five degrees until 60° was reached; Carlsbad salts twice a week; and a non-meat diet. She passed twelve ounces of urine during the first four hours after the first pack. It continued to increase daily until the quantity is reached far beyond the normal. This treatment was continued until November 1. The last albuminous urine (a trace) is reported for October 11, at which time a few granular casts were still present.

Dec. 27.—Since that time eight specimens have been examined, all of which are entirely free from abnormal elements. Patient has gradually improved, with the exception of three days of intense colic, which I attributed to gall stones. These were carefully searched for and found on November 26, since which time the pain ceased, the skin

cleared up entirely. For two weeks she had hot air baths, followed by the rain bath at 95°, reduced to 80° for twenty seconds, and the jet douche at 70° for two seconds, with massage. This tonic procedure improved her appetite. She is now taking two ounces olive oil twice a day in sarsaparilla syrup; and is allowed white meat three times a week, and beef once a week. In this case the action of the wet pack as a stimulant to cutaneous action, which relieves the kidneys of work was potent. Kussmaul, Friedrich Hoffman and others have pointed out the superiority of the cold pack over the hot in subacute cases of nephritis. Krull's injections have so frequently proven themselves the most efficient remedial agents in catarrhal jaundice, that the value of this hydropathic procedure need not here to be dwelt upon. Dr. Smith's prediction that this case required hydrotherapy proved correct.

Jan. 15.—Patient has been discharged several weeks with an allowance of meat every other day. She is perfectly well. Urine examined to-day is found normal.

Hystero—Epilepsy.—July 19, 1892.—A. F., æt. 15, was brought to the Hydropathic Institute by his father, who says on the 31st of March, 1892, on the day of his daughter's burial, the boy fainted. Ten days later he fainted in school and again two days later. Dr. S. P. Cahen was called and investigated the case at school, coming to the conclusion that it was "a form of epilepsy." The boy was kept from school and put on bromide potassium. The attacks becoming more frequent, Dr. Geo. W. Jacoby was called in consultation; the same treatment was continued. He continued to have attacks every day lasting from five to ten minutes. At first he lay unconscious, without any movement whatever, then the attacks became violent, frequently requiring several men to hold him down and prevent him from doing himself bodily harm. Dr. Jacoby was again called in consultation and made an unfavorable prognosis. Several physicians who had been called during the attacks, gave him hypodermics of morphine. Patient has also received electrical treatment from Dr. Cahen. Status presens—Face covered with acne, eyes restless, hand tremulous, gait unsteady, appetite fair but capricious, gastric oppression after meals, bowels constipated. Patient appears to be brominized.

Treatment.—Resorcin 3 grs. in ½ pint hot water an hour before lunch and dinner. He was ordered to be at once well scrubbed with soap and water. This was followed by a wet pack, sheet wrung out of water at 70° reduced daily two degrees. This to be followed by a rain bath at 90°—25 lbs. pressure gradually reduced during 30 seconds 75°.

Aug. 20th. This treatment had been used daily, the temperature of the bath being reduced two degrees every day. He had a slight attack five days after treatment was begun, none since. He was ordered to Long Branch to take surf baths.

Sept. 29. Patient has called on me several times reporting steady improvement. He was discharged cured. Up to this writing Jan. 1, 1893, no further attacks have appeared. Besides these, there were a number of cases of chronic rheumatism, neurasthenia, bronchitis, asthma and sciatica sent to the institute, for treatment by Drs. Starr, Dana, Geo. Jacoby, Sachs, Lezinsky, Walton, Feschner, Pritchard, Willy Meyer, Allen, Schoeney, Lincoln, Offenbach, Sayre and others, the results of which will doubtless be reported by some of these gentlemen. If the few clinical histories here offered will induce practitioners to utilize water more frequently as one of their remedies, I will be content.

Discussion.

Dr. Mary Putnam Jacobi: One can hardly do better than to repeat what Dr. Baruch has said in almost the words

employed by him, that in water by means of the various forms of its application we have a type of almost every other possible therapeutic measure, and only one remark should be added to mitigate the fanaticisms of certain treatment does not go far enough to meet all the indications. I have followed with the greatest interest Dr. uneducated water enthusiasts, namely, that the water Baruch's various contributions to the subject of hydrotherapeutics, and have been exceedingly delighted to see that the subject has begun to be taken up seriously in New York City where, I think, until Dr. Baruch began to study and investigate it, had been much neglected. It is curious that German physicians who think water is good for serious and intractable diseases should regard it as dangerous in ordinary hygiene. That seems to be a notion prevalent among the German population of this city, and also in Germany. I would cite the remark of Uffeeman recommending with caution that children should have the face and neck washed every day, while the possibility of washing the child's whole body every day seems never to have occurred to him. In another treatise by a German author it is said to be exceedingly good to have a course of cold water treatment a few weeks, but to be continued permanently it is altogether too exciting to the nervous system. And this superstition that the cold bath is too exciting to be tolerated and that it is something which people can only gird themselves up to with great energy and strength of will is very frequently encountered among the laity and many physicians. I remember having rather an acrimonious controversy with a doctor because I had advised the cold water douche for a lady patient. She was a typical neurasthenic. He had once had the same trouble, he said, and had suffered such tortures from the cold douche that he should never be cruel enough to ask that a delicate girl be subjected to it. I think Dr. Baruch must have had great influence over the young lady whose case he has just related to induce her to continue the treatment after she had fainted under it on several occasions. My own observation has been that if patients feel at all tired after they have undergone one seance with the water treatment they consider that they have entirely gone to pieces, and will not discuss the matter further lest they be persuaded to continue it. It seems that where persons feel so badly after beginning the cold water treatment it is because the vaso-motor system of nerves have been exceeded out of proportion to the excitation which should be conveyed to the spinal nerve centres. It is an elementary truth to which Dr. Baruch has referred that the characteristic result of the application of cold water to the skin is a very great stimulus to the nerve centres and dilatation of the cutaneous vessels, but in some instances, instead of there being excitation of the centres in the cerebro-spinal system of nerves, the excitation is expended upon the vaso-motor system, producing contraction of the blood vessels and diminished blood supply as a tertiary rather than as a secondary effect, so that the subject remains cold or chilly and the surface pale. There is also apparently contraction of the blood vessels of the brain which may account for the intensely wretched feeling from which the person suffers. It is evidently entirely improper, as Dr. Baruch has pointed out, to begin the treatment in such cases by applying cold to the surface. One must begin with heat. I suppose when the blood vessels on the surface are mechanically dilated by heat that there is such a degree of stimulus of the cerebro-spinal nerves they are not exhausted by the subsequent application of cold.

It seems to me the value of hot water in the treatment of Bright's disease is due to lowering the blood tension by dilatation of the blood-vessels on the surface of the skin. I cannot see that it acts directly to make the kidneys better,

but that by lowering the blood tension it overcomes one of the elements of the disease.

I would ask Dr. Baruch his opinion of an assertion by Dr. Weber, of London, that persons who have commencing uric acid deposits should not be subjected to the use of cold water, Dr. Weber advising only hot water. Would Dr. Baruch regard this simply as a fancy?

Dr. Frederick Peterson:—Although I came in too late to hear the paper read, yet being acquainted with the views of the author, I am sure I should coincide with most of his statements. I am particularly in favor of hydrotherapy in nervous and mental diseases. I think there are many conditions of mental disorder in which hydrotherapy is of great value. In incipient melancholia we have no other agent quite as efficient as prolonged warm baths. In motor excitation of acute mania there is, I think, no agent quite as useful as the hot wet pack. I have found by experience that it is much better than the strait-jacket and injections of hyoseyama. In a conversation with Professor Winternitz (winter?), of Vienna, who has had much experience with hydrotherapy in chronic diseases, he told me that fully two-thirds of his cases are of nervous diseases; that he found this agent successful in many diseases considered incurable. Not that it cured them, but that it alleviated many of the symptoms. Hydrotherapy should be much more used. It is valuable in chorea, epilepsy, and many spinal disorders.

Dr. A. D. Rockwell:—It would be a good thing if some one would enumerate all the drugs which have come into vogue, had their day, and then were abandoned. It would show that much useless drugging has been going on, and the superiority of rational methods. As to therapeutic methods other than medication, we cannot but be struck by their permanency. Hot and cold water, exercise, etc., have been known since the beginning of medicine, and the more we know of them the better do we appreciate them. I quite agree with Dr. Peterson as to the great value of water in nervous conditions. I would like to refer to a special use of water, a mechanical use it is true, but yet one of great value, namely: intestinal irrigation. We all know the vast misery from chronic constipation, whatever it may arise from, and we know how much the person is improved by having the bowel flushed. It does seem unphysiological to throw such large quantities of water into the rectum; it does interfere with peristaltic action, and many who have commenced it have had to give it up. To prevent the occurrence of paralysis of the bowel I have found nothing better than electricity applied by the bipolar method.

Dr. Charles C. Ransom:—I can confirm what Dr. Baruch has already said by my experience at Richfield Springs, where I have occasion to use water in many cases during the summer. I can speak particularly of its value in nervous conditions. The few nervous cases which I have seen there have been mostly of neurasthenia in business men worn out by close attention to their affairs. In them I have used the cold douche with the most excellent effect. It relieves their insomnia, increases the nerve tone, and aids digestion.

Dr. Baruch:—My object in reading the paper was to give practical details and demonstrations, showing that water can be applied to the most delicate subjects. I have seen this demonstrated very often at the Montefiore Home, where a condition of admission is the incurability of the disease. In most desperate cases there, we find patients who never took a bath before gradually becoming accustomed to taking it at a temperature of 65° F. every day.

I would impress the impropriety of using the term cold water or warm water. We do not tell patients to take quinine; we give them the dose, and special directions should be given as to the temperature at which a bath

should be taken, the necessity for securing reaction, etc.

Referring to Dr. Jacobi's question, I may say that no person is better able to judge than she of the influence of water upon tissue metamorphosis, about which she wrote the best article in the English language as long as ten years ago.

I have endeavored to show that the judicious application of water is an agreeable remedial measure, free from shock or other unpleasantness, and produces striking results in some intractable diseases. In my propaganda for hydrotherapy I have in some quarters been charged with unwarranted enthusiasm. If a conscientious proving of all remedial agents in vogue and proposed during an active general practice of thirty years entitles a man to an opinion on therapeutics, I would reiterate with emphasis the conclusion given in Hare's System of Practical Therapeutics.

To sum up the aims, capabilities and results of hydrotherapy, it may be said we possess in this method a valuable auxiliary to medical treatment of many, *though not all*, acute and chronic maladies.

In many chronic diseases it has proved so successful after failure of medicinal remedies, that *no case should be yielded up as hopeless until hydrotherapy in some form has been tried.*

My observations at the Montefiore Home, which receives only incurable cases, demonstrate this fact.

Domestic treatment will suffice in most cases, but if this fails, a methodical treatment under an expert hydrotherapist may be of advantage to the patient.

The best consultants in Germany, Italy and France, men like Leyden, Charcot, Nothnagel and Erb, send their patients to these institutions, with their diagnosis and general suggestions, rather than with specific directions.

Finally, so much depends upon the reactive capacity of each individual, that only systematic observations can determine the most useful procedure in each case.

American Electro-Therapeutic Association.

Second Annual Meeting, held in New York, October 4, 5 and 6, 1892.

WILLIAM J. MORTON, M.D., PREST.

FIRST DAY OCTOBER 4—EVENING SESSION.

(Continued from page 218.)

THE VALUE OF VOLTAIC ALTERNATIVES IN OPTIC NERVE ATROPHY.

By Charles Eugene Riggs, A.M., M.D., Professor of Nervous and Mental Diseases in the University of Minnesota, St. Paul, Minn., Member of the Neurological Association, Member of the American Electro-Therapeutical Association.

My attention was first called to the value of voltaic alternatives in atrophy of the optic nerve by Dr. Webster Fox, of Philadelphia, who said that he had obtained from their use some results so surprising that he hesitated to publish them because of the incredulity with which he felt they would be received by the profession.

This strong recommendation from so eminent a man resolved me to make trial of them in my own practice should occasion arise, but for some time I was deterred from the habitual use of them by the fact that in the ordinary instrument the only way of alternating the currents is by the hand, which is not only tiresome in the extreme, but also undesirable as the frequent use of the commutator in this manner renders the battery unreliable for careful diagnostic work. Also in using the hand the precision of the make and break will necessarily vary a little; consequently there will not be the same smoothness of current as though the action were automatic. To remedy this defect I requested Dr. H. E. Waite to construct for me an auto-

matic commutator, which has proved satisfactory in every way.

I first tried the voltaic alternatives upon a patient sent to me by Dr. Graham, of Minneapolis. He reported that when first examined he found the media clear, hyperæmia of the optic disc, with outlines slightly blurred, veins slightly enlarged and tortuous, arteries reduced. The treatment before the use of the voltaic alternatives had been iron, quinine and strychnia, with no improvement resulting. After the use of voltaic alternatives had begun she improved very slowly, by almost imperceptible degrees. She was under this treatment for two or three months, and examinations made in the meantime by Dr. Graham showed unquestioned improvement in the eye condition. At the end of this period she was obliged to leave the city, but wrote me at the end of six months that the improvement had been continuous and was still going on.

For the next case that I treated I was indebted to the courtesy of Dr. E. H. Wood, of St. Paul. I subjoin the report of the case as taken from Dr. Wood's notes.

"J. W., aged 52, farmer. July 26, 1891. Says six months ago eyesight began to fail and 'everything looked milky.' No pain in head or eyes.

Examination:—Vision in right and left eyes, counts fingers at ten feet; not improved by glasses. Cornea clear tension normal. Pupil acts to light and accommodation.¹ Ophthalmoscope shows both optic discs very pale, medium-sized physiological cup, blood vessels medium-sized, vitreous clear and rest of fundi normal. No history of injury or syphilis. Says memory is getting very poor and that he often forgets what he came to town for. Has numbness of legs and arms, spastic contraction of fingers, no ankle-clonus, but there is increased knee-jerk in right and diminished in left leg. Diagnosis, atrophy of optic nerve. Treatment: Elix zinc ferri et strychnia, hypodermic of strychnia in temples and electricity, also large doses of potassium iodide.

Aug. 14, R. V.=6-36. L. V.=6-60.

Aug. 27, R. V.=6-24 + 1.5 D.=6-9. L. V.=6-36, not improved by glasses. Patient returned home.

My examination of the man demonstrated the existence of nervous trouble, indicated by the symptoms Dr. Wood had observed. The result of the use of voltaic alternatives in this case was most astonishing.

After the first week's treatment the patient declared himself decidedly improved, and the improvement was rapid and continuous while he remained under my care. That the improvement was permanent is witnessed by the subjoined note of Dr. Wood, who made a special re-examination of the case for the purpose of this paper a few weeks ago.

"Sept. 4, 1892.—Examined him and found that he had been working most of the time; said memory continued good, numbness and spastic contraction did not return and that his eye-sight remained about the same.

"R. V. without glasses 6-24, with plus 1.5 D. = 6-9.

"L. V. without glasses 6-36, with plus 1.5 D. = 6-9.

"Field of vision has never been carefully taken."

In a third case which was sent me by Dr. Chamberlain, of St. Paul, the treatment produced no beneficial result. This patient became discouraged after six weeks or two months treatment, and falling into the hands of "faith-healers" discontinued treatment, so that I do not consider in view of the fact that the trouble was of long standing, that the treatment was given a fair trial in this instance. I subjoin notes of Dr. Chamberlain upon the case.

"X. Y., aged 46, general office in R. R. land dept., came to me in April, 1890, complaining of a strained feeling about his eyes.

"R. V. 20-100. "L. V. 20-200.

"Myopic astigmatism of about two dioptries in each eye; this corrected gave him R. V. —20-30, but did not improve the left save, as he said, to brighten it up a little. His work being largely reading of correspondents and examining fine lines on the maps and fine figures in books, I prescribed rest in addition to change in his glasses, the latter he obtained but the former he did not take.

"In giving his history, he said that six years previous while his eyes were undergoing an examination, he found that he had very little vision in his left eye, something he had not known before. The ophthalmoscope showed the left disc to be very pale and vessels reduced in size. The right disc, however, seemed nearly normal. He returned to his work and had no trouble with his vision until about June, 1890, when he returned to me saying that his vision was getting bad in the other eye. He had been working very hard and was reduced physically, so I advised immediate rest. The retina and optic disc of the right eye were in an irritable and somewhat congested condition. After a months rest, though physically improved, he could see absolutely no improvement in his vision, which at this time equalled part of 20-40 with the right eye, the optic disc being paler than normal, and the vascular condition being somewhat reduced. I put him upon potassium iodide and also strychnine, both hypodermically and by the mouth. I referred him to Dr. Riggs for electricity.

"Sharpness of vision slowly decreased. September 20 it was only a guess at 20-40; September 30 it was only 20-50, and by November was reduced to 20-60. About this time he passed out of my sight."

I am at present trying voltaic alternatives in a number of cases representing various forms of brain disease, but the experiments have not yet been sufficiently prolonged to justify me in recording any opinion as to results.

The stimulating affect of this current and its influence on nutrition is evident if one considers it in its physiological aspect. That the reversal of the polarity of the electrodes in its use is much more energetic than the simple closures, is very evident if one understands the nature of the phenomena.

De Watteville (*Medical Electricity*, p. 108) says, "When the electrode on the nerve is alternately changed from anode to cathode, and from cathode to anode, a series of closure excitations are given, which fall alternately in the polar (when the electrode becomes cathodic) and the peripolar (when the electrode becomes anodic) region respectively. Now in either case the excited region had just before been under anodic influence, and physiology teaches us that as we shall presently demonstrate on the human nerve, the instant the polarizing current ceases to flow the anodic region passes into a state of increased excitability. This augmentation is the more marked the longer the anodic influence has lasted. We see, therefore, how it is that voltaic alternatives act more powerfully than simple closures of the circuit, and that their action is intensified by previous current duration. We understand also why rapid reversals are the more effectual; for the positive modification after an electrotonus diminishes rapidly after the circuit has been broken; the longer the interval which elapses between the polar change of the electrode the less the hyper-excitability of the nerve will be, until it has returned to its normal state."

Althaus (*Medical Electricity*, p. 225) emphasizes also the fact of the increase of excitability when the voltaic alternatives are frequently repeated.

It is to be hoped that such workers in this line as Dr. Webster Fox and his coadjutors will soon lay before the profession the results of their large experience. In this article I have only designed to be suggestive and to stimulate my confrères to investigation, that the true value of

this therapeutic measure may be thoroughly ascertained. If in the use of voltaic alternatives has indeed been found the remedy for even a part of the cases of atrophy of the optic nerve, the fact cannot be too soon established or too widely known.

LACERATIONS OF THE CERVIC UTERI AND THEIR TREATMENT.

By F. von Raitz, M.D., of New York.

Before entering upon the delivery of this subject, I feel it my duty to protest against any assumption which could tend to place me in one line with those who call themselves "Electricians," for I am a physician, and as such I use any agent which in my opinion is the best for a given pathological condition, be it water, fire, air, drug, electricity or the knife. And this paper here, which I have based upon 73 cases, which I treated, with various agents, is a clinical picture of nude facts, therefore, I shall first report of which characters they were. According to the depth of the rent, I arranged them in four classes as follows:

Class No. 1, slight lacerations.—19 left lateral; 4 right lateral; 6 bilateral. 29 cases. Subjective symptoms: none at all or various degrees of leucorrhœa, nervousity.

Class No. 2, lacerations about one-half inch deep.—4 left lateral; 2 right lateral; 14 bilateral; 1 posterior; 1 stellate. 22 cases. Subjective symptoms: uneasiness in the pelvis, pain in the back, lancinating pain, bearing down, menstrual, nervous and digestive disorders. Loss of strength and flesh. Leucorrhœa or not. Occasional dyspareunia.

Class No. 3, lacerations about three-fourths inch deep.—14 bilateral; 2 stellate. 16 cases. Subjective symptoms: similar to class No. 2, but the cases with mild symptoms are less in proportion. Occasional dyspareunia in same.

Class No. 4, lacerations near or up to the internal os.—6 bilateral. Subjective symptoms; as class No. 3, but still more severe in some cases. In one case, however, there were no subjective symptoms.

This classification shows in what relation the depth of the rent stands to the subjective symptoms; that is, slight lacerations may cause subjective symptoms, similar to those of deep lacerations.

Of Class No. 1, 29 cases, 14 only called medical assistance for leucorrhœa. Eight of these cases presented erosions of various degrees and also endocervicitis. The rest of these 14 cases, six, had endocervicitis but no erosions. The endocervical discharge was various in character and degree but mostly purulent. The cervixes were increased in size by congestion or some hyperplasia. Some cases had subinvolution of the corpus to a marked degree with tenderness on pressure.

Of these 14 cases, 4 I treated by electricity, tincture of iodine, glycerite-tamponade and hot douches, medicated with astringents or solvents, as the case required; 10 cases I treated as before but instead of electricity I used carbolic acid.

The rest of this class, 15 cases had no subjective symptoms,—the lacerations were smooth, the cervix, though slightly enlarged had a sound appearance. In some there was evidence that the rent was far deeper originally and was sewed by nature. These cases were treated with hot douches alone.

The manner in which I applied electricity, glycerites, carbolic acid, douches a. s. f. I shall describe later.

Of Class No. 2, the stellate, posterior and 3 of the bilateral lacerations induced very marked subjective symptoms: intermittent lancinating pains, bearing down symptoms, pain in the back, menorrhagia, traumatic metrorrhagia—after coitus—headaches, digestive disturbances, nervousity, loss of strength and ambition; leucorrhœa.

The objective symptoms in these 3 cases were: cervixes considerably enlarged by the congestion resp. hyperplasia;

the ora and lacerations angry looking, discharging glairy or purulent mucous; granular, postular or vegetative erosions.

Bimanual and instrumental examination revealed: more or less prolapsus uteri and laxation of pelvic muscles and uterine ligaments; uterus enlarged and variously displaced, mostly in retro-positions. (One case of the bilateral type so much in retro-version, as to place the os near the symphysis pubes and the fundus in the posterior cul-de-sac). More or less tenderness in the hypogastrium. In one case difficult and painful defecation.

The posterior and one bilateral case, I treated by the knife, after a preparatory course of treatment; the bilateral healed up by first intention, the posterior partly by granulation. The other three of the five severe cases I treated by electricity, massage and manipulation, tampons and douches. The rest of class No. 2, 17 cases, presented subjective, objective and palpable symptoms, similar to the severe cases, but less pronounced. In some there was but slight and temporary uneasiness and the cervixes, although congested, did not look bad at all, as the rent was smooth, and as there was no endocervicitis. One of these milder cases, a bilateral one. I treated with the knife, three bilateral and one left lateral with electricity, the rest, 12 cases, I treated with tampons *a. s. f.*

Class No. 3, 16 cases, presented symptoms similar to class No. 2, but here 4 cases only were really mild, (one stellate belonging to the mild ones). Six cases, bilateral, were quite severe, being complicated with periuterine inflammations. In some cases erosion of the lips was very marked, but the surfaces of the lacerations were smooth, though angry looking near the cervical canals which discharged scantily or moderately glairy mucus, speaking of endocervicitis catarrhalis. There were no erosions, but there was, very likely, endometritis or metritis.—I say "very likely" for it is not safe to diagnose those lesions in a subinvolved uterus with certainty. The corpora were enlarged, admitting the sound from 4 to 5 inches, and variously displaced: two in retro-versio-flexio, one retroversion, one retroflexion, one sinistro-lateral, one antilexion. There were rectal and bladder symptoms.

The rest of class No. 3, six cases, were not severe, though the subjective symptoms, compelled them to seek the bed at times. The uteri were in some slightly in version, mostly posterior, in others the position was normal. But all in a state of subinvolution and more or less descended.

Two of the severe cases I treated by the knife, one after preparatory treatment by electricity, one without it. The result in the first case was primary union and great satisfaction; the second case healed also in the end, but it gave some trouble and took more time. Six cases, including the stellate, I treated with electricity, and eight cases by tampons *a. s. f.*

Class No. 4.—Six bilateral. Concerning the symptoms there was no difference, except that the eversion of the lips was more marked. In one case the lips were very much everted, and yet the lady did not suffer at all and called at my office, only to be examined, as she thought to be pregnant. She was 36 years of age, had two children and two abortions.

When I made the digital examination I did not know what I felt. I hunted for the cervix but found none, instead, however, two tumor line bodies of elastic quality. And not until I placed her in "Sims" position, I knew I was dealing with a lacerated cervix, the lips of which were enormously congested and hyperplastic. The fundus was greatly enlarged and placed upon the cervix, hanging down in the posterior pouch. She was then, according to her statement, about six weeks in pregnancy. At about 4½ months she miscarried.

Two patients had peri-uterine inflammations.

Of this class, one I treated by the knife after preparatory treatment with electricity, two by electricity, three by tamponade with astringents and solvents, *a. s. f.*, all, of course with hot douches also.

When I speak of treatment with the knife in connection with lacerated cervix, I mean the performance of trachelorrhaphy.

I treated six cases by trachelorrhaphy; 15 cases by electricity; 37 cases by caustic and tampons; 15 cases by douches. Seventy-three cases.

The etiology of laceration of the cervix is always pregnancy. Now and then there may be a case due to rapid dilatation for pathological reasons. A diseased cervix will tear more readily than a sound one. Miscarriage will cause laceration. Superficial lacerations will grow deeper with each subsequent parturition.

The pathology is nothing but a solution of continuity of those structures which are torn, and has to be considered like a fracture of bone as far as the existing rent goes. As I have shown, the depth of the tear has no direct relation to the symptoms in general, therefore, other causes must necessarily, induce the complications on which the symptoms depend, for we have deep lacerations which are associated with slight subjective symptoms, and we have slight lacerations which are associated with much suffering. But subinvolution, congestion, and hyperplasia are directly depending on the tear and must therefore, be considered with the pathology of the laceration.

The manner in which subinvolution is caused is simple, in so far as clinical observation goes, for we know that involution of the uterus is retarded or interfered with in proportion to the length of the tear. Some sympathetic filaments around the os externum, which are more important than we ever shall know, are torn with the other structures, consequently the communication of the cervix with the corpus is interfered with in proportion to the extent of the damage and the vaso-motor contractors are not called to work. Now, the venous blood vessels, remaining engorged with blood, keep the capillaries and capillculi in a state of distension, which gives rise to what we term congestion, which again prevents perfect oxygenation of the tissues. As this condition persists, the muscular fibres lose their tonicity and the top-heavy fundus will bend them in just that direction which will be given by the influencing bladder or rectum, consequently we will get those various flexions. Or, if the tonicity of the muscle fibres is still strong enough to oppose bending, absolutely or partly, the top-heavy fundus will gravitate downward just the same, and also in the same direction given by the bladder or rectum, and we get the various versions or versio-flexions. And as the habit of the patient will be concerning defecation and urinating, we will get either retro or anti-displacements. So the bladder and rectum are influencing the direction of displacements and after displacement is finished, the fundus will influence them also, and we get bladder and rectal symptoms.

Now the interference in circulation is still greater, the uterus grows more and more heavy, the ligaments are taxed in proportion, lose their tone, and we get descent, and even prolapsus. Finally there comes a time when all pelvic structures will suffer more or less congestion. As congestion persists, and as oxygenation becomes more and more imperfect, changes in nutrition must follow and consequently, we get hyperplasia.

Now as there is congestion and hyperplasia, that is altered nutrition and tissues, the nerves suffer also, and we get reflex phenomena which make some women objects of pity. There are headaches, digestive disturbances, palpitation of the heart, restlessness and sleeplessness, and I do not know

what else, in addition to the pelvic aches and pains.

As there is altered nutrition, there of course must be altered function, and we get menstrual disturbances due to perverted innervation, due to mechanical obstruction with some degrees of flexion and version. The altered condition of the mucous membrane, naturally, is a main factor, for a long-standing congestion will cause fungosities of various character, endocervicitis, endometritis catarrhalis, even suppurans, which again may grow into metritis and peri-uterine inflammations. Fungosities and endometritis may cause metrorrhagia. Of course, the just named inflammations, even if associated with laceration, may have another cause.

Erosions, of whatever character, are due to endocervicitis, and we have them without laceration just as well; and, as a matter of fact, these lesions are complicating the superficial lacerations more often, for the reason that the deeper the rent, the more cervical mucous membrane, the factor of the discharge, is destroyed. The more purulent and acrid the discharge the easier erosions can form. Coitus will then aggravate them. It is perhaps wrong to consider these lesions under this head, but as congestion causes endocervicitis, they may be mentioned here. The same may be said of endometritis, metritis and peri-uterine inflammations.

Symptomatology and diagnosis need no further consideration.

The *prognosis* of even the worst cases is good in the hands of an intelligent and energetic surgeon. It depends, if trachelorrhaphy is to be performed, not only on the operation, but more so on the skilful preparatory treatment and on the after-treatment.

The *treatment* must necessarily vary according to individual cases, but yet, if we rest upon pathology, this knowledge will give us valuable rules, according to which we can treat. And, as we have seen, the laceration itself does not often require treatment, but the secondary manifestations. Thus, if we have to treat a superficially lacerated cervix, without endocervicitis and erosions, but with hyperplasia and a subinvolved uterus, our aim must be to reduce the size of the cervix and corpus. The laceration will then take care of itself.

Now, considering the means of reduction, we find that douches and electricity take the foremost place, but astringent tonic applications, as various acids, fluid extract of hamamelis, Kennedy's white fluid extract of pinus canadensis—which contains alum and zinc-sulphate—tincture of iodine and of chloride of iron, are useful adjuvants.

There is a great difference in the efficiency of hot douches. To expect the best effect, hot douches have to be taken in the recumbent position with the pelvis considerably elevated; but the posture must be so as to allow the patient perfect comfort. This is experienced when the head is raised to a physiological level to the heart. To increase the effect of the hot water, alum with borax or carbolic acid, sulphate of zinc or any other astringent, may be added in a proper proportion; they act at the same time as antiseptics. The water should be as hot as can be borne (some will tolerate 120° F.), and the quantity should be a gallon. Douches properly taken will allay nervousness, produce sleep, and inspire the patient so that she will gladly take three per day, and if they are persevered in, they alone will cure many cases. The importance of elevating the pelvis has been demonstrated anatomically and pathologically before this, but it is surprising that there are still gynecologists who take it lightly.

In case the congestion and subinvolution demand more vigorous treatment, electricity is the agent. Charge the cervical cup with the constant current, and place over the hypogastrium, or umbilical region, a suitable electrode with the negative pole.

If the cervix is properly protected by absorbent cotton, and if the external electrode is large, a current up to 100 ma., gradually attained, is borne for about five minutes, without much complaint. After this, and without changing the electrodes, a high tension faradic current of good but agreeable strength is given for about five minutes. Then the cervix will be dried and treated with an astringent by the brush or on a wool tampon, which latter remains *in situ* for twenty-four hours, during which, of course, no douches are given.

Keeping the pathology in mind, it must be clear why in congestion (subinvolution is the same), the positive pole must act, and why the constant and faradic currents are useful.

Those who have applied the negative current under these conditions have been disappointed, though they relied on some authors who speak of hyperplasia and of hypertrophy cervicis or uteri as if they were of one and the same character, while they ought to know that hypertrophy is but seldom a pathological condition, but a consequence of over-physiological function, as in the heart or in a bone, or any muscle. Hypertrophied tissue shows a normal histology.

Hyperplasia is quite a different condition, and histological examination always shows the tissues in pathological association. It is due to inflammation of any character, to perverted nutrition and to congestion. And therefore a cervix and uterus can never hypertrophy, but they can be in hyperplasia or congestion.

We have cervices which are hard or soft. A congested cervix may be as hard and as large as a hyperplastic one; we have also cervices which present both conditions in one patient. Often it is difficult to differentiate between these conditions, but if we remember that a congested cervix has a deeper hue and a hyperplastic cervix a paler hue, we will without difficulty know whether we have to deal with one or the other condition or with both.

In those cases which present both conditions, the positive pole must be applied to the cervix first, and when the congestion is dispersed, then the negative pole takes its place.

A hyperplastic cervix calls for the negative pole and for solvents, such as glycerine, with lysol, or similar acting agents. Douches, of course, when the tampon is removed.

After there is some softening, the positive pole and astringents are brought into play; and when the positive pole and the astringents or alterans have acted sufficiently, then the negative and solvents; and so on, changing till reduction is accomplished.

The frequency of sittings depends on the strength and idiosyncrasy of the patient—as a rule twice per week, but for some three times per week. Some patients again, with decided nervous symptoms, will not tolerate more than once per week.

The strength of the current depends also on the idiosyncrasy of patients, but weak currents of long duration are far more successful than strong currents of short duration, and it is of importance to avoid cauterizing. As a rule, about 40 ma. for from ten to fifteen minutes are all that is necessary, and are borne with ease if the cervix is well protected with absorbent cotton.

Erosions have to be treated by caustics of which the positive constant current, also mildly applied, is best; but as it is depending on endocervicitis this lesion has to be treated at the same time.

Endocervicitis is generally associated with hyperplasia cervicis, and seems to be the cause of this condition as well as of erosions. To combat this complication, nothing is more useful than the galvanic negative pole attached to a nude uterine copper electrode. From four to six sittings, each of about ten minutes with a current of from 15 to 20

ma., followed by glycerite or pinus-tampons, will effect a cure and at the same time help the hyperplasia. If associated with a congested cervix the positive pole must be used after two or three negative applications. But then the positive must not exceed 15 ma. for eight minutes. The treatment for *cervicitis* is as for hyperplasia.

Endometritis and *metritis* is to be treated as the *endocervicitis*. Curetting is inferior here and more objected to by patients.

Periuterine inflammations complicating laceration of the cervix have to be treated as if they were not complicating it.

Menstrual disturbances complicating laceration depend on either *endometritis*, lesions in the adnexa, *subinvolution* or *malposition*; and perhaps also on *perverted innervation*. As soon as these causes cease, the menstrual disturbances will also cease.

Malpositions, or displacements as others term them, of all kinds of versions, flexions and prolapse, complicating laceration, are due to *subinvolution*, and therefore it is worse than useless to correct the malposition before a certain degree of *subinvolution* has been overcome. Pessaries are injurious; operations for replacement are rarely successful, but the course of treatment mentioned before always accomplishes enough reduction to allow the prolapsus, version or flexion, if it is free from adhesion, to approach its physiological locus, especially when massage and manipulation are applied; because the engorged viscera are depleted and the muscular, serous and mucous structures regain their tonicity. Massage and manipulation combined with hot douches, will replace in all cases, the uterus, even if there are adhesions.

Rectal and bladder symptoms are due to malpositions of the uterus, and to pelvic inflammations, and will disappear with their causes.

Sterility is due to *endocervicitis* and to *endometritis* in many cases, in others an advanced degree of congestion or hyperplasia is the cause.

Abortion is due to sharp-angled flexion, congestion and hyperplasia.

Miscarriage, however, is due to the rent itself, when it occurs in a patient with deep laceration; the internal os is deprived of its support and gives away to the increasing pressure.

The various neurotic phenomena, which are a great source of anxiety in some patients, are not depending on any degree of laceration, for some patients with moderate lesions will greatly complain about these phenomena, while others with severe lesion won't notice them at all. But as these nervous symptoms improve with the improvement of the *subinvolution*, that is, hyperplasia, or congestion of the uterus, it is reasonable to attribute them to *perverted nutrition* in consequence of which the cervix and corpus not only grow sensitive, but also transfer their troubles reflexly to distant organs.

Moreover, it seems to me that hyperplasia causes nervous symptoms more pronounced than congestion; and this explains why some observers speak of *anæmia cervicis* and pressure by the hardened tissue on the filaments of the sympathetic as causes of these troubles.

Occasionally there will be in some patients, *dysparennia*, which depends on the morbid sensitiveness of the cervix and also on the erosions.

Thus far I have not mentioned anything concerning *trachelorrhaphy*, as I intended to consider this operation after all other means have been ventilated, but now comes up the question,—is *trachelorrhaphy* ever necessary? Before answering this question for any given case, we have to consider the character of this lesion, the degrees of the complications, the severity of the subjective symptoms, the age of

the patient with reference to her procreative power, and lastly the wish of the patient.

Suppose a patient calls a gynecologist and complains about severe subjective symptoms which point toward her sexual apparatus. He, examining her, finds a bad laceration almost up to the internal os with everted and enormously enlarged lips, which are hard and painful to the touch; the fundus, flexed upon the cervix, hanging down in the posterior pouch, being also painful to the touch. He learns there is constipation and painful defecation, and that she is growing from bad to worse and disgusted with her life. He also learns that she was treated already by one or more physicians but without relief. He advises *trachelorrhaphy* and enters upon a real good preparatory treatment, but without using electricity. The patient improves now in every way and this misleads her to refuse the operation. But after a time she feels her troubles returning and hears that electricity was used on some women with similar complaints, quite successfully. Being afraid to undergo the operation for *trachelorrhaphy*, she is now treated with electricity, receiving of course, hot douches per vagina and rectum, and also, later, massage. She improves now very much quicker, for the congestion and hyperplasia yield to the currents and so allow the uterus and pelvic structures in general to regain their normal tonicity. Finally the uterus returning to its physiological locus, removes the rectal symptoms, leaving the patient comfortable, and after awhile cured.

In case such a patient does not live in sexual relation she may nevermore experience any trouble, but if she is to have sexual intercourse the *membrum verile*, especially if it be long, will find its way between the lips and will irritate the laceration and give rise to similar troubles she was suffering before; or, in case she goes pregnant, she will suffer a miscarriage at about the 4th month. Therefore such a patient ought to have her cervix sewed up, and will generally consent to the operation if she will be made to understand her condition.

Hot water, electricity and massage, combined with constitutional and hygienic treatment, where it is necessary, will practically cure most cases of laceration, but the deep lacerations which cause eversion of the lips, occurring in women of sexual activity, must be sewed up. But even those cases which require the operation should be treated with electricity during the time of preparation as it insures far better results.

No. 101 West 132d Street.

Discussion.

Dr. Goelet said that while electricity might relieve or cure many of the results of lacerated cervix, Emmet's operation of *trachelorrhaphy* was the only cure for this condition itself.

Dr. Gunning said that his curiosity had been aroused by the general plan advocated, but he was rather at a loss to understand its special application to the conditions attacked; he did not know how much to attribute to the electricity, and how much to the other treatment employed at the same time.

Dr. von Raitz, in closing, said he performed *trachelorrhaphy* on those cases which needed the operation, but the treatment advocated in the paper was directed especially against the complications resulting from the laceration, as it was from these, chiefly, that the patient suffered. When he had treated these cases without electricity, much more time had been consumed in securing the results, and they had not been so good. He was firmly convinced as to the utility of this preparatory treatment.

PUBLISHED WEEKLY.

SUBSCRIPTION PRICE, INCLUDING POSTAGE:
PER ANNUM, IN ADVANCE \$5.00
SINGLE COPIES 10 CENTS.

Subscriptions may begin at any time and be sent to

THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION,
NO. 68 WABASH AVE., CHICAGO, ILLINOIS.

All members of the Association should send their Annual Dues to the Treasurer, RICHARD J. DUNGLISON, M.D., Lock Box 1274, Philadelphia, Pa.

MEMBERSHIP IN THE AMERICAN MEDICAL ASSOCIATION.

This is obtainable, at any time, by a member of any State or local Medical Society which is entitled to send delegates to the Association. All that is necessary is for the applicant to write to the Treasurer of the Association, Dr. Richard J. Dunglison, Lock Box 1274, Philadelphia, Pa., sending him a certificate or statement that he is in good standing in his own Society, signed by the President and Secretary of said Society, with five dollars for annual dues and subscription for THE JOURNAL. Attendance as a delegate at an annual meeting of the Association is not necessary to obtain membership. On receipt of the above amount the weekly JOURNAL of the Association will be forwarded regularly.

SATURDAY, MARCH 4, 1893.

THE INDICATIONS FOR LITHOTOMY.

After strivings as long and as devious as the history of civilization, the problem of removing the stone from the urinary bladder may fairly be declared solved. That minor improvements in the crushing procedure or advances in the prevention of calculus disease are yet possible is not to be denied, but there can be no exaggeration in the assertion that no equally painful, disabling, and eventually destructive malady has been more perfectly placed within curative power; no more important surgical measure reduced nearer to proximate perfection.

To master, not by methods essentially preventive, a disease of like prevalence, passion and mortality, so completely, so quickly, by means most agreeable to the feelings of the patient, and yet with a mortality of probably from one to five per cent., is a surgical triumph unsurpassed. The achievement is also remarkable, if not unique, in the lines upon which it has been wrought. Most other decisive victories of modern surgery rest confessedly in a large measure, upon aseptic wound treatment and anæsthesia. The conquest of vesicle calculus is a feat of engineering and technical skill resting almost solely upon mechanical ingenuity and the tactus eruditus, elements which in recent surgery of other lines have been brushed aside by clumsier, if better qualities. In the solution, asepsis, and especially anæsthesia have doubtless played a role, yet, as accessories rather than principals.

Logically, the stonecutter's occupation, like OTHELLO's, is gone; but the genius of vesicle surgery mellow with age, antedating authentic history, and mindful of the indiscretions of his youth, modest and patient, clamors not for the exclusiveness of the abdominal folk, but waits without scolding, till others learn the better way. Hence, although litholapaxy, in both sexes and all ages, in the hands of

experts has reduced the mortality to a point with which no cutting operation may hope to compete with prompter recovery, and by methods more acceptable to the patient, yet lithotomy is still practiced more or less on every hand.

What then, are the indications for lithotomy to-day? In a literal sense their existence is questionable. There occur frequently, possibly always will remain, cases of vesical disease in which stone exists and for which a cutting operation should be chosen. The knife, however, is indicated not on account of the stone *per se*, but chosen rather for the other conditions. The stone is frequently but an epiphenomenon, and the factors, which in judicious counsels decide against the lithotrite, are practically always other than the calculus. Why longer apply to an operation the name of an indication for which it is never more to be judiciously done? Plainly, stone is best treated by litholapaxy. Many conditions, some of them complicated by or consecutive to vesicle calculus, are best treated by incision of of the bladder. This latter operation is cystotomy, and only the soothing bonds of tradition hold us to the name of an obsolete, if not lost art. It may be argued that lithotomy is a name too illustrious and well known to be changed, reasoning that fails when as in this case, a name is a silent teacher of error. It beguiles many into the belief that the knife is still a competitor with the lithotrite in the treatment of stone, *per se*, an objection sufficient to demand the burial of the dead; yet worse, it constantly complicates and obscures the consideration of vesicle operations by bringing the prejudices, the traditions and the dead statistics of operations undertaken chiefly or wholly for the removal of stone, to cystotomy, now applied chiefly to a different class of affections.

It is not long since such factors as great hardness, size above an inch in diameter, the impubic urethra and inexperience in the operator were prominent among indications for lithotomy. To-day they are deservedly allowed but little weight as primary indications. Probably the stone rarely, if ever, exists of a density capable of resisting a combination of the best modern lithotrites and the highest operative skill. Size alone is found of less importance, while increasing popular intelligence and wide diffusion of professional skill renders the future occurrence of immense calculi unnecessary, even scarcely possible, while the work of KEGAN and others have shown that childhood as an indication for lithotomy and a bar to crushing is very largely a figment of an imagination imbued with satisfaction with the results of a favorite but inferior method. The argument of inexperience in the operator falls with strange inconsistency upon ears accustomed to the special sollicitude shown the female abdomen, at least in the lit-

erature. Is it more sweet to die of a wound of the bladder than the belly? Future historians might, with some fairness, conclude that during the past decade the chiefest ignominy had been death from incompetent operation upon the abdomen, since so little comparatively is said of preventable deaths from other equally important and often more difficult operations.

But for the purpose of solving this problem it is not necessary to plead the specialist doctrine: a gospel at once full of truth and inconsistency. Indeed it goes without saying that special skill and experience are always an advantage in whatever line, but this is not always best and most consistently secured by an artificial specialism. It is idle and disingenuous, if not demoralizing, to discuss the ethics of choosing an inferior method because, forsooth, of inexperience with a safer, in the midst of a redundancy of competence. But such a discussion is rendered wholly gratuitous by the simple fact that lithotrity has always in all hands been, on the average, less mortal than lithotomy in like hands. In practice these old indications for lithotomy must receive some considerations, but they must be dislodged from a place among prominent or decisive indications for the knife, and cannot longer go unchallenged as formal teachings to soothe the conscience of those inclined to cut for stone because it pleases their convenience, whim, or indolence to choose this method.

Quite otherwise is it with those cases of diseased urinary tracts containing stone, such as vesical tumor, very severe chronic cystitis and prostatic hypertrophy in which operation is desirable, or which presents great obstacles and even positive barriers to litholapaxy, encysted stone, uncrushable foreign bodies, and deep urethral stricture. These conditions being well established are operated for and the stone incidentally removed. It would seem the height of inconsistency to term these indications for lithotomy. There exists stone and other disease, on account of the latter the urinary reservoir requires to be invaded and relieved by operation, during which the calculus is easily disposed of.

Having recognized this principle, the question of which method of lithotomy shall be chosen is more easily solved. Discussions and comparisons of the various perineal incisions and the supra pubic as modes of lithotomy of necessity leads to battles of the windmills. Not only are they comparisons of unlike, but of largely imaginary quantities. We shall probably never know practically and on a large scale, whether lateral or supra pubic lithotomy is the better operation for stone, certainly there is little to prove that the revival of the *sectio alta* for calculus was more than a fashion; whereas, there is quite as much certainty that supra pubic cystotomy for the

purposes for which we at present invade the bladder is much more efficient in most cases than any form of perineal incision, while the incision of lateral lithotomy has little, if any place in the surgery of to-day. Its applicability is certainly not wider than that of the knife for stone, *per se*, which has already it is believed been reduced to *nil*. This would undoubtedly relegate most of these cases complicated by or consecutive to stone to the supra pubic route, this, however, must not lead to the deduction that the *sectio alta* is *per se*, the best means of opening the bladder. Indeed regarded as an operation pure and simple, there can be no question that entrance by the median perineal route, even when the incision involves most of the prostatic fibres, is an operation of less severity, more easily executed, more rapidly recovered from, and less troublesome to patient and attendants in its immediate after treatment, and it manifestly should be chosen when it is clearly adequate to the work to be done. When not chosen it is simply because in most of these cases it is inadequate to the best performance of the object in view.

With the more accurate determination of the exact work to be accomplished before operation is begun now being largely achieved by the cystoscope, the perineal route will doubtless more often be chosen, but only in isolated cases complicated with stone. Cases of deep or bad stricture, with very small stones, or foreign bodies, or certain clearly defined tumors easily removable through the prostatic urethra, dilated to admission of a digit or partially incised, should without question receive this treatment. In short the whole aspect of vesical surgery has so completely changed within recent times, that it is manifestly inexpedient to longer gravely discuss lithotomy and its indications, the scenes have so shifted that truth and perspicuity are better served by other terms. Litholapaxy having been practically perfected for vesical calculus, we now have to labor for the greater perfection of supra pubic and perineal cystotomy for a number of diverse pathological conditions, with some of which stone occasionally coëxists; and one of the first steps in the new questions is doubtless a more preliminary topographical survey and diagnosis. In the past the high operation has not seldom been done for conditions which could have been as thoroughly and more judiciously dealt with by the simpler method had assurance of the state of affairs found been previously made out, and others undertaken by the perineum, which might have been better managed by the supra pubic plan, had it been possible to know as much before as after entering the bladder.

THE TITLES of papers to be read in the Sections at the ensuing meeting of the American Medical Association should be sent to the Chairman or Secretary of the Section where such papers belong as soon as possible, in order that the Section officers may be able to select gentlemen to lead in the discussions.

THE OBJECTOR.

Once upon a time it was our melancholy duty to attend a general meeting of the members of the medical profession, which had been called to take action pertaining to the decease of a highly respected brother physician. A chairman and secretary were selected, and on motion the usual committee was appointed to bring in resolutions suitable to the occasion. These were promptly reported, and after several speakers had referred to the exemplary character of the deceased, one of the brethren arose, and said he felt it a duty incumbent upon him and somewhat unpleasant to perform, but he could not sit still and witness the passage of those resolutions without a personal protest, inasmuch as the preamble referred to the dead man as a distinguished physician. That he never knew of the deceased having done anything to merit so eulogistic a title as that of being a "distinguished" member of the medical profession. The speaker said he knew that Dr. W. had been a successful teacher of anatomy in one of the colleges, had served as surgeon of a regiment during three years of the war, and a term of years as superintendent of a lunatic asylum, but all this, in addition to years of everyday private professional practice, did not entitle the gentleman to the prefix of "distinction" before his name, and hence his objection, and moved that the offending word be erased from the preamble. As there was no second to the motion, the mover thought his motives and remarks were not appreciated, and feeling lonesome, concluded to flock by himself and took his departure.

In most respects the objector was a good man, but saw nothing good in anything unless it presented an opportunity to object or enter a protest.

In a neighboring city the active working elements in the medical profession have for a number of years been segregated, and their influence greatly weakened, by being divided up in a number of societies. Attempts at a union of all in one have heretofore been frustrated by a few who held on to some ancient traditions, which gave them an opportunity to object to any sort of an amalgamation. Good and able men, every one of them, but one of the supreme purposes of their lives could not be let pass without their protest going on record. We are pleased to say, the union is an accomplished fact, and we predict that great good will come of it.

In another large city the local profession is divided into a number of rival elements for the support and conduct of a number of medical schools. In professional attainments the physicians of that city are the peers of those in any other city that can be named. Each school has one, two or more men in its faculty who are qualified for their positions and have the gift of easily imparting knowledge to others, and are excellent teachers, but the influence of these

men is greatly impaired by their professorial associates, who may be superior practitioners of their art and excellent in every other way, but are not capable teachers. These gentlemen of both classes will say, and honestly too, that they favor the advanced, the new medical education that is rapidly pressing its way to the front, but when a proposition is made, to unite all the city schools, so as to form one great teaching university, where everything pertaining to the art and science of medicine can be taught by thoroughly trained teachers, the objector rises to enter his protest against such a union, remarking that there are certain vested rights to be considered in the formation of such a combine. That certain gentlemen have in the past made contributions of time and money that cannot be ignored, and although they are not equal to the best of teachers in their department, still, they must be provided for, and such a union as that contemplated, will cause these gentlemen to be left out. And anyhow the objector goes on to say, two or more schools engender a healthy rivalry, that is better for all concerned, than to have one school alone in a great city. Forgetting that there may be a rivalry not only between the several professors in a great institution, but also between the great schools of the great cities.

One great school in either Berlin, Edinboro, Vienna or Paris is sufficient to absorb the acceptable medical teachers of an empire. So we are free to say one great school of medicine amply endowed with laboratories, and all needed accessories, including a faculty holding endowed chairs, is sufficient to meet all the wants of all the medical students whose homes are geographically tributary to any city west of the Allegheny mountains.

The time has passed and is forever gone for the organization of Commercial Medical Colleges, and the time is right now and propitious for the contemplation and bringing about of a union of all such contiguous institutions, and for the creation of colleges that have a firm and lasting foundation; which will stretch forth and draw into their faculties a corps of men who are trained to teach, and may be truly designated as medical pedagogues.

It is with great pleasure that we note the creation of a Section to be devoted to medical pedagogics at the Pan-American Congress. Such a Section in the American Medical Association would be singularly useful.

To the Editor of the JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION:

Dear Sir:—On page 191 of the February 18 number of THE JOURNAL, is an article in which Dr. L. S. Pileher, President of the Medical Society of the State of New York, gives the American Medical Association to understand that *he* and *his* society are grandly indifferent as to anything the American Medical Association may do or say. And you, in commenting upon the same, say:

"In this action of the New York State Medical Society, there seems to be a rolling back and away of the clouds and mists that have obscured the relations of that organization with the American Medical Association," and further you say "that you look hopefully to the committee appointed by the American Medical Association at its last meeting to report for approval of and adoption by that organization of a Code of Ethics, Constitution and By-laws that will be acceptable, and provide an organic law that will make possible a unification and membership in one body of every practitioner of rational medicine in this country."

Now will you kindly permit me to have a say-so in this matter? If Dr. Pilcher and his society are totally indifferent as to any action the American Medical Association may take in the way of bringing about peace and harmony in the profession, what can the committee hope to do in the premises? Is there any hope of making peace with a man who regards you with perfect contempt? If there is a man in the United States who can frame words that are more expressive of utter contempt than are found in Dr. Pilcher's remarks on the past action of the Association, let him stand up. And if the committee appointed by the Association at its last meeting have no more back-bone in them than to try to pacify Dr. Pilcher and his society, they deserve all the contempt with which they have met at his hands. Very respectfully,

W. P. HOWLE, M.D.

Oran, Scott Co., Mo., February 23, 1893.

If the JOURNAL's correspondent will carefully read the proceedings of the New York State Medical Society he will observe that DR. PILCHER, in his address recommended the appointment of a committee to confer with the committee from the American Medical Association, and that the Society as a body went even farther than this in their desire for a condition of amity, and by a unanimous vote forestalled the purpose of those committees, by revoking the new Code of Ethics which had been created and adopted by the society some years ago.

The purpose of this action seems to us to have been intended to act as a removal of a serious bar of antagonism that stood in the way of a speedy renewal of the old relations of affiliation with the American Medical Association. Our natural inference is that such was the motive and spirit that actuated the members of the New York State Medical Society. So mote it be.

So far as even an apparent expression of contempt on the part of DR. PILCHER is concerned, we fail to perceive it, and do not believe he had any intention of making use of an expression conveying such a meaning.

So far as our own reference to a revision of the Code of Ethics is concerned, we are free to say this was demanded by the American Medical Association at its last meeting, or it would not have appointed a committee for that purpose.

NEBRASKA STATE MEDICAL SOCIETY.—The yearly meeting of the Nebraska State Medical Society will take place at Nebraska City, May, 16, 17 and 18.

DOMESTIC CORRESPONDENCE.

Removal of the Ovaries, etc., in Public Institutions for the Insane.

To the Editor of the JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION:

I am quite in sympathy with Dr. Rohé in his protest (in the current issue of THE JOURNAL) against the editorial article of February 4, under the above title. I was minded to attack it myself immediately upon its appearance, but desisted because it seemed to me that an attack would have more weight if it came first from an experienced gynecologist. But now that this attack has been made, I venture to add (and I am not a gynecologist at all) that as against the deliverance of the "legal member" of the Lunacy Committee of the Pennsylvania State Board of Charities—that neither the patient nor her friends for her can give legal consent to the operation, etc.," it may be said that neither can she, nor her friends for her, give legal consent to the disposition of her body or her property. But as this might work hardship to herself or her friends, or both combined, the courts may undertake, upon the representations of competent and reliable persons, to do either or both for the benefit of the insane person.

If therefore the courts can order her incarceration as a precaution against personal injury, or the disposal of her property to prevent financial loss, may they not have authority to order an operation, if surgeons of acknowledged skill and integrity decide it to be advisable? And does not this make, as it should, the judgment of these surgeons, after all, the judgment of the court of last resort?

As against the idea of the chairman of the committee (Dr. Morton) I want to suggest that outside of the question of cure, there is a sociological question which should not be forgotten.

If every insane woman could be kept in a detention hospital, where there could be no association with any but her own sex, this might be of little importance. It may be so in Pennsylvania. But in Iowa it is the custom to return the incurable insane to the care of their friends at home if they have homes, and if not, to the "county house" of the county from which they came. In either case there is more or less commingling of the sexes, and occasionally undesirable results follow.

Recently a friend of mine made an oöphorectomy upon a selected case in the "county house." She made a rapid recovery from the operation, and for a time gave promise of a return to sanity. Later on, however, she relapsed into the old mental condition. But inasmuch as her insanity had a markedly erotic type, we all felt that the operation was properly undertaken; because it gave the woman, as well as the public at large, a safeguard worth having, even if it was negative in result from a remedial standpoint.

This view, I think, must commend itself to all reasonable people.

H. B. YARSG, M.D.

Burlington, Ia., February 18, 1893.

Revision of the Code of Ethics.

To the Editor of the JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION:

Dear Sir:—THE JOURNAL of February 18, 1893, contains two parts of an address by the President of the Medical Society of the State of New York, and one part of the report of a committee on the President's address. A few comments on those parts of the address and on the committee's report may be in order, since they relate to the ethical question now under discussion.

1. In June, 1892, the American Medical Association appointed a committee to meet like committees from the New

York State Medical Association and the Medical Society of the State of New York, and hold a conference "for the purpose of adjusting all questions of eligibility of members of the said Medical Society of New York to membership in this Association." It is apparent that the object of the American Association was to learn the particular grievances of the disaffected and to devise means to soften them, to bring back many who had strayed from the fold, and to stifle the bitter disputes which have proved so injurious to them and to the whole medical profession; but they have rejected the proposition in a spirit that scarcely indicates tolerance. The resolution transmitted by the Permanent Secretary of the American Association seems sufficiently explicit, but is caviled at, although its intent is acknowledged.

2. In the address delivered before the Medical Society of New York, the following may be noted: "It (the American Association) is a voluntary association, responsible to no one, and may change its standard of admission at its will." The American Association, like many other scientific organizations, is voluntary, but it is responsible for its acts to all honest men. It is not less pure because voluntary, and being voluntary does not lower its standard of morals, while this enables it to admit to its ranks those only who subscribe in good faith to its code of morals. The disaffected would probably like the Association to change its standard of admission not at its will, but at theirs.

3. Another noteworthy specimen of the tone of the address is the following: "It (the New York Society) must content itself with regulating its own standards, as it now does, suggesting in turn that it is equally indelicate for organizations which have no supervising relations to it to extend advice as to its internal affairs." This is the same as saying that the American Association must not meddle with the affairs of the New York Society, which shall have no ethical code if it so decides; and it has so decided. After this decision, the American Association will be justified in saying that it will not meddle with a society that repudiates good morals.

4. The committee on the New York Society address concluded their report by offering a resolution which, with the report, was "unanimously adopted." The resolution is to the effect that the Society deems it unwise to appoint the Committee requested by the American Association "but the Society ventures to express the hope that the American Medical Association, at no distant day, will take such action as will remove the merely technical obstacle to the most cordial coöperation between the two societies." To hope that there can ever be any coöperation of two bodies of men, one of which recognizes no code of morals, seems as futile as to expect Christians and Mohammedans to join hands on questions of faith! There is no mere technical, but an insurmountable obstacle in the way until the Medical Society of the State of New York readopts the system of morals of the National Association; until then how can there be comity or any kind of recognition, if the "general sense of the profession" be rightly interpreted?

5. The "no coders" may imagine that they shall be able to do as they please, but will find themselves constantly confronted by customs, by ethics good and bad from which to choose. All kinds of men, savage or civilized, honest or dishonest, have their ethics. About two centuries ago the ethics of beggars were codified by a scholarly mendicant. The perusal of the document is as instructive as it is entertaining. Bandits, burglars, cutpurses, sneak thieves, receivers of stolen goods, and other miscreants, have their written ethics, among which is the well known provision that there should be honesty among rogues. Men of these several classes adhere consistently to their ethics, and are unanimously in favor of abolishing the criminal code and the decalogue, which are in such conflict with their actions. But

it does seem incredible that men belonging to a liberal profession should reject a code of good morals which tells them to be just and how to be just! It is a monstrous anomaly, in this enlightened age, that men of reason should not want laws which forbid that injustice should be done to them! One of the sayings of the "no coders" is that "no man shall regulate their actions." As every student of philosophy knows, moral laws are not made by single individuals; they result from the researches of many moralists who compile the records of good actions, good customs, which, by others, are arranged systematically, and which are finally codified by organized associations of men, just as many laws have been compiled and codified from the most ancient customs.

6. The opponents of the National Code do not appear to have found out how laborious it is to codify and properly formulate moral maxims. If they had been aware of the difficulties of accomplishing the task creditably, they probably never would have rushed forward with their "new code" and the "newer code," and most likely would not have attacked the American Code. The last hasty performance of the State Society of New York was the abrogation of its "new code" and the immediate declaration for "no code," as its committee and all the members may have thought, but the committee, seemingly without intending to do so, did recommend a "new code No. 2," which they style rules, and which was unanimously adopted by the Society. In order that this "new code No. 2" be clearly and unmistakably understood, its sentences will be separated so as to represent distinct paragraphs, as follows:

a. "The Society reserves to itself the right to punish its members for any unprofessional conduct."

b. "The determination of what shall be considered unprofessional conduct shall rest with the Society."

c. "If at any time charges are preferred against a member of the Society, these charges shall be referred to a committee which already exists for a similar purpose."

d. "This rule shall take the place of paragraph eight of chapter six of the by-laws, as well as the rules adopted by this Society in February, 1892."

Such is the present Code of Ethics of the New York Society, despite its declaration that it has no Code. It is unpleasant to be placed in a wrong position, but it is unpardonable in a committee to render ridiculous the body it represents. The commentary on these four remarkable paragraphs will be brief.

a. Assuredly the Medical Society of New York would not be likely to delegate the "the punishment" of its own offending members to some other institution. Without meddlesome intent, it is mildly suggested that the rule reserving the right to punish seems superfluous.

b. It does not appear that the State Society of New York has determined what shall constitute unprofessional conduct. If such determination is not in its archives no member can with justice be tried and condemned for the violation of a law which is not clearly defined and recorded.

c. It seems like the extreme of inconsistency and injustice for a society to entertain charges preferred against a member, when that society has neither published nor established an intelligible standard of morals, notwithstanding that there already exists a committee for a "similar purpose."

d. The committee very properly gives the name rules to this "new code No. 2" which is to replace the set of rules called "new code" in February, 1882, because most codes of morals consist of a statement of rules of conduct. But unfortunately neither the abrogated "new code" nor its substitute "new code No. 2" contain distinct statements of rules of conduct. Unprofessional conduct is too general, too vague, it has many degrees which should be stated.

This brief examination leads to the conclusion that "new

code No. 2" is incomplete and that it will probably require at least seventeen paragraphs, but if the new paragraphs be like the first four, no member need fear to be "punished."

7. It is not safe to attack a carefully prepared document known to have stood the scrutiny of many scholars for forty-five years in respect of its teachings and literary merits. Its detractors having failed to show cause why it should be abrogated, their case will probably be dismissed and they will consequently have no standing in the Association. Fanatics may repudiate the admirably phrased moral precepts of the Code, but these maxims will be read as long as truth is loved, as justice is revered, as honor is prized, as virtue is cherished, as sublime thoughts are admired, and as long as there is the least semblance of literary taste.

8. The advocates of the American Code have had no other motive than the defense of the production of such moralists and scholars as Percival, Hays, Clark, and others, from the gratuitous attacks that have been made upon it by the disaffected and by their champions, who characterize its language as obscure and redundant, and its provisions as unnecessary and useless. But these attacks have consisted of mere assertions unaccompanied by evidence or argument. On the other hand, after repeated examinations, the defenders of the Code found its dominant characteristics to be explicitness without verbosity, fullness of detail without undue expansion, and conciseness without obscurity. These qualities added to the exalted moral precepts which it inculcates give it the greatest value as an ethical system for the use of the profession and of the people.

9. In this strife, which has lasted ten long years, many utterances, spoken and written, have doubtless stung consciences and offended pride; but was there ever contest without painful incidents, was ever contestant exempt from blame? Let the disaffected yield to truth and justice, let their rancor cease, let there be a truce, and there will surely follow peace, good will, harmony, union, prosperity, good fellowship, and oblivion of the past! Again all loyal members of the profession fervently exhort the disaffected to cease consorting with the enemies of truth and justice and unite with the great national confraternity to sustain scientific medicine. Such a close union would be most beneficial to the nation, glorious to the profession, honorable to all, and to the best interests of individuals. Charlatanism and crafty ignorance would then quake at sight of the solid phalanx of intelligent honesty.

A CONSERVATIVE MEMBER.

MISCELLANY.

OPHTHALMOLOGICAL SECTION OF THE PAN-AMERICAN MEDICAL CONGRESS.—Dr. Julian J. Chisolm of Baltimore, who is the Chief of the Ophthalmological Section of the Congress, has organized his Department with the following gentlemen, well known, as ophthalmic surgeons.

The honorable presidents of this Section are: Dr. Herman Knapp, New York; Dr. Eugene Smith, Detroit; Dr. Stephen C. Ayres, Cincinnati; Dr. X. C. Scott, Cleveland; Dr. Abner Calhoun, Atlanta; Dr. Herbert Harlan, Baltimore; Dr. Chas. W. Kollock, Charleston; Dr. Stephen C. Riehy, Washington; Dr. Jose Ramous, City of Mexico; Dr. G. C. Savage, Nashville; Dr. J. E. Minney Topeka; Dr. W. H. Carmelt, New Haven; Dr. H. J. Baldwin, Montgomery; Dr. Aurelio Alareo, Lima, Peru; Dr. Carlos Finley, Havana, Cuba; Dr. Hasket Derby, Boston; Dr. J. C. Kipp, Newark; Dr. Dudley S. Reynolds, Louisville; Dr. Maxim^o Gienfuagos, Santiago; Dr. Chas. E. Michel, St. Louis; Dr. Samuel D. Risley, Philadelphia; Dr. R. H. Lewis, Raleigh; Dr. T. E. Murrill, Little Rock; Dr. E. C. Rivers, Denver; Dr. C. M. Shields, Richmond; Dr. J. W. Fulton, St. Paul.

In the Advisory Council are the following ophthalmic Surgeons: Dr. Adolph Alt, St. Louis; Dr. L. W. Fox, Philadelphia; Dr. Geo. T. Stevens, New York; Dr. Edward Jackson,

Philadelphia; Dr. B. A. Randall, Philadelphia; Dr. H. V. Wurdeman, Milwaukee; Dr. R. Sattler, Cincinnati; Dr. J. L. Thompson, Kansas City; Dr. L. Connor, Detroit; Dr. R. L. Randolph, Baltimore; Dr. J. A. White, Richmond; Dr. S. M. Burnett, Washington; Dr. A. B. Baxter, Cleveland; Dr. J. P. Parker, Kansas City.

Dr. Geo. M. Gould, of Philadelphia, English-speaking Secretary; Dr. J. Harris Pierpont, of Pensacola, Spanish-speaking Secretary.

SECTION ON ANATOMY OF THE PAN-AMERICAN MEDICAL CONGRESS to be held at Washington, United States of America, September 5, 1893. Executive President, Dr. John B. Roberts, 1627 Walnut Street, Philadelphia, Pa. Secretaries, Dr. D. S. Lamb, (English speaking); Dr. A. M. Fernandes, (Spanish speaking) 194 W. 10th St., New York, N. Y.

This Section will be devoted to the study of Human and Comparative Anatomy and of Biology as departments of natural science as well as in their relations to practical medicine and surgery. Members of the medical profession in Latin American countries are urged to prepare scientific communications to be read before the Section. Much valuable material will thus be collected and articles of scientific value will find permanent place in the Transactions of the Congress.

The regulations applying to papers and discussions, which have been adopted by the Executive Committee of the Congress are as follows:

Contributors are required to forward abstracts of papers not to exceed six hundred words each, to be in the hands of the Secretary-General not later than the tenth of July, 1893. These abstracts shall be translated into English, French, Spanish and Portuguese, and shall be placed upon the program which has not been thus presented by abstract. Abstracts will be translated by the Literary Bureau of the Congress at the request of contributors, and should be forwarded through the Secretaries of Sections. Papers to be presented to Sections must not consume more than twenty minutes each in reading, and when of greater length should be read by abstract not exceeding twenty minutes in length. Papers read by abstract may be printed in full in the transactions, subject to approval by the Editorial Committee. Papers and discussions will be printed in the language in which they may be presented. All papers read in the Sections shall be surrendered to Secretaries of the Sections; all addresses read in the General Session shall be surrendered to Secretary-General as soon as read; and all discussions shall be at once reduced to writing by the participants.

The Executive President of the Section asks the cooperation of all interested in Anatomy and Biology, in making the deliberations of the Section valuable to those present at the meeting and worthy of preservation in the Volume of Transactions of the Congress.

HIGHER MEDICAL EDUCATION AND THE WOMAN'S MEDICAL COLLEGE OF PENNSYLVANIA.—It will encourage the friends of higher medical education to know that all matriculates hereafter entering the Woman's Medical College of Pennsylvania must take four annual courses of lectures before obtaining the degree of Doctor of Medicine. This Philadelphia school for women has long been in favor of advanced standards; and with four compulsory graded courses of seven months each ought to prove its efficiency in supplying the community with well educated women physicians.

OFFICIAL LIST OF CHANGES in the Stations and Duties of Officers Serving in the Medical Department, U. S. Army, from February 18, 1893, to February 24, 1893.

Under the authority of an Act of Congress approved February 8, 1893, Capt. James A. Finley, Asst. Surgeon, is, by direction of the President, placed upon the retired list of the Army, to date from February 16, 1893, the date of his acceptance of his appointment under the provisions of said Act.

Major James P. Kimball, Surgeon U. S. A., is granted leave of absence for three months, on surgeon's certificate of disability, with permission to leave the Dept. of Texas.

OFFICIAL LIST OF CHANGES in the Medical Corps of the U. S. Navy, for the Week Ending February 25, 1893.

P. A. Surgeon E. P. Stone, ordered to Naval Hospital, Chelsea, Mass.

Surgeon C. U. Gravatt, from Naval Hospital, New York, March 3, and granted three months' leave.

ABDOMINAL SURGERY AND ITS EVOLUTION AND INVOLUTION.

Read and discussed before the Marion County Medical Society,
November 15, 1892.

BY JOSEPH EASTMAN, M.D., LL.D.,

LATE PROFESSOR OF ANATOMY AND PROFESSOR DISEASES OF WOMEN AND
ABDOMINAL SURGERY, CENTRAL COLLEGE OF PHYSICIANS
AND SURGEONS, INDIANAPOLIS.

While walking with a professional friend in the city of Chicago, I asked what had become of a certain doctor with whose name I had become familiar through his contributions to surgical literature some five years ago. The answer was, "He is doing some practice now." This good doctor's answer impressed me and begat other questions. How much of our current literature comes from those who write before they practice? How much from doctors who practice before they write, and what is the real motive which prompts the writer? Is it to place upon the altar of science the tithes of his experience? If so, have they been tested in the crucible of truth, and is he giving us only the atom of gold which he has found among the dross, or is our embryonic specialist intoxicated with the little knowledge gained by reading plus that obtained by his maiden efforts in operating, and like the bumblebee, largest when he first emerges from the comb, "seeking to be heard for his much speaking." If the latter is true, the average student must be wide awake to winnow the wheat from the chaff when the literature of abdominal surgery is burdened with productions from those who have little surgical aptitude, less originality and still less wisdom born of experience. Having read an article headed "Who Should and Who Should Not Teach Gynecology?" it will not be considered impertinent, I hope, to ask who are our teachers? What is their warrant for teaching? Really, are many of them specialists at all? Prof. J. T. Hodgen, of St. Louis, defined a specialist as "a most accomplished physician and surgeon and something more." "Too often," said the doctor, "he is something less." It is incontestably true that the cultivation given a mind, already broad, by a dozen years of general practice, widens and rounds up the specialist's professional character as nothing else can do. At the same time, as one extreme follows another, so the great master workmen in our specialty have been and are men who by strong will powers forced broad faculties to work in a narrow channel, becoming educated to the work, capable of comprehending the great principles of our science, and so acting in a given emergency as to bring honor, not disgrace to our noble art. These masters, most of them, first became familiar with all diseases, their complications and their treatment. Then finding it necessary that the mind be relieved of the burden incident

to the thorough study of so broad a subject, they abandoned general practice to the end, that their faculties could be unrestrained in their tendencies toward special studies and investigations. It is the taking the mind off from many things that enables it to concentrate with force and effect on a few things. To plow deep implies no attempt to turn a wide furrow. What contributions to science and blessings to humanity have come from concentration of the thoughts of great brains into specialties! To illustrate, I need only to mention the name of Edison. Before the hard-working general practitioner concedes to their demand for recognition as a specialist, it might be well for him to ask a few questions: What natural adaptation, what general research in anatomy and pathology has the alleged specialist acquired? Has he served for a sufficient time under a master? Is he so located and situated as to warrant him in abandoning all else and making it a life's work, and thereby acquiring a large experience? In much of our work the mind follows the educated finger by faith where sight is impossible. I still cling to the aphorism used before our State Society some years since, that honor to American statistics was in the direction of many operations by the few and fewer operations by the many. That there must be amateurs on every stage may be true. It is equally true that the great masters of the drama added to natural talent long and thorough drill under a master. These masters will not essay a single performance without their accustomed support. The surgical stage should be no exception, at least until our great actors shall be able to avert the heartaches which come to them when the curtain falls on a death scene. The emphatic statement of J. Greig Smith is in point: "Abdominal surgery is no longer a field for legitimate and versatile experiment. Certain fixed and useful laws and customs have been laid down by the dearly bought experience of great men. The abdominal surgeon ought to begin fully equipped with such knowledge as has been gathered for him." This being true of the operator, what of the adventurer who with limited experience seeks to achieve fame by writing up his maiden efforts in operating. When one seeks recognition as an operator or teacher, we have a right to know what reasons they have for the faith they would teach. The facts seem to warrant the assertion that some of the current literature is dangerous. There are many things contained in the literature of what is now our established specialty which would seem to indicate that the writers were not willing to depend upon merit for professional preferment. I have neither time nor inclination to give more than a few examples. They will serve, as I believe, to bring up points enough for the discussion of the evening.

The contributions to our literature which retard rather than aid progress do not all come from begin-

ners. Some distinguished operators write that which the hand of progression will soon obliterate. I have written a few things myself which a riper experience would not have given to the profession. In the *America Journal of Obstetrics* of July, 1889, one Curtis Miller announced that living in the city of Charleston, W. Va., he had found 144 cases demanding abdominal section; had operated on all of them, and in this number there had been no death. The query instinctively came to my mind, not only how a beginner could have such success, but how could he secure so many cases in so short a time. I wrote to a friend near the Virginia line making inquiries about this phenomenal report, intimating that such an operator could well afford to locate his patients or give the name of attending physician. My friend answered my interrogation by saying he thought this man Miller had been with Tait and was not handicapped by former professional or surgical methods in obtaining cases or records in operating. The statement that this operator had been with Tait was explanatory. I could, as I believed, read between the lines. I have not seen any reports from this operator since. I have, however, seen reports from other operators which I must consider as startling as this. It seems to me that the time has come when our standard medical journals should require something more than the say-so of the operators who publish such astonishing results. Unfortunately, reports are published by operators and those visiting them, and reported from journal to journal, which would put an interrogation point into the eye of Dr. Thomas Keith, of London, similar to those seen when told of the phenomenal results obtained at the hands of Mr. Tait. A number of those who have been to Birmingham use more than the Staffordshire knot in exemplification of their tutor. A few seek every opportunity to differ with a more conservative fellow-worker, and violate the laws of common decency in the use of sarcastic epithets, and then with a sort of "tin horn huxtering" for patients and notoriety make the assertion, that they do all kinds of intra-abdominal operations with a fatality of less than 3 per cent. From the lips of one of Tait's pupils I heard the statement that in 100 cases of removal of the appendages, Tait nearly always had at least five deaths. There are hundreds of women in a state bordering on desperation, with neurasthenia expressing itself locally in one or more of the pelvic organs. They are willing to submit to anything under heaven which the enthusiastic but misguided coeliotomist would advise. His mind, intoxicated with the idea of the removal of a reflex cause, scarcely realizes that the consummate wisdom of a veteran in this line of work is often inadequate to decide whether pelvic symptoms are a local expression of a general neurasthenia or whether the general condition is reflected from a diseased pelvic organ. Physical deterioration is the law of advancing civilization. All neurasthenics are in a condition of mental and physical hyperæsthesia, these general conditions constantly expressing themselves in painful menstruation and tender ovaries. A resort to surgery in such cases is another instance where boldness is not tempered by wisdom, and where cutting does not cure. Numerous cases have been brought to my observation by doctors who had been reading the dangerous surgical literature of the day; they supposing that I would unhesitatingly open the

abdominal cavity in all stages of peritonitis (and this disease has been very prevalent since the epidemic of la grippe) from the very beginning, to the time when the abdomen was enormously distended, with complete obstruction from cobwebbed adhesions of the bowels to cases *in articulo mortis*. Some of them I watched for days and weeks, at last finding indications for operation—operated with success—but in more of them a time never came when I could see my way clear to advise opening the abdominal cavity. For example: In the suburb of Irvington I saw five cases in consultation with Dr. Barnhill, my former pupil. The first one we opened the abdominal cavity, finding extensive pelvic peritonitis involving the vermiform appendix, tubes and ovaries; she made a good recovery. The second had only been sick a few days. The abdomen was distended, the pulse so rapid and feeble that I unhesitatingly stated that no operation was to be thought of, as it would only launch the patient from the operating table into eternity. The third was a well pronounced case of appendicitis which made a slow but sure recovery without any operative interference, notwithstanding I saw the patient a number of times, fully expecting the time might come when an operation would be demanded. The fourth and fifth cases were both well pronounced cases of perityphlitis, neither of them presenting indications for operation and both making good recoveries. Other towns that I have visited over the State have furnished their list of similar cases. The pendulum of surgical aggression has been swung to the extreme. Too many are saying that operative interference offers the only hope. Too often beginners urge operations as practically without danger, not on the basis of their own experience, but on what they believe to be the large and honestly reported experience of those whose reckless use of language in condemnation of a fellow-worker is suggestive of reckless struggling with the truth in reporting cases. I have had my small share of surgical triumphs, and my profession has given me abundant credit for the same, and honored me fully up to my deserts. Far be it from me to be envious of the achievements of any one who is conscientiously doing his best in the service of humanity. On the contrary, I extend the hand of fellowship to all disposed to engage in this specialty, but when my credulity is overtaxed I have a right to console myself as did Hume in his philosophy. He reasoned that Christ never rose from the dead, because he had only the testimony of the twelve apostles, and firmly believed that in that day and age of the world lying was twelve times more common than the resurrection of dead men. In a circular sent me from a life insurance company I read: "During the early part of the current year the death-rate throughout the country was unusually large. La grippe and pulmonary disease made sad havoc everywhere." I believe this to be true. I saw evidence of the epidemic expending its force within the abdominal cavity in a large number of cases. I make chemical tests of urine to determine what anæsthetic to use and to assist me in appreciating the dangers of operating in a given case. In 30 per cent. of my cases I find the specific gravity ranging from 1030 to 1040, with varying quantities of sugar and not unfrequently albumen. This I did not find before the epidemic referred to, but during and since. For successful surgical work I consider good kidneys of very great

importance, and am convinced from observation that in more than 5 per cent. of cases demanding surgical procedure the excretory function of the kidney is so impaired as to be worthy of serious consideration as an element of danger following our work. I have looked in vain for some statement from these phenomenal operators that they were a little less successful during the epidemic. Does the abdominal surgeon stand alone, and not have his death certificates number the more in consequence of these fatal epidemics? Are we to believe that in the hands of these men abdominal sections are uninfluenced by and are a preventive of la grippe? If so, I shall not be surprised if the literature of the near future contains a series of abdominal sections for Asiatic cholera with an astonishing number of successes. Another point to which I would invite attention is, what is meant when the statement is made that A or B has made so many operations without a death? One instinctively asks, "Did the patients simply not die on the operating table? Did they rally from the shock, live until the sutures were removed, regain their feet, and was their condition made better or worse by the operation?" If a statement accompanied these reports as to what is meant by the words "without a death, with success," etc., the truthful operator would have less hesitancy in comparing his record with the truthless.

Exploratory incision has now been accepted as a means of diagnosis, and the current literature of the day would lead the average physician to believe that it was comparatively free from danger. This is true to a certain extent. At the same time, I am well convinced that the so-called simple exploratory incision should only be undertaken by the well equipped and thoroughly competent abdominal surgeon. If the abdomen contains an ovarian cyst or a fibroid tumor, there is strong probability that the diagnosis can be made with reasonable accuracy before the abdomen is opened, but when we admit that the operation is made for diagnostic purposes, we should be willing to concede that the one who does it should have the nimble wit in the ends of his fingers which enables him, by the sense of feeling, to differentiate between the normal anatomy and pathological changes. Not only this, but he should be competent to do anything known to the surgery of the abdomen and do it according to the principles established by the dearly bought experience of our master craftsmen. Many cases have come to my mind where practitioners anxious to obtain the prestige presumably gained by abdominal section, have ventured to open the swollen abdomen with no definite idea what they were going after, where they were going to locate it, or what they were going to do with it, after they had found it. After opening the abdomen freely, with the hope that they might see something which the fingers had not been able to feel, as their fingers had taught them no more about the abdominal viscera than the fingers taught the obstetrician in his first examination, they found the intestines distended with gas, piled up in formidable stacks over the abdomen and even falling down on the table. Their position was something like the man who attempted to repair the clock; he had no difficulty in taking the clock to pieces, but when he attempted to put it together again he imagined he had wheels enough for fourteen clocks. So the amateur operator would believe there were intestines enough to fill fourteen

men or women. In cases where the abdomen is markedly distended, the experienced operator might do no better; but the veteran in abdominal surgery, never having much faith in operative procedure for peritonitis, has learned to know that unless there is some evidence of localization of the process and products of inflammation, surgical interference is worse than useless. Who for a moment would think of plunging a trocar into the chest in acute pleuro-pneumonia, much less to think of making free incision for the purpose of irrigating and destroying the germs of inflammation. A little later, when the pleural cavity is filling with serum and the absorbents are not able to take up the same, or if this fluid is becoming purulent, then opening the chest, with a thorough washing and drainage, is a surgical procedure where boldness is tempered by wisdom. The same reasoning applies with even greater force to the serous lining of the pelvis. In abdominal surgery, as in medical practice, the judgment we use in the adaptation of the remedy, not only to the disease but to the particular stage of disease, is the measure of our success. I know of no inflammation that is not of septic origin. In the earlier stages of septic peritonitis surgical interference is but adding fuel to the flames. Knowsley Thornton (*American Journal of the Medical Sciences*, October, 1888, p. 371) says: "The more I see of abdominal surgery the more I am convinced that operation during acute peritonitis is very dangerous; whereas in the subacute and chronic stage the patient bears the operation as well, or better, than with a perfectly healthy peritoneum." There are additional agents which materially aid in tiding the patient over the acute stage of disease to the time when the microorganisms have become materially less active, so that surgical efforts are curative by removal of the localized products of inflammation. Some of the literature of the day, given out by distinguished members of the profession, is to my mind strikingly misleading, if not dangerous. For example, Mr. Tait, whose fame is world-wide, and who has been a great benefactor of women, in his book on Diseases of Women and Abdominal Surgery (page 117) says: "The proposal to deal with cancer of the uterus by complete removal of the organ meets, I need hardly add, with my strong disapproval. My reasons are, that its primary mortality must always be heavy, and that the few cases in which the disease does not recur are clearly errors of diagnosis. Further operations for a disease which give unjustifiable secondary results have no place in good surgery; and it complicates in the confused mind of the public, the issue of electing to have operations performed the secondary results of which are perfect. As I like my work to be stable, I have always opposed this cutting out of the uterus for cancer, and my first judgment has been confirmed by the results." That many women are given a respite from death, others' lives materially prolonged, while still others are being cured by this operation, some of us know. For my part I could produce more than a score of women who have been blest by this operation, done at intervals from six years down to one week. It is very gratifying to Mr. Tait, no doubt, to make the reference he does to the uselessness of extirpation of the cancerous uterus or Emmett's operation on the cervix. It would be very amusing to me to see these great benefactors of womankind, and Mr. Tait in particular, defend him-

self in the presence of a few dozen of these women who are enthusiastic in their expression of the blessings they have received from these operations. It is not surprising, however, that vaginal extirpation of the uterus should have been slow in gaining recognition as a comparatively safe procedure. It has been practiced by many with an utter disregard of the sound surgical principles which govern opening the abdominal cavity above the pubes. Even recently, I note a doctor insisting that many forceps to secure the broad ligament are equally as good as a lesser number. When an operation is done in that manner, it leaves the contused gangrenous portions of the broad ligament to come in contact with portions of the omentum, mesentery and intestines, thus inviting septic peritonitis. Now, all of this could be easily prevented by first constricting the broad ligaments to a round mass by a single ligature, bringing them down into the angles of the wound, and transfixing with additional ligatures or applying a single clamp. In this way we have, not only complete sero-serous approximation of the entire wound with no raw surface whatever left within the peritoneal cavity, but more than that, by this rounding and bringing down of the broad ligaments and fixing them in the upper angle of the wound, we have the patient guaranteed against vaginal prolapse and its resultant cystocele and rectocele; sequelæ almost invariably following the operation where many forceps are used, and the broad ligaments are not first rounded. When about to visit Birmingham, Eng., some years ago, a professional friend, whose reputation in gynecology is international, provided me with a letter of introduction to Dr. Savage. I thought I knew of the man, believing that he was the author of a book on the female pelvic organs. I was mistaken. My introduction was to another man who in reality I had never heard of. I found him sitting as Chairman of the Gynecological Section of the British Medical Association. I shall always love my friend the better because of his kindly efforts to have me know this man. The meeting adjourned at 3 p.m. I accompanied him to his private hospital, saw him remove a kidney. I then rode with him to the Birmingham Hospital for Women, a distance of two miles, saw him make two abdominal sections. I never saw a more careful, painstaking, and at the same time rapid operator handle an instrument. I looked at my watch and found that I had been introduced to the doctor just two hours. I found that he had equal rights in the Birmingham Hospital for Women with the renowned Lawson Tait and was doing the same amount of work there, and wondered why the world had not heard more of this man. I learned that he had as much work as he could possibly do, and that there was so much reckless reporting of cases, that he was disinclined to compete with those less conscientious and truthful in their work. Most of our American cities have similar men. The reports of their conscientious, painstaking work are rarely seen. They are unwilling to compete with the modern hustlers with their loud declarations of success in societies and journals, aided by sycophants whom they employ to write their praise. Our literature has its good and bad teaching coming from those high and low in the profession; coming from those hustled into notoriety by cliques and rings, and coming from those manfully struggling against many obstacles thrown in their way. After all, we find in

it an abundance of knowledge and some wisdom.

"Knowledge and wisdom, far from being one,
Have oftentimes no connection; knowledge dwells
In heads replete with thoughts of other men;
Wisdom in minds attentive to their own.
Knowledge, a rude unprofitable mass,
The mere materials with which wisdom builds,
Till hewed and squared and fitted to its place,
Doth but encumber whom it seems t' enrich.
Knowledge is proud to think it knows so much;
Wisdom is humble that it knows no more."

—*Comper.*

By all the sacred memories which cling to the words mother, wife, sister or daughter, let him, who aspires to be the physician of women, be a gentleman. "A man of the keenest sensibilities and the most delicate sympathies." Let him be an *honest* man. Let *truth* ever be his guiding star. I can say in all sincerity that I believe my profession and my specialty have as large a per cent. of honest men and honest women as any other profession or any other business, and have no remedy to suggest to correct the wrong doing of the few who, disregarding that beautiful aphorism, "the surest way to secure professional preferment is to merit it," hustle for business in a way that would be beneath the dignity of men engaged in commercial pursuits.

"It were a heaven on earth
To have our minds illumined with knowledge
To move in charity
And turn on poles of truth."

—*Sir Wm. Gull.*

A DAY WITH PROFESSOR VIRCHOW AT CHARITÉ HOSPITAL, BERLIN.

BY ROBERT REYBURN, A.M., M.D.

PROFESSOR OF PHYSIOLOGY AND CLINICAL SURGERY, MEDICAL DEPARTMENT
HOWARD UNIVERSITY, WASHINGTON, D. C.

Among the most interesting memories that I retain of my trip to Europe last summer, was a visit that I paid to Professor Rudolph Virchow in Berlin, on July 23, 1892. Professor Virchow, to all Americans (and indeed to all men of every nation who sympathize with the cause of free speech and free thought), is the most interesting scientific man in Europe. He is not only preëminent as a scientist and pathologist, but is a man who always has aided the cause of freedom everywhere and especially in his own country. He was the man whom Bismark in his days of arbitrary power especially hated. In 1849, and for seven years thereafter, he was banished from his professional chair at Berlin, on account of his liberal opinions, but was recalled to his duties in the University in 1856. During the period of his absence he distinguished himself by the lectures he delivered in the University of Wurtzburg these were the first germs of the ideas, which finally developed into his great book on cellular pathology. Professor Virchow is director of the famous pathological institute of the University of Berlin, which is one of a group of buildings composing the medical department of that institution. The Charité Hospital, in which clinical instruction is given to the medical students of the university, and the laboratory buildings in which Professor Koch carries on his investigations, are also situated on the same grounds. In company with Dr. Fulleborn I attended Professor Virchow's lecture, which was held at 10 a.m., the subject of the lecture was carcinoma. I need scarcely say that I was deeply interested in both the man and

his subject. The room in which he lectured will probably accommodate two hundred students; every seat was filled and the students were almost all engaged in taking notes of the lecture, and were apparently eager to catch every word that fell from his lips. Around the table near which he lectured were a large number of pathological specimens, both in jars and on dishes, illustrative of the lecture. These were passed around the class from hand to hand as the lecture proceeded thus fully illustrating the subject.

Professor Virchow lectures in an easy colloquial manner. He speaks beautiful German and every word is pronounced so clearly and distinctly that he is easily followed even by foreigners who have an imperfect knowledge of the German language. After the lecture was over I went to his private office in the university building, and presented my letter of introduction from Howard University, and was very courteously received. Professor Virchow is of medium height, he is somewhat stout in figure, and is apparently in excellent health and vigor for a man of his years (he having passed his seventieth birthday).

He speaks excellent English and seems very kindly disposed towards Americans. During our conversation I asked him if he could not come over to Chicago during the coming year to our Columbian Exposition, and assured him that I felt certain he would receive a royal welcome from the medical profession in America. He replied, "No I think I cannot come; I am now past seventy and America is very far". His office was nearly filled with a large number of skulls of varying shapes and sizes, which he had brought there for the purpose of study. He stated to me that he was now engaged in writing a book upon the crania of America, which would be published during the coming year. On parting from him he expressed a desire to be remembered to his professional brethren in America. After leaving Professor Virchow I went to his demonstration room, where every day are brought the pathological specimens procured from the bodies of the patients who had died in the hospital during the previous twenty-four hours. These specimens are procured for examination and study by the medical students of the university, and were brought in on fifteen wooden dishes or trays, about sixteen or eighteen inches in diameter; each one of the dishes contained from one to three specimens. When we remember that all these were the results of the post-mortems made in the hospital in a single day, we can form some idea of the wealth of clinical material available for study by the medical students of this great institution. In front of the tables in this room is a miniature railway, by which the microscopes can be propelled along the rows of students, so that they can be examined by each one of them without interrupting the lecture or demonstration. I then paid a visit to the ward for contagious diseases, and to the surgical wards of Charité Hospital. The wards were clean and fairly ventilated, but I confess I was not as favorably impressed with them as I expected to be; there was a lack of that exquisite neatness that I have seen in some other hospitals, and some of the wards were much overcrowded. I went to the operating room of the hospital, and witnessed an operation for the removal of a tumor from the right side of the brain of a patient, an in-

mate of the hospital. The operation was performed by Professor Bartleben assisted by Professor Joli. It is scarcely necessary to say that the operation was performed in the masterly manner that might be expected from surgeons of such eminence. The operating room in which the above operation was performed, somewhat disappointed me. It was small in commodius and would not have accommodated more than sixty or seventy students. The operation was performed aseptically and under the influence of chloroform anaesthesia. Sulphuric ether used as an anaesthetic seems to be seldom employed on the continent of Europe at the present time—at least such was my experience during the summer of 1892. One very grave fault in the operation was the allowing of the students and assistants to touch the patient and the surgical instruments used during the operation. This to my mind vitiates entirely the possibility of performing an aseptic operation under such circumstances. The very essence of an aseptic operation presupposes an aseptic patient, operated upon by an aseptic operator with aseptic surroundings. No person or thing should be allowed to touch the patient until after the wound is dressed and thoroughly closed from the air and all risk from contagion. (During my stay in England I saw the very same error committed in three of the larger hospitals in the city of London.) No carbolic spray was used during this operation and in fact during the whole summer I was in Europe I never saw it once used. The many layers of protective gauze, mackintosh, etc., are now replaced by a simple layer of iodoform gauze, with an abundant layer of aseptic cotton, firmly retained by means of bandages. Another remarkable change both among the surgeons of Europe and in this country is the growing disbelief in the efficacy of the ordinary antiseptic solutions that are used as germicides during surgical operations. Solution of carbolic acid has been shown to be a very weak germicide, and the same may be said of solutions of boric acid and of the other solutions commonly used for this purpose. Mercuric chloride has until the present time been our sheet anchor as a germicide. Yet recent investigations in our own country, at the University of Michigan (and published in the *Medical News* of October 1 and 8, 1892) and at the Johns Hopkins University (published in the *Johns Hopkins Hospital Bulletin* of April, 1891, p. 50,) have shown that solutions of mercuric chloride, when used as a germicide, are often inert, and still oftener actually injurious when applied to the tissues during surgical operations. Observation teaches us that the consensus of opinion of the great masters of surgery is fast settling upon the conviction that there are practically only two methods of keeping surgical and all other wounds aseptic. One of these is to keep wounds made during surgical operations as dry as possible (in this way diminishing the growth of bacteria, by eliminating as far as possible the moisture which is essential to their existence). The other method is to use only recently boiled water in contact with them. Every instrument and surgical appliance used must be sterilized immediately before using, either by boiling in water containing 1 per cent. of carbonate of soda, or by being exposed to a dry heat above the temperature of boiling water for at least one-half hour. To this, of course, must be added absolute cleanliness of the operator, the assistants, nurses and of all the appliances used in surgi-

cal operations—the operating room and all the surroundings included. Perhaps I ought not to close this article without some mention of the famous pathological and biological laboratories of Professor Koch which are also located in the grounds adjoining Charité Hospital. These comprise three very unpretentious frame buildings, which contain the bacteriological apparatus microscopes etc., required in the investigations which professor Koch has conducted and still carries on, in his experiments on the preparation of tuberculin and analogous products.

I did not try to see Professor Koch, as I was informed he was so engrossed in his studies that he was very difficult of access. The week before I reached Berlin the highest official in rank of the medical department of British India had come to visit him, bringing with him the highest credentials, and had failed in securing an interview with him. I presume he considers it absolutely impossible for him to see the multitudes of callers who visit him from all parts of the world, and prefers to keep his time sacred from intrusion, so that he can pursue his investigations undisturbed.

In an article of my own, published in the *Medical News* of December 17, 1892, I have given the details of my visit to the Paris hospitals in August, 1892, and at the risk of offending some of my friends I am compelled to say that neither in the hospitals of London or Berlin did I see aseptic surgery carried out with such perfection of detail and magnificence of results as I saw displayed in the hospitals of Paris.

Finally, I would say to American students, that it is entirely unnecessary for those who desire to study the principles of aseptic surgery to go to Europe at all. At the German Hospital, the Roosevelt Hospital, the Polyclinic and others in the City of New York, and at the principal hospitals of Philadelphia, Chicago, Baltimore, Washington, etc., aseptic surgery is taught and practiced as perfectly as it can be found anywhere in the world. If American students desire the culture that only travel can give, by all means let them go to Europe; if they desire boundless wealth of material for clinical study, let them go to London, Vienna or Berlin; but if they desire, besides these advantages, to see fineness of technique in carrying out the principles of aseptic surgery, my advice to them would be to go to Paris and study there. I am very certain they will never regret their choice.

DIURETIN.

Read before the Pathological Section of the Chicago Academy of Sciences, Feb. 9, 1893.

BY JAMES B. HERRICK, A.B., M.D.,

ADJUNCT PROFESSOR OF PRACTICE, RUSH MEDICAL COLLEGE, PROFESSOR OF PRACTICE AND THERAPEUTICS, WOMAN'S MEDICAL SCHOOL, ATTENDING PHYSICIAN, COOK COUNTY AND PRESBYTERIAN HOSPITALS, CHICAGO.

The experiments of Schroeder reported in 1889, and confirmed by clinical observations made at Schroeder's suggestion, the same year by Gram, of Copenhagen, established the value of the alkaloid theobromine, a product of the seeds of *Theobroma cacao*, as a diuretic of great power, acting by direct stimulation of the renal epithelium and lacking in the unpleasant effects upon the nervous system, tinnitus, restlessness, insomnia and delirium, attributed to its homologue caffeine.

Gram, after trial of many compounds, overcame

the disadvantage of the insolubility of the alkaloid by forming, by combination with salicylate of sodium, a double salt, sodium-theobromine-salicylate, which should contain at least 46.5 per cent. of the theobromine (Knoll's is said to contain 48 per cent.) and to which the name diuretin has been given. The therapeutic as well as commercial value depends upon its richness in theobromine. The compound occurs in the form of a white powder, soluble in less than its own weight of warm water, the solution remaining perfect on cooling. Pure diuretin should burn away without residue and should dissolve readily in soda solution. The daily amount administered—sixty to one hundred and twenty grains—is best given in divided doses of fifteen or twenty grains in solution, pill or capsule. Exposure to the air permits of the absorption of carbonic dioxide, forming an insoluble compound, so that the drug should not be given in powder. With acids or syrups containing the fruit acids the theobromine is precipitated as a white powder. For solutions, therefore, water is the best vehicle, being flavored if thought advisable, to conceal the slightly sickish-bitter taste, with peppermint, wintergreen, or some other aromatic. Usually very little, if any, objection is made by the patient, because of its taste or any unpleasant effects.

Since Gram's paper in January, 1890, numerous observers have reported their experiences with diuretin. Hoffman, Koritschoner, and Kouindji-Pomerantz, published articles the same year, confirming Gram's and Schroder's position as to the remarkable diuretic effect of diuretin and its value in removing dropsical fluids. In Koritschoner's series of thirty-eight cases from the Vienna Hospital, excellent results were obtained in all, save five who came to the hospital practically *in extremis*. The cases successfully treated included dropsies from cardiac and renal diseases, from cirrhosis and cancer of the liver and from tubercular peritonitis. The only unpleasant effects noted were, occasionally vomiting and diarrhœa. Koritschoner, after a dosage of one hundred and fifty grains a day found palpitation and extremely anxious expression of countenance to follow. He produced this result both in a patient and in himself by this dose, which may therefore be looked upon as a maximum daily amount. The removal of the dropsical fluid in some cases was so rapid as to cause alarming collapse. Koritschoner, therefore, advises that the first doses should be small and gradually increased in size until the maximum dose is given, or the desired effect produced. In twenty-three of the thirty-eight cases the effect was most excellent and it could only be said to be a failure in the five before mentioned cases, who entered the hospital beyond all hope of aid. In dropsies due to cardiac disease the result was most brilliant. Not only was no irritating effect produced on the renal epithelium, but in two cases of acute scarlatinal nephritis it caused prompt response in an increased activity of the kidney, and during its administration blood and casts disappeared from the urine.

Hoffmann made careful observations in Erb's clinic at Heidelberg, on seventeen cases of dropsy in which diuretin was given, and found the effect in dropsy of cardiac origin most remarkably satisfactory. In nephritis his results were not uniformly good, the best being obtained in the acute form. In cirrhosis of the liver the result was negative. Hoff-

man calls attention to the fact that the amount of urine passed under the influence of this drug, is in direct proportion to the amount of dropsical fluid present, while the specific gravity decreases with the increase in the amount of urine. It may be mentioned in this connection, that others, as Masius and Kress, have seen the specific gravity of the urine remaining high, owing to the greater amount of solids eliminated, notwithstanding the free diuresis. Contrary to Schroeder and Gram, who regarded diuretin as a purely renal stimulant, he finds as the result of careful watching of the pulse and heart, including the use of the sphygmograph, that under its influence the pulse becomes slower, fuller, stronger and more regular. The only unpleasant effects noted were, in a few cases, slight vomiting and diarrhoea, completely offset by the removal of the dropsical effusion, the improvement in the heart's action, disappearance of bronchial catarrh, dyspnoea and insomnia.

Mme. Kouindji-Pomerantz, as the result of experimental and clinical investigations in the laboratory of Dujardin-Beaumez, reached the conclusions that diuretin, in daily doses of forty-five to seventy-five grains, is a diuretic of greater power, though less toxicity, than caffeine, with no action upon the nervous system and little effect upon the heart and producing no unpleasant urethral symptoms. It acts by stimulating the renal epithelium and is of great use in dropsies where this epithelium is not so hopelessly damaged as to be out of reach of all drugs. Patients do not become rapidly habituated to the drug. It should be given about three hours after meals to avoid unpleasant gastric symptoms supposed to arise from the action of the gastric juice upon the remedy, when it is taken with the food.

During 1891, reports from various sources, mostly German, appeared confirming, in the majority of instances, the conclusions of the observers of the year previous. Geisler had excellent results in the dropsy of valvular heart disease and in that of acute nephritis, while in myocarditis, chronic nephritis and hepatic cirrhosis the results were negative. Pfeffer in forty cases had good results in cardiac dropsy as well as in chronic nephritis and hepatic cirrhosis. His experience in acute nephritis was not so favorable. In some cases the amount of urine for twenty-four hours was six litres. Both Geisler and Pfeffer regard diuretin as a cardiac tonic and found after its use an increase in blood pressure. Schmieder and Siefert agree with others that the best results are obtained in cardiac dropsy and where there is general circulatory disturbance, though the latter obtained fairly good effects from diuretin in dropsy from portal vein obstruction.

In this country, Dr. Robert H. Babcock, of this city, was one of the first, if not the first, to report on the use of diuretin. He had excellent results, especially in dropsy dependent on valvular heart disease, and was convinced that, as Hoffman early asserted, the remedy has an action upon the heart as well as upon the kidney. Laganà regards diuretin as the very best diuretic known, acting as well in acute as in chronic affections, having no deleterious influence on the kidney and more certain in its effects the more extensive the dropsy. He employed it in dropsy of heart disease, nephritis, hepatic cirrhosis and in acute and chronic pleurisy. Demme obtained good results in children in scarlatinal nephritis and

in cardiac dropsy. Oedema in acute nephritis disappears, according to his observation, more rapidly under the influence of this drug than of any other.

Two unfavorable reports were made, one by Chmelnicku from Würzburg, and the other by Nickstaedt from Erlangen. The former found it of small benefit not alone in nephritis and portal vein dropsy, but in valvular diseases of the heart. In cardiac dilatation due to emphysema, however, the good effect was obtained. Nickstaedt by doses of sixty grains per diem produced in the healthy and the sick, malaise, headache, vomiting. He obtained less favorable results than with squills, acetate of potassium or calomel and thinks the use of the drug should be restricted to cases of dropsy where other diuretics fail.

In 1892 several reports have come in, among them an unfavorable one from Hare, of Philadelphia, and a favorable one from Frank of Prague. Hare's report is but preliminary and based on the observation of four cases. His cases are not the ones in which we should expect the most marked effects from the remedy when we consider that it is in cardiac dropsy that its influence is most pronounced and the effect shown on the urine is in proportion to the degree of dropsy. His first case was one of valvular disease with albumen, but no dropsy; no diuresis. Second, valvular disease, moderate oedema, moderate diuresis, which Hare attributes to digitalis rather than to diuretin. Third, general anasarca, albumen, no valvular disease; no increase in amount of urine. Fourth, enlarged prostate, concentrated urine, no oedema; no marked effect, though no accurate measurement of urine was possible.

Frank in von Jaksch's clinic, as the result of experience with thirty-four cases, regards diuretin as a superior diuretic in cases of dropsy and as a heart tonic, though inferior in this latter respect to digitalis. His best results were in cardiac dropsies, though in chronic nephritis, pericarditis, hepatic cirrhosis, he had fairly good results. In one case of chronic nephritis the effect was most remarkable. The patient passed, on the fifth day after taking the remedy, 3750 c.c. instead of 250 c.c. of urine. With this there was improved action of the hypertrophied and laboring heart and a rapid disappearance of the hydrothorax, hydroperitoneum, etc. Diuretin was stopped and digitalis begun and the amount of urine decreased at once. That the improvement in the heart's action was due to the effect of the remedy on the heart and not alone to the disappearance of the dropsical fluid, was proven, because in many of his cases "the pulse was good so long as the diuretin was continued, but became poor when it was stopped." Others have noted the bettering of the heart's action before the disappearance of the oedema, indicating a primary effect of the drug on the heart. In all of Frank's cases where any favorable result was obtained there was a six to fifteen fold increase in the urinary secretion. There was no renal irritation. In two cases albumen disappeared while the drug was being taken.

I desire to submit reports of the following cases:

Case 1.—Mrs. K., forty years of age, resident of Peoria, came under my care in 1891 with marked oedema of lower extremities, abdominal ascites, hydrothorax. The valvular disease of the heart, that was at the bottom of the trouble, had been previously unrecognized and consequently untreated. The heart was hypertrophied and dilated, arrhythmic in its beat and a loud murmur could be plainly heard. This was made out later to be a mitral regurgitant

murmur, it being impossible at first to locate definitely the valvular lesion on account of the tumultuous and irregular action of the heart. Mrs. K. suffered from intense dyspnoea and orthopnoea. This seemed a favorable case for treatment by rest and digitalis, which were prescribed and in addition, diuretin in fifteen grain doses four times a day was ordered. The effect was seen inside of twelve hours. Urine was passed in large amount every hour, day and night, and the abdominal ascites began to diminish at once. In two weeks all evidences of œdema had disappeared, the pulse was much more regular, and breathing became easy, the patient being able to lie down in bed without a sense of suffocation. Diuretin was discontinued and she returned home with instructions to continue the digitalis. In three weeks I had a letter from her asking for the other medicine (diuretin) as she was now passing a small amount of urine and was again becoming dropsical. Since then I have heard nothing from her.

Case 2.—Mr. K., from Ohio, fifty-two years of age, gives history of acute rheumatism nine years ago and of heart trouble ever since that date. Has taken largely of digitalis, yet during the last six months the heart's action has grown more irregular, dyspnoea more annoying and abdominal ascites and œdema of legs have reached an extreme degree. Entered the Presbyterian Hospital November 1, 1892.

Examination showed Mr. K. to be somewhat emaciated, jaundice fairly well marked, abdominal cavity tensely distended with fluid, legs œdematous, fluid in either pleural cavity. Mitral regurgitant murmur very loud, tricuspid systolic murmur, pulsation of jugulars. Urine, \bar{x} i, trace of albumen, casts.

November 3, tr. strophanthi gtt. vii t. i. d. and diuretin gr. xv q. i. d. ordered. Urine was passed in the next forty-eight hours, as Mr. K. said, in "enormous quantities." The first night he did not close his eyes in sleep, as he had to urinate every thirty minutes. The diuretin on November 6, was given in doses of eighty grains per diem. November 8, amount of urine over one gallon. In two weeks there was no œdema of the legs, the waist measure was lessened by nine inches, the heart was more regular and the enlarged liver, firm yet smooth, could be clearly made out extending two inches below the costal arch in the mamillary line. It pulsated synchronously with the heart and seemed to be the liver of passive hyperœmia of uncompensated heart disease and to give an explanation of the jaundice. After taking diuretin for three weeks in doses of eighty grains every day, Mr. K. had a slight chill, sudden rise in temperature to 103° F., nausea, though no vomiting. There was no sign of exacerbation of endocardial trouble, the urine showed the same amount of albumen as formerly and a few hyaline casts. The diuretin was stopped and in two days all unpleasant symptoms had disappeared. Twenty-four hours after stopping the diuretin there was a perceptible lessening in the amount of urine voided. After three days rest from the drug, its use was resumed and again the free diuresis began. The patient left the hospital December 1, with the abdominal ascites almost unnoticeable, with no œdema of the legs and with the heart beating with a fair degree of regularity and with good force.

Case 3.—H. C., male, 13 years of age. Had acute rheumatism four years ago and has had several attacks since. Has been treated for heart disease during these four years. Late in November 1892, I was called to see him and found a little œdema of the legs and a considerable amount of fluid in the abdomen. There was a loud mitral murmur, the heart was hypertrophied, liver enlarged; occasional vomiting. He now began to fill up with fluid quite rapidly and in a week his trouser's band failed by three inches to encircle the waist. He had to sit up in a chair one night in order to breathe easily. While continuing the capsule of digitalis, spartein and nux vomica he had been taking, he also took now, ten grains of diuretin three times a day. He noticed the next day the increase in the amount of urine passed and in the frequency of micturition; he had to rise four or five times at night. In a week he was able to button his trousers and felt so well that he went to the theatre. After the ascites had disappeared the diuretin was stopped. In about ten days there was a reaccumulation of the fluid, which promptly disappeared a second time under the influence of diuretin. I had this patient buy the drug by the ounce, the druggist putting up a sample ten grain powder, the dose equivalent to the sample powder being measured out and taken in water. For about three days he took forty grains of diuretin daily, but as no perceptible benefit was apparent I dropped back to thirty grains. No unpleasant symptoms showed themselves during the exhibition of the drug.

Case 4.—Mr. B., 55 years of age, from Indiana. Came to Presbyterian Hospital Oct. 5, 1892, with typical history of alcoholic hepatic cirrhosis of some four years standing. Excessive ascites. Never had been tapped and desired to have fluid removed by drugs rather than by operation. He was given salts every a.m. when necessary, and thirty grains of diuretin daily. Urine, before giving the drug was twelve to twenty ounces daily, after taking diuretin twenty to thirty ounces were passed. The daily dose was increased to 60 grs., without perceptible improvement. Dyspnoea became so marked that I aspirated the abdomen October 28th, no bad effect following. October 30, diuretin was given in eighty grain doses. Nov. 2, there occurred a chill, temperature 103° F., pulse 128, vomiting and purging. I stopped the diuretin and in twenty-four hours all these unpleasant symptoms had disappeared. November 11, diuretin was resumed in forty grain doses, and on the 13th, in sixty grain doses. At 8 p.m. on this day the patient had a chill, nausea, diarrhoea, and rapid pulse as before. There appeared also in the left groin a purpuric lesion with a wide erythematous border, that extended half way to the knee and was somewhat tender. The diuretin was at once stopped, a wet boric acid dressing applied over the thigh and in two days the patient was about as before. The skin lesion, save the purpuric stain, promptly disappeared. I aspirated a second time November 18. He left for home November 30, in about the same condition as upon his entrance. I heard from him one month later; he had been tapped twice since leaving the hospital but had had no febrile attacks.

In a case of acute scarlatinal nephritis in a child of 11, the urine under thirty grains of diuretin a day has increased from eight ounces to thirty-one and the albumen has decreased from 50 per cent., by volume, to about 2 per cent. The case has only been under treatment for the nephritis for five days but at this writing the diuretin appears to be acting favorably.

It will be seen that in the case of cirrhosis of the liver the result was unsatisfactory, for though there was a slight increase in the amount of urine, no diminution in the dropsical fluid was perceptible. In the three cases of dropsy due to valvular heart disease the effect was eminently satisfactory, there following promptly, increased amount of urine, rapid diminution of dropsical fluid, strengthening of the heart's action with slowing and regulating of its rapid and irregular beat, improvement in appetite and disappearance of dyspnoea and cyanosis.

In these cases I administered at the same time a cardiac tonic, strophanthus in case 2, and digitalis in the others. In case 1, a part of the improvement can, perhaps, justly be attributed to the digitalis, as this remedy had never before been administered; but the free diuresis and rapid disappearance of dropsy were far beyond anything I have ever seen from ten drops of the tincture of digitalis three times a day, and after stopping the diuretin fluid rapidly reappeared in the abdomen. In cases 2 and 3, digitalis and various other heart tonics had been taken almost constantly, in the one case for nine years and in the other for four. In the latter case, in fact, I had the patient continue with exactly the same capsule (pulv. digitalis, spartein sulph., ext. nuc vom., etc.), he had been taking for many weeks and during the taking of which, the fluid had accumulated in the abdomen. In all three of these cases, too, the diuretin was stopped and within forty-eight hours there was a diminution in the amount of urine and in cases 1 and 3, a reaccumulation of dropsical fluid. Return to diuretin produced the same favorable consequence as at first. The effect of the diuretin cannot, therefore, be questioned. It has seemed to me an advantageous method of administering the drug to combine it, in these heart cases especially,

with digitalis or some other heart tonic. In my cases in this way, a moderate dose of sixty grains a day produced all the results that could be asked. I find that Frank regards this as an excellent method, and Demme, in the case of a child, gave first digitalis and then diuretin after the effect of the former drug on the heart was manifest. The unfavorable consequences, vomiting, slight chill and fever and diarrhœa, disappeared promptly on stopping the remedy. These effects were possibly cumulative, the drug having been administered in the one case for three weeks and in the other for eight days, in either case in increasing doses. Cumulative effect is not noted by other observers and it may be that the effects noted by me are no more than the vomiting, diarrhœa, etc., spoken of by others. The skin lesion which appeared in case 4, is different from anything I have seen noticed. Its occurrence at the time of administration of the maximum dose for this patient, as evidenced by the gastro-intestinal symptoms and its rapid disappearance upon stopping the drug, lead me to regard it as due to the remedy and not solely accidental. Demme, in a ten years old child with amyloid disease of the liver, spleen and kidney, produced by diuretin a rash resembling that of measles. Ninety grains were given in the course of four days. Profuse diarrhœa occurred at the same time the rash appeared. I find no other record of skin lesion due to the ingestion of the drug.

Since writing this article I have had kindly placed at my disposal by Dr. A. E. Halstead of this city, the notes of four cases occurring in his practice, in which diuretin was employed. An abstract of these notes is here appended.

Case 1.—Mrs. E. G., mitral regurgitation; chronic parenchymatous nephritis with acute exacerbation. Total urine for 24 hours $\bar{3}v$; vomiting, twitchings, slight coma. Given calomel gr. $\frac{1}{4}$, and diuretin gr. x, every two hours, and in addition a hot bath. Gradual improvement. At end of one week, urine $\bar{3}xxiv$ daily, no vomiting, mind clear.

Case 2.—J. G., mitral stenosis and regurgitation, chronic nephritis. General anasæra, severe dyspnoea; amount of urine secreted in 24 hours, $\bar{3}xv$. Treatment, magnesium sulphate, $\bar{3}ss$. A.M. and P.M. tr. digitalis mx., t. i. d., and diuretin gr. x, every four hours. On the second day urine $\bar{3}xl$. At end of week $\bar{3}cxxx$. At end of two weeks entire disappearance of œdema, dyspnoea, etc.

Case 3.—A. H., aged 83. Diagnosis. Arterio-capillary fibrosis; contracted kidney, secondary mitral insufficiency. General anasæra, ascites, hydrothorax. Under diuretin, pulse harder, dyspnoea greater, headache and vertigo marked. Diuretin discontinued and jalap, cream of tartar, and later, nitro-glycerin substituted. Under latter treatment amelioration of all unpleasant symptoms.

Case 4.—Miss M., age 17. Chronic nephritis with acute exacerbation; uræmic prodromes marked. Urine $\bar{3}viii$. Given digitalis, diuretin and calomel. Urine at end of two weeks $\bar{3}L$.

In these cases of Dr. Halstead's, it will be noticed that a favorable result was obtained in three, while in the case of capillary fibrosis there seemed to be an increase of blood pressure and exacerbation of all the unpleasant features of the disease. The most marked result, in case 2, was in a patient suffering from valvular disease with excessive dropsical transudation, apparently the kind of case in which we are to expect the best effects. While all the benefit derived in these cases cannot be ascribed to diuretin, for other remedies were freely combined with it, Dr. Halstead assures me that from his observation of the cases diuretin deserves the great share of the credit.

That diuretin properly employed, is a remedial

agent of great value, must I think, be admitted by all. While the exact pathological conditions that call for its exhibition cannot as yet be specifically stated and disappointing failures will therefore attend its misapplied use in many cases where too much will be hoped for, yet, a study and comparison of the results of the various observers who have employed this remedy in the past three years, yield facts from which certain conclusions can be drawn.

My study of the literature of diuretin, and experience with the remedy seem to warrant the following deductions:

1. Diuretin is a diuretic acting by direct stimulation of the renal epithelium and best suited to cases in which there is general dropsical effusion.

2. It is the best medicinal remedy for removing dropsical fluid due to valvular disease of the heart, after digitalis and pure cardiac tonics have failed.

3. It can be advantageously combined with digitalis and pure cardiac tonics.

4. It probably has a direct effect upon the heart as well as upon the kidney, slowing and strengthening its action and improving its rhythm. (This is disputed by some; viz.: Cohnstein, *Ueber den Einfluss der Theobromine, etc., auf den arteriellen Blutdruck*. Inaug-Diss., Berlin, 1892).

5. Diuretin has oftentimes a beneficial effect in other circulatory diseases with dropsy, as myocarditis, pericarditis, aneurism, arterio-sclerosis. Its action is here more uncertain than in valvular disease.

6. In the dropsy of nephritis it can be used without danger of irritating the kidney, the effects in acute nephritis being more certain than in chronic nephritis. Where the renal epithelium has undergone too extensive degeneration, the drug may fail to act.

7. In the dropsy of portal obstruction, and especially of cirrhosis of the liver, it usually fails to give good results.

8. It occasionally causes nausea, vomiting, diarrhœa, palpitation, headache and slight fever; rarely, skin eruptions follow its use.

9. The maximum daily amount that can be given with safety is 150 grains; the average daily amount is 50 to 120 grains, given in divided doses. When combined, in heart cases, with cardiac tonics, smaller doses of diuretin can be employed.

10. It should be given in solution in water or milk, or in pill or capsule, without acids and by preference between meals.

ADDRESS ON DIETETICS—MEDICAL FOOD
ETHICS NOW AND TO COME.

Read before the Section of Physiology and Dietetics of the American Medical Association, at its Forty-third Annual Meeting held at Detroit, Mich., June, 1892.

BY EPHRAIM CUTTER, M.D., LL.D.,
OF NEW YORK CITY. SECRETARY OF THE SECTION.

(Concluded from page 244.)

Take La Grippe.—My patients who are on the strict diet of beef and hot water rarely take it, and if they do, have mild attacks. So when patients do have it they should be fed especially for the severe and almost inexplicable prostration. Oat meal is one of the things to help the grip along, but not the patient. In the same category come the starches and sugars in excess, fruits, all vegetable foods, especially when they have been long kept and are not fresh. The best material for cough drops I ever used was beef. I am prepared to hear my learned and skilful laryngological friends say, "Well, this is cranky and new to us, and not to be entertained." I would like to know why we are meeting here in Detroit if not to find out what each one knows? I have sought for others to tell these things but they do not. I think this testimony ought to be known, and if it has come out through such a poor witness as me, please forget all about him, but remember the testimony and defeat it by practical tests, not by opinions unbased on facts!

Otology.—What more frequent cause of deafness than closure of the normally open Eustachian tubes by thickening from catarrh of the post-pharyngeal space, especially by the thickening of the posterior pillars of the palate near the tube. And yet bad food has everything to do with this abnormal thickening. Indeed, nearly all ear diseases have been laid to bad diet by an observer, and I think he is correct in the main, correct enough to wake up otologists to a more lively course of food ethics. One thing is certain, that oatmeal does not enter the diet list of cases of deafness, as it causes fibroid thickening.

Section of Diseases of Children.—Children are the fruit of man. Potatoes are the fruit of the *solanum tuberosum*. Who raises the largest and best crop of potatoes? He who gets the best seed, proper manures (soluble mineral food), cultivates and opens the soil so that air can circulate in it, and removes weeds which cut off the food which the crop should have. Nature does her part with rain and sun. Who gets diseased potatoes? He who does not feed well nor care properly for his crop. Other things being equal, the very weakness of the crop makes it a prey to parasites. The principle has been established that good fine fruit of man or vegetables can not be obtained without normal feeding. What a revelation would happen if this Section could enforce proper food in motherhood!

But we must take things as we find them. What is the best way to treat diseases of sucklings? One is, to feed mothers two-thirds animal and one-third vegetable food, and thus ensure a good supply of breast milk; this would sweep away a majority of the diseases incident to dentition, cholera infantum, tuberculosis, stunted growths, etc. To change the conventional ethics of infant feeding needs the active, persistent and interested help of all in this Section. One reason of the resistance is that those who have personal acquaintance with food, at least three times every day of their lives, consider that they know

more than the doctors about it, and will not believe wholly what is said.

Section of Oral and Dental Surgery.—I have often seen the decay of teeth arrested in my patients when they obtained the proper amount of mineral food in their diet, so that I have no hesitation in saying to the Fellows of this important Section, one of whom discovered etherization, who have honored our age by the marvellous skill of their dental appliances. Perhaps it may not be out of the way for me to say that the fearful condition of the teeth of my own family roused my attention to the subject of food and I found, as I believe, the trouble to be with common flour at that time (1872), having only one-fourth of the mineral food it ought to have. I am thankful to say that the flour millers have improved the products so that the proportion is nearly doubled if I remember rightly. A large manufacturer of flour, a patient, told me that the miller would make any kind of flour that the public wanted. I was glad to know this. I wish to say also that dentists everywhere have been outspoken and zealous advocates of better feeding. Our associates, such as Dr. J. M. Williams, and G. B. Harriman of Boston, W. E. Dunn of New York, the Maryland and District of Columbia Dental Association, to name no more, have committed themselves to the good cause of better food ethics in dentistry. It is then unnecessary to charge this Section in relation to this matter. They will attend to it perhaps better than any other. The Section of American dentists leads the world. This Association is to be congratulated on the full representation with us of this Section, for I know it will strengthen us in our food ethics.

Neurology and Medical Jurisprudence.—In a paper read to the Association in 1888, I tried to point out the close connection of food with the neuroses. Whether I did so or not, the effort justifies me in connecting food with this Section. I will cite but a few other examples. Take fatty degeneration in the head producing paralysis, apoplexy, aphasia, etc. Take male neurasthenia, due in my opinion to a catarrh of the genital tract, it is a food disease and a cause of insanity and mainly curable by good feeding in severe cases. Constipation is in my opinion a neurosis because the nerve forces controlling digestion are partially paralyzed by the gases arising from bad feeding. Neuralgia and headaches are neurological lesions often due to bad feeding. The Section of neurology would do well to pay more attention to the subject of food as a cause and cure. Indeed, till it does, the present prevalence of neuroses in my opinion will continue. I think it a great mistake to deal with results and not the causes of disease, and if the medical food ethics to come include the prevention of fatty degeneration and genital catarrhs for two things—a blessed consummation will be accomplished.

Jurisprudence.—Probably no more important matter of medical jurisprudence has come before our country than the Paddock Food and Drug bill now passed the Senate and waiting in the House. Should it pass it must be sustained by public sentiment and this should be fostered by this Section. The rights of physicians and patients are recklessly violated by frauds in foods and drugs. [N.B.—The Paddock Pure Food and Drug Bill passed the U. S. Senate, and was endorsed by the Section. It was not endorsed by the Association, as Secretary Atkinson affirmed that

"we do not know enough about it to vote." Is it possible that senators know more about *pure drugs and foods* than the largest representative medical body in the world?]

It has been said that those who feed largely on baked beans and other indigestibles are litigious and quarrelsome; I once saw a judge decree a divorce in a minute or two on the unsupported evidence of physical violence given by the wife who sought the divorce and who was the only witness. It might have been all right but I think the judge wanted to get his dinner as almost every one had done so! After his dinner he would have been less hasty. I took the ground that food, nervousness and divorce were related as cause and effect. I still think that if one hundred married couples were fed so as to prevent nervousness, and if another set of one hundred were fed so as to be nervous, *i.e.*, on sweetmeats, pies, cake, ice-cream, cream of tartar biscuit, white flour bread, asparagus, apples, etc., that the number of divorces would be greater in the latter set than the first. I would also add that more suits for mal-practice would be found in the latter than in the former set, more insanity, to name no more. The subject of food ethics is one of the most important of all that come before this Section in my opinion.

Dermatology and Syphilography.—The skin is the largest gland in the whole body. Many diseases of the skin are now simply classed under inflammation from special and general causes. The germ diseases find a fruitful field on the skin, *i.e.*, great and small-pox, measles, scarlet fever, eczema; even in consumption, we find the epithelia of the skin invaded with the germs of these diseases in bad cases. Now as in the vegetable kingdom, the parasites flourish on those specimens which are debilitated by bad feeding, the same idea is voiced when it is said that one does not have skin diseases badly because of good constitution; but the good constitution came through good feeding! I know a man of my age who has spread it all his life in liquor and vice and yet his wonderful constitution has resisted syphilis which could not be found in the blood. My father knew a nurse who cared for cases of small-pox in the war of 1812; this nurse had been known to sleep in a bed all night, just after a soldier dead from small-pox had been removed, with no change of bed clothes! He did not have the disease till he became an old man and then, when acting as a nurse during an epidemic, contracted it and died. Food figures in the causes of skin diseases, for example, lobster and clams in urticaria in some; salt food in scurvy; so I think it will not be denied that food ethics ought to have a great deal to do with this section in time to come.

Materia Medica and Pharmacy.—The lively interest as to foods which we see at the present day in all stores of druggists, and the great predominance of food stuffs in the exhibits of our Association to-day, palpably and incontestably prove that food ethics is an intensely alive subject with those of this Section. If I have said anything against pharmacists offering so much instruction as to foods and seemingly to charge them with slopping over it may be said, as lately in New York, "those that do not slop over have not enough to slop over." Now that we have this Section in our body on equal footing with the other sections, I think I may say as I was an advocate of this exaltation of pharmacy into equal broth-

erhood here—that I am willing to have the profession instructed by the members of this Section; not only willing but anxious. But I am not willing that all the responsibility of medical food ethics should slip away from the other Sections, nor am I willing to be dictated to by those whose only object is to sell a food which they alone make and which does not come up to the standards even of their own circulars. I think this Section should control the admission of food advertisements in our Association JOURNAL. I am disgusted to see some ads. which are sailing under false colors.

Section of the Practice of Medicine.—Here food is paramount, so much so, that it seems needless to discuss food ethics. If physicians are for the purpose of curing disease, they must remove causes predisposing and exciting. I do not like very much to make any comparisons between others practice and my own; nor am I disposed to shield my own imperfections. Mr. Lawson Tait said in the Section of Surgery of the British Medical Association, 1889, when my paper on "Galvanism of Uterine Fibroids" was up, that I was bold to put my deaths first; I said I wanted to tell the truth, no matter about myself. So here if my testimony favors myself, I ought not to withhold it, as we are after the curing of our patients more than anything else. I am intensely interested in diseases of the heart. I found a physician who was curing cases of hypertrophy, angina pectoris and even with valvular lesions. I found I could treat likewise. It is far more satisfactory to cure these cases than to have them die, especially when they are in your own family, as when your own father and mother have died from heart failure caused by organic and functional disease. Such is my case.

Lately a lady came to me—34 years old, married, no children, quite fleshy. She had been sick with a bad cough which resisted treatment; heart enlarged and tumultuous in action. She had been treated as a case of consumption, so regarded if not expressed. I found the following: 1. The blood did not have the morphology of consumption. 2. Crepitant rales rather coarse at base of both lungs behind; no dullness on percussion. 3. Heart's impulse felt and sounds heard from beneath the left axilla to front of sternum; no valvular lesion. Impulse heavy; dullness marked over and beyond the normal precordial limits. 4. Urine highly albuminous. No casts nor fatty epithelia. 5. Uterus anteverted and anteflexed: cavity three and a half inches; hyperaesthesia. This case was put on broiled beefsteak with hot water one hour before meals; no tea or coffee and no vegetable food; relishes, pepper, butter and salt. Iodoform applied to uterus. At once she could sleep all night; heart did not trouble her; cough gone; albumen almost disappeared. She took cold afterwards in her bowels by exposure to an east wind; had return of albuminuria; pain and colic in abdomen; treatment still kept up with the effect of almost complete disappearance of albumen; uterus reduced to normal size; heart quiet, and less external impulse; sleep good; spirits returned; twenty-six pounds lost of flesh. Now, as she is obedient, I think it will not be long ere she is well. [N.B.—She was disobedient, and died later.]

I put it to you, was it not better thus to treat this patient by food as a basis than to treat her as she had been treated? No doubt I could not have done any better had I not been so intensely interested in

such cases, and been permitted to learn that it was better to strengthen a big, fat weak heart and remove the fatty degeneration by food than to let it keep on saddled with bad feeding and no relief?⁹

Consumption.—Probably without knowing it, the practice of medicine includes food treatment. If air is food, then what means the fashionable change of climate to Florida and elsewhere for consumption. I do not believe that bad air causes consumption unless the patient is very much reduced by bad feeding (diet again). I have inhaled, and others have inhaled, millions of the bacillus of Koch with impunity. It has been proved that consumption is not communicable to animals in perfect health from normal feeding. Dr. L. A. Sayre, when a young man collated some forty cases of consumption cured by forced inhalation of air. I have known cases where expansion of the chest by singing cured consumption. Mr. William Ludden, of Brooklyn, (Ludden, Bates & Co., Savannah), has told me of such cases. Rev. Peter Kimball, of Perth, Amboy, who will be one hundred years old if he lives to March, 3, 1893, has played the fife with special view to protection from consumption of the lungs. I myself now think that if I had not taken the air food treatment by marrying my music teacher and always participating in good home vocal music, I would have had consumption of the lungs following consumption of the bowels. The full expansion of the chest with fresh air I believe will prevent the deposition of tubercle sometimes. Music is a medicine.

At the tenth International Medical Congress, 1890, Berlin, I reported one hundred cases of consumption treated by food, of which forty were permanent arrests and most of them of ten years' standing; some longer. I should not have presented them were it not that I believed I was doing my duty to hand in such a contribution as I had from my own experience; I must say that only the head of my paper was published, the body, arms and legs were left out with the electrotypes appended; I was sorry but an invitation to court at Potsdam was a solace, though I think the Germans in my case manifested not the same regard to a correct presentation of medical subjects as there was manifest in the Ninth Congress at Washington. These one hundred cases do not comprise all that I have had under my care; I took the histories of the seventy cases I published in the transactions of our Association in 1880, and brought their histories down to date as far as I was able, adding thirty cases; there are perhaps one hundred more cases, but their histories are too recent; Koch cured reported consumption in a few weeks; I did not care to publish mine till a reasonable time had elapsed; these one hundred cases have been tabulated and are presented with this address.

A wedding in place of a funeral.—A young woman of eighteen was pronounced incurable in consumption. There was no mistake in the diagnosis, as there were lung fibres in her sputa, signs of cavity in the right upper third front chest; blood had the morphology of consumption. She also had uterine disease. Never did a patient do better on the diet for consumption, and uterine disease treatment; she recovered, and when Christmas evening, 1889, came, in about eighteen months, she was married under an arch of botanic specimens to the happy man of her choice;

her first child weighed fifteen pounds (so I was informed by the grandmother) and died at birth; a second child of about two months now blesses her home thus made happy by a wedding in place of a funeral, which would have been impossible but for the medical food ethics I adopt in the practice of medicine. I think these facts are enough to prove that the Section of the Practice of Medicine has everything to do with food.

I want these facts tested, not with opinions not based on facts, but with facts procured in a like way and fairly treated. This will be, I hope, ere the most of us have passed on from these earthly scenes. For some of us the time is short. It behooves us to do what we can now and not waste our energies in combatting opinions not based on facts. It is better to treat causes than results, as Dr. Koch does. So long as any member of the medical profession acts according to the rules of polite society just so long is he entitled to a fair hearing. If he has said the truth it will live: truth is immortal and deathless. No faults of character can undo the truth of physiological or pathological experiments with food and the treatment of diseases. Good work done will prevail in the end when those who have refused it are all forgotten, even if they were millionaires and controlled the medical food ethics of the present day.

The way to do is to test by feeding; I hope that the Section of Practice will not forget its relations to medical food ethics; if it does not forget, in place of a few weddings, there will be tens of thousands to the great honor and glory of our whole profession.

Gentlemen:—In what I have said to the other Sections, I have been trying to impress you with the length and breadth, the height and depth of our own Section. If I have convinced you of the importance of food to the other Sections I beg to assure you of its greater moment to you, and to somewhat take in its far reaching scope. Remove all the other Sections, and you could sustain the work of medicine better than it is now sustained. If the other Sections refuse to consider the subject of food ethics there is more reason for you to take it up and thus help them even when they will not help themselves. I charge you to enter with zeal and vigor on this grand work; let there not be so few to work on so momentous a subject; come and use the Archimedian lever of food ethics to pry up the medical profession to a higher plane of usefulness and honor. Our President, Dr. Marcy, says that the American Medical Association represents the largest body of medical men in the world, that its constituency is greater than that of the British Medical Association; if so, to what a high honor and responsibility you are called! Do not fail to do your duty; if you will lead I will follow; if you will not lead, let some one else! This work must be done. It will be done by others outside, if not by us inside of the profession. Public opinion will compel this work to be done as it did compel the retirement of venesection (to its harm, in my opinion). Food plans which contain much of merit are being promulgated by non-medical women, and reach the laity and do good where I cannot reach. If one, and you may be that one, has an enlarged and fatty heart caused by bad feeding, are you going to throw away the chances of recovery by good feeding, because the medical profession has not endorsed in toto the principles involved in such treatment?

⁹ Phys. cases heart dis., Tenth Int. Med. Con. Jour. Am. Med. Assoc., Aug. 22, 1891

There is work enough for this Section to do for many years; I hope it will be harmonious, and industrious; medical societies beyond the seas will cooperate, I am sure. If America is the food store-house for the world, let it disseminate true principles of medical food ethics as well. It seems to me that a good plan of work would be to take up the dietetics of the Sections, beginning with the Practice of Medicine. Of course, while there is a main object anything germane could come in as side dishes if any had them to offer, besides there might be something of general medical interest, as the pure food and drug bill this year. [N. B.—The present disappearance of the Section of Physiology and Dietetics from the list of Sections, as advertised, is much against the wish of the Secretary, on the ground that it has more work to do than any other, and hence the greatest reason for existence.]

PERSONAL WORK.

Let every member of this Association personally encourage all efforts at improvement of Food Ethics by diet kitchens, cooking schools, all restaurants like Smith & McNell's, New York, where 8,000 meals are daily served from plenty of good food, well prepared and at moderate prices; all steamboats like the Fall River Line, one of whose stewards serves the best porter-house steaks I have ever eaten; all ocean steamships whose cuisine is excellent, as found on the Etruria; such railroad restaurants as found in the Pennsylvania depot in Philadelphia, all places where good coffee is served, etc.; on the contrary, let every member condemn poor cooking, as poor coffee, poor steaks, bad bread, impure drinking water, all places of public entertainment where the service consists mainly of high prices, spotless and brilliant table ware, servants dressed as if to be presented to court (not but that these things are as good as far as they go) but with poor food which does not nourish the body.

Let members when travelling in Europe, when told as I was that I must not drink the water, remember the dictum of Dr. S. W. Abbott, Secretary of the Massachusetts State Board of Health, "that the European hydrant water, as a rule, is better than ours and better managed." Let them not bow down and worship with colic and diarrhoea the menus of the table d'hote, when a meal of beef, bread and coffee taken (as wife and I took it in Paris) at the children and nurses' table, will nourish the body sufficiently in health. In fact, let every member do all he or she can to protect themselves and others from the evils of conventional feeding, which now carry off most of mankind to untimely graves, and this work, added to coöperative labors in other Sections cannot but redound to the honor and glory of God, who made our bodies to be living temples of the Holy Ghost, and says, "if any man defile the temple of God, them shall God destroy, for the temple of God is holy, which temple ye are." The destruction from defilement is automatic because the laws of nature make it so, just as water drowns, cold freezes and fire burns. If there were less physiological sinning I think there would be less sin of all other kinds.

I herewith append two tables of cases treated more or less by food. Table 1, of consumption of the lungs; table 2, of cases of tumor and so-called cancer.

All of these cases were more or less closely on a beef diet, *i. e.*, beef steak, roast beef, chopped beef.

Not all of them were under the absolute diet.

I may be permitted to give the following conclusions:

1. The graver a case of chronic disease, the better has it done on a diet of beef chopped and broiled as per directions appended.

2. This has occurred so often that I am forced by the sheer logic of facts to aim to use beef as much as possible.

3. I consider the idea of uræmia and the formation of stone in the pelvis of kidneys by the absolute beef diet a bug-a-boo; some and many of my cases I examine the urine of daily; I have never seen uræmia occur from a diet of beef alone and I have seen restored to health cases of full-fledged Bright's disease sent me by other physicians by the absolute beef diet covering a period of six or more months.

4. The same may be said of chronic rheumatism; it is not right to lay upon beef the sins produced by eating foods that undergo alcoholic and vinegary fermentation.

5. So long as I test the condition of my patients by morphological examinations of blood, sputum (if any), feces, urine, and the chemistry of the urine, and feed beef or other foods alone, or in any combination desired according as these methods of inspection and analysis reveal the status of the patient to be, I consider that I am not erring in my therapeutics.

6. But if I base my food therapy upon the opinions of manufacturers, pharmacists and clinicians who do not use the tests noted under 5, I consider that I am much more liable to mistake.

7. Those cases *needing an absolute diet of beef* will do better if fed on beef of animals about four years old, not over-driven before death and fatted on good food; take from the top of the middle of the round meat of such; cut into cubes of small pieces; run through the Enterprise chopper three times, each time cleaning from the plate at the distal end of the machine the white fibrous tissue; the meat should not be handled direct but with wooden spoon; should be moulded in cakes about one inch thick, and as many inches in diameter as needed; broil over or under bed of good live coals; charcoal best; gas good; kerosene stove may be used; the perforated broiler now in use will be found especially convenient. Season with pepper, salt, butter as desired; such beef when rightly prepared is exceedingly palatable; the cake presents outside a dark brown color and inside reddish but not raw appearance. Patients who have lived steadily on this beef, and thus prepared, have preferred it to turkey, chicken and other meats: such is simple history. Any one who will not take the care to buy good beef, and see that it is rightly prepared, must not condemn it as a form of food.

ONE HUNDRED CASES OF CONSUMPTION OF THE LUNGS TREATED IN GENERAL PRACTICE, MANY OF THEM TWENTY YEARS AGO, NOT COMPRISING CASES IN LATE YEARS, WITH FEW EXCEPTIONS.

SERIES I.—NON-ARRESTS—TWENTY-ONE CASES.

A.—Cases that were not improved—nine in number.

1. *Illustrative.*—(See Transactions American Medical Association, 1880, pp. 333-408, case 7). August 28, 1877. M. H. S., fisherman, Lamesville, Cape Ann, Mass., aged 33 years. Father died of phthisis. Mother living; been sick two months. He states that he took cold, and then went fishing. Was exposed, and took more cold; except two attacks of typhoid fever, was perfectly well before. General appearance bad; cough is constant and severe; no hæmoptyses; no dyspnoea except on going up stairs; severe pain in shoulders; appetite poor; bowels regular. Has lost flesh and strength; night sweats copious; pulse weak; hands shake badly.

Physical Signs.—Dullness on percussion and crackling over right upper third front and lower third back; feeble inspiration, almost flat on percussion; no crackling, but the respiratory murmur was heard

underneath. Inspection of the blood revealed spores and spore collect in abundance. Fibrin filaments thickened. Red corpuscles adhesive, sticky, irregularly massed; pale in color. Mr. S. went upon treatment with quinine for medicine. It was his intention to come up from the cage again, but he was unable to do so, and despite the means used, he died not long after.

Remarks.—At the time it did not seem to the writer that the case was hopeless. Still, his history teaches that one must not trust too much to first appearances. It is a disadvantage to see a patient only once. It was reported that he faithfully used the diet. It is well, however, to compare the case with some of the very sick ones that were cured as noted in series 3. The lesson taught is, simply, the physician should never refuse to take a case, and should not be too free with promises of recovery.

No. Date, Sex. Publications.	Condition when Placed on Treatment.	Remarks.
2. Man, middle-aged. Case 2, loc. cit.	Father of Case 43; not so much disease as in son	Death in a few weeks.
3. Woman, 35. Case 4, loc. cit.	Advanced disease; three years' standing	Digestion improved; diet relished, but of no avail; died in a few weeks.
4. 1873. Boy, 19. Case 8, loc. cit.	Acute tuberculosis and peritonitis. Blood morphology of tuberculosis	Treatment of no avail; diagnosis confirmed by post-mortem.
5. 1873. Woman, 55. Case 15, loc. cit.	Aphonia; larynx infiltrated and inflamed; vocal cords swollen, ash colored and stiff; tuberculous blood morphology; chest emaciated, flattened; coarse and fine rales and cavernous respiration at apices.	Symptoms relieved; death in nine months.
6. 1889. Girl, 22. Unpublished.	Tuberculous blood; crackling through right lung, front and back, and upper third left lung; asthma; diarrhœa; night sweat; copious expectoration; lung fibre in sputum	Slight amelioration of symptoms. Death in two months.
7. 1887. Man, 22. Unpublished.	Tuberculous blood; much disease in lungs	Plans followed out faithfully. Death.
8. 1886. Girl, Unpublished.	Tuberculous blood	Treatment carried out faithfully. Of no avail.
9. Woman, Unpublished	Tuberculous blood; cavity in apex of each lung	Had uterine disease which she would not have treated; retarded case; death.

Cases that were on partial diet; had bad surroundings, financial, climatic, etc.—twelve in number.

10. *Illustrative.*—(See Case 1, loc. cit.)—Widow, aged 43 years; small sized, thin, anxious and nervous. Asthmatic complication; old abscesses of the mediastinum; diarrhœa; dyspepsia; sleeplessness; severe cough; dullness on percussion, with constant crepitant rales over both upper thirds front. Great dyspnoea at times. Abnormal valvular sounds of the heart. No albumen in urine. Altogether the most distressed and suffering case of consumption I had seen for some time. The effect of the animal diet, bath of mineral acids, and quinine, was to relieve, in a measure, the night sweats and abdominal pain. But the appetite turned against the animal food, and it would often be rejected by vomiting. She was obliged then to carry out the regime only partially, particularly as she laid all her bad feelings, distresses and sickness to her food or medicine, and never to her disease. She suffered also greatly from prolapus of the uterus, aggravated by the severe coughing. This case was not relieved by the special treatment recommended. The weakness of mind and body, induced by the presence of organic disease in the thoracic and abdominal viscera, was too great to be reached by perhaps any treatment. Indeed, just here it may be stated that no pretension is made toward cure of any but one-third of the cases; but to insure that proportion it is necessary to have the treatment strictly carried out.

The present case was one in which there was really no hope, and only adopted as "a drowning man catches at a straw." It is thought best here to give simply the bad and good cases together, and let the reader judge for himself of the value of the data thus derived.

No. Date, Sex. Age. Publications.	Condition when Placed on Treatment.	Remarks.
11. 1879. Dr., 72. Case 3, loc. cit.	Tuberculosis, as diagnosed by Dr. H. I. Bowditch	Partial treatment; was improved; death in three months.
12. Man, 40. Case 5, loc. cit.	Grave general symptoms. Local disease in lungs not so well marked	Followed up treatment feebly; death in few months.
13. Woman, Case 6, loc. cit.	Advanced tuberculosis of both lungs; great weakness, prostration and impaired morale	Followed up treatment faintly; died in a few weeks.
14. 1887. Woman, 34. Case 9, loc. cit.	Acute tuberculosis in the puerperal state; hæmoptyses before and after labor; disease in upper third right lung; blood morphology tuberculous; patient poor, and house damp and dark	Died in two weeks. Life perhaps might have been saved if there had been a sanitarium to treat her case in.

No. Date, Sex. Age. Publication.	Condition when Placed on Treatment.	Remarks.
15. April, 1877. Irish girl, 17. Case 10, loc. cit.	Undersized, pale, thin, feeble, downcast; cough; copious expectoration; loss of flesh and strength; blood tuberculous; diet had been mainly flour, potatoes and tea	Did not follow up treatment closely; was improved, but died in October, 1877.
16. 1877. Dr., 37. Case 11, loc. cit.	Tuberculous blood; disease right upper third front and back; throat inflamed throughout	Throat treated with solution liq. per sulphate iron and glycerine, equal parts. Lived on New England rum and cream; some improvement and then gradual increase of disease, and death in three months. The blood was not improved by this dietary.
17. 1873. Woman, Case 12, loc. cit.	Early stages of disease; throat inflamed	Had bad surroundings as to finances, and did not follow out treatment; retrograded and died.
18. 1874. Girl, daughter case 17. Loc. cit., case 13.	Tuberculous blood; disease started in lungs	Not seen again; ordered on diet which was not followed out. Death in six months.
19. 1876. Irish woman, Case 14, loc. cit.	Tuberculous blood; disease in right lung	Treatment not followed out. Death.
20. 1875. Man, Case 16, loc. cit.	Marble-worker; vocal cords thickened and ulcerated; arytenoid cartilages enlarged; blood tubercular; disease at apices of both lungs	On strict diet for a month; wife sick in bed. Becoming discouraged, gave up treatment together. Died.
21. 1874. Woman, middle-aged. Case 17, loc. cit.	Been called consumptive for years; farmer's wife and a hard worker. Advanced tuberculosis; blood tubercular	Partial diet; great deal of medicine. Perhaps would have been saved if treated earlier.

SERIES 11.—PARTIAL ARRESTS—THIRTY-NINE CASES.

A.—Cases that followed the treatment faithfully—nineteen.

22. *Illustrative.*—(See No. 21, loc. cit.) Mr. W., aged 60, in 1874 had been consumptive for two years. His occupation was that of an overseer of an amber paint mill. He had, with a cough, marks of increasing debility, as loss of flesh, animation and courage. There was marked dullness on percussion, crepitant and sonorous rales over the upper part of both lungs. The blood also presented fibrin filaments and spores. It is some years since he has lived upon animal food diet; his wife has faithfully prepared the choicest meats for him, and what is more, has encouraged him in pursuing the uncommon diet. The case was rather unpromising at first, owing to its long standing and extent of tubercle infiltration. He is, however (1876), comparatively well. Cough is hardly perceptible. The physical signs are still to be detected, but with less marked characteristics. He attends to his business as usual. Says he expected to die, in which expectation the community shared. The blood shows great diminution in the foreign admixtures. 1879, still living, but very feeble. In October he died.

No. Date, Sex. Age. Publication.	Condition when Placed on Treatment.	Remarks.
23. Man, Case 18, loc. cit.	Severe pulmonary hæmorrhage; dullness on percussion and crackling over left upper third front; emaciation; cough and night sweats	Would not take cod liver oil, then, as now, a standard remedy; ate pound and a half of butter a day; restored to duties, and lived 12 years; death from profuse hæmorrhage; post-mortem showed lung healed—three cavities—on right side and some new disease in the left lung.
24. Woman, Case 20, loc. cit.	Primipara; disease right upper third front; after labor, suffered with prolapsed ovary, which caused much reflex pain; blood tuberculous	Treatment of pelvic disease successful. Restored to health. Lost sight of.
25. 1876. Man, Case 22, loc. cit.	Chest flattened; coughs all night; sweats; debility; dyspepsia, enteralgia and gastralgia; insomnia; gone to bed to die	Strict diet and no medicines; stopped cough in three days. Improved and returned to work as plumber; was drenched by water from a burst pipe; contracted pneumonia; was placed again on strict diet, but never recovered from shock. Death.
26. 1877. Man, Case 25, loc. cit.	65. Cough; expectoration; loss of flesh and strength; abnormal heart sounds; night sweats; dullness on percussion, expiratory crackling, left upper third front; tuberculous blood	Strict diet; returned to business in a year. Died in 1878 with cardiac symptoms.

No. Date. Sex. Age. Publication.	Condition when Placed on Treatment.	Remarks.
27. 1876. Man, 30. Case 28, loc. cit.	Tuberculous blood; distorted chest; severe cough; profuse hemoptyses; disease in both lungs; weight 65 pounds	Gained 20 pounds in four weeks; followed diet more or less closely for a year; disease arrested for a time; a man of great courage, and should have been treated earlier and saved.
28. 1877. Girl, 17. Case 30, loc. cit.	Throat inflamed; chest thin; ease as to blood and lungs between pre-tuberculosis and tuberculosis. Splenic enlargement . . .	Local treatment to throat; milk diet. Do not know final result. Case was improved.
29. 1877. Man, 33. Case 34, loc. cit.	Laryngeal inflammation; cardiac hypertrophy; tubercular blood; disease left lung; dyspnoea; prognosis doubtful	Local treatment for throat; milk diet; later, some leeway as to food. Case reported well, 1879.
30. 1877. Irishman. Case 35, loc. cit.	Disease upper part of both lungs; tuberculous blood. One month later, left upper third, tympanitic percussion, metallic tinkling, splashing on succussion; lower thirds flat; respiratory murmur absent . . .	On strict diet; did not expect him to recover from pneumothorax, but lung healed over and man died several years later of other trouble.
31. Young lady. 1873. Case 36, loc. cit.	Disease in both lungs; left lower third almost hepatized; blood tuberculous.	Improved while at home and on strict diet; visited, ate wrongly; disease lighted up again. Died in 1875.
32. 1874. brother case 31. Case 37, loc. cit.	Been sick four years; lived out of doors; depressed in mind, as he was not earning money	Case improved; was able to work as a clerk in a harbor steamer. Died 1880.
33. 1876. Man. Case 38, loc. cit.	Violent hemoptyses. Disease in both lungs. Not afraid to die.	Took cod liver oil besides the general plan here laid out. Jan., 1877. Blood and lungs much better. Living in Tennessee, October, 1879.
34. French woman; middle-aged. Case 39, loc. cit.	Disease right upper. Tuberculous blood	Strict diet, closely followed. Well at last accoutns.
35. 1874. Woman. 24. Case 40, loc. cit.	Dyspnoea; hypertrophy of heart; diseased apices of both lungs; had given up school teaching to die; tubercular blood	Adhered closely to diet. Local treatment for throat. Was able to return to her teaching; overworked; disease returned; profuse hemoptyses; death.
36. 1874. Man, 21. Case 42, loc. cit.	Marked diseased apices of both lungs; an unpromising case	Improved and went to California; died there.
37. 1877. Woman. 36. Case 43, loc. cit.	Blood tuberculous; laryngitis; uterus antverted; disease left upper third front	Unlike majority of cases, did not treat uterus; case improved, but finally retrograded and died.
38. 1886. Woman. 24. Case unpublished.	Disease in both lungs	Arrested for two years; died March, 1889.
39. 1887. Man, 24. Unpublished	Disease in both lungs, as diagnosed by his physician. Not seen by us	Improvement, and disease arrested for two years.
40. Man	Considerable disease	Arrested temporarily.

SERIES II.—PARTIAL ARRESTS—CONTINUED.

B.—Cases that did not follow the treatment faithfully—nine.

41. *Illustrative.*—(See Case 23, loc. cit.). Miss C., aged 22, residence Cape Cod. Seen July, 1875. Amenorrhoea; cardiac trouble; dullness on percussion in upper part of both lungs; expiratory rales in same location. Blood was full of evidence of disease, as shown by the enlarged white corpuscles, the spores and fibrin filaments; she had been under the hypophosphites of lime and soda. She was put upon the strict diet and mineral acid baths, and was removed to New Hampshire. She was thin in flesh, and unable to walk an eighth of a mile from prostration under the necessary effort. For the next three months was not herself thoroughly convinced of the utility of the measures now proposed; still, her friends were, and by means of their influence, she adhered closely to diet and baths. Immediately there was an improvement in the cough, in flesh and strength, which continued. She walked two miles readily. Returned home for a visit in November. Here the diet was abandoned, ate everything she liked, and took medicines. Remained at home four weeks. She ran rapidly down, lingering till she felt "she could not live two days." Returning to New Hampshire, she improved but little; remained there till April, 1876, when, being very much worse, she returned home to die; died in 1878. This case shows the power of the system to resist the disease, even when not following up the treatment; this resistance ought to be more relied on.

No. Date. Sex. Age. Publication.	Condition when Placed on Treatment.	Remarks.
42. Woman, 30. Case 19, loc. cit.	Between pretuberculosis and tuberculosis.	Attention dismissed early, and case died in six months.

No. Date. Sex. Age. Publication.	Condition when Placed on Treatment.	Remarks.
43. 1874. Youth. Case 24, loc. cit.	Advanced tuberculosis; diet had been mainly flour	Great improvement under strict animal diet. Returned to work. Resumed former diet; died in 1876.
44. Man, 50. Case 26, loc. cit.	Left upper third chest, cavernous respirations and amphoric tinkling; else where crackling and diminished respiration . . .	Rigid diet. Much improved. Appetite returned, and ate anything desired; death.
45. 1875. Man, 43. Case 31, loc. cit.	Malaria and abdominal tumor, 1870; cured; 1875, worked too hard, and lung and throat trouble came on	Improved while on treatment; not encouraged by wife; gave it up and died, 1876.
46. Woman, 29. Case 32, loc. cit.	Pretuberculosis. Under mental strain and grief; ran into tuberculosis	Was improved while under close observation and followed treatment; finally said she would eat what she pleased; did so, and died.
47. 1877. Woman. 34. Case 33, loc. cit.	Asthmatic. Disease in right lung. Arytenoid cartilage inflamed	Disease arrested. Went from observation and gave up treatment.
48. 1880. Man, 54. Unpublished	Heart enlarged. Angina pectoris. 1886, lungs becoming affected with great deal of disease	1880, heart reduced to normal size by diet. Would not follow diet, when lungs became affected, and died, 1889.
49. 1887. Woman. 46. Unpublished	Disease in both lungs. Asthmatic. Heart enlarged	Improved while following treatment closely; but could not control appetite, and would steal food; died 1889.

SERIES II.—PARTIAL ARRESTS—CONCLUDED.

C.—Cases that had bad surroundings; that died of pneumonia, etc.—eleven.

It may be said that we were not very successful in our treatment of pneumonia complicated with tuberculosis. The complication is a grave one, and is usually the result of carelessness; still, many recover. We have seen cases of tuberculosis under treatment who had gotten the blood in good condition, and on contracting pneumonia, almost always pull through; one difficulty is in not treating the cases early enough, i. e., not arresting the coagulation. But if the blood is full of emboli of yeast and fibrin filaments, and massed corpuscles, there is a great plenty of quick work to be done to relieve the engorged lung and help the heart. Each case needs its own treatment. Pneumonitis in those called well is a more fatal disease than it ought to be, as the laity have been educated into such a dread of it, that when pneumonia is pronounced, they are apt to give up all hope. Antipyrin and the newspapers killed many of the cases that died during the late epidemics.

50. *Illustrative.*—(See Case 27, loc. cit.). In October, 1874, Mrs. —, a woman with a very young child, that especially cried by night and kept his mother awake, was very pale and thin, coughing severely and crackling throughout the upper third of right lung. She adopted the diet and acid baths. In four months the cough was very slight. The physical signs diminished. Her softened lung tissue dried up. The appearance improved so much that a casual observer would have called her well. All the time she suckled her infant. Owing to the hard times, she was obliged to relinquish her diet, and would not accept it as a gift. Immediately she began to fail, and died in the course of six months. The improvement in health kept pace exactly with the imposed diet. When she ate bread, the cough returned; the expectoration was copious. The night sweats reappeared. This shows markedly the relation of animal food to consumption. It is well worth knowing, for if these things "are done in the green tree, what may be done in the dry?"

No. Date. Sex. Age. Publication.	Condition when Placed on Treatment.	Remarks.
51. 1876. Woman. 33. Case 19, loc. cit.	Lived in a damp, musty house. Caught severe cold. Disease upper third front. Tubercular blood. Throat much inflamed . . .	Improved. Passed from under my care. Disease returned. Treated by homoeopathy. Death.
52. 1876. Woman. middle-aged. Case 41, loc. cit.	Disease left lung; cough; expectoration; hæmoptyses	Did well while senior writer supplied her with beef. On his moving away from that town, supply ceased. Case died.
53. 1882. Man, 24. Unpublished	Small cavities in both lungs; disease arrested for two years	Died of pneumonia.
54. 1883. Man, 26. Unpublished	Cavity in right lung	Disease arrested for a year. Cough stopped. Died of pneumonia caused by exposure in a rain storm.
55. 1887. Man, 64. Unpublished	Disease upper third left lung	Improved. Died of pneumonia.
56. 1887. Girl, 22. Unpublished	Cavity left lung	Arrested for a year. Disgraced socially by a certain crime committed. Disease resumed its sway; death.

No. Date. Sex. Age. Publication.	Condition when Placed on Treatment.	Remarks.	No. Date. Sex. Age. Publication.	Condition when Placed on Treatment.	Remarks.
57. 1887. Man, 50. Unpublished.	Disease in both lungs . . .	Arrested for a year. Died of pneumonia; family refused the services of a trained nurse.	70. Woman, 31. 1877. Case 51, loc. cit.	1866, Dr. Buzzel, of N. Y., sent her to Wales to recover from hæmoptysis, cough and copious expectoration by diet of mutton, milk, and mountain air.	Results desired in 1866 achieved; 1877, blood pre-tubercular; was run down. Placed on diet and cured. Seen 1890; well.
58. 1887. Man. Unpublished.	Disease in both lungs . . .	Arrested. Death from pneumonia.	71. German, 32. 1877. Case 52, loc. cit.	Disease right lung; abject feebleness; no appetite; feared tubercle; night sweats.	Gallon of milk a day. Case made rapid progress to health.
59. Man. Unpublished.	Considerable disease . . .	Arrested for two years. Died of pneumonia.	72. Girl, 18. 1877. Case 54, loc. cit.	Disease lower part of left lung; blood tuberculous.	Was dieted faithfully and was cured.
60. Man. Unpublished.	Disease right lung	Arrested for one year. Died of pneumonia.	73. Irishman. 1876. Case 55, loc. cit.	Tubercle diagnosticated by other physicians, upper thirds both lungs. Blood tuberculous	Was cured.
SERIES III.—ARRESTS MORE PERMANENT IN CHARACTER, AND MIGHT BE TERMED CURE IF OCCURRING IN OTHER DISEASES.—FORTY CASES.					
61. <i>Illustrative Case.</i> —(See Case No. 53, loc. cit.) Mrs. W., Cleveland, Ohio, June 21, 1877. Present condition: Suckling a four months' child. Active and doing her own housework. Looks like a person in ordinary health. Coughs occasionally. No sputa. A good-sized, rather flat-chested woman, thirty-five years of age. <i>Chest</i> —Dullness on percussion and cavernous respiration over left upper third back. Dullness over the whole left back; elsewhere normal. <i>Blood</i> —Inspection showed normal looking blood. Red corpuscles not massed; are distinct, well defined, rouleauxed, no fibrin or mycelial filaments; white corpuscles not enlarged.					
This report is more interesting when taken in connection with the following history: In February, 1865, Mrs. W. had been sick in bed four months with the last stages of consumption. She was emaciated to a skeleton; weight, 60 pounds; usual weight, one hundred and thirty pounds. Her physicians, who were regularly educated and skillful men, pronounced her left lung gone—that is, riddled with tubercle that had softened and broken down in such a manner that the pulmonary substance was removed; had become useless, and of course they gave a decidedly fatal prognosis. There was at this time a great caving in or flattening of the antero-posterior diameter of the chest, due to atmospheric pressure conjoined with loss of lung substance. The patient's mother caused the treatment to be faithfully and assiduously followed out. Improvement slowly followed. In four months' time she was able to be out of doors and visit the city. After a time, she resumed her profession as school teacher, and taught successfully for four years. Five years ago she married, and has borne three children, all healthy and vigorous. She likes her meat diet best; lives on it, and works hard. The physical signs adduced show the marks of the ruin wrought in her lung, and also show the tremendous power of food in managing or in affecting the course of organic pulmonary disease, even in its third and hopeless stage. This history reads like fiction. November, 1888, we heard from her that she had continued in good health. A beef-eater.					
62. <i>Illustrative.</i> —(Unpublished). 1882; young man. Cavities in both lungs; heart enlarged; emaciated as badly as preceding case; profuse hæmoptyses; elastic and inelastic lung fibres in sputa; blood tubercular; was treated very carefully on these plans. Was cured—i. e., his cough ceased; the lungs healed; the heart regained its normal size; he took on flesh and strength; went through Yale college; was graduated with honors. Is well, and was seen by us in May, 1890.					
No. Date. Sex. Age. Publication.	Condition when Placed on Treatment.	Remarks.	No. Date. Sex. Age. Publication.	Condition when Placed on Treatment.	Remarks.
63. Woman, 20. 1865. Case 44, loc. cit.	Cough, expectoration; wasting of flesh; loss of appetite; dullness on percussion and crackling right upper third front. Predisposed to tuberculosis	Animal food diet repulsive, but she was encouraged by her relatives. Was cured, and remains so, 1878; thirteen years.	81. Woman, 1871. Case 63, loc. cit.	Blood tuberculous. Disease right upper third, front; cough; severe hæmoptysis; family consumptive; pharynx inflamed, especially patch on posterior pillar palate.	Health restored, 1877. Copious hæmoptysis after excitement; heart laboring too much, 1878; uterine disease; restored blood to its tubercular condition; treated energetically and remains well, 1880.
64. Man, Dec., 1862. Case 45, loc. cit.	Diagnosis, double pleurisy and tubercle, so made by the late Dr. Benj. Cutter. Medication did little if any good	Was ordered to have killed and tubercle, so made by the late Dr. Benj. Cutter, and to eat it. This was done; man seen again 1878; then alive and well; 1893, died of drunkenness.	82. Girl, 1875. Case 64, loc. cit.	Severe hæmoptysis; cough; lungs not much diseased; heart enlarged; blood tuberculous and syphilitic.	Cure.
65. Girl, 16. 1878. Case 46, loc. cit.	Sister dead of tubercle. Blood tubercular; disease right upper third front	Placed on rigid diet; was cured, and remained so, 1880.	83. Woman, 35. 1881. Unpublished	Cavity upper part left lung.	Was cured positively, and died of pneumonia, 1885.
66. Woman, 1872. Case 47, loc. cit.	Cough, emaciation, copious expectoration; dullness on percussion and expiratory crackling well marked over left upper third.	Followed treatment faithfully, and was rewarded by restoration to health.	84. Girl, 20. 1886. Unpublished	Hæmoptysis; lung fibres in sputum; blood tuberculous	Cured and remains so, 1890.
67. Girl, 24. 1875. Case 48, loc. cit.	Right upper third front and back dullness on percussion; crepitant rales and tubular respiration. Tuberculous blood. Diagnosis of tubercle given by late Dr. William F. Stevens, of Stoneham, Mass.	Lung healed by diet. Has been troubled by a uterine fibroid and pelvic abscess, but pulmonary disease in abeyance.	85. Woman, 50. 1887. Unpublished	Disease base right lung; breath fetid; heart enlarged	Is called a trophy, but may yet go under in her slavish attention to household duties. 1893, well.
68. Man, 1873. Case 49, loc. cit.	Copious hæmoptyses; lung breaking down	Heart's action controlled with veratrum; alcohol to outside of chest; rest; strict diet. Cure.	86. Woman, 1881. Unpublished	Crackling and cavernous respiration upper third right lung; inelastic fiber in sputum; retroversion uterus	Cured. Wore Cutter Stem Pessary. Died in 1889 of typhoid fever; lung remained healed.
69. Woman, 1873. Case 50, loc. cit.	Hard-working woman. Emaciation; cough; disease upper part right lung; blood tuberculous	1877, in quite good condition; 1889, Ang., no cough; dry rales right lung; has to work hard; troubled with uterine disease.	87. Woman, 48. Unpublished	Lung fibres in sputum; gravel of lungs; asthma; tuberculous blood; albumen, fatty epithelia and casts in urine; small fibroid tumor of womb; anteversion and anteflexion.	A tough case; cured of renal and pulmonary troubles; tumor disappeared under diet. Wore Cutter Stem Pessary to California via Isthmus of Panama. Comparatively well as a valetudinarian, 1892.
			88. Woman, 38. 1885. Unpublished	Disease in both lungs. Uterine disease	Cured of lung lesion, and fairly well. 1892.
			89. Girl, 20. 1885. Unpublished	Disease upper third left lung; lung fibres in sputum. Uterine disease	Cured; remains so, 1889.
			90. Man, 40. 1882. Unpublished	Cavities in both lungs; profuse hæmoptyses; night sweats. Said to be absolutely incurable	Cured, and remained so for two years. Have lost track of him.

No. Age.	Date. Publication.	Sex.	Condition when Placed on Treatment.	Remarks.
91.	Man, 60. 1889.	Unpub-lished	Disease in both lungs	Promptly arrested, and patient satisfied after three months of treatment.
92.	Woman, 26. 1877. Va. Med. Monthly, Dec., 1888, and Sept., 1889.		Disease through middle of left lung and at apex; uterine disease; hæmoptyses; lung fibres in spu-tum	Disease arrested, and patient died, Aug., 1889, from the results of a meningitis and bowel lesion of fibroid thickening.

93. B.—*Pretubercular cases treated that may come under this head.*

Illustrative Case.—(See case 65, loc. cit.). In April, 1876, a young man, eighteen and one-half years old, complained of feeling weak and listless. He had nocturnal and morning cough, with slight expectoration. He was pale and thin, and losing flesh. Consumption was hereditary on both sides of the family. There were no physical signs of pulmonary lesion. Inspection of the blood microscopically disclosed abundant signs of mischief, such as: Fibrin filaments were marked in character; spores and spore collections; mycelial filament; white corpuscles much enlarged, and too flabby, pale, sticky, outlines not clearly cut, aggregated. These, taken together with the history and the rational signs, induced a diagnosis of the pretubercular stage. Under the use of acid baths and strict diet, the sanguineous and other signs began to disappear, so that in a year he was enabled to proceed to Germany and study music. He has been a beef-eater; *i. e.*, eats more of it than people usually do. Alive and well, 1893.

No. Age.	Date. Publication.	Sex.	Condition when Placed on Treatment.	Remarks.
94.	Physician, 45. 1877. Case 66, loc. cit.		Takes cold easily; ulcerated sore throat; weak and debilitated; loss of flesh; slight diminished resonance on percuss-ion; diminished respiratory murmur, strong expiratory murmur, upper right front; blood tuberculous.	Diet, but not very faithfully. In 1880, well.
95.	Man, 24. 1876. Case 67, loc. cit.		Father dead of tubercle, and sister dying. He had lost flesh and strength. No voice; pale and anæmic; no lung lesion; blood pre-tubercular	Treatment resulted in removal of blood morphol-ogy of disease. Is well.
96.	Woman, 24. 1877. Case 68, loc. cit.		Phthisis hereditary; en-larged lymphatic glands; ertine disease; dimin-ished respiratory murmur throughout the right lung; pretubercular blood	Milk diet; blood became normal; glands nearly disappeared.
97.	Woman, 30. 1877. Case 69, loc. cit.		Small fibroid tumor of womb; menorrhagia; blood pretubercular	Blood restored to health, and tumor disappeared under diet influences.
98.	Girl, 21. 1877. Case 70, loc. cit.		Feeble respiration right lung; blood pretubercu-lar; debility; cough; uterine disease	Pyrophosphate of iron; strict diet; rest; entire recovery.
99.	Woman, 25. June, 1888. Va Med. Monthly, Dec., 1888.		Mother and brother dead of tuberculosis. Weight, 248. Red corpuscles pale in color and sticky. White corpuscles enlarged with spores of vinegar yeast. Spore collects in serum spaces. Also crystals of cystine	Fatty heart; dieted for six months; weight 150 lbs.; calls herself well, 1892.
100.	Man, 60. 1878. Unpublished.		Heavy cough. Brother dead of tuberculosis. Corpus-cles massed. Yeast and fibrin filament present.	Dieted and cured. Lived in Japan several years. Well, March, 1890. Diet principally beef and bread. Lives in the South in winter; is a hard worker in his profession. At work in Europe, 1892.

TABLE II.—CASES OF TUMOR AND CANCER—SO-CALLED. Cases 1-13—Tumor.

No. Age.	Date. Publication.	Sex.	Condition when Placed on Treatment.	Result.
1.	1873. Am. Jour. Obs., Oct., 1877, and Med. Bulletin, August, 1891	Woman.	Hard, large abdominal fib-roid, several years' growth; severe metrorrhagias; ex-haustion; health reduced; about to apply galvanism.	Placed on diet largely anti-mal food as preparation for galvanism; tumor re-duced one-third, and no operation done; living, 1888.
2.	1875. Loc. cit.; also A. J. Obs., p. 304. April, 1887	Woman.	Unmarried; multi-lobar fibro-myoid; abdominal and pelvic; uterus retro-flexed; strict diet for nine months; one application galvanism by abdominal and rectal puncture.	Growth arrested and partial reduction by diet; in good health 1892, alive, but few traces of disease.

No. Age.	Date. Publication.	Sex.	Condition when Placed on Treatment.	Results.
3.	1875. Loc. cit.	Woman.	Several abdominal lobes; sessile intra-uterine growth; alarming copious hæmorrhage	Strict animal food diet; growths reduced and health restored; 1888, alive and quite well.
4.	1877. Loc. cit.	Woman.	Four children, mother of; uterine growth posterior wall	Tumor disappeared under strict diet. Well 1883.
5.	1875. Loc. cit.	Woman.	Unmarried; aged 28; cen-tral, round, dense, unyield-ing tumor extending from umbilicus downward	Tumor reduced to a mere nodule by nine months on strict animal food dieting.
6.	1874. Loc. cit.	Woman.	Chain of six tumors trav-ersing abdomen; largest three inches in diameter; pregnancy	Strict diet for lung lesion; child born alive; woman's health improved; too much attention to house-hold and church-fair du-ties killed her.
7.	1876. Loc. cit.	Woman.	Married; childless; abdom-inal and pelvic multi-lobar tumor; also fibro-cystic disease	Disease reduced by diet; woman quite well, 1890.
8.	1882. Med. Register, April 2 and 9, 1887	Man, 60.	Fibroid disease of stomach, complicated with enlarged liver	Nourishment per rectum till beef preparation could be taken by mouth; cure; alive, 1892.
9.	1883. See Medical Bul-letin, Aug., 1891.	Woman.	Unmarried, aged 40; tumor at fundus uteri 3 inches in diameter; double in-guinal hernia	Wore truss for hernia; tu-mor disappeared under diet; wore Cutter stem pessary; well, 1892.
10.	1886. Loc. cit. & J. A. Cutter.	Woman.	Unmarried; aged 35; im-mense abdominal fibroid; kept in abeyance by diet so that could do literary work	Two applications galva-nism reduced growth.
11.	Man, 1889. Loc. cit. Drs. E. & J. A. Cutter.		Aged eighteen; father dead of scrofula and alcohol-ism; blood tuberculous and syphilitic; large tu-mor left side of neck, and small growths right side	Strict animal food diet; succus alteran and bin-iodide of mercury; gain in weight, thirty-five pounds in six months' time; tumors degenerated; hardly any signs of dis-ease, 1893.
12.	1883. Loc. cit.	Woman.	Unmarried, 40; tumor, Douglas' cul-de-sac	Kept in abeyance several years by diet; patient pro-fessional philanthropist, and killed herself by over-work.

Cases of Pseudo-Cancer—13, 14, and 15.

No. Age.	Date. Publication.	Sex.	Condition when Placed on Treatment.	Results.
13.	1889. Loc. cit. Drs. E. & J. A. Cutter.	Woman.	Married, aged 40; four chil-dren; tumor right breast, two inches diameter, very painful; uterine hyperæs-thesia; growth called can-cer by family physician	Diagnosis, fibroid; diet, two-thirds animal and one-third vegetable food; mild tonics; uterine hyper-æsthesia relieved by iodiform per capsule and vector; tumor disappeared in six months; no return, 1893.
14.	1889. Loc. cit.	Woman.	Tumor of breast, called can-cer by six dozen cancer specialists; much pain in growth; had been on milk diet, which had done her some good; great uterine hyperæsthesia	Diagnosis of fibroid; pain reflex of womb; patient disappeared from observa-tion.
15.	1890. Unpublished. Drs. E. & J. A. Cutter	Woman.	Aged fifty; professional philanthropist; growth right breast three inches in diameter and one inch thick; called cancer by eminent surgeons of Bos-ton, who advised immedi-ate extirpation; no in-volvement of axilla	Mutilation of breast strong-ly opposed; advised to do less for humanity and more for herself; two-thirds animal and one-third vegetable diet; growth entirely disap-peared, 1893.

Cases, in author's possession, called Cancer, and treated as such; some cases may have been pseudo-cancer. If so, the result still stands, for if the diet of surgeons had prevailed in Case 17, there would have resulted an opera-tion, with, in the end, cancer's degeneration. For a further explanation of this subject, see "Diet in Tumor and Cancer," reprinted from Medical Bulletin of July, August and September, 1891.

No. Age.	Date. Publication.	Sex.	Condition when Placed on Treatment.	Result.
16.	The late Dr. Amos Twitchell of Keene, N. H., Med. Assoc., 1847; see Memoir prepared by H. I. Bowditch.	Man.	Growth called malignant by eminent men in Amer-ica; removed by scalpel; recurrence; treated by local applica-tions	Disease removed by exclu-sive diet of milk, cream and bread.

No. Date, Sex, Publication.	Condition when Placed on Treatment.	Results.
In Cancer, Alb. Med. Annals, July and Aug., 1887, and Med. Bull., Aug. and Sept., 1891		
17. Loc. cit. Man.	Case of Dr. Twitchell called osteo-sarcoma of scapula, six inches in diameter; Dr. Twitchell had removed in a similar case arm, scapula and clavicle, case dying year or two after of carcinoma internal organ.	Dr. Twitchell advised his second case to eat nothing but bread and drink an infusion of water-dock; case did so, with result of disappearance of growth in two years.

Men may cavil against this evidence and say that Dr. Twitchell did not know what cancer is; but the intellect that did the capital operation referred to, and could abstain from many foods, must not be condemned in its judgments. Dr. Twitchell was a great light in New England surgery; do surgeons of the present day make any better diagnosis of cancer? The answer is given in the table of cases of pseudo cancer and of true cancer herein given.

Cases called Cancer treated by the writer alone, or in some association with his son. The plans used on the line of beef-feeding as preferable to the milk diet.

No. Date, Sex, Publication.	Condition when Placed on Treatment.	Results.
15. 1876. Woman. Alb. Med. Ann., July and Aug., 1877. Med. Bulletin, Phil., Aug. and Sept., 1891. . . .	Aged forty; niece of case dead of cancer of calvarium, heart and liver; several hard, round tumors back of womb; smaller growths in cervix; unhealthy vaginal discharges, not bloody; countenance cachectic; worried by separation from worthless husband, whom she loved	Diet of beefsteak and other animal food; tea and coffee; gentle tonics and mild laxatives; death of husband; systemic plans of treatment were enforced, with result of disappearance of disease in about a year; no return, 1887.
19. 1876. Woman. Age 50. Loc. cit.	Cervix uteri enlarged laterally, even to side of pelvis; ragged, rough and bleeding; punky to touch; subject to unrelievable domestic mental troubles; taking opium; diagnosis cancer by eminent surgeons	Beef and other animal foods exclusively fed; thrice weekly cervix buried in iodoform; simple tonics; in three months the ulcerative processes had almost entirely disappeared; against my judgment, returned to New Orleans; disregarded injunctions; disease resumed its course, and caused death.
20. 1880. Man. Loc. cit.	Occupation, shoe-cutter; disease existed thirteen months; hand swollen and open on dorsal surface; carpal bones necrosed; under surface of wrist, volcanic-like swelling inch and a half in diameter and one inch high; in axilla several enlarged stony, lymphatic glands, more or less fixed, some having fistulous openings with discharge which presented under microscope such varied and heterogeneous histological elements that I could not but call it cancer	Attending surgeons' diagnosis, cancer; as consultant, advised amputation at middle third forearm; operation resulted favorably; diet of beefsteak, tea and coffee; patient living in 1892, with disease in axilla quiescent. Is a book agent.
21. 1880. Woman. Age 35. Loc. cit.	Married, aged 35; childless; wife of an advertising physician; case appeared to me to be uterine fibroid cancerously degenerated; great pain in pelvis; profuse bloody discharges; some emaciation	Fed on beef essence made at home; case gained in flesh, strength, color and looks; hæmorrhages ceased; friction arose between husband and self, and case went from under my care; treatment dropped; death.
22. 1880. Woman. Sister preceding case. Loc. cit.	Mental condition bad, circumstances limited, countenance cachectic; vaginal discharge, not bloody; knobbed enlargements of and cervix uteri	Absolute beef diet; with tea, coffee and milk; disease disappeared; 1891, disease in stomach called cancer by attending physician; disappearance under same plan of treatment.
23. 1889. Woman. 65. Loc. cit. Dr. E. & J. A. Cutter.	Occupation, gentlewoman; small growth in left breast; sessile growth right chest wall above breast and one in right axillary space; uterine hyperæsthesia and anteversion; chronic diarrhoea	Growths in right axilla and right chest removed with galvano-cantery; no return; uterine hyperæsthesia relieved by iodoform by capsule and vector, and case wore Cutter stem pessary for over two years. Growth in left breast is quiescent; has been more or less disturbance in left axilla; diet for months of beef chopped and broiled; tea and coffee; later, entire wheat bread, 1893.

No. Date, Sex, Publication.	Condition when Placed on Treatment.	Results.
24. 1889. Woman. Drs. E. & J. A. Cutter	Abdominal fibro-cystic disease giving appearance of woman at full term; case aged 65; widow, one child; has run a boarding house, and worked very hard; splendid mind and good will power; broke left floating rib (one or more) some ten years previously; when first seen, had peritonitis; pelvis not involved; umbilical hernia.	Case did well under strict diet of chopped beef, and was able to travel ten miles to New York; after about a year became financially straitened, from which condition she never recovered; disease increased; received two applications of galvanism by abdominal puncture; softening and diminution of growth; aspiration of fluid chocolate colored and syrupy in feel; disease began to increase in left side, and caused death; post-mortem revealed much improvement in abdominal cavity, but a large epitheliomatous mass existed in left side.
25. 1890. Woman. Drs. E. & J. A. Cutter. Loc. cit.	Aged 64; disease in breast called cancer by regular physician; taken out by pastes, leaving large, open sore; patient in California.	Under systemic plans breast healed; patient came East in 1891, and pelvis was found to be packed with large growth. Has disappeared from observation.
22. Woman. 1882. Loc. cit.	Discharged from Washington hospital with malignant disease of womb; seen by Dr. R. J. Nunn, of Savannah, Ga., and called cancer by him; patient unmarried; middle-aged.	Tumor gradually and wholly disappeared on systemic treatment; 1884, seen in N. Y. for first time, and found then an enlarged womb; 1887, no growth.
27. Woman. 1877. Loc. cit.; also, Feeding Patients Against the Appetite, case 3, Medical Register, April 2, 1887.	Father dead of cancer of stomach; case sick in bed of great grief, caused by sudden death of last surviving daughter; cardiac hypertrophy and insufficiency of left auriculo-ventricular valve; attacks of angina pectoris; retroversion, engorgement, hardening of womb; eversion of os uteri; behind womb, four small, hard, marble-like tumors; profuse vaginal discharge, not bloody; loss of flesh and strength; nausea; aversion to all food	Fed, against the appetite, with beef, and only on the dictum that if not, would die of cancer of the womb; nausea left in about three weeks; was one year before could walk 500 feet; 1893, heart normal in size and action; uterine disease and post-uterine growth disappeared.

120 Broadway, Equitable Building, New York.

SOCIETY PROCEEDINGS.

American Electro-Therapeutic Association.

Second Annual Meeting, held in New York, October 4, 5 and 6, 1892.

WILLIAM J. MORTON, M.D., PREST.

FIRST DAY OCTOBER 4—EVENING SESSION.

(Continued from page 254.)

USE OF THE ROTARY TRANSFORMER IN MEDICINE.

By R. L. Watkins, M.D.

The machine on exhibition is a combination motor and dynamo. By means of it, we can convert the electricity from a storage cell into motion and force for drilling and other purposes for which motion and force are needed; and can transform the storage current into one with a voltage varying from 0 to 150, as may be necessary—the ampèrage of course diminishing in proportion to the increase in voltage.

The current obtained is equivalent to that from forty primary cells, and is the "dynamo current," though the effect produced (on sensation and otherwise) is the same as by the current from a battery. Such a current has not been used heretofore, chiefly because, in the author's opinion, there has been no means of obtaining and applying it easily, cheaply and conveniently. It was with the idea of overcoming these obstacles that this machine was constructed.

The power, as I have indicated, is obtained from a storage battery—this being the safest and most convenient source.

While it is possible to keep these batteries charged and in order by primary cells, it has been found that it is much better to have them filled at an electric light station or

some place where they have special facilities for doing it—for instance, in New York the Storage Battery and Supply Co. They will also express batteries out of town.

[Mr. Bunce will describe the machine and cabinet and demonstrate its uses.]

1. Faradic.
2. Cautery.
3. Direct current.
4. Drill, etc.
5. Throat light.
6. Cystoscope light.

The Association then adjourned to the reception at the Electric Club.

SECOND DAY, OCTOBER 5—MORNING SESSION.

THE NEED OF GREATER SIMPLICITY AND UNIFORMITY IN ELECTRO-THERAPEUTIC APPARATUS.

By W. J. Herdman, M.D., Ph.B., Professor of Diseases of the Nervous System and Electro-Therapeutics, University of Michigan.

In forming the purpose of asking the attention of the members of the Association for a few moments to the consideration of the subject of uniformity and simplicity in the apparatus employed for electro-therapeutic purposes, I was much encouraged by reading the proceedings of your first annual meeting. I then discovered, what I already felt must be the case, that I was not alone in the belief that the time has come for "standardizing" the instruments which individual experience has proved to be of service in adapting electricity to the cure of disease. I was impressed with the truth of the statement in the paper read at that meeting by Dr. Goelet upon "The Action and Application of the Faradic Current in Gynecology," that "imperfectly constructed apparatus is the cause of the indifferent results that have been obtained by various observers," and I found myself in hearty sympathy with the declaration of the present President of the Association when he said, during the discussion that followed, "A standard induction battery is desirable—a standard coil—a standard length of wire; then comparative observations could be made." That this opinion at that time prevailed among those present, was shown by the appointment of two committees, charged with

the duty, as I understood it, of considering and reporting upon a suitable form of induction coil and milliamperimeter for electro-therapeutic needs. It is my intent, at this time, to simply call the attention of the members of the Association to the importance of enlarging upon the purpose which called those committees into existence, and to urge upon you to persist in such efforts as are necessary to secure a standard for every piece of apparatus indispensable to a complete electro-therapeutic outfit.

We are convinced of the value of electricity as a therapeutic agent. We feel confident that we have through it gained good results. We know that we have brought about cures with it that could not have been effected by other means. We are satisfied that in all branches of medical and surgical practice it is capable of replacing to advantage certain methods of treatment now in vogue. Both here and elsewhere, members of this Association, and others, have furnished unimpeachable testimony in support of these propositions, and our concurrence in the opinion they express is the bond of our union in this Association. We meet with a view of interchanging such testimony and extending our knowledge, both as to the theories of the action of this mysterious force and the range of its efficiency in the practice of medicine and surgery.

But when it comes to a question of what form, what method, what machinery is best calculated to bring about a desired result in any particular case of disease, we are likely to be as various in our opinions as we are numerous in our membership. Any attempt that any number of us might make to secure the same result with the tools at our command would repeat the experiences at the Tower of Babel, and such efforts would end in like confusion. We are for the most part self-educated in the knowledge we have gained, and each has pursued his search for truth after his own method, and with instruments peculiar to himself, often self-devised.

But the time has come when a union of these individual experiences will result in mutual helpfulness, and the progress of electro-therapeutics toward that period when it will be regarded as one of the most, if not the most, exact methods of treatment, can be materially hastened; for I think we are convinced that second to no other therapeutic agent, electricity, in the treatment of disease, is capable of being established on a scientific basis.

But be it remembered, a science based upon one opinion is not a science in the true acceptance of the term, whatever otherwise be the scientific value of the personality that entertains it. A concensus of the opinions of many who have witnessed like results, from similar conditions, with unvarying accuracy, can alone command a respectful hearing, and lay the foundations of a science. If it is our desire and purpose, therefore, to inaugurate a *science* of electro-therapy, it is fitting that we bear in mind what are the conditions essential to this, and that we take heed of the obstacles that beset our pathway in attempting to meet these conditions, that we may wisely direct our united efforts toward the removal of such impediments. Among these obstacles I need not name the skepticism which has long prevailed in the minds of many worthy members of the medical profession regarding any possible therapeutic value to be derived from electricity. Such skepticism has been justified by the failure and lack of uniformity in results of those who have employed it, but to a much greater degree can it be traced to a natural repugnance aroused by the preposterous claims of blatant charlatanism, which has availed itself of the mystery that enshrouded the workings of this powerful agent to reap a golden harvest from credulous sufferers. The innocent agent must needs share the reproach justly due those who ignorantly and fraudulently

employed it, since the disgusted observer of such practices is not prone to nice distinctions. The dawn of true scientific methods witnesses such obstacles as these rise and float away like morning mist. Neither charlatan nor skeptic can withstand the truth, and if our confidence in the value of electro-therapy is well grounded on demonstrable facts, from them we have nothing to fear.

The real obstacles with which we have to contend in creating a scientific electro-therapy are:

1. A lack of systematic preparatory education in electro-physics and physiology.
2. A lack of uniformity in the appliances by which electric treatments are given.
3. A lack of simplicity in these appliances.

Not a very formidable array, and one which will readily yield before the united efforts of the members of this Association. The appliances that are now considered essential to a complete electro-therapeutical equipment are not few.

The physician who wishes to be furnished with all the apparatus whereby electricity is adapted to therapeutic needs must have:

1. A static or influence machine.
2. Continuous current generators, both stationary and portable, adapted, *a*, for ordinary treatment; *b*, for electrolysis; *c*, for cataphoresis; *d*, for cautery work; *e*, for lighting exploring lamps; *f*, for running motors.
3. Induction coils.
4. Current controllers or rheostats.
5. Milammeters.
6. Coulombmeters.
7. Electrodes of a variety of patterns.

None but the specialist would, in all probability, supply himself with so complete an outfit, and there are those who, with some show of reason, strongly advocate that the practice of electro-therapeutics be confined to the specialist. But this limitation is, to my mind, neither practicable nor desirable. That there will always be ample field for the special practice of electro-therapeutics, I have no doubt, but there is a wide range of disorders with which the general practitioner has to deal, wherein he finds electricity the most suitable agent he can employ, as has been well shown in the paper of Dr. Hutchinson, of Providence. And what is true of the general practitioner is true likewise of the physician or surgeon whose practice is limited to any class of diseases. There are none of them but do, or would find electricity, at times, their most efficient handmaid when they are made aware of its capacities.

This being the case the preparatory education needful for the right understanding of those principles of electric action which lie at the foundation of all intelligent use of it in therapeutics, should be required of every medical student. What one of you, who has acquired any skill in handling electricity in your practice, would have done so but for the knowledge you possess of electro-physics and physiology? And I venture to assert there is not one of you but deplores the fact, as I do most heartily, that in this respect his earlier education was not more systematic and thorough. Let us therefore, remember that every man owes a debt to his profession, and in no better way can he discharge it, than in doing what he can to perfect its methods and aid it in the attainment of better results. Let us not permit those who may follow us in this line of practice to be hampered by difficulties with which we had to contend, but give them, as we may be able, the benefits of our experience.

Instruction in electro-physics and physiology properly belongs to the medical schools, and should be included in their curriculum or among their entrance requirements. At present, however, there are but few schools where either

of these provisions are made, and nine-tenths of medical graduates are sent out with little or no knowledge of the laws governing electric action, either without or within the human body. Colleges are seldom the leaders in broadening medical education, but self-preservation forces them to provide what the profession demands. This Association is in a position to fix the standard of requirement for the physician who wishes to practice electro-therapeutics, and sooner or later all colleges worthy of the name will conform to that standard by making suitable provisions in their course of instruction.

The remaining hindrances that I have mentioned as obstructing the progress toward a scientific electro-therapy it is the duty of this Association to remove. Uniformity in construction of the instruments employed, is the first step necessary to secure uniformity in results. By this means alone can our experience in treatment be made available for the discovery of general principles and laws. The literature on electro-therapeutics in the language of all civilized nations has become quite voluminous. There is much chaff mixed with the wheat that has appeared in text-books, monographs, and in periodical medical literature upon this subject. It is time that we undertake to prove all things, claimed in the name of electro-therapeutics, and hold fast to that which is good. To do this successfully our measuring rods must be of equal length.

Great skill and ingenuity has been displayed by physicians, electricians and mechanics devising instruments for electro-therapeutic work and as a result we have in the market many admirable tools with varying degrees of excellence in one direction or another, but each aiming at some peculiar quality which has given rise to the greatest diversity in pattern, action and effect. Let us take, for example, any two patterns of induction coils, or static machines, or milliampèremeters now presented for our inspection by the manufactures represented at this meeting and we will find that upon the same patient, other conditions being equal, their action would differ largely. This statement I have taken frequent occasion to verify and I doubt not that many of you have made similar observations. I do not claim that with a "standard" apparatus in the hands of different operators the results would always be uniform, for the personal equation of the operator cannot be left out of the account, but the sooner we succeed in eliminating the wide and useless range of uncertainty that is the necessary consequence of the variety of appliances now in use the sooner will the value of this personal equation be determinable.

By fixing a standard for each piece of apparatus I have enumerated, the physician is not alone benefited. The manufacturer's risk is greatly lessened. He will then know what the practitioner of electro-therapeutics must have and can devote himself, to supplying the need with the best article he can produce, and with confidence that it will find a ready sale whenever electricity is employed. Greater precision and uniformity in action in these appliances will render electric treatments more fruitful of good results and, through the simplifying of methods and making familiar to all the construction and pattern of instruments employed, the demand for them will rapidly increase.

It will be my pleasant duty as soon as standard instruments are adopted by this Association, to subject them to practical tests in laboratory and hospital, where careful records will be kept and the results made known, and with others doing the same we will soon have gathered a mass of statistics out of which a science of electro-therapy will grow rapidly and surely.

It is not a part of my purpose, neither do I presume to suggest any special form of apparatus as worthy of adoption as a standard by this Association. The plan already insti-

tuted by you, of selecting a committee composed of men whose knowledge and experience well fits them for the task assigned them, and of giving them a year in which to investigate and report, is the one best calculated to reach a conclusion and one in which all are most likely to concur, as to the best form of instrument to be adopted as a standard, and I am confident that I voice the wishes of a vast body of practitioners who daily use electricity in their practice, when I make the request that committees similar to those already appointed, be created at this meeting, whose duty it shall be to report at the next annual meeting, upon standards for the *static machine, constant current generators and electrodes.*

Reliability in action of the *static machine* has been found to depend very largely upon its construction. It has its limitations as to size and number of plates. It has a field in therapeutic uses peculiar to itself wherein it is capable of doing most excellent service. Its capacities should have the recognition of this body and the essential features in its construction for therapeutic work should be indicated. The *continuous or galvanic current*, while it is conceded to be more serviceable than any other form of electric energy which we employ, yet it is, as is well known, but seldom used by the practitioner, and I have found many specialists who have shunned it because of the perplexities that constantly arose from its mode of generation. But simple and efficient methods for generating and controlling continuous currents, both for office and bedside practice are in use and need but the authoritative sanction of this Association to be generally adopted. As to *current controllers, or rheostats*, their form must be determined by convenience and in their construction, uniformity in design is not so important as efficiency in action. The use of the coulombmeter will, no doubt, become more general when our science has reached such a degree of advancement as to require the precision of electrolytic decomposition for determining dosage. For the present we must be content to put up with coarser tools until our hands become skilled for finer workmanship.

But in the matter of *electrodes* some attempt should certainly be made to bring order out of the chaos that now prevails in this kind of appliances. If it is generally agreed that *current density* plays the important role in treatments that is claimed for it by several well-known authors and teachers, then the *size, shape and material* of the electrodes through which the body is brought under the influence of such current should receive our careful attention.

With the introduction of uniformity must come simplicity in structure. When all the essential elements of an instrument are preserved simplicity is synonymous with efficiency and economy.

The American watch—an excellent time keeper—having done away with all superfluous parts, has found its way into the pocket of every school boy. Duplicates of its parts can be found at all jeweler's. The little jeweler around the corner can set it to rights at a moment's notice, provided its owner does not care to do it himself, while the unique and elaborate hand-made chronometer from Switzerland must be laid aside as useless upon the breaking of a cog.

Many a would-be therapist has had his enthusiasm for this field of practice dampened by the continual drain upon his purse, time, and good nature, required to keep his electric outfit in working order.

If the time arrives, as it will speedily with our help, when worn-out or corroded parts in electric apparatus can be renewed in a moment by the operator or his assistant, or an accident can be remedied by replacing a broken piece by a new one obtainable at the nearest supply store for a trifling cost, the science of electro-therapy will, in its course,

have cleared the obstructions in the harbor and those who practice it will find it less difficult to preserve intact the third number of the Decalogue.

Discussion.

Dr. Hutchinson said the author had echoed his own sentiments completely, when he said that with our help, the time is coming when repairs to our apparatus can be easily and properly made. Our apparatus is altogether too complicated, and composed of too many parts, which are only accessible to the manufacturer. No part of an electrical apparatus used by a medical man should be so constructed that he cannot repair it, and it was on this account, that he had fought so hard and so persistently against the use of closed cells.

Dr. Goelet was glad to see that the author had recognized the difficulties he had to contend with in the use of electro-therapeutic apparatus, and how particularly annoying this lack of uniformity in construction was in consultation practice. For instance, a physician from a distant part of the State brought a patient into his office yesterday morning for consultation. He had used faradic applications without benefit, but the faradic apparatus which the speaker employed, gave her relief at once. The consultant told the attending physician how he could have a proper coil constructed from which he would obtain practically the same results, but he could not direct him to any manufacturer who would furnish him with such a coil from his regular stock.

In connection with the subject of electrodes, and the material for their construction, he desired to refer to a paragraph which he had seen in the *Pacific Record* for September 15, of this year, in which a short description is given of a new alloy of lead which it is claimed will take the place of platinum. It is very malleable alloy, which is scarcely acted upon acids, and it has been proposed to use it in the manufacture of accumulator plates. It consists of 945 parts of lead, 22 of antimony, and 13 of mercury. The lead is first melted, and then the antimony and mercury added in the order first mentioned, the mercury being added at the moment of pouring into the ingot mould. There has been a tendency to economize in the construction of apparatus, but this is a mistake. A few years ago, he had himself been guilty of this, for he had advocated the use of iron prepared by a special process. Further experience showed it to be unsatisfactory. Tin is a little better, but it is acted upon by the current, and it is possible that it may exert an injurious effect upon the interior of the uterus.

Dr. W. T. Bishop, of Harrisburg, Pa., thought the great obstacle to progress in the direction of uniformity and simplicity of construction was to be found in the fact that we did not ourselves know what we wanted. At present, it was only practicable to adopt a standard of strength and of interchangeability of parts. A sick machine is like a sick man—sick all over; and it is rare that a medical man is capable of taking proper care of even the simplest instruments.

Dr. Waite, on behalf of the manufacturers, said that the difficulties they met with were very great, and perhaps the chief of these is to be found, as had been already said, in the general lack of knowledge on the part of the purchaser as to the use and limitations of the different forms of apparatus. For instance, one medical man wrote to him recently to know if he could charge a storage battery from a static machine. The voltage of the instruments in the market is well known; the trouble is chiefly with the electrodes. These are usually *moistened*, when in use, instead of being thoroughly wetted. The great diversity of construction in faradic coils is well known, but the manner in which this

can be overcome is far from being settled. There is a difference in the cell which charges the coil, in the size of the wire, in the windings of the coil, the number of vibrations and many other factors, which must be taken into consideration. The only way to settle this matter is by actual tests and extended experiment, just as was done in determining the construction of the dynamo. The manufacturers are trying to make their apparatus as simple as possible, but they are constantly called upon to make this or that change to suit individual whims.

Dr. Nunn said that one of the most annoying things about this subject of the construction of apparatus, is the variations made by different manufactures, and even by the same manufacturer, in the screws used to make the various connections. If the committee could only induce the manufacturers to make the connections interchangeable, they would accomplish a great deal. Why should not this Association adopt a standard for plugs and screws, just as the Microscopical Society has done? In determining the construction of faradic coils, the committee will have to prescribe the proportion between the primary and secondary coils, but in adopting a standard, there should be a wide range permitted, and each point in construction, should be determined from a therapeutic standpoint. Much unnecessary confusion also results from the manufacturer making various changes without realizing the possible importance of these changes.

Dr. von Raitz thought a certain sum should be placed at the disposal of the committee for their investigations.

Dr. Kellogg said that for the past seven years, one of Brown-Sequard's assistants had been engaged in studying electrical currents by the graphic method, and for the past six months, he had himself been carrying out such experiments. So far, his results verified those obtained in Europe, and brought out many new and interesting features. By a proper arrangement of an electro-magnet and a solenoid, or coil of wire connected with a long and slender lever, it is possible to get tracings illustrating the character of each current. Studying the faradic current in this way, shows that the second current is very much stronger than the first, the first being impeded by induction, and the second being reinforced by the primary current. It is possible by proper construction of the apparatus, to partially equalize these currents. The current is also greatly modified by the adjustment of the induction apparatus.

Dr. Herdman, in closing the discussion, said he was gratified that there was such a harmonious expression of opinion concerning the necessity for the Association to take up this work. It was undoubtedly true, as had been said, that much of the trouble was due to our not knowing just what we wanted, and he could furnish hundreds of illustrations like that cited by Dr. Waite. Just before leaving home, he had received a letter from a college graduate of high standing, asking if two axo cells would give him all the current he needed, yet the writer did not state just what he wanted to do with the current! The speaker said he had nothing but praise for the manufacturers; in fact, he thought they had done much to educate us. They must, of course, aim to meet the demands made upon them, and it is a positive detriment to them, as a rule, to have their instruments made after some peculiar pattern, as this interferes with their general use. He was sorry to say that there were a few manufacturers who hoped by some peculiarity of construction to keep up their trade, but such sharp practice really results in throwing the instruments out of the market. The more uniform their construction, and the greater their simplicity, the larger will be the demand for the instruments. Admitting that we do not yet know just what we want, this is no reason why we should not make a step in the right direc-

tion. The same objection might have been made to any system of measurements at the beginning; standards frequently require to be changed, before a perfect system is constructed. We are ourselves responsible for what the manufactures are doing; they have taken the field because we have failed to do so. To inculcate upon his students the importance of simplicity of construction, he had taught them in his laboratory to begin with the simple Volta cell, and then to construct batteries of several cells, making the proper connections to obtain a certain required voltage. The speaker then exhibited a battery cell which he had devised for the sole purpose of illustrating simplicity of construction. It has zinc and carbon elements, with bichromate solution; there is a simple rheostat on one side, and on the other, is a pole changer. The controller consists of a U tube filled with a saturated solution of sulphate of zinc, and of a platinum wire dipping into the solution, and admitting of adjustment. If the zincs have been accidentally left in the bichromate solution, they can be renewed in five minutes. The discouragement arising from the inability to make the needed repairs, leads many to abandon the practice of electro-therapeutics, and, therefore, it is to the interest of the manufacturers, as well as to the interest of the user, that the construction of these instruments should be simplified. But the responsibility rests upon us as a national organization, and the first step is to appoint a committee to investigate this subject, and in their work, they should not forget to give most thoughtful consideration to such physiological experiments as had been alluded to by Dr. Kellogg. He suggested that three committees be appointed; one on static machines, one on constant current controllers, and one on electrodes.

(To be continued.)

BOOK REVIEWS.

FERMENTATION, INFECTION AND IMMUNITY. A NEW THEORY OF THESE PROCESSES WHICH UNIFIES THEIR PRIMARY CAUSATION AND PLACES THE EXPLANATION OF THEIR PHENOMENA IN CHEMISTRY, BIOLOGY, AND DYNAMICS OF MOLECULAR PHYSICS. By J. W. McLAUGHLIN, M.D., Austin, Texas. Copyright, 1892. Austin, Texas, 1892. Pp. 240.

The author of this little book will be recollected as having described a micrococcus in the blood of patients suffering from dengue or breakbone fever; his observations, though not yet confirmed on account of the absence of opportunity as no epidemic has occurred during the last two years or so, are about the only ones extant on the specific etiology of dengue.

McLaughlin's present work is an interesting contribution to the study of the processes and problems indicated in the title, problems just now occupying the minds of students and investigators the world over. The book really consists of a number of articles published here and there during the last few years in which the etiology of acute, infectious diseases has been discussed from various standpoints; to these articles considerable new matter has been added. The "physical" theory of immunity here introduced is elaborated in an interesting manner, the relation between this theory and the bio-chemistry of to-day is established and on the whole, it must be said that the book will amply reward its perusal. There is no index, but the list of contents at the beginning is quite complete; yet the absence of an index really detracts from the book.

CHICAGO reports one thousand four hundred and seventy-nine deaths from typhoid fever during 1892, against one thousand nine hundred and eighty-seven during 1891.

THE
Journal of the American Medical Association
PUBLISHED WEEKLY.

SUBSCRIPTION PRICE, INCLUDING POSTAGE:
PER ANNUM, IN ADVANCE \$5.00
SINGLE COPIES 10 CENTS.

Subscriptions may begin at any time and be sent to

THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION,
No. 68 WABASH AVE., CHICAGO, ILLINOIS.

All members of the Association should send their Annual Dues to the Treasurer, RICHARD J. DUNGLISON, M.D., Lock Box 1274, Philadelphia, Pa.

MEMBERSHIP IN THE AMERICAN MEDICAL ASSOCIATION.

This is obtainable, at any time, by a member of any State or local Medical Society which is entitled to send delegates to the Association. All that is necessary is for the applicant to write to the Treasurer of the Association, Dr. Richard J. Dugglison, Lock Box 1274, Philadelphia, Pa., sending him a certificate or statement that he is in good standing in his own Society, signed by the President and Secretary of said Society, with five dollars for annual dues and subscription for THE JOURNAL. Attendance as a delegate at an annual meeting of the Association is not necessary to obtain membership. On receipt of the above amount the weekly JOURNAL of the Association will be forwarded regularly.

SATURDAY, MARCH 11, 1893.

SOME MEDICAL FRICTIONS.

The English medical public have protested with great indignation against the position of Mr. LAWSON TAIT, the distinguished gynecologist, who has endorsed the anti-vivisection society in its attacks on medical men for experimental vivisection. The position he has taken, is so untenable from a scientific point of view as to suggest some grave defect of his intelligence. Charges and counter-charges have been made and much bitterness of feeling has been provoked. The impression one gets from this distance, is that however eminent a physician may become, it is not safe to trust to his judgment outside of his special studio. Being an eminent surgeon, gynecologist or specialist, in any department, does not bring superior judgment in other fields of science. Often men who have become prominent in some department of medicine, assume that such knowledge extends to all other topics, bringing with it equal capacity and wisdom. There are many LAWSON TAITs in this country, whose assumptions of knowledge are painful, and whose influence is not unfrequently a direct encouragement of the worst forms of quackery and an obstacle to progressive medicine. Almost every year investigating committees of the State legislatures are formed to ascertain and correct the abuse of incarcerating sane men in asylums for some mercenary object. These are sometimes encouraged and often directly instigated, by eminent practitioners, and persons not only ignorant, but devoid of common or reasoning sense. No one ever hears of practical results, from such committees, and no one is ever found who is sane and has been locked up in an asylum for fraudulent purposes. A few years ago the New York State legislature spent six thousand dollars to investigate such a case, which proved at last to be a most dangerous lunatic. Two such committees are now at work on similar charges, and thus the delusion

goes on year after year. If those physicians who advise so wisely on these matters would turn their attention to the really fearful abuse and wrong, of permitting insane men to be at large, and only recognizing their conditions when they commit crimes, the most practical good would follow. Just now the same dangerous criticism and advice concerning cholera, and other epidemics, appear, coming from men who have no practical acquaintance with these diseases. Boards of Health will cite the opinions of persons as authority, who have no other knowledge except that obtained from the most superficial reading of newspapers. The significance of this will be apparent to every reader, and serves to bring out more distinctly than ever the fact, that whoever becomes a judge and critic of matters of science, must bring some claim to be heard, other than ability in other fields. The great surgeon's judgment on the conduct of a medical journal is of no more value than that of the country doctor. The asylum specialist, and the egotistical teacher in a medical college, are not to be accepted as authorities on matters outside of their every day work. The field of medical science has widened to such an extent that no one man, however eminent, can form a correct judgment of parts of the country he has never traversed. It is fatal to the intelligence of any medical man to join the numerous reform societies, whose work is based on fragmentary truths, that are yet only theories, and are not supported by persons who have the best opportunities to study and observe their assumed facts. Thus opinions on hypnotism, on criminality, inebriety, pauperism and prostitution, with other themes that the public are concerned with, and look to physicians for direction, should be given with great care, and not until the author is confident that he has mastered the facts and their probable meaning.

The old time practice of evolving from ones own inner consciousness, truths of science and practical life, will not bear the test of modern thought. The physician who has any opinions or advice to offer, must give some reasons or facts to sustain it, or have some experience that will add weight to his judgment.

Every year physicians are becoming more influential advisors in medical and hygienic matters in all communities. The need of a larger acquaintance with public sentiment and the evils that are inseparable to every neighborhood, demands better knowledge and a spirit to advise wisely on all occasions. To be skilful in diagnosis and therapeutical resources is not enough to make a great physician. The community demand something more from him as an educated man. A very good eastern physician is rated in his community as of excellent judgment in medicine, but an idiot on other topics. This man's egotism sustains him in the belief that his medical

knowledge, brings with it capacity in all other branches. Such men support anti-vivisection societies, and societies to prevent people from being declared insane, believes in specifics for consumption and inebriety; and advises against surgical operations on the supposition that the surgeon is a "crank," and thinks the knife the only medicine; he claims equal knowledge with experts on all topics, and superior disinterestedness, which gives his judgment great force. The evils which are constantly springing up from this course, are clearly chargeable to the low standard of professional attainments in the past. Men have entered the profession, who were of defective judgment naturally, and who never had solid training. They may by industry, become fairly eminent in some department, but they will always suffer from narrowness, and astigmated vision of science beyond their every day life. Physicians of this class are always sources of trouble and controversy, wherever they go, and should be recognized and rated on the level where they belong. When this is done the general profession will not be disturbed with these weaknesses but pass them by unnoticed.

MUNICIPAL ASEPSIS.

Our most recent European exchanges inform us of little outbreaks of cholera in quite a number of localities, and they also tell of the greatest activity on the part of both National and municipal governments in efforts at placing all cities and towns in the cleanest possible condition. Special attention is given to the improvement of water supplies. Strict and stringent sanitary laws are enacted and rigidly enforced by the strong arm of monarchical governments, in the hope that such measures will prevent a breaking out and spread of the cholera scourge. The enactment of quarantine measures for the stoppage of Eastern immigration is also resorted to in Germany, and is being considered in England for the same purpose.

We regret that we are not able to report similar sanitary activities in many American cities and towns, every one of which is in a greater or less degree threatened by this same dreaded scourge.

Streets, alleys and sewers should be scrubbed and scoured until they are in as nearly an aseptic condition as possible.

Very few of our cities have a pure and uncontaminated water supply. This is a matter of the utmost importance. Within the past two years (1891 and 1892), there have been more than thirty-four hundred deaths in Chicago alone from typhoid fever, a disease that is known to be traceable either directly or indirectly to an impure water supply. Some other cities have suffered severely from the same cause. In order that the city may be recorded as in even an

approximately aseptic condition, a vast amount of scrubbing, scouring and cleaning must be done.

Infectious diseases have their homes and breeding places in many of the vile sinks, called tenement houses, from which they are not only allowed, but made to spread here and there, through the cupidity and avariciousness of landlords and dealers in wearing apparel.

The Nation and many States are going through the process of change of political rulers. A hope is entertained that the new brooms will sweep clean in sanitary affairs, for there is certainly room for a world of improvement in many localities.

At such a time as this public health considerations are of prime importance, and the health authorities should be clothed with autocratic power. In this connection the regulation of the practice of medicine is of equal importance.

While it is lamentably true that the members of the medical profession are sometimes held up and publicly criticised as alarmists in the face of an impending epidemic, let us not carp too critically at such exhibitions of sublime ignorance, but proceed to show to the world that our special knowledge of the history and treatment of infectious diseases is not only rational, but susceptible of accurate demonstration. Further, the people should be thoroughly informed that a violation of sanitary and hygienic laws is certain to be followed by a suitable punishment.

Having performed her own duty in this regard, and RACHEL is made to weep and mourn for her children and will not be comforted; let her maledictions fall first upon the heads of those in authority, and then upon those whose avarice has made it possible for her to live and see her children taken from her by preventable causes.

Local medical societies should appoint committees to wait upon the executive and legislative branches of State and city governments for the purpose of indicating to them prophylactic measures that should be rigidly enforced at this particular time.

The passage of the following bill by the Legislature of Minnesota is of particular interest:

STATE OF MINNESOTA.

Twenty-eighth } S. F. No. 328
Session. }

Introduced by Mr. Tawney.
February 16, 1893.

A BILL For an Act to Protect the People of the State of Minnesota Against the Importation of Acute Contagious Diseases by the Regulation of Interstate Immigration.

Be it enacted by the Legislature of the State of Minnesota.

SECTION 1. For the better protection of the people of this State against Asiatic cholera and other contagious diseases the State board of health may establish a system of quarantine against the introduction of pestilential diseases by the various railway and navigation companies doing business in the transportation of passengers across the borders of this

State; the members of the State board of health, or their properly constituted representatives, are authorized to board any railway conveyance used in the transportation of passengers across the borders of this State, or any vessel entering the waters of this State, for the purpose of sanitary inspection to ascertain the existence of cholera or other dangerous contagious diseases.

In case it is found any such conveyance named is infected with such disease, the said officer may, in his discretion, isolate and quarantine all passengers so infected or endangered by or from exposure, together with their baggage and effects, and detain the said conveyance or vessel until it is rendered safe by proper disinfection and fumigation.

SEC. 2. Any and all transportation companies shall afford the officers of the said board reasonable facilities for the sanitary inspection of cars and vessels by furnishing necessary transportation to inspectors, by detention of cars and navigable vessels during isolation of passengers, together with their effects, and shall immediately submit to the fumigation and disinfection of such conveyances and cars as may be deemed necessary by the board for the protection of the public health.

SEC. 3. The necessary expense of fumigation and disinfection of cars and vessels shall be at the expense of the owners of cars or vessels so inspected.

SEC. 4. When it is made apparent to the Governor of this State that any railroad company or other transportation company is not exercising due or reasonable vigilance against the introduction of Asiatic cholera or other dangerous contagious diseases, he shall announce such conclusion by proclamation, and thereupon and thereafter the entire expense of quarantining immigrants or emigrants or passengers shall be a direct charge against said company.

SEC. 5. Whenever the said board shall discover the existence of cholera or any infectious diseases on any railway car or vessel without the boundaries of this State, they shall cause notice of such fact to be served upon the agent or officer of the company operating such car or vessel, and thereupon and thereafter it shall be unlawful for such company or any of its officers or agents to bring or cause to be brought within this State such car or vessel, except it be in accordance with such reasonable rules and regulations as the said board shall adopt applicable to such case. Any person or corporation who shall violate any of the provisions of this act shall be punished therefor by a fine not to exceed one thousand dollars (\$1,000) or by imprisonment in the State prison not more than one year, or by both such fine and imprisonment.

SEC. 6. This act shall take effect and be in force from and after its passage.

THE PATHOGENIC ACTION OF TYPHOID BACILLI ON ANIMALS.

GAFFRY, SIMONDS and FRAENKEL, and after them many others, have studied the pathogenic action of typhoid bacilli in animals by means of inoculation with pure cultures and the results have appeared, as a rule, to be due to an acute intoxication with the soluble products of the microbes rather than to an actual bacillary invasion and proliferation. Quite recently this matter has been thoroughly investigated by CHAUTESSE and WIDAL, whose previous joint work on the action of typhoid bacilli in animals is well known, and also by SANARELLI (*Annales de l'Inst.*, Pasteur, Nov., 1892), and the interesting

results obtained by these investigators agree in all main points.

The somewhat contradictory results announced by previous workers were undoubtedly due to the fact that cultures of varying intensity were used in the experiments; the typhoid bacillus is of unstable virulence and appears to lose its activity soon, unless cultivated uninterruptedly. CHAUTESSE and WIDAL found that the virulence of the typhoid bacillus can be exalted by inoculating guinea pigs successively with the serous fluid found in the peritoneal cavity of an animal of this kind which has succumbed to the effects of an inoculation; that is to say, the first animal was inoculated subcutaneously with a certain quantity of fresh culture from the effects of which it died after twenty-four to forty-eight hours; a small quantity of the peritoneal serum of this animal, which was found to swarm with bacilli, was now injected into the peritoneal cavity of another animal which succumbed very rapidly, and by passing the bacilli in this way from animal to animal, their virulence was found to increase in a very remarkable manner. The preliminary injection of a moderate quantity of sterilized cultures of streptococci, or of the colon bacillus, or of proteus vulgaris, and then inoculating the same animals with cultures of typhoid bacilli, was also found to intensify the virulence of the typhoid germs in a most marked degree. The bacilli of typhoid fever would be found in large quantities and in pure culture in all the organs, in the blood, and in the serous cavities as well as the intestines; the spleen was greatly enlarged, the intestines congested, the Peyer's patches and mesenteric glands swollen and tumefied in the animals subjected to these experiments. The action of the soluble products of the microbes mentioned appeared to greatly and directly facilitate the invasion of the bacilli of typhoid fever. This point may throw some light on the etiology of enteric fever in man in whom the toxic products are produced in the intestinal canal by streptococci, by the colon bacillus and other microbes, which may so modify the general condition of health as to favor typhoid infection.

The investigators mentioned were also able to utilize the fixed virulence by typhoid bacilli created in the ways referred to for the immunization of animals against the typhoid virus. Immunity was produced by inoculating animals with a certain quantity of virulent culture in divided doses. There being an interval of several doses between each inoculation, and also by means of other methods. An immune animal remained unaffected by doses of virulent virus fatal under ordinary circumstances. The injection of serum from typhoid fever patients and from persons who had passed through an attack of fever also produced immunity, though of short duration, in guinea pigs against virulent virus. The next

step in this work was to show that the serum of animals rendered artificially immune was not only prophylactic but also curable, by injecting serum of a vaccinated animal into the body of a guinea pig soon after it had received a fatal dose of virulent virus, when great modification of the usual symptoms occurred and recovery ensued. Finally it was attempted to demonstrate what curative effect, if any, the injection of the serum of immunized animals would have on patients suffering from typhoid fever, and CHAUTESSE and WIDAL made two experiments of this kind on two patients, but the course of the disease was not modified. In spite of the failure of these efforts, it would nevertheless seem, that as long as the serum of animals vaccinated against typhoid infection has actual therapeutic properties, it will not be long before this important discovery can be successfully applied to the actual treatment of enteric fever.

MEDICO-LEGAL POINTS.

In a case recently tried in the Supreme Court of the State of Illinois, the following decision was given:

Siebert v. The People. Supreme Court of Illinois. (Opinion filed October 31, 1892.)

3. EVIDENCE—*Competency of expert to give his opinion.*—A practicing physician who is shown to be a graduate of a regular medical college, and to have practiced his profession for many years, is competent to give his opinion upon an hypothetical question setting forth the symptoms of a deceased person, whether the death was from the effects of arsenical poison, although he may not be shown to have had any case of such poisoning. A medical witness in giving his opinion as an expert, is not confined to opinions derived from his own observation and experience, but may give an opinion based upon information derived from medical books.

11. CRIMINAL LAW—*Instruction as to reasonable doubt.*—On the trial of a criminal case, it is not error to instruct the jury that it is not necessary to prove each link in the chain of circumstances relied on, or every fact in the case, beyond a reasonable doubt, but it is sufficient if, taking the evidence as a whole, they are satisfied beyond a reasonable doubt of the defendant's guilt.

15. EVIDENCE—*Offer of vial and box embraces contents.* When a vial and box containing poison is offered in evidence and admitted, the only object of offering them in evidence being to get the contents to the jury, an instruction to the jury not to consider the contents is properly refused.

DOMESTIC CORRESPONDENCE.

To the Editor of the JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION:

¶ The first article in THE JOURNAL for Feb. 25 causes me to make one more effort to set the profession right on the subject of "Drunkenness."

Webster is cited as authority on the meaning of the words—law and drunkenness, but it would take a very learned man to distinguish the difference Webster makes in the meaning of the two words, drunkenness and inebriety, and I do not think there is anything to be gained in quibbling over the question as to whether a man is a drunkard or an inebriate; and from a legal standpoint it is of no consequence. If there is ever a law passed for the protection of the drunkard in his many evil deeds, the same law will apply to the inebriate. The point to be settled is this: Is

the drunkard responsible for his crimes? I claim that he is now, and ought to be hereafter. I will state a few reasons why I think so. Every State in the Union gives men a legal right to drink intoxicants, and notwithstanding the many laws prohibiting the sale of intoxicants, not one law says that man shall not have the right to drink. This is evidence that the law making power concedes man the legal right to drink or not drink, as he may elect. The law is silent until the results of *too much drinking* are manifested. So soon as man begins to violate law, whether drunk or sober, the right to check him is upheld in all law abiding communities. Now if the government is a unit in the opinion that all men have a right to drink intoxicants, how can it consistently say that a man shall not be held responsible when he violates this right and privilege by drinking *too much*. It is evident that the crime is not in the act of drinking (all men have a right to drink) but of drinking *too much*. I now venture the assertion that there is not a drunkard on the face of the globe that does not know that *too much whiskey* will make him drunk. And he further knows that if he takes this *too much whiskey* (in this country) he will likely get into trouble. Now apply this knowledge to any other species of crime, and see whether or not it is consistent to let the transgressor go free and unpunished.

Now, about drunkenness as a disease. If drunkenness is a disease when does it become so? How are you to know the victims? Is a man a drunkard *before* or *after* he drinks *too much*? I believe that the law will say that the drunkard is such only *after drinking too much*. I know that some learned men say that drunkenness is a hereditary disease, but this, if true, would only complicate matters. Let me show you some of the results that would happen if the law making powers should conclude that drunkenness is a hereditary disease, and not a vice. Every drunkard in the land would go unpunished; every criminal would plead disease as an excuse for crime. If he had been living soberly, he would claim that he had the disease in his blood, that his grandparents were drunkards; and most every man could prove that such was the case. How few men can boast of an ancestry clear of drunkenness? No, sir; this fad won't go. Drunkenness is a vice. The Bible defines it as such. Christianity teaches it and has taught it from the time of the apostles up to date.

The precedent that drunkenness is a legitimate excuse for crime would ruin any people that adopt it. It is contrary to reason, contrary to right, contrary to the Bible, contrary to God's established law, and lawyers and doctors should be the last men to say, let the drunkard go unpunished. I know that many drunkards become insane, but the law should make a very marked distinction between the two troubles. One, drunkenness, is a voluntary act, insanity cannot be helped. The law heretofore has been able to distinguish one from the other, and the physician who tries to make them identical is an ass. Without intoxicants it would be impossible to create drunkards, but the country has plenty of insane people who are in no sense, drunkards. This is enough to show the differentiation. Drunkenness is the result of too much intoxicants. Insanity is a result of a diseased brain. But why labor to prove established facts.

W. P. HOWLE, M.D.

Oran, Mo.

To the Editor of the JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION:

Dear Sir:—It has this day been my privilege to examine a most marvelous instance of human physical precocity. The subject is a boy, Charles Edward by name, who was born unto Mitchell and Mary Jane Paulk, who farm for a livelihood in Irwin county of this State, on the 24th day of

November, 1888, and is now four years and three months old. He measures around the chest, 29 $\frac{1}{2}$ inches, shoulders, 37; waist, 30; hips, 34; is four feet, three inches high, and weighs 90 lbs. The hair under the arms and over the pubes, and the genitals are as fully developed as those of the average adult. There is neither mental precocity nor imbecility. There are 20 deciduous or milk teeth, and he has a splendid bass voice. There was nothing unusual at birth, at which time he is supposed by the parents to have weighed about eight pounds. The father weighs 189 pounds, the mother 110 pounds, and there are three other children of natural proportions in good health. This is a case having but few parallels in history—notably, that described by Mr. Dawkes, a surgeon at St. Ives; the boy of "Salamus," mentioned by Pliny, and that seen by Craterus, who was in the short space of seven years, an infant, an adult, a father, an old man and a corpse. J. G. HOPKINS, M.D.

Thomasville, Ga., Feb. 23, 1893.

MISCELLANY.

THE ELEVENTH INTERNATIONAL CONGRESS OF MEDICINE

Will be held in Rome, September 24 to October 1, 1893. President, Prof. G. Baccelli, Rome; Treasurer, Prof. L. Pagliani, Rome; Secretary-General, Prof. E. Maragliano, Genoa.

The inauguration of the Eleventh International Congress will take place the 24th of September, in the presence of H. M. the King of Italy.

The work of the Congress will begin in the nineteen Sections on the morning of the 25th of September. It will be continued in accordance with the arrangements to be made and published both for the general sessions and the Sections. Some of the general sessions will be devoted to scientific addresses delivered by scientists of all nations.

LIST OF THE SERIES.

1. Anatomy; 2. Physiology; 3. General Pathology and Pathological Anatomy; 4. Pharmacology; 5. Internal Medicine; 6. Diseases of Children; 7. Psychiatry, Neuropathology and Criminal Anthropology; 8. Surgery and Orthopedy; 9. Obstetrics and Gynecology; 10. Laryngology; 11. Otolaryngology; 12. Ophthalmology; 13. Odontology; 14. Military Medicine and Surgery; 15. Hygiene; 16. Sanitary Engineering; 17. Dermatology and Syphilology; 18. Forensic Medicine; 19. Hydrology and Climatology.

REGULATIONS.

1. The Eleventh International Congress of Medicine will be inaugurated in Rome, on the 24th of September, 1893, and will close on the 1st of October.

2. Any physician may become an active member of the Congress by fulfilling the conditions of membership, inscribing his name, and securing his admission ticket.

3. Scientists of other professions who, through their special studies, are interested in the labors of the Congress, may acquire the rights and assume the duties of active members, and participate in the work of the Congress, both by communication and discussion.

4. The fee for admission to the Congress is twenty-five francs, or five dollars.¹ It entitles to a copy of the Transactions of the Congress, which will be forwarded to the members immediately after publication.

5. The character of the Congress is strictly and exclusively scientific.

6. The work of the Congress will be divided amongst nineteen Sections; every member is requested to indicate, on paying his admission fee, the Section for which he desires to be inscribed.

7. The provisional committee will arrange the appointment, in the opening session, of the permanent officers. There will be a president, three vice-presidents, a number of honorary presidents and secretaries. Each Section will elect, in its first meeting, its President and a certain number of honorary presidents, who shall alternately take the chair during the session. Some of the secretaries will be

chosen from among the foreign members, in order to facilitate the recording both of communications and of discussions in the different languages.

8. There will be daily sessions, either general or sectional. The times and numbers of the general sessions, and the business to be transacted in them, will be arranged by the President of the Congress.

9. The general sessions are reserved, *a*, for the consideration of the common work of the Congress and its common interests; *b*, for addresses and communications of general interest and importance.

10. The addresses in the general sessions, and in such extraordinary sessions as may be arranged, will be delivered by members chosen by the committee for the purpose.

11. Papers for and communications to the Congress must be announced on or before June 30, 1893. A brief abstract of every paper and communication, with their conclusions, must be sent to the committee on or before July 31. All of them will be printed and distributed to the members by authority of the president. Such as arrive after that date cannot be expected to find a place on the regular order of business, and will be accepted only if time will permit.

12. The business of the Sections will be arranged by their presidents, who will also determine the hours of meeting, avoiding those reserved for the general sessions. Two or more Sections may hold joint meetings with the consent of their presidents. There will be no vote on scientific questions.

13. Fifteen minutes are allowed for the reading of a paper or communication. In the discussion every speaker can have the floor but once, and for five minutes only. To close the discussion the author of the paper is allowed ten minutes. Additional time may be given him by the president, by special resolution of the Section, if the importance of the subject under discussion appear to require it.

14. The manuscript of all addresses, papers and communications read either before a general session or a Section must be handed to the Secretary before the close of the meeting. A special committee on publication, appointed by the president, will decide which or what part of them shall be published in the Transactions of the Congress. Such members as participate in the discussions are required to hand to the Secretaries their remarks in writing.

15. The official languages of the sessions are, Italian, French, English and German. The regulations, programs and daily bulletins will be published in the above four languages. During the meetings, however, a member may be permitted to use for a brief remark, any other language, provided some member present expresses his willingness to translate such remarks into any of the official languages.

16. The president directs the discussions according to the parliamentary rules generally obeyed in similar assemblies.

17. Persons not classified under Article 3, who are interested in the labors of a special section, may be admitted by the president of the Congress. They will receive a special ticket on paying their admission fee; will not be entitled to a copy of the Transactions; and cannot speak in the general sessions nor in any section other than that for which they were inscribed.

18. The president may invite or admit students of medicine to attend and to listen. They will be given a special admission ticket, free of charge.

GENERAL INFORMATION.

Journeys and Reduction of Fares.—The provisional committee has made arrangements with the different Italian and foreign railway and navigation companies, in pursuance whereof special reduced prices have been granted on the steamers and railways of this country and of the countries which the members of Congress are to traverse.

In Italy the members will find tickets for round trips, starting from Rome; they will thereby be enabled to visit the most important cities and the various universities. In regard to this, further notice will be given.

The Ladies of the Members will be furnished ladies' tickets, which will entitle them to the reduced fares granted to the members, and to participate in the festivities connected with the Congress.

Festivities.—Besides the receptions which the kind and hospitable citizens of Rome will offer to the members, the Italian colleagues will endeavor to return to the best of their power, the kindness they experienced during their stay abroad.

On some evening yet to be decided, the members of the different sections will join at a dinner which will be given in one of the first hotels of Rome.

¹ Money order to the Treasurer, Professor Comm. L. Pagliani, Rome, Italy.

The Italian physicians have formed special committees to show the most hearty and kindly hospitality towards the foreign colleagues.

International Exhibition of Medicine and Hygiene.—On the occasion of the Eleventh International Medical Congress, an Exhibition of Medicine and Hygiene will be inaugurated in Rome, which will gather all that may practically interest physicians and specialists. A special committee has already insured the coöperation of all the most important manufacturers of the world.

Hotels.—All the first and second-class hotels of the Italian capital will afford to the members, during their stay, all desirable comforts.

THE TRI-STATE MEDICAL SOCIETY OF IOWA, ILLINOIS AND MISSOURI will meet in Keokuk, Ia., Tuesday and Wednesday, April 4 and 5, 1893. Following is the program:

1. A New and Rapid Method of removing the Uterus, with Specimens, Emory Lanphear, M.D., Kansas City, Mo.
 2. Professional Secrets, W. R. Allison, M.D., Peoria, Ill.
 3. Cardiac Stimulants, W. H. McGaw, M.D., Swedesburg, Ia.
 4. Treatment of Uterine Fibroids, J. H. Buehler, M.D., Revere, Mo.
 5. Sanitary Science vs. Epidemics, Geo. P. Neal, M.D., Ft. Madison, Ia.
 6. Some Gall-Stone Cases, J. F. Keeper, M.D., Sterling, Ill.
 7. J. M. Shaffer, M.D., Keokuk, Ia., subject not announced.
 8. Cerebro-Spinal Meningitis, J. A. Schreck, M.D., Cameron, Ill.
 9. Cystitis, with Post-mortem Specimen, R. L. Murdy, M.D., West Grove, Ia.
 10. Ellen H. Heise, M.D., Canton, Ill, subject not announced.
 11. Bacteriological Diagnosis, Conrad Meyer, M.D., Keokuk, Ia.
 12. Observations in a recent Epidemic of Typhoid Fever, A. J. Baxter, M.D., Astoria, Ill.
 13. Some Accidents in Parturition, J. W. Holland, M.D., Osceola, Ia.
 14. Impetigo Contagiosa following Vaccination, Louis Becker, M.D., Knoxville, Ill.
 15. H. C. Eshbach, M.D., Albia, Ia., subject not announced.
 16. Fractures of Long Bones, John I. Skelly, M.D., Pekin, Ill.
 17. Puerperal Fever, C. C. Heady, M.D., Bloomfield, Ia.
 18. Amputation above the Hip Joint, E. J. Blair, M.D., Monmouth, Ill.
 19. M. S. Marcy, M.D., Keokuk, Ia., subject not announced.
 20. a—Treatment of Intra-cranial Lesions; b—Demonstration of Intestinal Anastomosis by Murphy's Buttons, C. E. Ruth, M.D., Keokuk, Ia.
 21. Bacteriology of Female Genital Tract, O. B. Will, M.D., Peoria, Ill.
 22. Mercuric Intoxication, J. Fred. Clarke, M.D., Fairfield, Ia.
 23. Epilepsy, Charles W. Hall, M.D., Kewanee, Ill.
 24. L. B. Ryan, M.D., Galesburg, Ill., subject not announced.
 25. The Rubber Bulb as an Aid in Intestinal Surgery, Francis Reder, M.D., Hannibal, Mo.
 26. Localization in Diseases of the Spinal Cord, Frank Norbury, M.D., Jacksonville Ill.
 27. Lecture; subject not announced, Woods Hutchinson, M.D., Des Moines, Ia.
 28. Prostitution, its Cause and the Relation of the Medical Profession to its Abolishment, J. F. Percy, M.D. Galesburg, Ill.
 29. Cancer of the Cæcum, W. B. Sisson, M.D., Kahoka, Mo.
 30. George Edward Marshall, A.M., M.D., Keokuk, Ia., subject not announced.
 31. W. E. H. Bondurant, M.D., Downing, Mo., subject not announced.
 32. Hints on Treatment of Typhoid Fever, S. K. Davis, M.D., Libertyville, Ia.
 33. Removal of a Foreign Body from the Larynx, W. B. Maddox, M.D., Montrose, Ia.
- W. H. MARTIN, M.D.,
President.
- J. M. BALL, M.D.,
Secretary.

SECTION OF LARYNGOLOGY AND OTOTOLOGY.—The Section of Laryngology and Otology, which is now to be counted among the most flourishing and productive of the Association, promises another strong program for the Milwaukee meeting. Papers are announced by: E. L. Shurley, Detroit;

C. H. Knight, N. Y.; H. Knapp, N. Y.; D. B. Delevan, N. Y.; Leartus Conner, Detroit; Alexander Randall, Philadelphia; C. W. Richardson, Washington, D. C.; F. Crossfield, Hartford; Normal H. Pierce, Chicago; George Williamson, Omaha; H. C. Heath, Indianapolis; E. Cutter, N. Y.; C. H. Burnett, N. Y.; Holbrook Curtis, N. Y.; W. H. Dale, Pittsburgh; E. Fletcher Ingals, Chicago; Lucien Howe, Buffalo; S. C. Miner, Detroit; A. B. Thrasher, Cincinnati; D. S. Campbell, Detroit; Don M. Campbell, Detroit; S. McCuen Smith, Philadelphia; A. J. Erwin, Mansfield; S. G. Labney, Louisville, and others.

To participate in the discussions are: Drs. W. E. Casselberry, Chicago; Samuel Sexton, N. Y.; Dr. Reeves, Toronto; Dr. Brown, Toronto, and others. Members of the American Medical Association, who desire to contribute, and others who have been invited to do so, are requested to send the title of their papers before May 1, to the Section Secretary, Dr. J. E. Boylan, 113 Broadway, Cincinnati, in order that they may appear in the preliminary list.

PAN-AMERICAN MEDICAL CONGRESS.—SECTION ON HYGIENE, CLIMATOLOGY AND DEMOGRAPHY.—Persons proposing to present papers before this section are requested to communicate with either of the undersigned *immediately*, that the subjects may be properly classified for the program of the proceedings of the Congress. The only limitation as to subject matter is that it shall have a sanitary climatological or statistical bearing. Members of the Section on State Medicine of the American Medical Association, of the American Public Health Association, the American Climatological Association, the American Academy of Medicine, and of State and Municipal Boards of Health, are especially invited to contribute the results of their several experiences. The authorized languages of the Congress being Spanish, Portuguese, French and English, papers may be presented in either, to be translated in the others, for which reason their text should be in the hands of the secretaries at the earliest possible date. Peter H. Bryce, M.D., Secretary, (English) Toronto, Canada; Pedro José Salicrup, M.D., Secretary (Spanish), 129 East 12th Street, New York City. Albert Gihon, M.D., President, 145 East 21st Street, New York City.

SECTION ON MEDICAL PEDAGOGICS.—The Pedagogic Section will devote its attention especially to the history of the development of medical education in America.

In the papers presented by leading teachers, recent advances in methods of instruction will be considered.

The *art of teaching*, which is regarded as a study of great interest in other branches of learning, has received hitherto but little attention from the medical profession.

The Section on Medical Pedagogics will therefore be made a prominent feature of the Congress and it is hoped that those interested in medical education will coöperate in the work of this Section by being present, and by actively engaging in the discussion of subjects presented.

Any inquiries or communications may be made through the secretaries. J. Collins Warren, M.D., Executive President, Boston, Mass. Charles L. Scudder, M.D., English speaking Secretary, Boston, Mass.; Wm. F. Hutchinson, M.D., Spanish speaking Secretary, Providence, R. I.

OFFICIAL LIST OF CHANGES in the Stations and Duties of Officers Serving in the Medical Department, U. S. Army, from February 25, 1893, to March 3, 1893.

Major Edward B. Moseley, Surgeon, now on duty in Washington, will report in person to the Surgeon-General of the Army for duty in his office, as soon as Major Robert M. O'Reilly, Surgeon, shall report for duty as attending surgeon in Washington. By direction of the Secretary of War.

Major Robert M. O'Reilly, Surgeon, the suspension of the order directing him to report for duty as attending surgeon in Washington is, by direction of the Secretary of War, removed.

Major Robert M. O'Reilly, Surgeon, having reported to the Major General commanding the Army, is assigned to duty as attending surgeon in Washington, to date from February 28, 1893.

Major John H. Bartholf, Surgeon U. S. A., is granted leave of absence for six months, to take effect March 13, 1893, with permission to go beyond sea.

ORIGINAL ARTICLES.

A CONTRIBUTION TO THE STUDY OF CHOREA LARYNGIS.

BY W. PEYRE PORCHER, M.D.,

OF CHARLESTON, S. C.

Lecturer on Laryngology and Rhinology and on Materia Medica and Therapeutics in the Charleston Medical School. Visiting Laryngologist to the City Hospital, Charleston, S. C. Formerly lecturer on Laryngology and Rhinology and on Materia Medica and Therapeutics in the Medical College of the State of South Carolina, etc., etc.

The Hippocratic maxim, "naturam morborum curationes ostendunt," the cure shows the nature of the disease applies with more force, perhaps, to the study of chorea laryngis than anything in the whole field of medicine, for so erratic and inexplicable are the movements of the larynx and so hidden are the causes of the disease, that the most skilled pathologist or diagnostician finds himself at a loss to account for them.

Of the twenty-six cases already reported all but two have been followed by insensibility, but as this occurs so frequently after violent paroxysms of cough it cannot be regarded as a diagnostic symptom. The fact that not only may the choreic movements of the larynx exist without insensibility following them, and even that the cough also may be absent, makes it exceedingly difficult to classify any case as coming directly under this head, unless all the symptoms are considered as a whole, together with the general neurotic tendency of the family, etc.

In the *Medical News* of Philadelphia, March 19, 1892, Dr. W. C. Phillips, writes, "Of the various neuroses of the larynx, none is so rare or so unique in characteristics as that described as 'laryngeal vertigo,' 'laryngeal epilepsy' and 'complete glottic spasm in adults.'" So few cases of this affection have been reported that it would seem to be the duty of observers to report such cases as may come under their care, and for this reason I take occasion to add another to the list."

The case reported by Dr. Phillips, was accompanied by loss of consciousness after each attack of coughing, but Knight, McBride and others do not consider loss of consciousness as an essential feature to the disease. In fact two cases have been reported in which there was no cough, or loss of consciousness.

The history and nomenclature of the affection have already been so fully and ably discussed by others that no further elaboration is needed at my hands. I will therefore proceed at once with the report of the two most interesting cases which have so far come under my observation. In neither was there any insensibility at any time present and the second case was not even characterized by the complete closure of the glottis which existed in the first.

It was however, impossible to classify either case as anything but pure laryngeal chorea.

The treatment pursued in both cases was necessarily as varied as the symptoms themselves, for that which proved most effective in the first case was of but little benefit in the second. There were only three points which were common to both cases, viz.: the general chorea and neurotic element present, the violent and exhausting paroxysms of cough and the fact that in both cases treatment directed to the nose and naso-pharynx was of more benefit than that applied to the larynx or anything given internally.

The first case was that of a spinster aged about 40, white. She was of a neurotic temperament with a very anæmic complexion. For several years past she has been subject to sudden attacks of closure of the glottis, lasting for several seconds, preceded by a violent cough and recurring at varying intervals, especially during the winter. As she describes it, "she was rendered speechless but not insensible." She had many years ago been subject to a very severe nervous strain, having witnessed the sudden and fearful death of a near relative, since which time she has had but little control over her nerves. She was especially liable to take cold and of course her symptoms were aggravated at that time. Her sight and hearing were good. She had no aural vertigo nor any stupor or mental confusion. The heart's action was sound but inclined to be weak. There was no perceptible disease of the lungs. The posterior turbinated bodies were somewhat hypertrophied, and the larynx and pharynx were very pale with profuse discharge of mucus from which she constantly endeavored to rid herself by clearing her throat. Her menstrual functions had been exceedingly irregular, months frequently passing without any return of them. She had no special diathesis except perhaps a slight malarial cachexia.

The laryngeal spasm was so annoying that she was obliged to take her meals in private, for fear that the excitement from the presence of others would bring on a paroxysm of coughing and a return of the spasm. There was no stupor or insensibility of any kind following these attacks. To test the paræsthesia of the larynx, however, on her first visit to me, I passed a probe armed with a pledget of cotton into the naso-pharynx; instantly there was a spasmodic closure of the glottis and the patient lost her breath completely, her face became livid, and several seconds elapsed before she was able to regain her breath. The uvula being somewhat elongated, I first removed a portion of it, and then began a series of manipulations in the naso-pharynx, as advised by Lenox Browne, "that the treatment should be directed rather to the pharynx than to the larynx." A solution of argentic nit. alternated with the glycerine iodine, and iodide of potash solution was applied to the naso-pharynx every other day. Sulph. of codeia, grs. $\frac{3}{4}$, dissolved in alcohol and simple syrup was given her at night and repeated pro re nata, and the following spray was ordered to be inhaled every time the cough began, viz.: R. eucalyptol, oil pipsisewa, aa grs. ii; menthol, grs. iv; benzoinol, ounces iv. At the end of about a month she reported a complete cessation of the spasms and stopped treatment. At that time I could make any application to the naso-pharynx without exciting the slightest spasm of the glottis, and this freedom from spasm continued for perhaps two years, during which time she had no return of it of sufficient severity to cause her to apply for treatment again.

At the expiration of that time, however, she was brought back by her attending physician, and she then stated that she had had a violent and continu-

ous cough, all during her waking moments, for three months previous but not accompanied either by the spasm or any loss of consciousness. Her behavior proved the accuracy of this statement for she coughed so incessantly during her visit to me that she could only with difficulty describe her case. Her physician stated that he had tried every form of cough mixture, anodyne, etc., without avail. Anticipating that it might be due to some reflex irritation from the gastro intestinal tract, I ordered a mercurial cathartic, to be followed by the sulph. of codeia and inhalation as before, and I was myself surprised, as well as her friend, at the rapidity which her cough was checked. At her next visit on the third day, she reported that the cough had almost entirely left her, and the change for the better was extremely noticeable. In a recent note she informs me that she has had occasional returns of the cough during the winter but none of the spasmodic attacks, then or since, and adds "that the cough was finally paralyzed by the sulph. of codeia which her family physician advised her to take in the form of a powder three times a day, and that she is now enjoying a respite which she hopes will never cease."

Case 2.—Like the first, this was a case of chorea laryngis with paroxysmal cough. It was superinduced upon an attack of pernicious anaemia, but the symptoms of prolonged closure of the glottis followed by insensibility were both absent.

The patient was a maiden lady aged about 35, white. She had had a persistent cough for several years past. She had also one or more attacks of malaria which finally culminated in a severe attack of pernicious anaemia. She was exceedingly pale, eyes large and easily suffused. The violence of the paroxysms of cough had increased greatly during the last few months previous to her coming to me, and she was correspondingly weakened and prostrated after them.

Her family history was phthisical, having lost a sister from that disease. She had no heart disease, nor was there any perceptible derangement of the lungs and bronchi. The mucous membrane of the larynx and pharynx was very pale and exceedingly sensitive to irritation, and there was considerable engorgement of the tonsillar tissue and vessels at the base of the tongue.

The mucous membrane of the nose partook of the general condition: The middle turbinate on the right side was hypertrophied and pressure upon it by a probe would immediately set up a paroxysm of coughing. Referring to my notes on the case, I find that treatment for the first two or three weeks was without avail and during this time many things were tried. She was given large doses of syrup of ferri iod. Fowler's sol. of absenic, sulph. of codeia, etc., internally; and locally anodyne inhalations and applications of various astringents and pigments were made; among which was a solution of fld. ext. krameria, sulpho carbonate of zinc, and eucalyptol, as advised by Dr. Roe of Rochester, N. Y., and the tonsillar tissue of the base of the tongue was thoroughly cauterized with the galvano-caustic needle. Very little benefit was derived from all this except that she seemed to think that the character of the cough had, to a certain extent, changed. I then noticed that after using a 10 per cent. spray of cocaine in the nose, which I did in order to facilitate examination, that although her voice would become decidedly hoarse, her cough would be distinctly lessened while the effect of the cocaine lasted she was therefore given a 4 per cent. spray of cocaine to be used in the nose during the paroxysms of cough and the right middle turbinate was cauterized with the galvano cautery. The effect was marked and satisfactory. The cough was materially lessened and the patient's general health greatly improved. This improvement continued for about two weeks, when I was obliged to leave the city for a short time and a relapse occurred. The cough and incessant clearing of the throat returned with almost the same severity as at first, and the patient complained very much of the weakness following the attacks. She was then ordered ferri carb. precipitata, grs. xv. between meals, sulp. codeia grs. $\frac{3}{4}$ to 1, at night, and the middle turbinate and lingual varix were cauterized. Improvement has again taken place, the

cough has greatly diminished and the patient's recovery is now assured.

It will be noticed in both of these cases that the treatment from which most benefit arrived, was directed rather to the upper than the lower respiratory tract. In the second case the effect of cocaine in the nose is of especial interest, as most writers, notably Drs. Roe, Major, and others, agree that cocaine, when sprayed into the larynx, is rather injurious than otherwise. The patient herself thinks that the cocaine spray had a better effect than anything else that was used, and so stated to me.

Further comment on these cases is perhaps unnecessary, but it is interesting to note that in spite of the general chorea, the disease affecting the larynx was undoubtedly purely reflex, as proven by the treatment—which only succeeded in the second case after I had experimented with almost every method of treatment which has, so far, been recommended, that I am aware of. At one time this patient and myself had almost become discouraged; she at having taken so much medicine without avail and I at having almost exhausted the pharmacopœia, and it was only by repeated assurances that her recovery was both possible and probable that I persuaded her to submit to further treatment. The discovery was then made of the influence of cocaine and cauterization in the nose, and it finally resulted, in the cure of the case.

4 George Street.

THE EXTERNAL TREATMENT OF ACUTE VESICULAR ECZEMA.

Read in the Section of Dermatology and Syphilography, at the Forty-third Annual Meeting of the American Medical Association, held at Detroit, Mich., June, 1892.

BY LOUIS A. DUHRING, M.D.,

PROFESSOR OF SKIN DISEASES, UNIVERSITY OF PENNSYLVANIA.

There is no cutaneous disease in the acute stage that the general practitioner is called upon to treat more frequently than eczema. In one variety or another in its earliest manifestations he is continually meeting with it, inasmuch as it falls to his lot rather than to that of the specialist. The latter, in private practice at least, seldom has the opportunity of observing the disease in the first stage, and rarely until some application, soothing or irritating, has been employed. Frequently it is the latter kind of remedy that has been applied, thus augmenting the already actively inflamed cutaneous surface, increasing cell proliferation and exudation, serous or plastic, as the case may be. Such examples of acute eczema, undoubtedly aggravated by the application used, injudicious as to the remedy itself, or, as is often the case, as to the strength, frequently find their way to the specialist. It is with the view of directing the attention of the general practitioner to some of the remedies and formulas that I have found most useful in treating this stage of the disease that I beg to present the following remarks.

The subject in its several aspects is capable of such extension that in order not to consume too much time it will be necessary to exclude a great deal that might be touched upon. I will consider, therefore, one variety of the disease, acute vesicular eczema, the variety in which this disease frequently manifests itself as an acute eruption. It generally makes its appearance rather suddenly, and often spreads rapidly, in the course of a few days demanding

active treatment. A variable amount of itching and burning exists, which is usually severe, together with more or less erythema, vesiculation, or an open, excoriated surface, cutaneous oedema, and infiltration. Owing to the irresistible desire to scratch, the weak and seriously infiltrated epidermis is soon excoriated, and the disease thereby aggravated. It is just at this stage of the pathological process that so much can be done by local treatment to relieve the condition of congestion and cell proliferation, both of which usually gain force rapidly from day to day if permitted to pursue their course unchecked. There is no pathological process which runs a more rapid course, especially after the horny layer has been raised or detached. Now is the moment for suitable applications, and it is gratifying to note frequently how much may be accomplished in twenty-four hours towards arresting the process and in affording comparative ease to the patient. It is not essential for my purpose that the regions affected should be specified, nor does it matter whether the disease be confined to a small or a large area. In most cases, however, the eruption occupies considerable surface upon a given locality, as for example, the face, or one or both forearms, upon which the lesions may be either widely disseminated or in the form of patches. Sometimes large surfaces, as the abdomen and sides of the thorax, or the thighs are invaded.

The mode of applying the remedies selected is more important than most physicians are inclined to think. To the majority of skins it makes a vast difference whether an ointment or a lotion is used. Experience shows us every day that to some skins ointments are more acceptable than lotions, and *vice versa*. One may relieve, the other may aggravate. In other instances the firmer and more consistent pastes prove more serviceable than the salves. In the majority of cases they are decidedly more valuable than ointments, and consequently play an important part in the therapeutics of eczema. To say whether one or the other of these modes of application is indicated in a given case is, I believe, largely to be determined by experience, but even with this advantage the wrong mode may be selected. There are, however, some indications to which attention may be directed which may aid in deciding this question. Thus we find that in acute erythematous eczema, washes are generally tolerated better than salves, and pastes better than salves. In acute vesicular eczema, mildly stimulating washes followed by salves or pastes are usually more serviceable than washes alone. Salves alone, employed in the form of inunction, the popular method of applying them, are as a rule not beneficial. The general physique, complexion and nutrition of the patient, and especially the nutrition of the integument and its vascularity, together with the dryness or scalliness of the horny layer, should all be taken into consideration. Skins possessed of good nutrition and with a fairly healthy vascular tone, and fleshy subjects, do best under washes, while the thin, pale, anæmic skins generally improve under fatty applications in the form of pastes and salves. There is one point of practical importance in the use of applications of whatever kind they may be, and that is that in acute eczema they should never be rubbed in. Friction in this stage of the disease is always injurious. It is distinctly aggravating to the disease, and is to be

deprecated. This is an important principle to be remembered. Prescribe an ointment and commit it to the patient without explicit directions as to the mode of using it, and the chances are that it will be applied with more or less friction. Patients, even the most intelligent, require to be told precisely how to use the remedy ordered. The principles of the treatment should be explained to them. By friction the deranged skin is further stirred up, excited and irritated, when just the opposite effect is desired. The object to be attained by applications is to ease the congested capillaries of the skin by backing the fluids or keeping them as much as possible from the surface, and secondly to give relief to the irritated terminal nerve filaments supplying the germ layer of the epidermis and the papillary layer. The regulation, therefore, of the distribution of the blood and lymph, and a direct local sedative action upon the cutaneous nerve filaments, are the two most important effects to be striven for.

Having thus briefly alluded to the existing pathological condition and to the general principle involved in the treatment, reference may be made to some of the remedies, and, what is of great importance, to the formulæ. I shall refer more particularly to those which are in common use and are obtainable in any drug store. The local therapeutics of diseases of the skin are to some extent influenced by the fashion of the day, as in the case of surgical dressings in general, but there are certain drugs and standard formulæ that will always remain in vogue. One of such remedies for acute vesicular eczema is the officinal black-wash, employed according to a certain method. It is to be diluted with one or two parts of lime water, to which a little alcohol or mucilage of tragacanth may be added, about a half-drachm to four ounces. This is used after the manner of an evaporating wash, dabbed lightly on the vesicular or oozing surface with the sediment for twenty or thirty minutes and then allowed to dry on the skin, when a layer of oxide of zinc ointment, thickly and evenly spread on soft cloths, is to be applied and bound on with a bandage. The manufactured, spread oxide of zinc muslin-salve, as devised by Unna, may also be employed, with the advantage of being accurately spread, and consequently neater and cleaner. The applications of wash and salve should be repeated three or four times in the twenty-four hours. Relief from the itching and burning is often experienced immediately, and in a day or two a decided subsidence of the symptoms may be looked for. This plan of treatment is one that I have employed in innumerable cases for many years past, both in hospital and private practice, and can be recommended as being both simple and efficacious. A saturated solution of boric acid, to which sometimes a few drops of alcohol or glycerine, or both, may be added, will also prove soothing in some cases, especially where the horny layer is macerated or wanting, leaving the germ layer exposed. In these cases, too, a weak resorcin wash may be prescribed, as follows:

R. Resorcin, ʒss-ʒj.
Glycerin, fʒss.
Aq. dest., fʒvj. ℞.

The strength of the resorcin it will be noted is weak,—five or ten grains to the ounce. Where the integrity of the horny layer is not much impaired, the strength may be increased, but as a rule the best

results are obtained with a weak strength. It is a remedy of value not only in acute but also in other stages of eczema, and in some other diseases, especially dry seborrhea of the scalp. As in the case of salicylic acid, the action of resorcin depends largely upon the strength employed. Both of these drugs, which have been in dermatological use for about ten years, possess two kinds of action, one soothing, when applied weak, the other stimulating or mildly caustic, and destructive to the epidermis when used strong. Salicylic acid, especially in the form of an ointment spread on cloths or a paste proves most beneficial in the strength of about ten grains to the ounce. It is, however, of more value in the subacute stage and in recurrences of the disease than in the first outbreak. The paste referred to has as a basis from two to four parts of oxide of zinc to four parts of petroleum.

Another formula, proposed by Lassar, consists of oxide of zinc and powdered starch each two drachms and four drachms of petroleum. Pastes of this kind, soft or stiff in consistence, according to the needs of the case, and simple or medicated, are especially useful as night dressings, but they may be employed with equal benefit through the day. For the face and hands, in order to overcome the objectionable white color of the zinc oxide, I have substituted a certain amount of calamine for the zinc, a drachm or two to the ounce. Pastes of this kind should be lightly smeared over the surface, so as to form a thin coating. They adhere to the skin satisfactorily, drying in more or less rapidly, according to their consistence. They should never be rubbed in with friction. In cases where fats are not tolerated by skin, good results may be obtained from the employment of a plasma, or basis-substance composed of tragacanth, glycerine and water, as has lately been brought forward by Prof. Pick, of Prague. I have experimented considerably with this plasma, made in various proportions, but usually employ the following formula: Tragacanth, 5 parts; glycerine, 2 parts; boiling water, 93 parts. Triturate the tragacanth until a smooth mass results, when the glycerine is added; a thin, jelly-like substance is obtained, which is spread easily over the skin and dries rapidly, forming a film or coating. As it tends to sour on being kept long, I usually add two per cent. of boric acid. With this plasma as a basis-substance may be incorporated for acute vesicular eczema, such drugs as oxide of zinc, calamine, litharge, and boric acid, in small quantities, in order not to make the preparation too stiff for satisfactory use. It possesses the advantage of being removable by washing, although if much zinc oxide, which is adhesive, be used, it adheres and is easily removed.

I desire also to call attention to a class of lotions containing in suspension powders, for the most part bland or soothing, which act favorably upon inflamed, vesiculating skins by the deposit excluding the air, and through the cooling effect of evaporation. A formula of this kind consists of prepared calamine, in fine powder, 3s; oxide of zinc, 3s; glycerine, xv; lime water, ʒiv. This is to be dabbed lightly on the skin for twenty or thirty minutes every few hours. Subnitrate of bismuth may be substituted for the calamine and zinc. To washes of this character other more active ingredients may sometimes be added with benefit, in all instances in weak strength. Thus, resorcin which is freely soluble in water, five

or ten grains to the ounce; the tincture of coal tar in the same strength or weaker; carbolic acid and ichthyol, both in similar strength, are all serviceable. But such remedies should be used tentatively, at first, for the skin often rebels against them, preferring the blander applications. Sulphate of zinc in solution, from a quarter of a grain to a grain to the ounce, either alone or with other lotions, as the calamine, sometime acts as a mild astringent and as a sedative. Similar in its action, though less caustic, is the compound zinc sulphide lotion, made as follows: Zinc sulphate and potassium sulphide, each from two to five grains; water, four ounces. This forms a light, white precipitate. The salts must be fresh and each mixed with a little water separately and then combined.

The protective and soothing ointments of most value are diachylon ointment, made with the finest olive oil and litharge, or with equal parts of diachylon plaster and petrolatum. The latter is an inferior ointment to the first for the purpose. Oxide of zinc and bismuth subnitrate, one and a half drachms to the ounce of lard or petrolatum are also grateful to the skin. Refrigerant salves are also acceptable at times. These, owing to the evaporation of water they contain, are often cooling. Examples of them are found in the numerous so-called cold cream ointments, all of which contain water. To all of these ointments as a basis various soothing and sedative substances, such as boric acid, carbolic acid salicylic acid may be incorporated with advantage. Bland dusting powders are sometimes of service in acute vesicular eczema, but my experience with them shows that they do not benefit so much as the modes of treatment already referred to. They are most useful following the application of soothing lotions. Medicated dusting powders are liable to irritate, notwithstanding the favorable reputation they possess. Cleansing agents more or less detergent, to remove crusts and scales, should be used cautiously, and in most cases are not called for, the effete material being removable more effectually and without irritation by lotions, pastes or salves. Plain water should be used as little as possible. Soaps, even the milder or neutral kinds are not well borne, and the same may be said of medicated soaps. Alkaline washes are usually irritating, and so are oils and glycerine. This latter substance extracts and absorbs moisture from the diseased and macerated epidermis and the papillary layer, and thus aggravates the disease.

A word may be said concerning the importance of rest and position, where the eruption occupies considerable surface or exists upon the extremities. The skin and especially the capillary circulation calls for rest and freedom from all possible sources of irritation. Motion or exercise of any kind that tends to draw the circulating fluids to the part is injurious and should be avoided. In the case of an extremity, the various local symptoms will be arrested more speedily by means of the remedies used if attention be paid to this point.

I have thus endeavored to sketch very briefly the principles which should govern the local treatment of the acute vesicular variety of this disease. The subject might readily be elaborated into a lengthy essay but the aim has rather been to put the essential matter into as few words as possible. The remedies and formulæ given are those in daily use in hospitals and private practice, and I think may be relied upon in suitable cases.

ONE YEAR'S WORK IN TUBAL AND OVARIAN LAPAROTOMIES. THIRTY-SEVEN CASES WITHOUT A DEATH.

BY FRANKLIN H. MARTIN M.D.,

Professor of Gynecology, Post-Graduate School, Chicago; Surgeon to Woman's Hospital; Chief of Staff and Gynecologist to Chicago Charity Hospital; Member of American Gynecological Society and Chicago Gynecological Society, etc.

Between August 1, 1891, and August 1, 1892, I performed thirty-seven laparotomies which involved the removal of the tubes or ovaries of one or both sides. Of these cases, seventeen were for pyosalpinx, one for tubal hematocoele, one for extra-uterine or tubal pregnancy, three for removal of appendages for fibroid, one removal of appendages for hysterio epilepsy, twelve ovariectomies for ovarian cysts, and one for solid ovarian tumors. These thirty-seven cases were operated upon without a death. Neither does this series of successes represent a lot with death at either end. Back of them, in May, 1892, was my last death in this kind of work, there being nine successful operations between it and this report, and four successful ones since August 1, the end of this report, making a gratifying, and not altogether usual series of fifty consecutive cases without a death. This report, however, deals alone with the year's work of thirty-seven cases.

A successful operator, like an orthodox Christian, should be a trinitarian. The parallel holds good to the extent that if he neglects one member of the trinity, he is as effectually lost as though he neglected all. The operator's trinity consists of, 1. Thorough preparation; 2. Thorough operating; 3. Thorough after-treatment.

PREPARATION.

I can speak only of the immediate preparation of a patient for an abdominal section. It must be taken for granted that the patient has been examined physically, and pronounced in a general way, in a condition for a severe operation.

Kidneys.—When a patient enters the hospital for an operation, the house physician gives orders to measure the urine passed in twenty-four hours. It is carefully examined by the house physician, chemically and microscopically. If, in this examination, the urine is found approximately normal in quantity, if it contains no albumen, pus, sugar or casts, preparations are commenced for the operation, and the day before it is to be performed the urine is submitted to a second examination. If at this time it passes muster, the patient is considered safe, as far as the kidneys are concerned, if they are carefully watched after the operation.

These precautions, however, have not always served me. I have had three cases in which albumen was not present before operating, which developed serious symptoms subsequently, proving that my preparatory examination of the secretion was at fault, and that in reality the patient had an undiscovered chronic nephritis when I operated, which was lying dormant, only to be roused into serious activity by the anæsthetic and shock of the operation. Through consultation with my friend, Dr. C. W. Purdy, in a few of these cases, I have learned that I am not safe until I have demonstrated the quantity of urea to be of the correct proportion, and also that valuable hints may be obtained by noting the arterial tension, etc.

Bowels.—In preparing patients for an ordinary laparotomy I begin preparations of the bowels two nights before the morning of the operation. The first point is to seek thorough emptying of the bowels throughout their entire length. The second point should be to render their contents thoroughly aseptic and the third point should be to impart to them a maximum tonicity.

The bowels are emptied by means of mercurials and salines. The first night of preparation of the bowels gr. vi of blue mass is given. The next morning at 6 A.M., 3i doses of each, citrate magnesia and sulphate magnesia, are given every hour until the bowels move, or feel as though they would move with the aid of a small enema. This ought to insure a thorough movement of the entire length of the intestinal canal. If the movements of the bowels are such, with the above treatment, to insure a thorough evacuation, and to start a free flow of bile, as indicated by the yellow glistening appearance of the stool, no further catharsis is necessary. The lower bowel should be thoroughly evacuated, however, by the employment of large enemas of soap and water, repeated four or five times during this second day of preparation. The last enema should be given late in the afternoon of this second day of preparation, if the operation is to be done the following morning, and the next morning if the operation is to be performed in the afternoon. The bowels are rendered aseptic by large doses of bismuth and salol. During the first and second days of preparation, gr. x of salol and gr. xx of subnitrate of bismuth should be given every six hours.

The bowels are stimulated by means of a carminative, an alcoholic stimulant and strychnine. The second day of operation, 1 drachm doses of tr. cardomons in 1 oz. of brandy are given every six hours. Strychnine is commenced three days before operation in $\frac{1}{40}$ gr. doses every eight hours, and gradually increased in quantity until $\frac{1}{20}$ gr. doses are given. The bowels should be kept in a thoroughly aseptic condition by feeding the patient a milk diet for two days before the operation.

External preparation of the patient.—The first day of the preparation the patient should receive a thorough general bath and then be placed in clean clothing and a clean bed. The abdomen should then be rubbed with a saturated solution of permanganate of potassium until it is of a uniform mahogany color. This should now be scrubbed off by means of a sponge or brush and the application of a saturated solution of oxalic acid. A green soap compress should now be bound on to the abdomen, this latter to remain all night. Vaginal douches of first soap and water, second, $\frac{1}{5000}$ bichloride solution, and third, plain sterilized water should be employed this first night. These should be repeated the night before the operation, and a last vaginal douche given immediately before the operation. The second night of preparation should begin with shaving of the abdomen and pubis, and should be followed by applying a bichloride compress. Immediately before the operation, after this compress is removed, the abdomen should be scrubbed with green soap and hot water, this to be followed with alcohol or ether, and covered with antiseptic towel until the incision is made.

The bladder should be evacuated by means of a catheter immediately before the operation.

Dress.—The patient is put into a long loose woolen night gown immediately after an operation, and is thoroughly covered, except the abdomen, with flannel blankets during the operation.

The room should be relieved of all superfluous furniture, thoroughly sealed and then fumigated by burning stick sulphur. The bed should be aseptic and provided with rubber sheet, draw sheets, etc.

OPERATION.

Assistants and nurses.—These participants, in a peritoneal section, should be required to take a general bath the night preceding the operation and to put on clean linen and underclothing. The hair should be included in the bath. Before entering the operating room, all heavy clothing should be removed and a clean white wash-suit substituted. The hands and forearms should be scrubbed for fifteen minutes in green soap and warm water, the water being changed frequently. The nails should be cut short and well cleaned. The hands should then be thoroughly scrubbed in $\frac{1}{1000}$ bichloride solution.

The instruments.—Silk ligatures and silkworm gut should be sterilized by boiling, steam or dry heat, and then placed in shallow trays on a small table to the right of the operator, and covered with sterilized water.

Operating room.—A steam or dry heat sterilizer containing dressings should be convenient to the nurse. Reservoirs of sterilized water, hot and cold, should be placed near the sponge table. A large glass irrigator should be at hand. The table with which the Trendelenburg position may be obtained is necessary, and should be placed in an advantageous position for light and assistants. The arrangements should be approximately as follows: The table near the centre of the room with head of patient toward the chief window. Anæsthetizer at head of patient. Operator on right of table (from head). Chief assistant and assistants opposite operator with the chief nearer the head of the table. The surgical nurse in charge of instruments at stand to right of operator. Nurse in charge at foot of table with sponge dish on small stand in reach of second assistant. Assistant nurse to her right, the latter to work sponges, and to attend to irrigator, sterilized water, etc. Superintending nurse without regular assignment ready for emergency. To left of operator, small table with sterilized solution for hands. Back of the assistants a similar table. Visiting physicians, admitted after everything is ready for the operation to begin, are arranged around the room out of reach of the operating corps or any concerned in the operation.

Operation.—I am suspicious of an operator who operates on time. The best operators are those who operate well in the smallest space of time; this implies that the best operators are slow operators. An abdominal incision should be a clean, true, unhaggled cut, so that accurate coaptation is possible. Cold sponges should be employed on the external incision in order to contract the capillary vessels and check their bleeding without the necessity of a forcep. Forceps should be employed, however, everywhere in abdominal surgery where their use will save blood, because, most of our old fashioned shock was caused by unnecessary loss of blood. Keep the operative field free from oozing points if possible, even at the loss of a little time. The peritoneum is best

opened between two catch forceps after being elevated so as to present a thin fold. After a small opening is made, the finger passed into the cavity should act as a guide upon which to complete the incision. The peritoneal edges should be attached to the integumentary edges by means of catch forceps, to prevent its subsequent peeling off from the abdominal walls by the manipulation. In all pelvic surgery of smaller tumors, the pelvis should at this point be elevated by means of the Trendelenburg table; the elevation being just sufficient to draw the bowels away from the field of operation, and to elevate the contents of the pelvis. Sterilized silk should be employed for any pedicle which it is safe to tie and drop. Catgut may be employed to close simple peritoneal rents. Means of securing pedicles in abdominal hysterectomy will not be discussed here further than to say that they should be secured externally, either in the abdominal incision or in the vagina. Where practicable, I prefer the latter.

Drainage should be employed in all cases where extensive enucleation has occurred, or where there is a slow venous oozing from separated adhesions. Drainage, in competent hands, never does harm, therefore, where there is the slightest doubt, it should be employed. It has saved many lives, and makes more comfortable those who might not have died without it, but who have been given the advantage of it.

After my operation is finished, the peritoneal cavity is flushed, if that procedure is considered necessary; then if there has been at the operation a process of enucleation, leaving of necessity slight oozing points, or in cases where ordinary adhesions have been separated, after drying the cavity as far as possible, I place in the cul-de-sac a glass drainage tube and pump out any remaining fluid. I next protect the abdominal contents from the abdominal wound with a large flat sponge, and insert the sutures, after which I again pump the drainage tube. If there is more than a drachm of bloody fluid, I leave tube in until the sutures are nearly all tied and the sponge removed; then I make a last trial of the tube. If the fluid amounts to $\frac{1}{2}$ drachm or more, and is bloody, I allow the tube to remain; if, on the contrary, the tube is nearly dry, or the contents is simply colored water, the result of the flushing, I remove the tube. Of course what has been done influences one in regard to drainage. I almost invariably drain after it has been necessary to flush. I believe the peritoneum is satisfied, to an extent, by the flushing, and will consequently neglect, in a degree, to absorb any remaining fluid. Experience seems to sustain that argument. Mikulicz drain is almost indispensable in a limited number of cases. Cavities may be packed with gauze which cannot be reached with a glass drainage tube. Hæmorrhages in cavities so packed will cease, when a glass drain would not avail. Operations are now possible with the Mikulicz drain which were impossible without it. The question about drainage is not, shall we drain? but how, and how often shall we drain?

To Prevent Intestinal Obstruction.—One in abdominal surgery is constantly watching the behavior of the intestines. They are our prominent point of attack in our preparatory treatment, they are our greatest source of anxiety during the operation, and upon their management after the operation much watchfulness is imposed. All of this anxiety is

caused by our desire (with the exception of care against wounding when operating) to prevent obstruction. It, therefore, is a point in the technique of this work to which discussion may profitably be directed.

The pathology of obstructions is well summed up by a recent valuable contribution on this subject by Dr. Ashton of Philadelphia, from which I quote.

"1. Adhesions between the intestines and raw surfaces.

(a) To an omental stump.

(b) To the edges of the vaginal wound following supra-pubic or vaginal hysterectomy.

(c) To a pedicle.

(d) To raw surfaces on the intestinal wall.

"2. Paralysis of the intestines.

"3. Local spasm of the intestines.

"4. Impacted feces.

"5. Bands of inflammatory lymph.

"6. Adhesions between coils of intestines or between the gut and neighboring parts, due to traumatic inflammation.

"7. Kinking or twisting of the intestines, due to faulty technique.

"8. Including the intestines within the loop of a suture of the abdominal wall, or between the edges of the abdominal incision.

"9. Slipping of a coil of intestine through a slit or an aperture.

Under the first head, "Adhesions between the intestines and raw surfaces," we must seek our remedy during and following the operation. Intestines should be handled and exposed as little as possible in order not to produce hyperæmia or denudation of their surfaces. An omental stump of any considerable size should be selveged by inverting its raw edges with a running catgut, or with ligature. When denudations of the pelvic or intestinal peritoneum cannot be reinforced by a superabundance in the neighborhood, care should be taken to carefully arrange the intestines in as near the normal position as possible. A pedicle of large size should be covered by securing over its end the peritoneal covering with a running stitch. Raw surfaces of any considerable size on the intestines should be covered with an omental graft, with the edges well secured. Paralysis of the intestines may be avoided by emptying them thoroughly previous to operation of all irritating matter (which may ferment and cause distention) by rendering the contents aseptic by means of bismuth and salol, and the employment of full doses of strychnia to act as a muscular tonic. Carminatives, such as wintergreen, cardomon, etc., may also be employed as antiseptics and muscular tonics. During the operation the intestines should not be handled or chilled, in order to avoid paralysis. After the operation, nourishment of a non-fermentive and easily absorbable nature should be employed. The bowels should be stimulated to easy action in order to keep them empty and avoid the beginning of distention, which soon lead to paralysis. An early movement of the bowels, or free passage of flatus, too, assures a normal disposition of the bowels as regards location. If they adhere after such time, it will be in an advantageous, not cramped position.

A flat sponge beneath the abdominal wound, after carefully spreading down the omentum and before the wound sutures are inserted, will avoid including an intestine within the loop of a suture, or between the edges of the abdominal wound.

When ventral fixation is practiced, great care should be exercised in disposing of the intestines in such a manner as to avoid their slipping through the opening left between the uterus and the abdominal wound.

Pelvic Suppuration.—I think the more one operates and becomes familiar with pelvic suppuration, the more one is inclined, in dealing with such cases, to go into the abdomen to unravel the tubes and ovaries, the invariable (with rare exception) seat of such suppuration, and to make a sure thing of the case by removing them. In other words, while most of us might open a pelvic abscess of long standing which is pointing low in the pelvis, through the vagina, and drain it, we are pretty certain, from our surgical experience in the abdomen, that the other side, entirely disconnected with the first, is also suppurating. At best, we have only temporized, and must finish up at some other time, or allow the woman to go on suffering. I must confess that I have never found pus in the pelvis that was not directly traceable to the fallopian tubes. Again, I must confess that I have rarely found pus in one fallopian tube that both did not contain it. Case six in my year's work was a notable exception to this. The right side only was infected the abscess being enucleated with great difficulty, involving apparently the head of the cecum. The source of the infection was undoubtedly the appendix vermiformis. That, of course, takes it out of the category of strictly pelvic suppuration.

It is a comparatively easy matter to enucleate a tubal abscess after a little practice. Where we find one tubal abscess, we are liable to find two. When we go at these abscesses through an abdominal wound we can remove both sources of pus together with its walls and secreting surfaces through one opening. When the abscesses are removed in this way, the case is at once put in a position to get absolutely well in as short a time as she can recover from a laparotomy—say four weeks.

It is a comparatively easy matter to incise an abscess which can be felt through the roof of the vagina. It is an easy matter, after the pus flows out and the opening is dilated, to put in a drainage tube and wash out the cavity. It may be an easy matter for a nurse to continue this washing-out process for several weeks or months. It may not be necessary in all cases for the drainage tube to be worn for a long time; but, in a large percentage of cases, drainage for a considerable time is required, while in a few cases it goes on forever. Now after all this, but one tube is drained unless two incisions have been made. This is not often likely to be the case, as one side is more liable to appear prominent than both. The case is left unfinished, therefore, or at least, uncertain.

With our present light, then, considering that the immediate mortality is about the same with either operation, I should most emphatically favor the abdominal operation for pelvic suppuration, except, possibly, in very rare instances. As to what those rare instances might be, I am not quite clear.

AFTER-TREATMENT.

Immediate treatment consists in stimulating the patient out of any tendency to nervous shock which may exist. She is placed in bed and surrounded with dry heat. If there has been any considerable

loss of blood, the feet may be elevated in order to restore normal blood pressure in the brain. In severe cases of shock from loss of blood, it is well to bandage the blood out of the lower extremities by means of elastic bandages. A saline solution under the integument may assist to fill the blood-vessels. Oftentimes the difficulty is not lack of fluids so much as lack of tone, which allows a patient to bleed to death, as some one has put it, "into her own dilated capillaries and venules!" Here direct arterial stimulants and vaso constrictor remedies are called for, as well as strong nerve stimulants. In these cases, I immediately order hypodermics of nitro-glycerine, strychnine and digitaline. Stimulating enemias of whisky and warm water may also be given. What is done for shock should be done promptly, as patients who are allowed to go on for a few hours with a sub-normal temperature and high pulse, are with great difficulty recovered.

Dressing Tube.—The drainage tube, when it is allowed to remain, should be dressed the first time in one hour. If the fluid is more than a drachm it should be dressed again in an hour, if a drachm or less, the interval between dressings should be increased one hour, and the same rule followed until the fluid is less than a drachm and of a light amber color, and the interval from four to six hours. At this time the tube may be removed. If the tube is left longer than thirty-six hours, it should be carefully washed out with warm sterilized water before removal, and a piece of sterilized gauze left in its place for six hours—when the latter is removed and the wound is closed with slight pressure, and its closure is obtained by extra pressure of external straps.

Dressings.—The wound is closed with silkworm gut and dusted with iodoform, and the dressing is a thick one of iodoform gauze held in place by adhesive straps tight enough to take the strain off the sutures without puckering the integument. Over this is placed a good allowance of absorbent cotton, and all retained with a binder.

The dressings are not disturbed for four days unless there is pain or temperature. At the end of the fourth day, the dressings are carefully removed, and the wound is thoroughly but carefully washed with equal parts of 95 per cent. alcohol and 1-5000 bichloride solution. Iodoform is again applied and the dressings renewed. The seventh day, before the stitches are removed, I again have the wound washed in the same manner and, after their removal, dressed as before.

Bowels.—If flatus has not passed freely per rectum in twenty-four hours by the simple employment of the rectal tube, I employ the "One, one, one" enema, —one oz. of sulphate of magnesia, one oz. glycerine, and one oz. water. If this does does not start the gas in two hours, I order it repeated in double quantities. If this enema is not retained, and flatus has not passed, I order an enema of soap and water one pint, with one-half drachm of turpentine. If they are still obdurate, I begin one-half grain doses of calomel in ten grains of bicarbonate of soda, given every two hours for four doses, or until gas passes, alternated with drachm doses each of gran. citrate of magnesia and sulphate of magnesia in an ounce of water. Following these remedies in one hour, another "One, one, one" enema is given. It must be an obstinate case indeed that will not yield under

the above remedies. If the stomach is irritable and will not tolerate the bicarbonate of soda, the calomel may be given dry on the tongue. Other salines may be substituted for the above if they are objectionable.

The bowels should be moved from above on the fifth day with small doses of some effervescent salt, or, if required, a more vigorous laxative.

Diet.—First week, fluids; second week, semi-solids; third week, semi-solid and solid food in small quantities; fourth week, good substantial food, with a few curtailments.

As soon as the patient is out of the anæsthetic, I begin to give hot water in teaspoonful doses as often as every fifteen minutes. If the stomach tolerates this, the quantity is increased to one-half ounce, and the interval may be increased in length. If the patient is nauseated and the hot water causes vomiting (and it should be hot water), or increases the nausea, it should be withheld. When the patient can take the hot water, and still complains of thirst and begs for cold water, the nurse is instructed to let her rinse her mouth with cold water. Ginger ale is a good alternate with water for the first twenty-four hours. After twelve hours, drachm doses of peptonized milk may be sandwiched with the water. If peptonized milk is offensive, plain sterilized milk may be substituted, or sterilized milk and lime water. Milk in some form, I feel to be the most perfect food. It should be increased every hour until 3ss. doses are given by twenty-four hours, to one ounce by forty-eight hours, and to two ounces by the end of sixty hours. Barley water may be alternated with the milk. Later, the monotony may be relieved with the meat and shell-fish broths, thin gruels, etc. The fourth or fifth day the patient may be allowed to extract the juice of broiled beef by chewing it; the fibre, of course, should be rejected. Tea may be given the second or third day as a relish. Orange juice, and the juice of other fruits, may be given in small quantities the third or fourth day. Rules cannot be laid down in regard to the diet of these patients, general principles only can be hinted at. The patient should be seen each day, and her wants studied. If stimulants are required, one of the best is good brandy. Champagne is all right if its sweetness does not make it objectionable. If patients are unable to retain enough by stomach to properly nourish them, enemias of either plain milk or stimulants should be resorted to.

Getting Up.—Uncomplicated cases are gradually bolstered up until they can sit in a bed with a bed-rest at about the fifteenth or sixteenth day, sit up in a large chair at the twenty-first day, and leave the hospital from the twenty-eighth to the fortieth day.

CASES.

Case 1.—Mrs. F., age 40, came to me suffering with uterine hæmorrhages because of uterine fibroids. The whole tumor, including the uterus was not more than a half larger than a normal uterus. The body of the uterus contained three distinct centers of development of small fibroids projecting into the peritoneal cavity. Electricity was employed on the case but without accomplishing more than a tonic effect because, undoubtedly, of the multiple development. Like all tumors of this sort, there was great suffering at the menstrual period, as well as during the intra-monthly period. The removal of the appendages was at last decided upon as being likely to give the best results with a minimum risk. August 26, 1891, the operation was performed at the Woman's Hospital. The woman made a slow but complete recovery and now, more than a year after the operation, is in perfect health.

Case 2.—Mrs. P., age 30, was referred to me by Dr. A. H. Burr, of this city, because of distressing pelvic trouble, accompanied with an enlargement in the left side. Her attacks of pain were periodic, and there was a history of one or two attacks of peritonitis. Specific infection was not altogether out of the question in the case. Laparotomy was agreed upon as the best method of getting at the real difficulty, and of removing it when it was revealed. She was taken to the Woman's Hospital, and the operation performed August 29, 1891. The incision revealed a cystic ovary on the right side as large as one's fist, with an enlarged and suppurating tube on the same side. The opposite tube was enlarged, suppurating and adherent. The recurrent peritonitis having been caused, without doubt, by leakage of the tube. The cyst of the right ovary had been conveyed by infection from its corresponding fallopian tube. The infection was undoubtedly gonorrhoeal. The patient made an ideal recovery, and is now a perfectly well woman.

Case 3.—Mrs. H., age 35, was referred to me because of a tumor developing in the left side. It had been noticed for a year. It was accompanied with considerable pain. She was sent to the Woman's Hospital, and was operated upon September 14, 1891. An ovarian cystoma the size of a large cocoon was removed from the left side, and the appendages of the right side, because of a small cyst of that ovary. The patient's recovery was perfect, without an untoward symptom.
