Carboniferous.	Permian?	Cutler.	Permian, Permo-Carboniferous, or Upper Carboniferous.		Shinarump group (all assigned to Triassic).
	Pennsylvanian.	Hermosa.	Middle Upper Carboniferous.		Aubrey.

All geologists who have examined the Mesozoic section of western Colorado have been impressed with the strong lithologic resemblance exhibited by several hundred feet of strata occurring immediately below the Dakota to the fresh-water Jurassic beds found along the eastern base of the Front Range and characterized by the wonderful dinosaurian fauna exploited by Marsh and others. With one exception to be considered below this lithologic similarity and the corresponding stratigraphic position have been considered sufficient to warrant the assignment of the western slope beds to the Jurassic.

The first to give a formation name to those strata was Eldridge, who called them the Gunnison formation. In the San Juan region it was found better to divide the Gunnison into the McElmo and La Plata formations, the former to include the alternating sandstones and variously colored marls and shales of the upper part of the section and the latter the heavy sandstones of the lower portion.

Before the McElmo beds were so named they had been studied in the Telluride quadrangle, at the head of San Miguel and Dolores Valley, and had been traced for some distance down each stream.

They are continuously exposed down the canyon of the former to the Dolores River and have a wide distribution in the Uncompahgre Plateau, about the La Sal Mountains and in the lower Dolores and the Grand River valleys. This is clearly stated by Peale in the report for 1875. * * *

The McElmo beds in characteristic development were seen by us in Dry Valley and on the eastern flanks of the La Sal Mountains, in Dolores Valley, and in many places on Uncompahgre Plateau, as far north as Unaweep Canyon. To the north from that locality Peale refers to the formation as maintaining the same general character. No representative of the marine Jurassic reported by Powell and others from Utah was observed by us.

Rumors of large bones, presumably in the McElmo beds, have come to my attention several times in recent years, but never with the exact locality named, and no trace of such remains has been found in the San Juan region.

The McElmo beds of Dry Valley are fossiliferous, locally at least, as proved by Newberry, who found saurian bones in place at about 500 feet below the Dakota in the southeastern branch of Dry Valley, named by him Cañon Pintado or Painted Canyon. From Newberry's description of the locality and our own observations of the Cañon Pintado from the mesa to the west, as well as on the route traversed through Dry Valley, it is certain that the saurian bones came from the McElmo. Newberry expressed no positive opinion as to the age of the bone-bearing horizon, but called it "Jurassic (?)" in his "General section of the valley of the Colorado."

The saurian bones found by Newberry were described by Cope as the type of *Dystrophæus viæmalæ*, and were said in positive but quite unwarrantable terms to have come from the Triassic, with no suggestion of the provisional assignment to the Jurassic by Newberry. Cope states that Newberry excavated the bones of *Dystrophæus* "from the red and green rocks usually referred to the Trias, hence from the same formation which yielded the *Typothorax* already described." The *Typothorax* in question was found in New Mexico with belodont crocodile and other forms, almost demonstrating that its horizon is the fossiliferous zone of the Dolores Triassic formation, the place of which in the Grand River section is nearly or quite 1,000 feet below the McElmo beds, as will be shown in a later section. Cope adds emphasis to his error as follows: "More than usual interest attaches to this fossil. It is the first one found in the Triassic beds of the Rocky Mountain region. * * * The rock is described by Prof. Newberry as the same as that which I have identified in New Mexico as the Trias and is of the usual red color." In harmony with the occurrence of *Dystrophæus viæmalæ* in the McElmo beds it has recently been pointed out by F. von Huene that its affinities are Jurassic rather than Triassic.

That the McElmo beds contain vertebrate fauna of the "Atlantasaurus beds" of Marsh has been demonstrated by Riggs, who discovered many dinosaurian remains in that formation near the junction of the Grand and Gunnison rivers at the northeastern base of the Uncompahgre Plateau. While this vertebrate fauna has not as yet been described, it is referred to by Riggs as clearly the same which characterizes the Jurassic beds of Wyoming and the eastern base of the Front Range in Colorado. It is said that "representatives of a single genus (*Morosaurus*) have been observed to range through the entire series," meaning a section some 500 or 600 feet in thickness below the Dakota. * * *

The term La Plata formation has been applied in the San Juan folios and other publications to the lower part of what Eldridge described as the Gunnison formation.

The La Plata consists of two massive sandstone members with an intermediate member of more thinly bedded sandstones and a variable amount of bluish fresh-water limestone. The sandstones are commonly not indurated, as in the Elk Mountains; instead they are rather friable and crumbling, although of homogeneous texture. Cross-bedding is a marked feature, and not infrequently a massive ledge as much as 100 feet in thickness has no prominent division planes. Of the two sandstone members the lower is commonly the thicker and much more massive than the upper. The latter is in fact occasionally thin bedded and shaly and may be inconspicuous.

The calcareous member is very variable in character. On the San Miguel River, in the Telluride quadrangle, it is in some places a pure massive blue-gray limestone in several beds and with almost no shale. Usually dark calcareous and bituminous shales and thin-bedded sandstones, with more or less of massive limestone, occur between the two main sandstones and sometimes reach a thickness of nearly 100 feet.

The total thickness of the La Plata formation varies, in the area we have examined, from about 100 feet in the Ouray and Telluride quadrangles to 500 or more in the La Plata Mountains, and it is known that to the west all members increase still further in thickness.

The sandstones are almost wholly quartzose, and their normal color adjacent to the San Juan Mountains is white or gray; but yellow, orange, or red tints have been observed in that region. The cement is often calcite.

In the Red Beds paper were given the observations of Spencer, who traced the La Plata sandstones to Paradox and Sinbad valleys, west of the Dolores, and of Gane, who followed them down the San Juan Valley to the Colorado Canyon. Both noted the prevalence of orange or pink color in the lower country.

On the strength of these observations and a study of literature it was concluded that "the La Plata formation is seemingly equivalent to the White Cliff sandstone. Its local assumption of red color has led to confusion with the Vermilion Cliff in certain districts and a reference to the Trias." This correlation is considered to be amply substantiated by the recent observations. * * *

The continuity of the La Plata sandstone from the San Juan Mountain flanks down the Dolores and San Miguel valleys, around the La Sal Mountains to Grand River valley, may be said to be perfectly plain and incontestable. In this distance the most notable change in the formation is its increased thickness. The massive texture and even grain of many strata, cross-bedding, variation in color, and other marked features are but emphasized by the greater volume. The intermediate strata are most variable in character, yet everywhere the two great massive sandstone members are separated by beds distinguishable through their thin bedding, darker color, and richness in calcareous cement or development of limestone.

From the district covered by our reconnaissance the ledges of gray, pink, or orange La Plata sandstone can be seen stretching to the west and south into the belt traversed by Green and Colorado rivers, where Powell has described the White Cliff sandstone. This great unit in the plateau country section was never described accurately nor in detail for any given locality, but there seems to be no ground for questioning the assertion of Powell that this formation is continuous with persistent characters from northeastern Utah to the great esplanade bordered by the White Cliffs in southern Utah, facing the Grand Canyon. The characters of the White Cliff repeatedly emphasized are its massiveness, "oblique lamination" or "false stratification," and its white, golden, orange, or light-red colors, which are so brilliant in the desert air.

The upper boundary of the White Cliff is the basal marine limestone of the Flaming Gorge group of Powell. The lower boundary is less clearly defined in the statements of Powell and others, but, with recognition of the stratigraphic break soon to be mentioned and the marked color line apparently everywhere present at the summit of the Triassic sandstones, it may be hoped that no great difficulties in drawing the base of the White Cliff will be experienced when the attempt is seriously made.

The far-reaching unconformity below the fresh-water Jurassic beds of central Colorado, by which they overlap all older Mesozoic and Paleozoic beds and in many places rest on the pre-Cambrian granites and schists, is well illustrated by the Hayden maps. This overlap is particularly well exhibited in the southern Elk Mountains and some of its details are shown in the Anthracite-Crested Butte folio.

The fact that no Paleozoic formations are present in the Uncompahgre Plateau was recognized by Peale and expressed on the Hayden map. If, however, the greater part of Peale's "Triassic" in that area be now referred to the La Plata Jurassic, as has been done in the preceding discussion, the question arises as to whether evidence of erosional unconformity between the La Plata and the underlying Dolores Triassic exists in that area or not. Our observations on this point were quite limited but tend to show that such a break does occur. It is certain that in the vicinity of the Unaweep Canyon the dark-red Triassic strata are much thinner than in the Dolores Valley to the west, and this decreased thickness appears to be principally due to erosion of the massive red sandstone forming the upper part of the Triassic.

On the north side of West Creek, which is the western stream flowing out of Unaweep Canyon, Messrs. Emmons and Kay found the La Plata to rest on granite near the shore line of the Permian (?) beds, which will be discussed in another part of this article. At the head of West Side Creek a few miles south of the Unaweep the pink La Plata sandstone rests on thin-bedded sandstones and shales belonging to the lower part of the Dolores formation, as shown by the presence of the fossiliferous "Saurian conglomerate." Near the head of Atkinson Creek on the western side of Uncompahgre Plateau, the La Plata seems to rest on gneiss. * * *

These facts and the evident variation in thickness of the massive Dolores sandstone, which we noticed at many places, seem to speak for a relation of the La Plata and Dolores very similar to that existing on the western and southwestern slopes of the San Juan Mountains. But much more careful observation is needed in the Uncompahgre Plateau to determine to what extent the absence or variable thickness of the Triassic beds is due to pre-La Plata erosion. Personally, I believe that the Triassic beds were originally deposited over the Uncompahgre Plateau and indeed all of western Colorado, and that they were in some places entirely removed by the erosion under discussion, but this view is not yet supported by enough evidence to warrant a positive assertion.

K 10. UPPER SACRAMENTO VALLEY, NORTHERN CALIFORNIA, AND SOUTHERN OREGON.

In northern California several minor but interesting occurrences of the Jurassic have been described by Diller.²⁷⁹ The Modin and Potem formations occur in the Redding quadrangle. The Modin consists of a basal conglomerate, followed by a succession of tuffaceous beds, which are overlain by gray shaly sandstones and shales with small limestone lentils. It rests unconformably upon the Triassic, and the tuffaceous beds include fragments of the underlying limestone and other older formations. The Potem formation consists of shale and thin-bedded sandstone with small limestone lentils, and it also includes some tuffaceous conglomerate. The thicknesses are stated by Diller at 3,000 feet for the Modin formation and probably several thousand feet for the Potem.

In the Taylorsville district, just north of the fortieth parallel, the Jurassic is represented by seven distinct formations. According to Diller ^{280a}—

The Trail formation is the oldest; then follow the Hardgrave sandstone, Thompson limestone, Mormon sandstone, Bicknell sandstone, Hinchman tuff, and Foreman formation in regular succession. With the exception of the last their surface distribution is limited to a comparatively small area about Mount Jura, and * * * it may be stated here that the whole set of beds have been overturned and that the Hardgrave sandstone apparently lies on top. * * *

The Trail formation includes a mass of strata composed largely of slaty shales with some interbedded sandstones and conglomerates. * * * The shales are often purplish or red but perhaps more frequently gray, with pencil structure locally developed, and contain in places numerous cherty nodules of carbonate of lime. Well-marked slaty structure is not uncommon. The sandstones are generally fine, often somewhat slaty, are thin-bedded, and vary from gray to almost black. The conglomerates of slate and sandstone pebbles, sometimes 3 inches in diameter, generally contain much volcanic material. Approaching the contact with the granodiorite in many places the fine sediments become darker and more compact, with conchoidal fracture, and pass into regular hornfels. * * * Some of the beds of tuff are well defined, ranging from 10 to 50 feet or more in thickness, and occasionally coarse. Tuffaceous conglomerates are most abundant on the side toward the Swearingen slate but extend throughout the formation, and a strip of 50 feet of slaty conglomerate occurs in the volcanics which bound the sediments on the northeast. * * * The thickness of the Trail formation was measured on the prominent spur next north of Hornfels Point descending into the sharp bend of Hosselkus Creek and found to be about 2,900 feet.

Undeterminable traces of plants and some small bivalves, possibly *Estheria*, but not any fossils which would determine its horizon, have been found in the Trail formation. It appears to be unconformable to the Swearingen slate, and thus to occupy essentially the same relative position as the Modin formation, at the base of the Jurassic sediments.

The Hardgrave sandstone is red or gray in color. It varies from fine shaly sandstone to conglomerate and is almost wholly of a tuffaceous character. The most common color is red, ranging from brick-red to dull brown, but much of it is gray, and the two colors are intermingled irregularly in the same bed. The bedding is generally well marked, but in a few localities the massive outcrops show little trace of stratification. Where the sediments are fine the sandstone passes into shale, which occasionally shows a decided slaty cleavage and breaks up into long, slender, pencil-shaped fragments. Generally the sandstone is so fine as not to appear granular and breaks with a splintery fracture. * * * When the coarser forms of Hardgrave sandstone are broken the fracture generally passes around the grains instead of through them, allowing them to stand in relief upon the fracture surface and make it rough. Rarely it is hard and flinty, much fractured, and veined. * * * Carbonate of lime is the principal cement, but in the red and weathered forms oxide of iron plays an important part. * * * Coarse gray sandstone and fine conglomerate are much less abundant than the finer forms. * * * [The material] is mainly volcanic sand, made up of crystal fragments of plagioclase feldspar with many lapilli, usually more or less vesicular, and often filled with minute lath-shaped crystals of feldspar, which are for the most part so altered that their polysynthetic twinning, if present, can not be seen. Many of the feldspar fragments are plagioclase, but a somewhat smaller number appear to be orthoclase and possibly some quartz. One of the striking features of this sandstone, apparent only on microscopic examination, is the paucity of quartz. * * * The maximum thickness of Hardgrave sandstone as measured half a mile north of Donnerwirth's may be 850 feet but is possibly much less.

According to Hyatt ^{280b} the Hardgrave sandstone contains many fossils having affinities with the lowest or infra Lias, and some which might even have occurred in the uppermost Triassic or Rhætic. Hyatt further says:

On the other hand, some forms have very close relations to the same genera as they appear in the Mormon sandstone, or Oolite, of the same locality. Pinna, Gervillia, Ctenostreon, Entolium, Trigonina, and Cidaris show an assemblage of upper Lias types. The species of Entolium and Ctenostreon are closely related to those of the oolite above, and one species of Trigonina resembles the young of a species from the Oolite of western Europe. The most conclusive evidence, however, is furnished by the single well-preserved specimen of Glyphea * * * and the Goniomya, allied to *G. v-scripta* Agassiz.

After giving a list of 28 species and discussing the significance of Glyphæa, Hyatt says:

Such forms as these and the evidently close alliance and probable continuity of the fauna through migration with that of the Mormon sandstone suggest that the Hardgrave sandstone should be classed as upper Lias in spite of the large number of forms which are represented by species occurring also in the lower and middle Lias in Europe.

Diller continues the description of the Jurassic strata as follows:

The Thompson limestone is gray and somewhat shaly, and on its weathered surface in places are round, oblong, or irregular patches of darker, more or less granular calcite, which at once suggests fossils, though their specific determination is a matter of difficulty. Where shaly it is generally red, highly argillaceous, and locally full of long, slender gastropods, which weather out and leave the porous argillaceous skeleton of the limestone full of "screw holes." * * * The relation of the Thompson limestone to the meta-andesite that bounds it upon the west may be clearly seen on the northern slope of Mount Jura, near the end of the lime road, where the red calcareous beds, full of slender gastropods, come into direct contact with the altered andesite. The fossils lie parallel to the surface of the volcanic rock, practically against it, without showing any alteration due to the presence of the igneous rock. This relation evidently indicates that the limestone was deposited upon the meta-andesite and is of later age. It has already been

shown that the same meta-andesite is younger than the Hardgrave sandstone. The general dip of the Thompson limestone is to the southwest beneath the meta-andesite by which it is bounded in that direction, and both pass beneath the Hardgrave sandstone. All have been overturned together.

Hyatt's comment on the age of the Thompson limestone, which he called the Opis bed, is as follows:

Mr. Diller's close and repeated investigations of the stratigraphy have placed the Opis bed below the Mormon sandstone in the chronologic series, and my studies, although they led me to incline to the opinion that the fauna was younger, have not succeeded in bringing to light any evidence that can be said to contradict his conclusions. The presence of a large form of *Nerinea* with the columella, showing the typical ridges of the normal forms of this group, indicates that this limestone is not older than the inferior Oolite, and if, as seems to be the case, it is older than the Mormon sandstone, it will probably be proved to be a member of the inferior Oolite.

A large species of Opis is as abundant in some places as the *Nerinea*, and this genus, which is recorded in Europe as beginning in the Trias, is usually small throughout the lower and middle Jura. The only European species approximating to that of this limestone is the *Opis paradoxa*, as figured by Buvignier, which occurs in the Corallian of the upper Jura. A species of *Terebratula*, apparently identical with the large characteristic species of the Mormon sandstone, also occurs abundantly in this bed. There are also a number of small gastropods and other fossils requiring further investigation.

The Mormon sandstone consists prevailingly of sandstone, passing on the one hand into conglomerate and on the other into more shaly beds. The most common and characteristic member is a gray compact sandstone so fine that to the naked eye it does not appear granular. Its color becomes brown on weathering and the rock frequently contains casts of a small *Rhynchonella*. Among the grains of which it is composed there are many of quartz and of feldspar, some of which is clear plagioclase with distinct twinning lamellæ. A few of pale-green augite, but most of them are of indefinite clouded material in which here and there small lath-shaped crystals of feldspar may be seen, indicating their derivation from igneous rocks. There is a small amount of carbonate of lime present, and it becomes somewhat more abundant in the coarser forms. The conglomerate of the Mormon sandstone is generally greenish but sometimes reddish. Its pebbles are in a few places mainly quartzite, but at most localities they are chiefly of meta-andesite with a few of metarhyolite, and range from one-eighth of an inch to 18 inches in diameter. Several pebbles of limestone were observed, but none contained fossils. In the conglomerate are masses of fine shaly red sandstone with decided pencil structure parallel to its stratification. This same sort of material occurs also to a limited extent entirely independent of the conglomerate, and in such cases it is thin bedded and finely stratified. * * * At a narrow point in the wavy belt across the western slope of Mount Jura the following section was observed: Adjoining the eastern side of the Thompson limestone is 45 feet of massive gray sandstone with a rich fauna. This is succeeded farther up the slope by 30 feet of conglomerate and finally by about 20 feet of finely stratified red shaly sandstone, the "Inoceramus bed" mentioned by Prof. Hyatt. The total thickness of this belt a short distance farther south increases to about 225 feet, and the conglomerate becomes more prominent but farther along again diminishes and is scarcely noticeable near the south end.

The maximum thickness of the Mormon sandstone noted by Diller is 550 feet. Diller quotes Hyatt at length in regard to the fossils and age of the Mormon sandstone, and Hyatt concludes that the horizon is that of the upper part of the inferior Oolite of Europe.

The Bicknell sandstone is composed chiefly of red and gray sandstone associated with some dark shales and tuffaceous beds. The dark brownish-red sandstone is largely feldspathic and contains much red oxide of iron, with more or less carbonate of lime. It somewhat resembles

the red Hardgrave sandstone but is darker colored, and though much of its material may be derived from igneous rock, its particles are not characterized by the presence of numerous small crystals of feldspar as in the Hardgrave sandstone. Sandstones, mottled gray and red, form transitions to the gray sandstone which is the most abundant rock of the formation. Much of it is fine dark bluish gray, very compact and hard, breaking with a conchoidal fracture, and flecked here and there by small particles of pyrite. It looks so much like hornfels that one is surprised to find it locally full of large shells. Associated with this form is more or less black shale, some beds of which weather white and look like fine volcanic dust. A thin section, however, shows no characteristic volcanic material, but instead extremely fine sediment with a multitude of minute microscopic crystals of rutile which have developed in the sediment since it was laid down.

A coarser variety of the sandstone is light gray or greenish and passes into a rock which is full of small white crystals of feldspar with a few scales of gray mica embedded in a dark ground-mass, and the general aspect is decidedly igneous. The fact that it contains distinct fossils shows that it is fragmental, and it locally becomes coarse, so that its real character is more evident. In thin section under a microscope the fine fossiliferous rock is clearly fragmental, and much of the sediment was evidently derived from the erosion of volcanic rocks.

The maximum thickness of the Bicknell sandstone is probably over 1,000 feet, but its thickness decreases both north and south of Mount Jura, so as to average less than 500 feet. Hyatt finds some elements of its fauna comparable with the youngest faunas of the Jurassic in Europe but concludes from the evidence of the ammonites that it may be really synchronous with the Callovian.

The Hinchman sandstone is composed essentially of coarse sandstone with shaly parts and some conglomerate which is generally fine and derived chiefly if not wholly from andesitic rocks. Much of it is decidedly tuffaceous. The most common form is greenish gray and contains darker-colored shaly patches but is not conspicuously fragmental. Examined microscopically it is found to be made up largely of fragments of feldspar, augite crystals, and varying proportions of andesitic rock, fragments of which are clearly microporphyrific. The feldspar is generally much altered. Some of the augite is fresh, but most of it is altered to chlorite, giving a greenish color to the rock. It is never coarse like volcanic agglomerate, though it is sometimes made up largely of ejected volcanic material, some of which is clearly pumiceous. The grains are rarely well rounded by attrition, though it is evident that they have been transported and loosely aggregated on the sea floor, affording corners and cavities where corals, belemnites, and a number of other marine forms flourished. Remains of these animals are not confined to one horizon but are scattered throughout the formation. The conglomerate locally becomes coarse and composed of pebbles, some of which are well rounded; others are angular. The largest pebbles are rarely a foot in diameter. One of the most abundant types is a reddish, decidedly microporphyrific andesite. Others less common are dark and macroporphyrific, with either feldspar or hornblende phenocrysts. Limestone pebbles or nodules occur sporadically, but none could be found with fossils.

In thickness the Hinchman sandstone appears to range from 50 feet to more than 500 feet. The most characteristic fossils are corals of the genus *Stylina*, related to species of the Corallian of the Upper Jurassic of Europe.

The Foreman formation is a succession of shale, sandstone, and conglomerate in which the sediment is for the most part derived from rocks which are not clearly volcanic. The shales are often slaty and locally have "pencil structure" and range in color from dark carbonaceous with traces of leaves through gray, which predominates, to shades and tints of red and yellow. A remarkable feature of the shales locally is their pencil structure, which is particularly well developed in the summit of Evans Peak. The beds of red and gray sandy shales making the summit of the peak break up into small columns, often of lead-pencil size but generally smaller. * * *

Almost as abundant as the shales are the sandstones, most of which are very fine and decidedly shaly. They are reddish brown and gray, sometimes mottled with darker spots, chiefly carbonate of lime. * * * Occasionally the gray sandstone is more siliceous and contains irregular particles which give to the mass the appearance of a fine tuffaceous conglomerate.

Conglomerate is less abundant than either shale or sandstone and is usually in thin beds of small extent scattered throughout the formation. The most characteristic conglomerate of this formation is composed almost wholly of small pebbles of cherty quartz, black and gray in color, and rarely over half an inch in diameter. Of this there are but few beds ranging from 5 to 12 feet in thickness. A more abundant form of conglomerate contains locally many shale fragments and well-rounded pebbles chiefly of meta-andesites and rhyolites, with a few of fossiliferous limestone. The majority of the beds are small and are made up of small pebbles, rarely as large as $3\frac{1}{2}$ inches in diameter. Associated with the limestone pebbles in the conglomerate are concretionary nodules of carbonate of lime, which occur also in the shale and sandstone. They do not contain fossils and grade into the inclosing rock instead of having a sharp contact, as is the case with the limestone pebbles.

The Foreman formation contains fossil plants, which were studied by Fontaine, who placed them in the Mesozoic and considered them as most probably older than Cretaceous. An examination of later collections by Knowlton led him to question some of Fontaine's determinations, and marine invertebrates in the formation suffice to prove that it is Middle Jurassic or later. Stanton is of the opinion that it may represent the youngest Jurassic of the region, and this view is confirmed by Diller's study of the stratigraphy.

The Myrtle formation of southwestern Oregon and the Knoxville of northern California are regarded by Diller, Stanton, and Knowlton as of the same age, but it is a mooted question whether they are wholly Cretaceous or in part Jurassic. According to Stanton, the Aucellas (*Aucella piochi* and *A. crassicolis*) show that the formations are not older than Lower Cretaceous. According to Knowlton, the plants which are associated with the Aucellas at some localities are characteristically Jurassic.^a The Myrtle and Knoxville are indicated on the map as Lower Cretaceous, largely to distinguish them from the adjacent Franciscan areas, which are colored as Jurassic, and without any intention of indicating a decision as to their Cretaceous or Jurassic age.

K 12. SOUTHWESTERN WYOMING.

In the survey of Uinta County, in southwestern Wyoming, Veatch^{839c} distinguished the Twin Creek formation and the lower part of the Beckwith formation as Jurassic. The Lower Cretaceous appears to be missing or to be represented in the upper part of the Beckwith, as the Bear River formation (Upper Cretaceous?) immediately succeeds the Beckwith, apparently without unconformity. Veatch gives a general description, which is quoted in the table on page 676, Chapter XV. From his report we take the following notes:

The fossiliferous marine Jurassic, to which has been given the local name Twin Creek formation, from the excellent exposures on that creek between Sage and Fossil, here consists for the most part of dark calcareous shales and thin-bedded shaly limestones, though occasionally showing lighter-colored sandstone layers. These are sharply limited above by the thick red beds which mark the base of the Beckwith formation. The thickness of the Twin

^a See quotations under K 10 in Chapter XIV, pp. 617-621.

Creek beds north of Twin Creek on two carefully measured sections was found to be 3,500 and 3,800 feet. * * *

The Beckwith formation, which directly overlies the Twin Creek, has been so named from its occurrence and extensive development on leased State lands now forming part of the Beckwith ranch, situated just east of Beckwith station on the Oregon Short Line. It is here and throughout the west side of this area composed of two rather distinct members, a lower red-bed member, composed of interbedded sandy clays, sandstones, and conglomerates 2,500 feet thick; and an upper member, composed of rather light colored interbedded sandstones and clays. The sandstones are commonly rather light yellow and the clays vary from yellow to light pinkish red. * * * The upper member has a thickness of 3,000 feet or more.

In the eastern belt of older rocks these two phases merge; in the area along the west side of the great fault just west of Hilliard these beds, while having a predominant reddish cast, are all light in color. The conglomerates, which near Beckwith are deep red, are here white to yellow. These reddish beds are exposed along the whole of the eastern side of the eastern belt just east of the Cretaceous exposures, and for the most part form the crest of the pronounced anticline which skirts this region on the east. These beds here reach a total thickness of 4,000 feet. * * *

This formation is lithologically distinct from the very fossiliferous, dark-colored beds which overlie and underlie it, and compared with them is essentially unfossiliferous. Dr. Stanton has found marine Jurassic fossils at two points in beds which are regarded as in the lower part of the Beckwith formation. At old Bear River City, just west of the great fault line and east of the principal conglomerate bed at this point, Dr. Stanton found *Belemnites densus* M. and H., *Trigonia quadrangularis* H. and W., *Myacites (Pleuromya) weberensis* Meek (?). In the exposures north of this point this horizon appears to be distinctly underlain by the characteristic unfossiliferous Beckwith beds, and unless it represents a portion of the Twin Creek which has been faulted up—and this is not regarded as probable—it is distinctly in the Beckwith formation. This fossil-bearing layer is here about 1,600 feet below the Bear River formation and 2,400 feet below the Aspen shales. South of Rockport, on Weber River in Utah, Dr. Stanton found a specimen of *Trigonia quadrangularis* H. and W. (?) about 2,000 feet above the characteristic fossiliferous blue thin-bedded limestone and shale of the Twin Creek formation and 3,500 feet or more below the lowest observed black shales with fish scales, representing the Aspen formation, which here, in the absence of the Bear River, is the base of the known Cretaceous.

The lower part of the Beckwith formation is thus clearly upper Jurassic, and the remainder probably contains time equivalents of the lower Cretaceous and Dakota beds, if these occur in this area.

Veatch gives a list of fossils from the Twin Creek formation.

K 12-13. NORTHWESTERN COLORADO.

In describing the Rangely oil district, Colorado, Gale^{353a} gives an account of the Jurassic strata which constitute the White Cliff and Flaming Gorge formations of Powell. He says:

Immediately below the Dakota sandstone is a mass of variegated badland-forming shale and clay, including some harder beds of limestone and sandstone, together with a peculiar dark cherty, siliceous conglomerate almost exactly like that commonly found with the Dakota formation above. The shale or marl is prevailing of greenish and pinkish shades, with some beds that weather yellow. The lower 100 to 150 feet of this formation is composed of darker-colored beds, fine greenish sandstone and calcareous rock. Limestone layers composed largely of shells are present near the base, although the general character of the beds seems to indicate much limy or marly material throughout. These beds have an approximate thickness of 800

feet, as measured near the base of Blue Mountain. * * * The lower strata of these variegated beds are of marine origin, as shown by the fossils they contain; the upper part, by analogy with other and better-known sections, is supposed to be composed largely of fresh-water deposits.

The variegated and shaly beds are limited at the base by a second group of sandstones which, like the Dakota, usually forms a steep rocky ridge. * * * It is usually very white and massive and cross-bedded to an extreme degree.

The variegated beds are of Jurassic age and probably correspond in their upper or supposedly fresh-water part to the Morrison formation east of the Rocky Mountains. They have also been variously named "Flaming Gorge," McElmo, and in part Gunnison in the Uinta Mountain and western Rocky Mountain regions. * * * The cross-bedded white sandstone is also of Jurassic age, as is shown by fossils obtained from this field. It is with little doubt the equivalent to the "White Cliff" sandstone mapped by Powell on the north side of the Uinta Mountains, and also seems to be with almost equal certainty equivalent to the La Plata sandstone of the southwestern Colorado sections.

Gale gives a list of fossils which are regarded as characteristically Jurassic.

K-L 13. WYOMING AND SOUTH DAKOTA.

The Jurassic is represented in the Bighorn Mountains and throughout central Wyoming by the Sundance formation and possibly by the Morrison formation, although the latter may prove to be of Cretaceous age. (See Chapter XIV, pp. 606-608.) Darton^{237e} states:

Typical marine Jurassic deposits, with an abundant fauna, extend continuously around the Bighorn uplift, and they are so similar to the deposits in the Black Hills that the same name is applicable. The thickness averages about 300 feet and the succession comprises a sandy series below and a considerable thickness of greenish fossiliferous shales above. At or near the base there is usually a hard fossiliferous limestone layer having a thickness of from 3 to 5 feet, increasing locally to 25 feet. Next above are soft sandy beds often containing large numbers of *Gryphæa calceola* var. *nebrascensis*. The greenish shales above contain thin layers of highly fossiliferous limestones and a few thin sandy layers.

In another paper^{244d} Darton describes the Sundance formation as follows:

The Sundance formation occupies a large area in central Wyoming, but it is absent in the Laramie Basin south of Rock River. In Wind River Basin it is mostly covered by Tertiary, but it outcrops extensively near Fort Washakie, Lander, and Dallas. It appears along both flanks of Owl Creek Mountains, on the north slope of Rattlesnake Mountains, in southeastern Natrona County, in northeastern Carbon County, in the flexures south of Douglas and east and northeast of Medicine Bow, and along the east side of Laramie Mountains from Iron Mountain station to Crow Creek. Although there is a long time interval between the Sundance and Chugwater formations, marked erosional unconformity is rare and in places it is difficult to draw the line between them. This is probably because the first sediments of the upper formation were derived from the one below. The upper limits are similarly ill defined. There is no discordance in dips of underlying or overlying formations.

In the Owl Creek Mountain region the Sundance formation consists of about 200 feet of soft gray sandstones and green shales with conspicuous hard layers. * * * The local stratigraphy varies somewhat. At the base are sandstones, the middle and upper beds are mainly shales, and there is more or less sandstone for about 40 feet at the top. The shales are greenish or dark gray and contain limestone in concretions and thin layers, often highly fossiliferous.

Section of Sundance formation on Owl Creek 7 miles northwest of Thermopolis, Wyo.

	Feet.
Green soft sandy shales and hard greenish fossiliferous sandstone in alternating layers	70
Gray sandstone	4
Green sandy clay	20
Gray limy sandstone	2
Dark greenish-gray sandy clay, with many belemnites	40

Green sandy shale	20
Greenish-gray sandstone, thin bedded	4
Hard buff impure limestone, breaking into small rectangular blocks	2
Green sandy shale lying on "Red beds"	2
	194

Along the slope of Wind River Mountains and in the uplifts passing east of Fort Washakie and Lander the Sundance formation is about 300 feet thick and consists of greenish-gray shales and sandstones, with thin but prominent ledges of impure, highly fossiliferous limestone in their upper part. In the northern foothills of the Rattlesnake Mountains, where the thickness is about 300 feet, there are gray sandstones at the top, and part of the medial sandy shales are of pronounced reddish tint, as in the Black Hills and some other districts in Wyoming.

Platte Valley to Rock River.—The Sundance formation presents most of its usual features along the south side of Casper Mountain, in Muddy Creek valley, and on Wagonhound Creek and North Platte River south of Douglas. In the extensive exposures in the big bend of the river south of Douglas there are 30 feet or more of massive gray sandstone, overlain by 30 feet of pale-greenish sandy shale, 5 feet of soft greenish massive sandstone, 40 feet of soft sandstones of bright-reddish tint, 15 feet of massive buff sandstone, and about 200 feet of green shale with three hard beds of fossiliferous limestone. * * *

Sandstone, white (on Chugwater red beds)	25
	300

In the Freezeout Hills and Rock River region the lower beds of the formation are predominantly sandy, while the upper part consists largely of green shales with hard fossiliferous layers. In an extensive exposure east of Medicine Bow the strata are as follows:

East of Laramie Mountains.—The thin margin of the Sundance formation outcrops continuously along the eastern foothills from North Fork of Horse Creek to the southernmost prong of Horse Creek and from the North to the South Fork of Lodgepole Creek. Small exposures appear on North and Middle forks of Crow Creek. The rocks are mostly light-buff sandstones, but some sandy shales appear. The average thickness is 40 feet. * * *

Fossils and equivalency.—The formation contains abundant fossils of Middle to Upper Jurassic age, and it is believed to be equivalent to the Sundance formation of the Black Hills region. The following are the principal fossils: *Belemnites densus*, *Gryphæa calceola* var. *nebrascensis*, *Campectonites* [*Camptonectes?*] *bellistriatus*, *Eumicrotis curta*, *Trigonia elegantissima*, *T. americana*, *T. conradi*, *T. montanensis*, and *Pentacrinus asteriscus*.

In Freezeout Hills the following fossils are reported by W. N. Logan in section given [above]: Bed No. 10, *Pseudomonotis curta*; bed No. 12, remains of *Ichthyosaurus* and *Plesiosaurus*; bed No. 13, abundant *Belemnites densus* throughout, and in the concretions *Pinna kingi*, *Pinna* sp. *Cardioceras cordiforme*, *Avicula beedei*, *Astarte packardi*, *Pentacrinus asteriscus*, *Tancredia bulbosa*, *T. magna*, *Lima lata*, *Goniomya montanaensis*, *Avicula macronatus*, *Pleuromya subcompressa*, *Cardinia wyomingensis*, *Pseudomonotis curta*, *Belemnites densus*, and *B. curtus*, and also remains of plesiosaurs and ichthyosaurs; bed No. 14, *Camptonectes bellistriatus*, *C. extenuatus*, *Ostrea densa*, and *O. strigilecula*; in a sandy limestone bed in base of bed No. 15, *Pentacrinus asteriscus*, *Asterias dubium*, *Pseudomonotis curta*, *Avicula macronatus*, and *Ostrea strigilecula*.^a

The Jurassic of the Black Hills is represented by the Sundance formation and probably by the Unkpapa sandstone (local) and the Morrison formation, although the latter two may prove to be of Cretaceous age. (See Chapter XIV, pp. 606-608.) Darton^{237d} says:

This name [Sundance formation] has been given to the marine Jurassic sediments of the Black Hills region, from the town in the northern portion of the uplift. The rocks are shales and sandstones in a series, some members of which vary locally. Over a wide area the succession consists of a lower member of dark-gray shales, averaging 50 feet thick; a prominent ledge of fine-grained sandstones of pale-buff tint; an intermediate member of sandy shales and sandstones of reddish color, and at the top about 150 feet of dark-green shale, including thin layers of very fossiliferous limestone. * * * Fossils occur also in the sandstone and all are of later Jurassic age. At the base of the formation there is often a massive red or buff sandstone occurring in extended lenses, and frequently attaining a thickness of 25 feet, lying unconformably. * * *

This formation extends along the slope of the Laramie Range, presenting its usual characteristics to the northward but thinning rapidly to the southward. In extensive exposures at the east end of Casper Mountain it has a thickness of about 350 feet. At the base overlying the

^a The spellings of fossil names in this list have been made to agree with those given by Logan in the article cited by Darton (Kansas Univ. Quarterly, vol. 9, 1900, pp. 112-113).—B. W.

limestone, which is supposed to represent the top of the Chugwater red beds, there are 20 feet or more of white to red sandstones, then a few feet of buff sandstones and shales with an 8-foot bed of gypsum, and finally an upper series of dark shales with limestone layers and concretions filled with characteristic fossils, including many *Belemnites densus*.

Along the North Platte River, in its big bend south of Douglas and to the west on Wagonhound Creek, the succession is as follows, from the bottom up: 30 feet or more of massive gray sandstone; 30 feet of pale-greenish sandy shales; 5 feet of soft greenish massive sandstone; 40 feet of bright-reddish sandy beds; 15 feet of massive buff sandstone; and at the top about 200 feet of green shales with a few thin beds of sandstone and limestone containing many upper Jurassic fossils.

The formation appears again on Chugwater and Horse creeks, consisting of an upper series of 30 feet of soft slabby sandstones, gray at the base and buff toward the top, with ripple-marked layers and much intercalated shale, and a lower series 50 feet thick, mostly of green and gray shale, with layers of soft thin-bedded greenish-gray sandstones lying on the Chugwater formation. * * *

This formation appears on the banks of North Platte River northwest of Guernsey and for some distance northward. The lower 145 feet are sandstones with a few thin beds of shales, over which there are 60 feet of interbedded slabby sandstones and clays, all containing characteristic marine Jurassic fossils. * * *

The Sundance formation extends only a few miles into Colorado from the northward, finally ending by thinning out. Dr. Hayden found fossils, "*Ostrea* and fragments of *Pentacrinus asteriscus*," on Box Elder Creek, in yellow sandstones and clays, with scattered layers or nodules of limestone. He suggested that the limestone sometimes found at the base of the Morrison formation may be a representative of the marine Jurassic, a suggestion based on its similarity in character and relations to a limestone on the Laramie plains, which contains *Apiocrinites*. As similar limestones exist in typical Morrison beds to the northward, where the marine Jurassic is represented, I feel certain that all those in the Front Range are of Morrison age. * * *

The Jurassic appears to exist only in the northwestern portion of the region to which this report relates, apparently owing to nondeposition in other portions of the region. In the Big-horn Mountains and Black Hills it is represented by from 300 to 400 feet of deposits, but these thin gradually to the southward in the Laramie Range and disappear in the northern portion of Colorado. The thinning appears to be general at the outset and the upper beds probably disappear first, but this point has not been definitely determined, and it may be that the upper beds merge into sandy beds and these thin out gradually together with the underlying sandstones.

The formation is evidently of marine origin, as indicated by its numerous molluscan remains, and its age is regarded as late Jurassic. It has not been divided into subordinate members, but in its regular succession it presents a succession of beds and faunas which are constant over a wide area, especially the sandstone near the base and the green shales above containing numerous *Belemnites densus*. It is probable that the Sundance formation does not extend far east of the Black Hills, nor to the southeastward of the locality at which it disappears in surface outcrops in northern Colorado, but there is no direct evidence on this question.

The Unkpapa sandstone, which succeeds the Sundance formation along the eastern side of the Black Hills, is a relatively local feature of unknown age. It appears to represent a local shore deposit in late Jurassic times, prior to the deposition of the Morrison beds. The horizon may possibly be represented in other regions by the almost general occurrence of a yellowish sandy bed at the top of the Sundance formation. If not, it is probable that in the area in which it is absent there is a small unconformity or hiatus at this horizon. There is a very abrupt change from the Sundance to Morrison sediments, but no direct evidence of unconformity has ever been found.

The latest notes on the Jurassic fauna of the Black Hills are given by Whitfield and Hovey.⁹²⁸ Summary statements concerning the correlation of the faunas are given by Stanton.⁷⁸²

L 11. EASTERN OREGON.

In the Blue Mountains of eastern Oregon occurs a red sandstone from which Jurassic fossils were obtained on Beaver Creek, a tributary of Crooked River. The fauna is that of the Hardgrave sandstone of the Taylorsville district, California, and is assigned by Hyatt⁴⁶⁸ to the Lias (Lower Jurassic). Hyatt mentions other localities at which there are characteristic occurrences of the same fauna and infers a connection between them extending from Inyo County, Cal., to the Blue Mountains.

L 12. MONTANA AND WYOMING.

The Jurassic of the Philipsburg quadrangle, Montana, is thus described by Calkins:^a

The beds immediately overlying the Quadrant formation in the Philipsburg quadrangle in southwestern Montana are correlated with the Ellis formation on lithologic and paleontologic grounds.

The Ellis in this area consists mainly of calcareous shales and sandstones and impure ferruginous limestone; locally it contains, near the middle, some conglomerate whose pebbles are mainly of chert like that in the Madison limestone. These rocks all weather in ochre-yellow colors which are characteristic of the formation as here developed.

The thickness of the formation on Gird Creek about 5 miles southeast of Stone, Mont., is about 400 feet. It is thinner in places and seems locally to be absent in a small area southeast of Twin Peaks. It appears to be structurally conformable with the Quadrant, but the absence of any deposits belonging between the Carboniferous and Jurassic marks a distinct hiatus.

T. W. Stanton has collected characteristic Ellis fossils from the formation on Gird Creek and on the Ovardo road about 6 miles east of Drummond. Those collected on Gird Creek lie from 50 to 100 feet above the Quadrant formation. They comprise the following forms:

- Ostrea strigilecula White.
- Camptonectes pertenuistriatus H. and W.
- Eumicrotis curta Hall.
- Trigonia sp.
- Pleuromya subcompressa Meek.

In this section east of Drummond calcareous beds from 200 to 250 feet above the Quadrant have yielded:

- Rhynchonella gnathophora Meek.
- Ostrea sp.
- Camptonectes bellistriatus Meek.
- Lima? sp.
- Cucullea haguei Meek.
- Tancredia? sp.
- Pleuromya subcompressa.

A conglomerate near the top of the Ellis formation here contains *Rhynchonella gnathophora* Meek, *Ostrea* sp., and *Gervilia* sp.

For an account of the Ellis formation as developed in Yellowstone Park, the *Yellowstone folio*³⁹² may be consulted. In that region the formation consists of a lower limestone division and an upper one chiefly of sandstone. The limestones are impure, argillaceous and gray, and associated with shales, and they carry marine fossils at several horizons. The upper sandstone member varies from a coarsely crystalline, fairly pure limestone carrying an abundance of fragmentary fossils to a true sandstone with conglomerate layers.

^a Unpublished manuscript.

The latest account of the Ellis formation in Montana is by Fisher,³³² who states that it—

includes a basal limestone of variable thickness, ranging from 15 to 60 feet, which in places merges upward into a coarse conglomerate that passes into a medium-grained sandstone, light brown to gray in color and more or less thin bedded. In other localities, however, the change from limestone to conglomerate is abrupt. The limestone and conglomerate contain marine Jurassic invertebrate fossils. Some of those in the conglomerate are fragmentary, but more are complete, with pebbles of limestone and quartzite several inches in diameter. The component parts of the conglomerate are bound together by a calcareous cement. The total thickness of the formation is about 80 to 120 feet. It rests unconformably upon the shale of the Quadrant formation in certain parts of the field, and upon the Madison limestone in others. * * *

The following sections illustrate the succession of the beds of the formation in different parts of the field:

Section of Ellis formation near Goodman siding, Montana.

	Feet.
Sandstone, gray, weathering brown, thin bedded.....	60
Sandstone, gray, conglomeratic, containing marine Jurassic fossils.....	29
Limestone, dove-colored, massive; basal member brecciated and containing Jurassic fossils...	60
	149

Fossil invertebrates, mainly *Ostrea* and *Camptonectes*, are present in great abundance in the two lower members of the above section. The numerous specimens of these genera and a few other forms are sufficient to determine that the rocks belong to the Ellis formation, which in the Yellowstone National Park and neighboring areas yields a characteristic upper Jurassic fauna. The sandstone of the Ellis formation throughout the Great Falls region is usually not fossiliferous, but the conglomerate and underlying limestone contain an abundance of Jurassic fossils.

The Morrison formation, which is regarded as probably Jurassic by some geologists, is described with the Lower Cretaceous in Chapter XIV (pp. 606-608).

L-M 10. OLYMPIC PENINSULA.

Arnold²⁹ refers to supposed pre-Cretaceous rocks in the Olympic Peninsula of Washington, which he mapped as Jurassic and which are so shown on the map of North America, as follows:

The formations involved in the geology of the coastal region of the Olympic Peninsula include serpentine, old diabase or greenstone, metamorphosed sandstone and quartzite, probably of Jurassic age; 6,000 feet of gray sandstone with minor quantities of carbonaceous shales, supposed to represent the lower part of the Puget group and of Cretaceous age; 1,200 feet of basalt and basalt tuffs of Eocene age; 15,000 feet of Oligocene-Miocene conglomerate, sandstone, and shale; 2,260 feet of Pliocene conglomerate, sandstone, and shale; and at least 300 feet of Pleistocene till, clay, and gravel. In addition to this, the Oligocene-Miocene breccia contains large quantities of angular fragments of hard black slate, indicating a probable widespread formation of this type of rock somewhere in the general region. Nothing is known of the age of the slate except that it is pre-Oligocene.

The supposed pre-Cretaceous rocks of the territory examined were confined entirely to the coast south of Cape Flattery, the most important areas occurring at Portage Head, 8 miles

south of the cape, Point of the Arches, $3\frac{1}{2}$ miles still farther south, and in the region from Point Greenville south to within a few miles of Grays Harbor. The types of rock composing this old series embrace old diabase or greenstone, serpentine, quartzite, conglomerate, etc.

These rocks are also described by Reagan ⁶⁶⁴ as follows:

Rocks supposed to be pre-Cretaceous in age are found in the central Olympic region, in the central ridge which extends westward from the Olympics to Cape Flattery, and on the Pacific front at Portage Head, 8 miles south of Cape Flattery, and at the Point of the Arches, 4 miles farther south, and in the region from Point Granville south to within a few miles of Grays Harbor, and a few other smaller exposures along the Pacific shore line. So far no rocks of this age have been found on the north slope of the peninsula. * * *

The series containing the syenite, gneiss, quartzite, protogene, crystalline and chlorite schists is here placed by the writer in the supposed Cretaceous. Its approximate area is not known, neither is its thickness where the central core of the western extension of the Olympics is exposed. Along the east and west axis of the western part of the peninsula, at Beaver Falls, in the East Clallam-La Push wagon-road, [it] is composed of a very hard dark-gray plutonic rock of more than 10,000 feet in thickness. This core, however, is exposed only in patches. Its greatest thickness is in the vicinity of Clallam Peak. Toward Cape Flattery it is capped with sedimentary deposits. Here it is composed of metamorphosed sandstone and quartzite. It may prove to be of Eocene age.

At Portage Head, Point of the Arches, and at Point Granville the type rock of this old series is conglomerate, quartzite, old diabase or greenstone, serpentine, etc.

This old series, wherever found, is much fractured and faulted and cut by quartz veins, which occasionally carry gold and silver in small quantities. The principal veins carrying precious metals are found in the Point of Arches group and in the vicinity of Clallam Peak and Beaver Falls. An odor of benzine is also given off from the serpentine and conglomerate rocks of this group in the Point of the Arches, derived likely from the shales that are found a mile farther south. There are no other shales or oil-producing rocks in the vicinity; the age of these shales is in doubt, but they are Cretaceous or still younger.

M 10. WASHINGTON AND BRITISH COLUMBIA.

A western occurrence of supposed Mesozoic strata is exposed on the northern portion of Nooksak River and is thus described by George Otis Smith: ⁷⁵⁷

For some miles below Shuksan the outcrops on the walls of the canyon of the north Nooksak are of sedimentary rocks distinctly less metamorphosed than those assigned to the Paleozoic. They are mainly sandstones, with some cherty layers and conglomerates. Green colors are rather characteristic of all the rocks. At Austin Pass there are greenish sandstones and banded shales which show on the average about the same degree of induration as the similar rocks of the Pasayten formation. On lithologic grounds, then, it appears probable that there may be a belt of Mesozoic rocks trending northwest from Austin Pass.

There is, moreover, some paleontologic evidence bearing on this question. In 1898 there were sent to Mr. J. S. Diller by Mr. W. H. Fuller, of Fairhaven, Wash., some fossils collected on Cowap or Canyon Creek and on the ridge north of it. Mr. T. W. Stanton examined the material and reported on it as follows:

“The * * * fossils * * * are evidently all from one horizon, which I believe to be upper Jurassic, this opinion being based chiefly on the distinctly striated form of *Aucella*, identified with *A. erringtoni* (Gabb) of the California upper Jurassic Mariposa beds. This species was collected at both localities. The collection from Canyon Creek includes also a fragmentary *Pleuromya* and the impression of a small belemnite.

“The collection from the divide between Canyon Creek and the waters of Fraser River contains the *Aucella erringtoni*, a fragment of an ammonite apparently belonging to the genus *Stephanoceras*, a small, slender belemnite like that from the last-mentioned locality, and the phragmacone of a large, robust belemnite.”

M 11. SOUTHWESTERN ALBERTA.

The Fernie shale, which was originally included by Dawson in the Cretaceous as part of the Kootenai formation, has been separated and is described by Dowling.²⁹² In the Cascade coal basin, Alberta, it consists of black shales with gray sandstones and local limestone beds which occupy the same position relatively to the Kootenai of the older rocks beneath as a similar series at Fernie, where there are Jurassic fossils. The thickness is given as approximately 1,600 feet.

The relations of the Jurassic and Lower Cretaceous of British Columbia are discussed in Chapter XIV (pp. 624-630).

M-O 9-10. WESTERN BRITISH COLUMBIA.

Dawson's descriptions of the "Porphyrite group" (Jurassic?) are given in Chapter XIV (p. 627).

O 4-5. ALASKA PENINSULA.

The Alaska Peninsula is composed largely of Mesozoic rocks, which, though known to comprise several terranes, have not yet been separated in mapping but are grouped under the color which indicates Jurassic. Brooks^{101h} gives a general account of the history of investigation of these strata. The latest and most complete study of the section as yet made is that of Stanton and Martin,^{786b} to whose account reference should be made for detailed sections and a statement of the stratigraphic relations, which they sum up as follows:

The Mesozoic section of southwest Alaska includes representatives of the Upper Trias, Lower, Middle, and Upper Jurassic, Upper Cretaceous, and probably Lower Cretaceous.

The Jurassic shows the greatest development, both stratigraphically and faunally, and is probably unequaled in these respects elsewhere on the American continent. The total thickness can not be much less than 10,000 feet, and the areas covered by the upper half of the Jurassic are large.

The faunal type is essentially Russian—that is, boreal—though it differs in the common occurrence of *Phylloceras* and *Lytoceras* at several horizons. The succession of the faunas from the Callovian to the top of the Jurassic is the same as in Russia, but the vertical thickness of beds through which each ranges appears to be very much greater in Alaska.

The Cretaceous and Triassic rocks so far as now known occur only in small scattered areas, and their faunas may be directly correlated with those of formations in California and elsewhere on the Pacific coast.

The general relations of the formations may be epitomized in the following section:

Tertiary.—Kenai formation. Shales, sandstones, and conglomerates with several beds of coal. The entire formation nonmarine and characterized by a large flora. Thickness, $\pm 2,000$ feet.

Unconformity.

Upper Cretaceous.—Lithologically similar to the Kenai, but including some marine shales and sandstones with an Upper Cretaceous fauna. Thickness, $\pm 1,000$ feet.

Unconformity.

Lower Cretaceous.—(Not seen within the area studied.) Shales and sandstones with *Aucella crassicollis*.

Unconformity(?).

Upper Jurassic.—Naknek formation. Conglomerate, arkose, sandstone, and shale with interstratified andesite flows. Thickness, about 5,000 feet.

Middle Jurassic.—Enochkin formation. Shales and sandstones with some conglomerate beds. Thickness, 1,500 to 2,500 feet.

Unconformity(?). (Possibly conformable on Lower Jurassic when that is present.)

Lower Jurassic.—Tuffs and sandstones. Thickness, $\pm 1,000$ feet.

Unconformity.

Upper Triassic.—Thin-bedded cherts, limestones, and shales usually much folded and contorted and with many intrusive masses. Thickness, $\pm 2,000$ feet.

Base not seen.

Martin ⁵⁷⁴ describes the district north of Alaska Peninsula and states the sequence of rocks as follows:

The region described in this report covers an area of about 4,900 square miles, situated in southwestern Alaska, west of the southern half of Cook Inlet and north of the Alaska Peninsula. It comprises the greater part of the drainage basin of Kvichak River, which is the outlet of Iliamna and Clark lakes, and of the streams flowing into Cook Inlet from the west, south of and including Tuxedni Bay. It lies between the parallels of 59° and 60° 30' north latitude and the meridians of 152° 30' and 157° west longitude.

Most of the northeastern part of this region lies within the Chigmit Mountains and consists of high, rugged mountain masses with narrow intervening valleys. The general elevation of these mountains is from 4,000 to 6,000 feet, although many peaks near the north end of Clark Lake are 7,000 feet high, and the highest peak of the whole district is Mount Iliamna, between 9,000 and 10,000 feet.

At Iliamna Bay the mountains extend eastward to the waters of Cook Inlet. Both north and south of this point a belt of foothills and lowlands from 2 to 10 miles in width reaches from the edge of the high mountains to the shore of the inlet. Much of the coast is deeply embayed, Tuxedni Bay, Iniskin Bay, and Iliamna Bay extending into the high mountains, while the other bays have their heads in the foothill belt. * * *

The following table shows what is now believed to be the probable geologic sequence:

General section of rocks in the Iliamna and Clark lakes region.

Age.	Lithologic character.	Areal distribution.
Quaternary.	Beach and flood-plain deposits, terrace gravels, and glacial till.	Entire region.
Tertiary.	Basaltic flows and tuffs with some interbedded sandstone.	Iliamna Lake.
	Shale, sandstone, and conglomerate.	Cook Inlet.
Upper Jurassic	Shale, sandstone, conglomerate, arkose, and tuff, with interbedded andesitic flows.	Cook Inlet.
Middle Jurassic.	Sandstone, shale, and conglomerate.	Cook Inlet.
Middle or Lower Jurassic.	Granite, quartz, diorite, etc.	Chigmit Mountains.
Lower Jurassic or older.	Rhyolitic and andesitic porphyries and tuffs.	Cook Inlet, Iliamna Lake, Clark Lake, east of Clark Lake.
Upper Triassic.	Chert, shale, and limestone.	Cook Inlet.
Triassic or older.	Tuffaceous greenstones.	Iliamna Bay, Pile Bay, Kakhonak Bay, Clark Lake.
	Limestone.	Iliamna Lake, Iliamna Bay, south of Iliamna village (?).
Late Paleozoic.	Slate and chert.	Iliamna Bay, Clark Lake, east of Clark Lake.
Paleozoic.	Limestone and calcareous schist.	Clark Lake, south of Iliamna village (?).
	Gneiss, mica schist, and quartzite, with some crystalline marble.	West of Iliamna Bay, south of Iliamna village, Clark Lake.

O 8. ATLIN LAKE, BRITISH COLUMBIA.

Gwillim,³⁸⁹ in reporting on the Atlin Lake gold district, describes an extensive area of sandstone and conglomerate about the southern end of Taku and Atlin lakes. The rocks are classed as Mesozoic but were not seen in contact with Paleozoic formations. "Their origin is chiefly igneous and they often pass imperceptibly from a sedimentary and stratified form into the mountain masses of porphyrite and andesite. The few fossils found in some of the bedded sandstones appear to belong to the Jurassic period." This general statement is followed by a more detailed description, as follows:

The prevailing variety of this sandstone series is of a greenish-gray color. It is usually in heavy beds. There are occasional bands of a darker and more argillaceous-looking material, also some thick deposits of thinly bedded fine-grained black and gray material. Conglomerates occur somewhat rarely. Such beds usually contain very coarse boulders, as large as 3 feet in diameter. These boulders are principally granite, with sometimes a considerable number consisting of crystalline limestone and porphyrite.

A very good section of this sandstone formation is found on the west side of Tory Inlet on Atlin Lake. An anticline occurs at this point. The northern slope of the beds forms the abrupt eastern face of Section Mountain. This section shows over 5,000 feet of thickly bedded sandstone of the greenish-gray false-bedded variety interbanded with some finer-grained beds of darker material. The upper portion of these beds is without conglomerate. The lower beds contain some narrow bands of which the boulders are usually small and consist principally of granite and porphyrites (hornblende and andesite porphyrite).

From microscopic examination of several specimens of this series, they appear to be of pyroclastic origin.

* * * * *

A few fossil forms were found in some of the darker fine-grained beds of this series of rocks. * * * From field conditions and lithological resemblance, this series of rocks was at first believed to be Cretaceous in age. The examination of the few fossil forms appears to place them in the Jurassic. * * * The following is a note on the specimens of fossils collected on Atlin Lake during the season of 1900 and submitted to Dr. H. M. Ami, for examination:

"The fossils are preserved for the most part in a rather imperfect manner in a dark, at times streaky, gray fine-grained calcareous rock, which, when examined in thin sections under the microscope, reveals the structure of a porphyrite or andesite tuff. * * * The fossils are for the most part fragmentary * * * but they represent several small collections * * * and possibly different horizons in the Mesozoic. It is very difficult to state precisely what is the age of the strata, * * * both on account of the condition in which the fossils are themselves preserved and on account of the fact that the fauna represented is practically a new and hitherto unrecognized one in that portion of North America. * * * The presence of a few ammonites, which had the general outward appearance of *Ammonites* not unlike *A. vancouverensis* seemed to indicate a similar horizon to that of the Triassic system of the Cordilleran belt, but as none of these ammonites show any of the sutures, it is impossible to state precisely in what section or division to place them."

Some of the most typical of these fossils were sent to Dr. T. W. Stanton, of Washington. He found it difficult to determine the ammonites even generically, since they showed no sutures. He says:

"These may possibly be Triassic, but I think it more probable that they are early Jurassic. They are certainly not as late as the Cretaceous."

P 8. LEWES RIVER, YUKON PROVINCE.

For a description of the conglomerate and sandstones near Lake Labarge, which Stanton considers probably Jurassic, see Chapter XV (p. 701).

R 3. NORTHWESTERN ALASKA.

The coast northeast of Cape Lisburne exhibits a section of strata constituting two formations, the lower one coal bearing and according to its fossil plants of Jurassic age, the upper one unfossiliferous. Collier^{164a,165b} has described these formations as follows:

Mesozoic rocks occur on the coast about 3 miles east of Cape Lisburne and extend beyond the limits of the area covered by this investigation. They consist of two members, of which the older is coal bearing while the younger is not only destitute of coal but also of fossils.

The coal-bearing member, which has been called the Corwin formation, begins on the coast line about 26 miles east of Cape Lisburne and about 2 miles west of Corwin Bluff. From this point it extends eastward to and beyond Cape Beaufort, the eastern limit of the area comprised in this investigation. This formation consists of rather thin bedded shales, sandstones, and conglomerates. The shales which form the greater part of the section, vary from greenish-brown calcareous to black carbonaceous beds, and in texture from mudstones to fine-grained sandy shales.

The sandstones occur at infrequent intervals through the formation, in beds usually less than 10 feet in thickness. Their outcrops form low ridges, which are easily traceable over eroded areas. The conglomerates are made up mainly of quartz and chert pebbles, ranging in diameter from one-half to 4 inches. A conglomerate bed about 15 feet thick, which reaches the coast at Corwin Bluff, makes a distinct ridge from 100 to 200 feet high, which has been traced southeastward for about 15 miles, giving a definite key to the stratigraphy of a portion of the field.

The thickness of the Corwin formation exposed along the coast near Corwin Bluff is not less than 15,000 feet. The base of the formation has not been observed, but it probably rests unconformably on the Paleozoic rocks.

Fossil plants collected from it indicate that the age is Jurassic.

The structure consists of several broad synclines and anticlines, the dips of the beds varying from 0° to 60°. There is no evidence of faulting other than minor shearing movements parallel with the bedding planes.

The Corwin formation is conformably overlain by a more arenaceous series of sandstones and shales in which neither coal beds nor fossils have been found. The contact of these rocks with the Corwin rocks may be seen about 2 miles west of Corwin Bluff, whence it extends southeastward for several miles to the limit of the area investigated. The western limit of the formation is a well-defined fault line extending southeastward from a point on the coast 3 miles east of Cape Lisburne, where the formation is in contact with the Paleozoic, which is overthrust. The structure of this formation increases in complexity from its base at the top of the Corwin formation as this fault is approached; there are intense crumpling and numerous minor thrust faults. For this reason it is impossible to estimate the thickness of the formation, but the evidence obtained indicates that its minimum thickness is not less than 5,000 feet.

R-S 27. NORTHEAST COAST OF GREENLAND.

Nathorst^{609a} gives the following description of the Jurassic strata on the northeast coast of Greenland:

Jurassic strata occur at two localities on Kuhn Island, on the south side and on the east side. At the first-mentioned place they consist of brownish fine-grained sandstones, with an inclusion of coal strata. There are in the sandstones fossils which, according to Youla, indicate the Middle Dogger. Of quite a different age are the sandstone and marl beds that are found about the easternmost point of the island; they are distinguished by a great richness in forms from the family Aucella, and further of *Perisphinctes payeri*, *Belemnites pandermanus*, besides others, and are therefore referable to the youngest Jurassic, the Aucella beds. The Jurassic at both localities is given as resting directly on the Archean. * * *

Above the Rhætic beds come others with marine fossils described by Lundgren. Aucella are completely absent, and Lundgren thinks that these beds should be referred to the Kelloway stage of the Jurassic system, and that they are very likely closely allied to the fossiliferous beds on the south side of Kuhn Island. Identifiable ammonites and belemnites were not found in the samples that were brought home, and most of the specimens are lamellibranchs belonging to the families Ostrea, Pecten, Avicula, Modiola, Astarte, Panopæa, Pholadomya, Lyonsia, and others. The fossils occur in an impure limestone that in places becomes conglomeratic or even changes into shell breccia. The fossil-carrying bed is 2.2 meters thick and is overlain by gray sandy slates, yellowish sandstones, etc., without fossils. A basalt bed 3 meters thick is interbedded with the nonfossiliferous layers. The beds dip about 6° S. 50° W. and rise therefore toward the inner part of Jurry Inlet.

CHAPTER XIV.

LOWER CRETACEOUS.

Color, Medium green.

Symbol, 8.

Distribution: Atlantic, Gulf, and Caribbean coasts; New Jersey to South America; Pacific coast, Alaska to South America. In Mexico areas mapped include Upper Cretaceous.

Content: Potomac group of the Atlantic slope, Georgia, and eastern Alabama; Comanche series (comprising Trinity, Fredericksburg, and Washita groups) of Texas, Oklahoma, and Mexico; Shasta series (Knoxville and Horsetown formations) of California and Oregon; Queen Charlotte group of British Columbia; Kootenai formation of the Rocky Mountains, Montana northward to fifty-second parallel and beyond; Lower Cretaceous, Alaska.

Lower Cretaceous areas.

FIGURE 16—Sketch map showing the distribution of Lower Cretaceous rocks represented on the geologic map of North America and the key to references in the text.

B-C 18. COLOMBIA.

We are indebted chiefly to Hermann Karsten,^{473a} a physician and botanist, for our knowledge of Colombia, and for the portion of that country shown on the map of North America we have followed his text. He distinguishes five terranes, of which the oldest is the Jurassic, recognized at but one locality in New Grenada. The next, the Lower Cretaceous, outcrops extensively throughout the mountains and is distinguished by a great variety of cephalopods. * Karsten suggests that the terrane may probably be divided into two formations owing to the presence of belemnites, *Ptychoceras*, *Humboldtianus* Krst., *Ammonites noeggeratii* Krst., *Am. rothii* Krst., *Am. santafecinus* d'Orb., *Am. boussingaultii* d'Orb., and *Hamites arboledæ* Krst., in the lower beds, which are principally marls. The third series, that of the Upper [?] Cretaceous, consists of thick deposits of limestones, sandstones, and siliceous shales and is identified paleontologically by a great number of Rudistes which appear in the eastern portion, and of Polythalamies [Foraminifera], which occur very extensively in the central and western districts.

Succeeding these Cretaceous formations are Tertiary and Quaternary deposits concerning which Karsten is quoted in Chapter XVII (p. 796). In introducing his description of the Cretaceous, Karsten refers to the absence of any trace of Paleozoic rocks, and mentions specifically the discovery of Jurassic beds on the upper Magdalena in New Grenada. As these beds appear to belong to the Lower Jurassic (Liassic), it is possible that the Upper Jurassic is represented in the higher strata which underlie the Cretaceous. Karsten states:

The oldest of the sedimentary formations is a sandy marl of a clear brown or yellowish-red color and distinct stratification. It frequently is of great thickness and sometimes contains in the upper portion beds of blue or dark limestone which completely replace the marl in the higher sequence. Sometimes a reddish-brown marl which closely resembles the preceding contains flakes of mica or fragments of mica schist, as, for example, at Guaduas and at Bucaramanga. The latter marl is, however, probably of more recent date than that which appears in contact with the plutonic rocks and which is very poor in fossils, is without mica, firmer, etc. This nonmicaceous marl occurring in the lower beds is found in all the eastern chain as well as at several places in the central and western chains. It contains the following fossils: *Ammonites santafecinus* d'Orb., *Am. noeggeratii* Krst., *Am. boussingaultii* d'Orb., *Ptychoceras humboldtianus* Krst., *Crioceras duvalii* Lev. var. *undulata* Krst., and may therefore be regarded as the equivalent of the Neocomien of Europe. At Cumanacoa remains of belemnites occur in a yellowish-red marl and in a black calcareous shale which lies upon it. * * * This marl has at Zapatoa a thickness of about 300 meters and is overlain by another bed which is also very thick, of reddish-yellow quartzose sand, that in turn is followed by clay shales and limestones of the horizon of the Gault, rich in fossil remains. The last-named lies upon beds of pebbles and conglomerates derived from these same strata.

Karsten describes several localities at which these strata appear and continues:

Although at the base of the Lower Cretaceous marls and shales predominate, the middle portion of the series consists chiefly of limestones and the upper part of sandstones. These sandstones here and there alternate with thick beds of siliceous shale and include also thin strata of clay shale which are generally white, light, or yellowish in color, and of fine grain. * * * In physical characters the beds resemble the Lower Cretaceous that immediately underlies them, but they may usually be distinguished by the organic remains, especially characterized by *Inoceramus*. The Upper is distinguished by an abundance of Polythalamies, *Orbitolina*, *Robulina*, *Nodosaria*, and similar species. In the accompanying limestones one

also finds the shells of Rudistes and bivalves: *Lucina*, *Cardium*, *Pecten*, *Ostrea*, *Exogyra bous-singaulti* d'Orb.; of echinoderms: *Ananchytes ovata* Lam., *Micraster cor-anguinum* Goldf., *Discoidea excentrica* d'Orb., *Echinus bolivarii* d'Orb., *Enallaster karsteni* de Loriol, *Galerites* sp., etc. This group of siliceous rocks, whose thickness may be estimated roughly at 1,000 meters, usually forms the summits of the eastern chain. The Paramo de Chita, which has an altitude of about 6,000 meters and is covered with eternal snow, [and other summits] are formed of these sandstones and siliceous shales. The beds which carry Polythalamies are unconformably overlain by micaceous sandstone which is either white or yellow and more or less coarse, or by sandstones and variegated marls containing beds of lignite.

This last group is assigned by Karsten to the Tertiary and further description of it is given in Chapter XVII (p. 796).

The geologic constitution of the Cordillera of Bogota was described in 1892 by Hettner,⁴³⁷ who distinguished several divisions of the Cretaceous as follows:

Although various explorers have from time to time collected fossils, we are indebted particularly to Karsten for an attempt to distinguish the sedimentary rocks of Colombia. He separated Lower Cretaceous or Neocomien, Middle Cretaceous or Gault, which appears with two definite variations, Upper Cretaceous, and Tertiary. The classification which I have adopted during my journeys agrees in general with Karsten, and Sievers has adopted approximately the same classification for the Cordillera of Merida in Venezuela.

The characteristic rock of the Neocomien is, according to Karsten, a sandy light-brown or red-yellow, imperfectly stratified marl with interbedded strata of blue or dark-colored limestone which predominates in the upper portions. Karsten found fossils in one locality only, near Caqueza. I must admit that I have not discovered any and that I therefore must classify this formation with the following one, the Gault, inasmuch as they are not particularly different in lithologic character. The Lower Cretaceous (Neocomien and Gault) is therefore in general a thick series of clay slates, shales, and bright-colored shaly clays, which are interbedded with thick strata of blue or more rarely black or white limestone, white quartzite, and white, sometimes reddish and greenish sandstones, as well as some other subordinate strata. Where they possess the typical character I propose to call them the Villetas formation, and the greater part of the limestones of the Middle Cretaceous which Sievers has distinguished in his profile sections probably. The principal part of the Villetas formation has been determined by Steinmann as Urgo-Aptien on the basis of its fossils; whereas the upper strata belong to the true Gault.

In the vicinity of Jiron and Zapatoca and elsewhere there occurs, in the neighborhood of the granite gneiss and porphyry, clay, reddish or white, and in part greenish sandstone which, together with violet-brown shales and reddish sandstones may be named the Jiron formation. This is the reddish-yellow sandstone which Karsten regarded as a special development of the Neocomien, and although there are fossils I would also class it as a portion of the basal Cretaceous that is peculiarly characterized through proximity to the crystalline rocks. Sievers also regarded this formation, which occurs apparently quite frequently in the Cordillera, as the lowest member of the Cretaceous. Elsewhere, especially in the snow-covered mountains of Cocui, a white quartzite which usually occurs only in thin beds in the slates and clays becomes so thick that it replaces all other rocks. This Cocui quartzite probably corresponds to the Uribante sandstone of Sievers. The blue limestone may, however, become the predominant member and entirely replace the slates and clays, as is the case in the neighborhood of Velez.

Toward the top the Villetas formation appears to pass by gradation into the next division, the Guadalupe (Karsten's Upper Cretaceous). The slates and shales become less frequent and occur only as thin interbedded layers. The greater part of this division is siliceous sandstone or a thin-bedded silicified clay rock, together with a heavy-bedded white quartz sandstone which in general overlies the other strata. Fossils are very rarely found and are not such as may be definitely determined. It is therefore doubtful whether the Guadalupe formation belongs to the Gault or to the Upper Cretaceous.

B-C 19-20. VENEZUELA.

As regards the Lower Cretaceous, Sievers^{71a} in describing the Cretaceous rocks of Venezuela distinguishes conglomerate and breccia at the base, followed by red sandstone, yellow and white quartzose sandstone, and limestone. From the descriptions of these several formations, which consist chiefly of details of local occurrences, the following notes may be taken:

The clay slates which are assigned by Sievers to the Archean and which for the sake of distinction have been placed by the present compiler in the metamorphic Paleozoic are unconformably overlain in many places in the Cordillera by massive deposits of conglomerate and breccia which Sievers calls the Lagunillas conglomerates. They consist of fragments of the "Archean" rocks embedded in a clay and sandy cement. Their horizontal extent is in places considerable; the thickness in the vicinity of Lagunillas is stated at 700 meters. Sievers leaves one in doubt as to whether the conglomerates should be assigned to the Cretaceous or not, saying:

These conglomerates appear widely distributed throughout the Cordillera and always occur between the Archean rocks and the succeeding red and yellow sandstones which we may well regard as Lower Cretaceous. Sometimes they rest upon gneiss, as at Lagunillas, sometimes on clay slate, but they always constitute an intermediate member between the Archean and the Cretaceous. One is obliged to regard them as a coastal formation developed around islands of the older gneiss and clay slate which now constitute the core of the Cordillera. The time at which these conglomerates were formed can not be determined with certainty, but they must be older than the red and yellow sandstone which we regard as the lowest member of the Cretaceous. It is therefore probable that they introduced this period.

After citing the localities at which the Lagunillas conglomerate occurs, Sievers continues:

The conglomerate and breccia are followed by the Cretaceous series, to which most of the sedimentary deposits of the Cordillera belong and which occupies a much greater area than that of the Archean formations. The determination of the age of these formations depends essentially on a few fossils from the blue limestone of Tachira and Barbacoas, which are mostly ammonites and may be correlated with the Upper Albien of the Middle Cretaceous as determined by Prof. Steinmann. The strata which underlie these limestones are therefore older Albien. There are red and yellow sandstones as well as the white sandstone. Unfortunately they are as a whole very poor in fossils, but they may be considered as Cretaceous, as in lithologic character they are very similar to the corresponding Cretaceous deposits of Europe. * * *

The red sandstone follows directly upon the deposits of the Lagunillas conglomerate. It is mostly coarse and rich in mica, though also sometimes fine grained, usually according to its relation to the conglomerate, whether directly deposited upon that formation or farther away from it. * * *

At many points in the Cordillera de Merida we observed a white to yellow coarse-grained saccharoidal quartz sandstone which in many respects strongly reminds one of the Quader sandstone of Saxony. * * * Although this sandstone resembles the Pläner (of Germany) and accordingly should be placed among the upper formations of the Cretaceous, it can not be denied that it occurs in the Cordillera under the limestone which is determined as equivalent to the Albien and outcrops together with the red sandstone. * * * The yellow sandstone frequently grades into the red but in general is much more widely distributed than the red sandstone. Where the red is entirely wanting—that is to say; throughout the eastern portion of the range—the white sandstone seems to replace it.

In describing the Cretaceous limestone Sievers refers to classifications by Wall and Steinmann. He cites three divisions of the Older Parian group, so named by Wall in his "Geology of the Island of Trinidad," and finds a parallel with divisions recognized by him in the Cordillera de Merida.

Referring to a report contributed by Prof. Steinmann on the fossils which Sievers had collected Sievers says:

Steinmann infers that there are three limestone formations which may be distinguished—(a) the dark bituminous limestones of San Cristobal, with *Exogyra*; (b) the succeeding Barba-coas formation, with many ammonites; and (c), still higher, the broad crystalline limestone with many poorly preserved fossils of *Exogyra*, *Trigonia*, *Cardita*, and *Astarte*, which occur extensively in northern South America. Of these formations the age of the Barbacoas alone can be determined accurately. It belongs to the Upper Albien, on the boundary between the Lower and the Upper Cretaceous, and is distinguished by the following fossils:

Schloenbachia inflata Sow.
S. varicosa Sow.
S. belknapi Marcou.
Hoplites tocuyensis.
Mojsisovicsia durfeldi Steinmann.
Cardium peregrinorum d'Orb.
Inoceramus plicatus d'Orb.

C 20. TRINIDAD.

Wall and Sawkins^{863a} described the Older Parian group of the Island of Trinidad as Lower Cretaceous.

The Older Parian group consists of a great variety of sandstones, fine or coarse grained and usually highly indurated, which properly seems referable to the extensive diffusion of siliceous cementing material; of shales of a dark color, characterized by flakes of silvery white mica; and of strata composed of an argillaceous base, with small equivalents of carbonate of lime and free silica. * * *

Limestones are rare, do not exceed 10 to 20 feet in thickness, are extremely compact, and their fossils usually partially or entirely transformed into highly crystalline spar. * * *

Very few fossils were collected in this formation, and those obtained were from a single limestone at Point a Pierre, but none of them offering any characters sufficiently precise for defining the geological position. Some fossil remains procured from the same series at Cumana, in Venezuela, fortunately present a more positive aspect and are referable to the later secondary period. It is highly probable that these strata are of similar age to the upper secondary deposits of New Grenada, which are attributed by Von Buch and D'Orbigny to the Neocomian or Lower Cretaceous horizon.

Disturbances are everywhere characteristic, the angle of dip is almost invariably high, and the strata are often vertical; but buried as the formation usually is in the center of the densest forests, it is extremely difficult to obtain sections adapted for resolving the details of position. These disturbances are by no means referable to a single series, since the consolidation, perhaps rapid, and the first elevation must have transpired before the newer Parian deposits were formed, and consequently anterior to the Miocene epoch. Ulterior movements, possibly repeated at intervals, affected both groups nearly equally, since in Naparima and the southern districts the Tertiary members are found at high angles reposing apparently conformably on the subjacent Older Parian.

E. H. Cunningham-Craig,²⁰⁰ Government geologist of Trinidad, made fourteen brief reports to the legislative council between 1904 and 1907 inclusive and described local details, especially of the oil fields in Tertiary strata.

C 17, D 16. HONDURAS AND COSTA RICA.

Sapper ^{696a} describes certain strata of southern Central America as the Metapan terrane, and says:

Under this name I included in describing the geologic formations of Guatemala a system of clays, marls, sandstones, and conglomerates with included limestone beds which conformably underlie the Cretaceous limestone. In Honduras the same formations occur with the same lithologic character and they have great extent in all the northern and middle districts; that they belong to the lower Cretaceous is shown by many fossils which have courteously been described by Dr. Joh. Böhm of Berlin.

In a footnote Sapper gives the following list of fossils as having been determined by Böhm:

From Carizal:

Glauconia cf. *picteti* Coqu.

Between Charizal and Cuevas:

Protocardia cuevasensis n. sp.

P. ventrosa n. sp.

Lima wacoensis F. Roem.

From Cuevas:

Lima wacoensis F. Roem.

Arca elongatior n. sp.

Protocardia cuevasensis n. sp.

The most important places at which fossils have been found occur in the interbedded limestone strata near Selila, near Neambar, between Comayagua and Potrero, as well as between Espinas and Esquias. The fossils are, however, not sufficiently numerous and not sufficiently widely distributed to give definite data as to the age of individual beds, and as the petrographic character of the Metapan terrane is often extraordinarily similar to that of the Upper Triassic Tegucigalpa formation, I have not been able to determine with certainty in regard to the occurrence in the departments of Tegucigalpa and Olancho whether we have to deal with the Metapan or the Tegucigalpa terrane.

The Metapan terrane is conformably overlain by a moderate thickness of Upper Cretaceous ["Meso-Cretaceous," Comanche] limestones, which in Honduras often form the mountain summits. * * * The limestones near the western boundary of the Republic of Honduras near Copan, are characterized by well-preserved Rudistes, and thus belong to the Upper Cretaceous ["Meso-Cretaceous," Comanche]. The correlation of the limestones which occur in the departments of Santa Barbara, Comayagua, Yoro, and Olancho and have a thickness of several hundred meters with the Upper Cretaceous depends simply on the fact that they lie conformably upon the Metapan terrane.

Cretaceous limestones have not been certainly identified in the Republic of Nicaragua, but it seems to me quite possible that the limestones of the middle course of the Rio Coco may be so correlated.

Sapper then goes on to mention occurrences in Costa Rica and, quoting R. T. Hill, describes a dark-blue massive limestone which outcrops in steeply dipping beds and is in large part composed of Rudistes and Inoceramus. He mentions several other localities in Costa Rica at which rocks of probable Cretaceous age occur.

D-E 15-16. GUATEMALA AND CHIAPAS.

The Mesozoic formations of Guatemala are described by Sapper, ^{695a} who says:

The Mesozoic formations occupy very extensive areas in Alta Verapaz (Guatemala), but the strata are nevertheless very monotonous and consist everywhere of limestones and dolomites, together with conglomerates and breccias of the same rocks, so that it is impossible to distinguish different horizons by lithologic differences.

It is true that in the south the limestones and dolomites are in general of darker-gray to black tones and are thus distinguished from those of the north, which exhibit clear, mostly yellowish color values. The conglomerates often contain interbedded layers which are colored red by iron oxide. The predominance of brighter colors in the limestones of the north does not, however, prevent the frequent occurrence of limestones and especially of dolomites of dark-gray tones in that region; but it has not been possible to show that there was any difference in age between the lighter and darker limestones.

The paleontological evidences also fail to bring complete satisfaction, for only the light-colored limestones contain fossils, such as the remarkable *Barettia*, and in other localities *Sphærolites* or remains of *Radiolites*, which have not yet been accurately determined. In many places there are organic breccias of mussels and snail shells, which, however, are not accurately determinable. Yet as they occur with well-recognizable traces of *Rudistes* they evidently belong to the Upper [?] Cretaceous.^[a] I find remains of *Rudistes* as far south as the crest of the Chicoj Range, but thence southward the limestones and dolomites of the Coban terrane, have failed to yield a trace of fossils. They seem to be older than the Upper Cretaceous limestone of the north. The boundaries of the Coban limestone with the Carboniferous limestones and dolomites on the south are as difficult to fix as are those of the Cretaceous in the north, and for that reason they are shown upon the map only by dotted lines.

Sapper estimates the thickness of the Cretaceous at about 800 meters.

Böse⁸⁸ in 1905 described at some length the Lower Cretaceous (Eo- and Meso-Cretaceous as he described the beds) of Chiapas and expressed the opinion that the Neo-Cretaceous (Upper Cretaceous) was lacking in that province. He says:

The Eo-Cretaceous of Chiapas is composed of argillaceous, sandy, slate-colored strata, red beds, slate-colored limestones, and sandstones in thick beds. These strata occur beneath the limestones with *Rudistes* and in the south in contact with the Todos Santos terrane. The limit between the basal Cretaceous and the Todos Santos has not been carefully studied. The Lower Cretaceous in the south is everywhere followed by Cretaceous limestones with *Rudistes*. Moreover, it occurs in the basin of Chiapas, where it is laid bare by erosion. The thickness of this formation is about 300 or 400 meters. It is followed conformably by Cretaceous with *Rudistes*, as may be seen to the south and west of Tuxtla, Gutierrez, and Chiapa. Sapper classed these beds as Upper Cretaceous and said that they rest upon the limestone with *Rudistes*. This is not certain. * * * The few fossils which I have been able to examine indicate rather an Eo-Cretaceous than a Neo-Cretaceous age. It should be stated that the greater part of the species which Sapper cites are contained in the private collection of the former director of the Instituto Geológico, which was not accessible to me. I have from those beds only an *Isastræa* sp. nov. very like an *Isastræa* of the Eo-Cretaceous of San Juan Raya, two examples of *Nerineopsis goyzuetae* Aguilera, n. gen., n. sp., and some poorly preserved corals. It is possible that to this division belong also certain gray and brown strata with masses of limestone which occur near Cancuc, at the northern base of the Mesa Central. * * * It is quite probable that these strata correspond to the upper part of the Metapan terrane, which is found in the southern part of Guatemala, in western Honduras, and in the northwest of San Salvador and which consists also of marls, sandstones, and argillaceous rocks and conformably underlies the limestones with *Rudistes*.

Böse then goes on to describe the Cretaceous limestones with *Rudistes* ("Meso-Cretaceous") and says:

This division is much the most important in Chiapas. * * * It consists of limestones and dolomites which generally occur in quite thick beds and only occasionally as intercalated

^a Probably Meso-Cretaceous of the Mexican Survey or Comanche series of the United States Geological Survey.—T. W. Stanton, comment on manuscript. See also citations from Böse and Aguilera, beyond.

lenses. Occasionally beds of limestone of brecciated structure are found. In the lower part there sometimes occur beds of limestone with chert concretions, but the upper part consists generally only of gray limestone with interbedded dolomite. It may be said that these strata everywhere contain Rudistes, especially radiolites.

Böse then cites a number of localities. In regard to the Neo-Cretaceous (Upper Cretaceous), he says that the strata of Tuxtla, Gutierrez, and Chiapa, which Sapper took for Neo-Cretaceous, in reality belong to the Eo-Cretaceous; that he himself has never observed strata which might with certainty be assigned to the Neo-Cretaceous; but that possibly the dolomites and limestones in the extreme north of Chiapas represent a horizon of Upper Cretaceous.

E 14. STATE OF VERA CRUZ, EASTERN SLOPE OF THE MEXICAN PLATEAU.

In the vicinity of Orizaba Böse⁸⁷ made a special study of a Cretaceous section which he divided into three parts, to each of which he gave a locality name. His account may be summarized as follows:

In the region which we are to describe and which includes the environs of the Rio Metlac and Boca del Monte branch of the Veracruz-Mexico Railway the only sedimentary formations that occur belong to the Cretaceous system. They have been divided into three parts, which may be distinguished partly by paleontologic criteria and partly by lithologic differences. The formations are, in succession from above downward: (1) Escamela limestones; (2) Maltrata limestones; (3) Necoxtla slates. * * *

The greater part of this division [the Necoxtla slates] consists of argillaceous slates which are yellowish, gray, and reddish, with the luster of silk, and which include not infrequently segregations of pyrite crystals. The slates also contain in some places small amounts of mica. They are very fissile. In the upper part of the slates one may observe an enrichment in lime and the slates are often arenaceous and sometimes merge into a greenish sandstone which contains a large proportion of lime and in some places is almost entirely composed of calcareous fragments.

The Maltrata limestones constitute an important division, which is often of great thickness. The greater part is composed of limestones in thin beds, is without fossils, and of a clear dark-gray or black color. The limestones contain numerous segregations of flint in the form of lenses. In the upper portion the flint occurs in the form of nodules and irregular bodies. In the lower part of the limestones there occur in many places intercalated argillaceous slates which are yellowish and lustrous like silk, but these never form heavy beds. In the upper part toward the boundary with the Escamela limestones, there occur gray limestones and dolomites in heavy beds in which the stratification is scarcely recognizable. Above these follow dark compact limestones which represent the passage to the Escamela limestones and which may better be considered a part of the latter. In some places there occur above the dolomites flinty limestones, and in that case the line between them and the Escamela limestones is sufficiently well marked.

The Escamela limestones are composed of a clear gray to a dark-gray limestone, in some places but slightly stratified and elsewhere in clearly distinct beds. Cherts occur only in the lower portion. There are no intercalations of slates or marls. The limestones resemble in their characters very often the Cretaceous limestones of southern Italy. They are petrographically very uniform and may be recognized with ease.

Böse's description includes lists of fossils and a study of the relations of the Cretaceous of Orizaba with that of Texas and northern Mexico and that of Europe. His correlation table is translated as follows:

District of Orizaba and Tehuacan; formations of southern Mexico.		Texas and northern Mexico.		Stages.
Orizaba limestones.	Escamela limestones, 600 meters.	Comanche series.	Washita division.....	Turonian.
	Maltrata limestones, 500-600 meters.		Fredericksburg division.....	Cenomanian.
	(?).....		
Tehuacan slates.	Necoxtla slates, thickness not determined.	Trinity division.		Aptien-Urgonian.
	Zapotitlan slates and sandstones.	(?).....	Upper Neocomian.
Black calcareous slates.				Middle and lower Neocomian.
Upper Jurassic and older formations.				Upper Jurassic.

Böse's paper has been reviewed by Stanton,⁷⁸⁰ who has also contributed the following notes in regard to the relations of the limestones in the vicinity of Orizaba:

The faunas of the two limestones indicate correlation with the Comanche series, and the underlying slates, though unfossiliferous, are correlated by lithology and stratigraphic position with the Lower Cretaceous of Zapotitlan, in Puebla.

The section at Zapotitlan and San Juan Raya has been described by Aguilera (*Guide géologique au Mexique*), who states that the Escamela and Maltrata limestones, which he refers to the Cenomanian, are represented here by a single unfossiliferous limestone called the Cipiapa division. The underlying Eo-Cretaceous includes the San Juan Raya and Zapotitlan divisions, which together are correlated by their faunas with the European Lower Cretaceous horizon from the upper Barremian to the Aptien, inclusive.

E 15. ISTHMUS OF TEHUANTEPEC.

Böse published for the Tenth International Congress an account of the geology of the Isthmus of Tehuantepec. He said in part:^{90a}

Before commencing the description of the excursion in the isthmus, we will summarily describe the geology of the terranes which extend from east to west in this region. West of the isthmus there is the mountain chain of Mexico, and on the left the chain of Central America. The former consists of the following formations: At the base there is a series of gneisses and mica schists, with ancient diorites and granites. Upon these rocks there rests in general the Cretaceous, but there are also islands of Rhætic, Liassic, and Upper Jurassic. The series is rarely complete, and the Paleozoic is always absent. The Cretaceous is composed of the lower and middle Cretaceous and covers probably the larger part of the country. In the north [of Mexico as a whole] these are supplemented by the upper Cretaceous.

From this distribution of the Cretaceous Böse infers an early elevation of southern Mexico, to which he attributes the absence of marine Tertiary in the high plateaus, and he says further:

In the plateaus we encountered deposits from extensive lakes which belong in part to the Eocene and Miocene, the Pliocene, or Quaternary. Their age has been determined in many

cases by means of fossils, both plant remains and vertebrates; in other cases it has been necessary to base an opinion upon the presence or absence of modern eruptive rocks in the conglomerate.

E-H 12-15. MEXICO IN GENERAL.

Cretaceous rocks, chiefly limestones, have great thickness and wide distribution in Mexico and Central America. Two classifications have been applied to them. One is that of Hill, who recognized the Comanche series in its characteristic development and also the Upper Cretaceous. The Mexican Survey, on the other hand, divides all the strata of the Cretaceous system into three series, which it designates as Eo-, Meso-, and Neo-Cretaceous and which are correlated on paleontologic evidence with European divisions. The Eo- and Meso-Cretaceous of this classification correspond with the Comanche of Hill's classification, and the Neo-Cretaceous is Upper Cretaceous, later than Dakota. Aguilera^{9b} refers to the synopsis of the geology of Mexico⁷ and says:

We divided the Cretaceous into Lower, Middle, and Upper divisions, which, according to the resolutions adopted at the International Geological Congress, should be called respectively Eo-Cretaceous, Meso-Cretaceous, and Neo-Cretaceous. In practice this arrangement has proved advantageous, although it has been abandoned elsewhere, as it is here very useful from the double point of view of lithology and paleontology. The limit between the Eo-Cretaceous and Meso-Cretaceous series should correspond to the bottom of the compact limestones which form the mountains of Mexico, where it is impossible for us to separate the Albien from the Cenomanien, as the former has not yet been identified by its fossils in Mexico; and the Eo-Cretaceous series thus ends with the Aptien. The Meso-Cretaceous extends from the Albien to the Cenomanien inclusive, and the Neo-Cretaceous is composed of the Turonien, Emscherien, Aturien, and Danien.

The Meso-Cretaceous series is very extensively developed throughout the country and forms almost all of the limestone mountains of Mexico. It is found from Sonora, Chihuahua, and Tamaulipas in the north to Chiapas and Tabasco in the south, and from the Gulf of Mexico to the Pacific Ocean. The predominant facies of the Meso-Cretaceous are those of the Rudistes and Caprinides. Up to the present time we have not succeeded in clearly separating the Albien from the Cenomanien. To the north the series is composed of marly rocks and in certain places carries a sufficiently rich fauna.

The following notes on the stratigraphy and distribution are condensed from Aguilera's descriptions, and arranged from south to north. For fossils and European equivalents, the original should be consulted.

Eo-Cretaceous strata occur as follows:

In the State of Oaxaca, at Tlaxiaco, the Eo-Cretaceous is represented by calcareous to gray calcareous argillaceous shales and by compact limestones of gray and grayish-black colors.

Near Cualac, in the State of Guerrero, are quartzose sandstones, gray to red in color, with grayish and yellowish argillaceous and marly shales. At the base are gray sandstones with impressions of plants. Red and yellowish quartzose sandstones and argillaceous schists occur near Tomixlahuaca.

In the State of Michoacan argillaceous shales of black and grayish colors alternating with yellowish fossiliferous sandstones are found at Cochixtla, and argillaceous marly shales alternating with calcareous fossiliferous shales at Parota, in the district of Coalcoman.

In the State of Puebla, at Zapotitlan and San Juan Raya, the terrane consists of gray argillaceous rocks, marly gypsiferous yellow shales, calcareous green sandstones, marly green sandstones, and varicolored shales.

In the State of Vera Cruz, at Necoxtla, occur argillaceous micaceous reddish gray or black shales, with beds of limestone in the upper part but without fossils.

In San Luis Potosi, at Catorce, there are in the upper part shales and marly sandstones and compact limestones.

In the State of Tamaulipas, at Miquihuana, there are beds of sandy shales and limestones which rest upon sand with pebbles of quartz but which are unconformable upon the older Mesozoic strata. According to Hill they closely resemble the beds of the Trinity group of Texas but have a different fauna. Felix and Lenk believe that these beds represent the littoral facies of their *Monopleura* beds of Tehuacan.

In the northern part of the State of Zacatecas (at Mazapil, Santa Rosa, Concepcion del Oro, and Canutillo) the Eo-Cretaceous begins with marl and limestone. Above these come bluish limestones and other limestones with large concretions of chert, having a thickness of 400 or 500 meters but poor in fossils, and yellowish marls containing many forms. These last-named beds may serve as the plane of separation between the Eo-Cretaceous and the "Meso-Cretaceous."

Occurrences of "Meso-Cretaceous" strata are specifically listed by Aguilera from the following localities in several States:

In Chiapas and Guatemala there are limestones and dolomites, in general in thick beds but in some places occurring in thin beds. Some of the layers present a brecciated structure. In the lower part the limestones include concretions and nodules of chert; in the upper part they inclose intercalations of dolomite. These limestones form an extensive belt which runs through the center of the State of Chiapas, passes on to Guatemala, and ends in the Gulf of Honduras.

In the State of Michoacan, at Coalcoman, are compact black and gray limestones. At Aguililla occur compact gray and blackish limestones with chert, but without fossils. At Huetamo are compact limestones and calcareous shales.

In the State of Mexico, at Zumpahuacan, in the Sierra de San Gaspar, are compact gray yellowish-white limestones. In Morelos the horizon is represented at Ayala and Yontepec.

In Jalisco fossils of the "Meso-Cretaceous" have been obtained at Saistra, Sierra de Tapalpa, and at the hacienda of Huilcalapa, Canton de Zapotitlan.

In the State of Vera Cruz the limestones of Orizaba may be divided, from above downward, into the Escamela limestones, which are gray and occur in thick beds with a facies of Rudistes and Chamides, and the Maltrata limestones, with blackish cherts and without fossils.

In the State of Queretaro, at Cadereyta, occur compact gray fetid limestones, limestones with chert, and calcareous and argillaceous shales.

In the State of Hidalgo, at Zimapan, are compact gray fetid limestones with calcareous shales.

In the State of Zacatecas, at Mazapil, Santa Rosa, Concepcion del Oro, Fresnillo, Comacho, and Noria de Angeles, occurs a pelagic facies. It consists of lime-

stones with black chert, having a thickness of 400 to 500 meters or more. In the vicinity of Colima there are limestones and shales. On the eastern slope of the Sierra de Tamaulipas, near Victoria, occur limestones and shales.

In the State of Chihuahua the transition stage to the Cenomanian occurs at several places in the Cerro Muleros, near Ciudad Juarez, with argillaceous sandstones and shales, and at Encantada, near Placeres de Guadalupe, where there are shaly limestones and marly schists. This stage corresponds to the Fredericksburg group, or some portion of it, of the Lower Cretaceous of the United States. At Arivechi, in the State of Sonora, there are calcareous and marly shales.

The Cenomanian is well developed throughout in the States of Chihuahua (Cerro de Muleros) and Coahuila (Hacienda de Vacas, Rancho de San Diego, Santa Eulalia, Javal, etc.), consisting of limestones and gray compact shales with a littoral facies and a rich fauna. Characteristic fossils occur in the limestones and shales of the Sierra Mojada.

For the Neo-Cretaceous (Upper Cretaceous) see Chapter XV (p. 644).

F 14. SAN LUIS POTOSI.

In examining the section along the railway line between San Luis Potosi and Tampico, Böse⁸⁹ studied a Cretaceous series which is distinguished by a peculiar facies that is not represented as a whole elsewhere in North America, except perhaps in Jamaica. He has described the fauna and correlation in detail. The following statement regarding the stratigraphy is extracted from his work:

The strata which contained the fauna described in this work constitute a complete whole to which we give the local name Cardenas division, for the facies is very different from that of any other Cretaceous formation in America. It has a sufficiently great thickness, which may be estimated approximately at 600 meters; this amount is naturally not exact, as the strata have been greatly folded, and it has not been possible to establish with certainty the existence of any younger beds. Lithologically, the Cardenas division is composed of various formations. Above the heavy-bedded limestones which form the canyon of Tamocopo, in the upper portion of which we have not been able to find determinable fossils, there occur in the vicinity of Canoas station arenaceous limestones, which alternate with marls and with clay and marly slates. Above these slates occur heavy beds of limestone, which are in part marly, and still higher there again appear marly and arenaceous slates, which pass gradually into heavy-bedded limestones. These are poor in fossils and are followed at first by yellow clay slates without fossils, upon which rest marly yellow slates with intercalations of sandstones of the same color, which are fossiliferous. The top of the division is composed of marls of a grayish-yellow color, with some beds of limestone. The beds are very strongly folded and their order of succession can not be made out.

Stanton^a states:

Near the eastern margin of the Mexican plateau, between San Luis Potosi and Tampico, there is a thick Cretaceous section which evidently includes the equivalent of a large part of the Comanche series as well as some Upper Cretaceous. A part of the latter which shows a faunal and lithologic facies not known elsewhere in North America has been described by Böse under the name Cardenas division and referred to the lower Turonian. Its thickness is estimated at 600 meters. The presence of *Exogyra costata* and *Gryphæa vesicularis* suggests its approximate correlation with the Ripley of the Southern States, but the rest of the fauna is distinct and in its general character more nearly resembles that of Jamaica and of the European Gosan beds.

^a Personal communication.

G 13-14. SIERRA DE MAZAPIL, ZACATECAS.

Burckhardt^{109a} thus describes the Eo-Cretaceous and "Meso-Cretaceous" of the northern part of Zacatecas:

The Cretaceous limestones that overlie the shaly formations which we have just described represent the complete series from the upper limit of the Jurassic to the Upper Cretaceous. Near the middle of their thickness these limestones are divided into two parts by a very fossiliferous bed of marl known as the "Parahoplites bed." Furthermore, there is at the base of the sequence a second marly bed, which is also rich in fossils, the "Holcostephanus bed." By means of these fossiliferous marls, it is possible to establish four subdivisions of the Lower and Middle Cretaceous of Mazapil. The lower marls, which contain Holcostephanus, are rather thin and separated from the Jurassic by thin strata of gray limestone.

These marls are generally yellowish and contain many nodules of iron oxide. They alternate with beds of grayish or brownish limestone. Fossils are very numerous.^a * * *

Above the marls with Holcostephanus there follow limestones which have a thickness of 400 to 500 meters and which are generally markedly distinguished by intercalations of chert. These cherts, which are usually brownish at the surface and bluish in the interior, are commonly of very irregular forms, and never assume a notably horizontal extent, as is the case with the layers of chert in the Middle Cretaceous. It is very difficult to extract any fossils from the rock, and the only fairly good specimen which I have found is a fragment of Holcodiscus. * * *

Between the limestones which have just been described and those of the Middle Cretaceous, there occurs an argillaceous terrane, which may readily be recognized throughout the Sierra de Santa Rosa. * * * The beds are not thick, but very characteristic—marls and marly limestones of a bright-yellow color, alternating with compact limestones which are grayish, bluish, or slightly brownish. They everywhere contain many fossils.^a * * *

The Middle Cretaceous is represented by a very thick series of grayish limestones, which are generally well stratified and alternate with layers of black chert. These limestones attain a thickness of 400 to 500 meters and are easy to recognize, as there is no other division of the Jurassic or Cretaceous of Mazapil which offers so great a thickness of well-stratified limestones in alternation with such regular beds and lenses of black chert. The intercalations of chert have almost always great extent. They are strata rather than lenses. The rocks are not poor in fossils. On the contrary, the beds abound in open ammonites, generally rather slender, belonging to the genera Hamites, Crioceras, Ancyloceras, and probably Hamulina. But these remains are not specifically determinable.

Burckhardt's table is given in Chapter XIII (pp. 552-553).

H 12. SOUTHEASTERN ARIZONA AND SONORA.

In the Bisbee district of Arizona Comanche strata overlap on Paleozoic, according to Ransome,^{658d} who gives the following section:

Generalized section of the Cretaceous rocks of the Bisbee quadrangle, Arizona.

Bisbee group (Comanche series.)	Cintura formation, 1,800 feet plus unknown thickness, removed by erosion.	Red nodular shales with cross-bedded, buff, tawny, and red sandstones. A few beds of impure limestone near base. Unconformably overlain by fluvialite Quaternary deposits.
	Mural limestone, 650 feet.	Thick-bedded, hard, gray, fossiliferous limestone.
		Thin-bedded, arenaceous fossiliferous limestones.
	Morita formation, 1,800 feet.	Buff, tawny, and red sandstones and dark-red shales, with an occasional thin bed of impure limestone near top.
Glance conglomerate, 25 to 500 feet.	Bedded conglomerate with rather angular pebbles, chiefly schist and limestone. Rests on irregular surface produced by erosion.	
Great unconformity.		

^a For list see the work cited.—B. W.

Ransome describes the four formations in detail. Fossils were obtained chiefly from the Mural limestone and Stanton reported on them as follows:

The collection consists of a considerable number of small lots of fossils, with seldom more than three or four species from one locality, and it includes a number of undescribed forms. The known species that are recognized, however, are sufficient to prove that only the fauna of the lower Cretaceous, or Comanche series, is represented in the collection. The identified species all occur in Texas, indicating that the waters in which the Arizona deposits were laid down were directly connected with the Comanche sea of Texas and Mexico, which probably did not extend much farther west than the Bisbee area.

In the Texan region three principal divisions are recognized in the Comanche series—Trinity, Fredericksburg, and Washita. All of the identified species in this collection occur in the Glen Rose beds of the lowest or Trinity division and only one of them (*Lunatia pedernalis*) is known to pass up into the lower members of the Fredericksburg division.

A list of species referable to the Glen Rose limestone of Texas follows.

Dumble²⁹⁵ cites Aguilera's description of the Cretaceous in Mexico and gives accounts of the strata west of Casita, near Zubiata, Hermosillo, and particularly near Cabullona, northeast of La Morita. He says:

By far the best exposure observed is that near Cabullona, northeast of La Morita. Here appears a great series of Cretaceous rocks, probably including strata belonging to both the Lower and Middle divisions of the Mexican geologists, with other beds of which I find no description at all.

A section made about 2 miles from the Cabullona ranch house gave the following:

1. Interbedded sands and clays of varied colors. The materials are altered in places by metamorphism, some being quartzitic, and some of the clays hardened and greasy. There are some intercalated andesitic beds and dikes of porphyry. The top was not seen, 1,000 feet.

2. Massive limestones; light-colored semimarbles at the top, followed by brown and gray limestone. All the beds are very fossiliferous, but the fossils appear only as cherty protuberances on weathered surfaces and in many cases are so broken as to be scarcely distinguishable. Among the forms certainly recognized were a small *Gryphæa* and a *Trigonia* (like *T. emoryi*). The middle beds carry flints in considerable quantities, and the *Gryphæa* occurs in the basal portion in great numbers, 500 feet.

3. A series of interbedded marls and marly limestones, with large numbers of a very heavy oyster, *Trigonia*, *Cardita*, and other forms, 900 feet.

4. Quartzites, sands and interbedded clays or marls; bottom not seen, 400 feet.

Except for their metamorphosed condition, the uppermost beds of this section resemble very closely the "coal series" of the section made at Eagle Pass, Texas, and, like those beds, they are coal-bearing. They cover quite an extensive area in this region but are badly cut up and disturbed by eruptive intrusions. These beds comprise alternations of sands and clays with ferruginous concretions (some of which are of large size), considerable quantities of gypsum, and some petrified wood. The sandstones vary from fine-grained to grit, and the clays from those nearly pure to those with a large admixture of sand. The metamorphism directly or indirectly due to the volcanic extravasations which accompanied and followed the deposition of these beds has produced, in addition to its indurating effects, bright-purple and greenish colors in some places, so that some of the beds closely simulate those of the tuff itself. The beds are somewhat faulted and broken. Our work did not extend far enough to the north to reach the top of the beds, which are certainly more than 1,000 feet in thickness. The only fossils found were specimens of a small square-beaked oyster, which occurred just below the coal.

There are two beds of coal, both highly altered. The lower is quite graphitic, and the upper, while retaining the structure of bituminous coal, is an anthracite in its composition.

The massive limestones underlie these sands and clays, and, as far as could be seen, without any unconformability. These limestones seem to correspond very well with Aguilera's description of the Middle Cretaceous. The Gryphæa which they carry in such abundance resembles very closely the variety found at the base of the Fredericksburg beds, in northern Coahuila.

H 13. QUITMAN MOUNTAINS, TRANS-PECOS TEXAS.

The Quitman Range crosses the thirty-first parallel near longitude 105° 25' and extends northward to Malone Mountain and southward to the Rio Grande. The development of the Comanche series in the southern portion of the range is thus described by Stanton^{177a} in Cragin's report on Malone Mountain:

Cretaceous rocks have a great development in this region and represent the three main divisions of the Comanche series—the Trinity, Fredericksburg, and Washita—as well as a part of the Upper Cretaceous. Lithologically the section differs greatly from that of central Texas, where the Comanche series has been most studied, and there are also considerable differences in the vertical range of some of the common species, so that it is impracticable to recognize many of the minor formations and horizons that have been studied. The general faunal succession is the same in both regions, and it is usually not difficult to classify the beds by means of the fossils as Trinity, Fredericksburg, or Washita, though it was difficult and sometimes impossible to assign each exposure to its exact position in the general section, because many of them are relatively small and isolated and the structure is complicated by folds, faults, and igneous intrusions. The most complete sections are to be found in the Quitman Mountains, especially toward the southern end and in the lower hills farther south on the Rio Grande, in the southern extension of the same line of uplift.

The description of the Quitman Range comprises notes on structure and on igneous intrusions, as well as on stratigraphy, and the more complete section near the Rio Grande is given as follows:

Still farther south, near the Rio Grande, the upper part of the section is much more complete and more simple, furnishing the key to the sections already discussed, which are parallel with it across the same line of uplift. The eastern end of the section is about 1 mile north of the Rio Grande in the first hills west of the broad valley of Quitman Arroyo. Here the beds are sharply folded and a prominent ridge shows an anticline consisting of argillaceous limestone belonging to the Washita division.

The western limb of the anticline dips 70° to 80° W., and the exposure is as follows:

Section in hills just west of Quitman Arroyo, about 1 mile north of the Rio Grande.

	Feet.
1. Argillaceous limestone, weathering in nodular form, with bands of harder limestone.....	200
2. More massive limestone, much seamed and fissured.....	30
3. Dark, fissile shale, with occasional bands of impure brown limestone, underlying a valley about 1 mile wide. Dips at first steep to the west, becoming variable and much less toward the middle of the valley and again steep to the west on the west side of the valley. <i>Inoceramus labiatus</i> and a few other Upper Cretaceous fossils were found west of the middle of the valley; thickness apparently several thousand feet.	
4. Massive limestone, probably same as No. 2.....	30
5. Argillaceous limestone with some bands of clay and sandstone; fossils: <i>Nodosaria texana</i> , <i>Enallaster texanus</i> , <i>Neitheia texana</i> , <i>Exogyra arietina</i> , <i>E. drakei</i> var., <i>Plicatula incongrua</i> , and other Washita forms.....	300
6. Heavy-bedded limestone (40 feet) forming a cliff, followed by argillaceous nodular limestone (30 feet), which yielded <i>Enallaster texanus</i> , <i>Gryphæa corrugata</i> , <i>Lima wacoensis</i> , <i>Neitheia texana</i> , and <i>Schlenbachia vespertina</i>	70
7. Similar limestones with dip not less than 45° westward.....	300

	Feet.
8. More argillaceous light-gray limestone, interstratified with dark clay shales; one of the limestone bands yielded <i>Epiaster whitei</i> , <i>Terebratulula (Kingena) wacoensis</i> , <i>Gryphaea washitaensis</i> (?), <i>Plicatula incongrua</i> , and <i>Schlaenbachia vespertina</i> , and another band farther west yielded <i>Epiaster whitei</i> , <i>Schlaenbachia acutocarinata</i> , <i>S. serratescens</i> , and <i>Hamites fremonti</i>	300
9. Dark clays with brownish calcareous bands; <i>Exogyra texana</i> abundant.....	50
10. Covered.....	100
11. Limestone, very heavy bedded above, with increasing bands of argillaceous limestone below; Requienia and a small conical Foraminifera abundant; <i>Exogyra texana</i> also occurs.....	300
12. Shales, limestones, and bands of brown sandstone, not well exposed.....	250
13. Argillaceous limestone, with some harder bands containing "Caprina" and Requienia.....	75
14. Generally more massive limestone with some bands of brown sandstone. Also contains "Caprina," <i>Ostrea</i> , etc.....	350
15. Quartzitic sandstone with thinner bands of clay shale and impure limestone, dipping steeply westward.....	400
16. Hard, blue limestone, full of <i>Orbitolina texana</i>	60
17. Sandstone and impure limestone with some clay.....	40
18. Sandstones and clays.....	250
19. Thin-bedded passing into massive limestone, full of <i>Orbitolina texana</i> ; at least.....	300

The steep western surface of No. 19 forms the eastern wall of the canyon of the Rio Grande at this point.

So far there has been no apparent serious break in the section, but the beds now become complexly faulted and folded. A short distance north No. 19 is cut off by a fault, and on the west, across the river, the same bed seems to be repeated in several postures.

It is evident that the eastern portion of the section crosses a syncline, so that in passing from No. 1 to No. 5 the same beds are all crossed twice. In the rest of the section, while there may be some repetition of beds due to small faults, there are no anticlines nor synclines, and the fossils show that in general the beds are successively older toward the west. No. 3 is Upper Cretaceous, of the age of the Fort Benton; Nos. 4 to 8 are Washita; Nos. 9 to 14, and probably 15, are Fredericksburg; and Nos. 16 to 19 belong to the Trinity. As the dips are all steep to the west it follows that all the beds from No. 4 to No. 19, inclusive, are overturned. It will be seen also that the succession of rocks and fossils is similar to that found on the east slope of the mountains near Quitman Canyon, and that there is no place for the great sandstone series of the "Mountain bed" within the Washita division. It must be older than the Orbitolina limestone.

H 13. CHISOS REGION, TEXAS.

For the region lying in the great bend of the Rio Grande in Brewster County, Tex., the report prepared by Udden in 1905 may be consulted. He sums up as follows: ^{819b}

It was not attempted to make out the succession of separate divisions in the Comanche series, for this would have required much more time than was at our disposal, but it may nevertheless be worth the while to sum up the observations made bearing on this subject.

1. The base of the series consists of sandy or clayey beds containing calcareous material also, weathering rather easily. At Cienega Mountain these strata have a thickness of about 150 feet.

2. At about 150 feet above the base there is a conglomerate or a pebbly sandstone measuring some 20 feet. These two members, and very likely a part of the succeeding beds above, are absent at Altuda, where they probably never were laid down, owing to an overlap.

3. At an unknown distance above this conglomerate there are some dark ledges of very compact limestone interbedded with some shaly seams, and these are followed upward by several hundred feet of heavy-bedded limestones of lighter color. These lowest three divisions are equivalents of the Presidio beds in the Shafter section.

4. Then follow 200 or 300 feet of more thin-bedded and less pure limestones, which weather more easily and contain a fauna resembling that found in the Shafter beds.

5. Above this there are several hundred feet of very massive light limestone, which is clearly the equivalent of the Edwards limestone.

6. The last and highest of the series is a compact limestone only some half a hundred feet thick, which is the equivalent of the Buda. It is separated from the massive beds below by some 20 feet or more easily weathering ledges which are frequently filled with organic fragments and which correspond to the Del Rio clay.

At Terlingua both the Buda and the Del Rio zones are much heavier than to the east of the Chisos. These formations clearly thin out or entirely disappear in this direction.

H 13. TEXAS, NEAR EL PASO, AND CHIHUAHUA, MEXICO.

Near El Paso, Tex., occur strata of Cretaceous age, which represent the Fredricksburg and Washita groups of the Comanche series. They consist of about 700 feet of limestone, shale, and sandstone of which Stanton and Vaughan⁷⁸⁷ gave a detailed section. This section is quoted below, with a correction in the relations of divisions 8, 9, and 10. As observed in the field and as described in the published section these beds were inverted.

The following is a description of the section beginning with the highest bed:

Columnar section of Cretaceous near initial monument of Mexican boundary survey, on west side of the Rio Grande from El Paso, Tex.

	Feet.	
8. Hard limestone with the same species of <i>Exogyra</i> in the top	15	
9. Clay shales, with bands of limestone nodules, containing great numbers of a large <i>Exogyra</i>	40	
10. Sandstone, white, yellow, or brownish, with shale beds.	200±	
7. Sandstone, white or brown.....	30+	
Washita division. {	6. Upper part of the bed, clay shales alternating with brown sandy flags. Brown sandy calcareous layers at base, containing <i>Gryphæa washitaensis</i> Hill and <i>Nodosaria texana</i> in great abundance. The <i>G. washitaensis</i> is confined to base; 30 feet above the base, <i>Ostrea subovata</i> ; <i>Ostrea quadriplicata</i> Shum. very abundant between 30 and 40 feet; 40 feet above base zone of <i>Kingena wacoensis</i>	60
	5. Flaggy argillaceous limestone, with shale partings. Layer of sandy flags at base. In the sandy flags, <i>Cyprimeria</i> . In the limestone bands <i>Schlenbachia leonensis</i> , <i>Gryphæa washitaensis</i> , <i>Protocardia</i> , <i>Trigonia emoryi</i> . The zone of <i>G. washitaensis</i> is at the top..	100
	4. Clay shales, with indurated calcareous bands. No fossils were found.....	125
	3. Ledges of hard limestone. Fossils not numerous; at the base there is a considerable number of an undetermined species of <i>Gryphæa</i> , <i>Gryphæa tucumcarii</i> , <i>Neithea</i> , and <i>Schlenbachia</i>	25
Fredricksburg division. {	2. Alternations of clay and soft argillaceous limestone ledges. Fossils: <i>Exogyra texana</i> , <i>Gryphæa tucumcarii</i> , <i>Gryphæa forniculata</i> , <i>Schlenbachia peruviana</i> , two other species of <i>Schlenbachia</i> , and a large <i>Neithea</i>	24
	1. Argillaceous limestone, in thick ledges, weathering into nodular limestone, the nodules surrounded by clay. Fossils: <i>Protocardia texana</i> , <i>Tylostoma pedernalis</i> , <i>Trochus</i> , <i>Turritella</i> , <i>Exogyra texana</i> , an anchuroid genus, two species of echinoids, <i>Pleuromya knowltoni</i> , <i>Requienia</i> , etc.; 11 feet from the top <i>Ostrea subovata</i> (?).....	79
	698±	
* * * * *		

Taking the fauna of the section as a whole, its essential identity with that of the noted Tucumcari region in New Mexico and of other localities on the western and northern borders of the Lower Cretaceous area is at once apparent.

The section studied by Stanton and Vaughan at El Paso occurs in the Cerro de Muleros, which extends into Mexico and has been investigated by Böse,⁹¹ who presents a different interpretation of the sequence. He says:

We have elsewhere stated that we differ on several points from the ideas of the authors mentioned. The errors of Stanton and Vaughan resulted from the fact that they did not clearly

understand the structure of the locality and consequently counted the same sandstone twice as two beds of different ages. At several points where the series of strata is clearly exposed and but little disturbed we have been able to observe the true succession. In our excursion we followed in part the road which Stanton and Vaughan followed, and we shall see what led to their mistake.

All of the sedimentary rocks with the exception of the recent conglomerate and sands belong to the Cretaceous. Stanton and Vaughan recognized only their lower part, of which they give a list of fossils, but their determinations differ in many cases from ours. With reference to this subject we would refer the reader to our publications.^a Stanton and Vaughan distinguished in this lower part ten horizons which we are obliged to reduce to eight, but these horizons can not be classed as real stratigraphic horizons. There are in fact in the lower part only two horizons, to which we must also add two higher horizons which may be considered as such. We give a summary of the distribution of fossils in the rocks.

In his monograph on the Cerro de Muleros, which was not published until the summer of 1910, Böse⁹² says:

According to my observations the succession of the beds is as follows (from above downward):

- No. 11. Brown sandstones alternating with argillaceous slate or shale, frequently containing *Inoceramus labiatus* Schloth.; 110 meters.
- No. 10. Whitish to yellowish sandstone, highly quartzose and fine grained, with satiny argillaceous shale at the base, without fossils; 250 meters.
- No. 9. White to clear gray limestone with *Exogyra ponderosa*; 10-20 meters.
- No. 8. Yellowish marls with *E. ponderosa*, *Hemisater calvini* Clark, etc.; 10-20 meters.
- No. 7. Red, brown, and black sandstone in heavy beds, with *E. ponderosa*; 20-100 meters.
- No. 6. Slate-colored brownish marls, sandstones, and limestones, with *Ostrea quadriplicata*; 10-20 meters.
- No. 5. Gray marls with marly shales and beds of limestone with *Schlaenbachia trinodosa*; 30-50 meters.
- No. 4. Argillaceous shales, marls, and beds of limestone, with *Schlaenbachia nodosa*; 30-50 meters.
- No. 3. Gray limestones in thin-bedded calcareous gray sandstones and brown to yellow marls and black argillaceous shales, with *Schlaenbachia* cfr. *belknapii*; 10 meters.
- No. 2. Brown marls with beds of limestone and calcareous sandstone with *Schlaenbachia bravoensis*; 10-20 meters.
- No. 1. Hard limestones in thick beds and of a gray color, with *Turritella vibrayeana*; 20-25 meters.

Our subdivisions 1 to 7 correspond to the horizons which were numbered 1 to 7 by Stanton and Vaughan, 8 and 9 to the horizons 9 and 8 of those authors, since in fact the limestones with *E. ponderosa* are above the marls which carry the same fossil. That which Stanton and Vaughan regarded as their horizon No. 10 is in reality the same sandstone as their horizon No. 7, and the two American authors did not see our subdivisions 10 and 11. We shall see in the discussion of the structure why they mistook a recumbent synclinal for a normal succession. If they had gone on to the porphyry they probably would not have fallen into this error, since one may there see clearly that the beds or the strata with *Ostrea quadriplicata* rest on the sandstone No. 7 of our classification, which is the horizon No. 10 of Stanton and Vaughan.

Richardson^{66a} studied the occurrences of the Cretaceous near El Paso north of the Rio Grande and made some subdivisions. He says:

The Cretaceous system is represented here by the Fredericksburg and Washita groups of the Comanche series. The Trinity group has not been recognized in this area, nor has the Upper Cretaceous been found (with the possible exception that a few small areas of shale in the city of El Paso are of Upper Cretaceous age), though rocks belonging to both of these ages occur not far to the south and west.

The Fredericksburg is separated into three formations—the Campagrande, the Cox, and the Finlay, which are differentiated by their lithologic features. All these contain Fredericks-

^a Böse, Emil, Monografía geológica y paleontológica del Cerro de Muleros, cerca de Ciudad Juárez, Chih.: Bol. del Inst. Geol. de México, No. 25.

burg fossils, but the faunas of the individual formations have not been collected with sufficient fullness to permit their paleontologic definition. * * *

The lowermost formation of the Fredericksburg group is composed of calcareous rocks that are well exposed in the Finlay Mountains, where, in the central part of the dome, they lie unconformably on the Hueco formation. At the base of the Cretaceous section is a limestone conglomerate about 25 feet thick composed of rounded pebbles of Carboniferous limestone averaging possibly about 2 inches in diameter. Above this are 350 feet of gray limestone, which is generally massive but locally contains nonpersistent, thin-bedded limestone grading into shale. * * *

The Campgrande formation is conformably overlain by the Cox formation.

The Cox formation consists of massive soft brownish sandstone, some intercalated gray limestone, and near the base a red-drab shaly member. The formation averages about 600 feet in thickness and is subject to variation in composition, so that no one section is typical. Sandstone predominates and composes probably nearly 500 feet of the formation. It is usually fine textured, but there are some coarse beds of no great thickness containing quartz pebbles as large as marbles. Locally the sandstone is pitted with rounded iron stains the size of buckshot, which seem to be due to the weathering of pyrite nodules. In places the sandstone is cross-bedded. The intercalated limestone and shale are usually thin bedded and are generally fossiliferous. The shaly member in the Finlay Mountains is about 100 feet thick. * * *

The Cox formation * * * is conformably overlain by the Finlay formation, [which] consists almost entirely of massive gray nonmagnesian limestone, but locally thin beds of brown sandstone are included. There are at least 300 feet of the Finlay formation exposed in this region, but the top has not been found. * * *

Rocks of Washita age are present as outlying masses in several localities. The thickness of the strata is not great and it has not been found practicable definitely to correlate the different exposures. They look much alike, being commonly buff-colored calcareous shale and thin-bedded limestone with occasional subordinate sandstone.

H 14. LLANO-BURNET REGION, TEXAS.

From his studies in 1910, the results of which are published in folio 183 of the Geologic Atlas of the United States, Paige gives the following sections of the Llano-Burnet region of Texas:

In the Llano-Burnet region only the Fredericksburg and Trinity groups of the Lower Cretaceous are represented. Although in the Austin quadrangle ^a to the southeast, the Trinity group was subdivided into the Glen Rose and Travis Peak formations, it was found impractical for the following reason to make this distinction in the Burnet quadrangle. The Travis Peak formation, while a definite lithologic and paleontologic unit in the southeast corner of the Burnet quadrangle, loses these characteristics toward the north. This change is due to changes in the conditions of sedimentation along a slowly subsiding coast line. Owing to the gradual transgression of the sea over the land and the concomitant lowering of the surface which supplied débris for sedimentation, the sediments grew finer and more calcareous, the basal beds thinner and less conglomeratic, until a condition existed where only nearly pure limestones were being deposited along low, gently sloping shores. The following formations have been mapped in the Llano-Burnet area: The Edwards limestone; the Comanche Peak limestone, including the Walnut clay; and the Trinity formation, including the undifferentiated Travis Peak and Glen Rose. The following sections afford examples of the several formations.

H-I 14. CENTRAL TEXAS.

From Hill's detailed monographic discussion of the Cretaceous of Texas⁴⁴⁵ are taken the following extracts:

The strata of the Lower Cretaceous, or Comanche series [in central Texas] * * * belong to three divisions, as follows, beginning with the lowest: Trinity, Fredericksburg, and Washita. The general characteristics of these divisions are as follows:

The Trinity division is especially marked by strata of friable white packsands, which do not occur in the other divisions and which in places constitute nearly the entire rocks of the division. In some places, especially south of the Brazos, these sands alternate with marly clays and chalky and clastic limestones, the latter being composed of minute shells or fragmental particles of shells and sands having a lithologic and paleontologic individuality by which they can usually be readily distinguished. All the calcareous strata are white or yellowish and occur in numerous persistent alterations of hard and soft strata of various thicknesses.

The rocks of the Fredericksburg division in the typical area of occurrence are almost entirely chalky limestone, initiated by beds of marly clay, which grade into the limestone.

The rocks of the Washita division include the beds between the top of the Edwards limestone of the Fredericksburg division and the coarse sands of the Woodbine (Dakota).

The sediments of the Washita division, while generally light in color in their lower half, show darker tones and greater ferrugination of rocks toward the top. They are composed largely of alternations of marly clays and firmer layers of limestone. The limestones of this

division, while slightly resembling others in the series, have a sufficient proportion of grit, and sometimes of iron, to make them relatively impure. The beds are successively shallower in origin in ascending series.

In general, rocks of the Trinity division were laid down upon a subsiding bottom of a former land surface; rocks of the Fredericksburg division (in this portion of Texas) upon a stationary offshore bottom of Trinity sediments; and rocks of the Washita division upon a shallowing bottom of Fredericksburg sediments.

TRINITY DIVISION.

This division includes the lower or initiatory beds of the Cretaceous formations of the Texas region, embracing all the rocks lying below the Walnut beds of the Fredericksburg division. * * * In general these strata consist of sands, clays, marls, and massive limestones (including in the latter shell breccias, agglomerates, and chalks), all of which grade imperceptibly into one another, both vertically and horizontally, according to their proximity to the shore line against which they were deposited. * * *

Studies of these three areas, the western border, the incised sections of the Grand Prairie, and the embed beneath the Black Prairie, show great differences in thickness and composition of the rocks of the Trinity division, indicating that they are thinner and more arenaceous along the western border region, where they are best exposed, and that they thicken and become calcareous to the east, being buried in the region of their greatest development beneath the Black and Grand prairies, where a knowledge of their nature can be obtained only by careful interpretation of the artesian drillings. * * * As a result of these variations of thickness and composition the rocks of the Trinity division along the eastern portion of the general area of exposure within the incised valleys of the Edwards Cut Plain present the aspect of several well-defined and mappable lithologic units of various kinds of rock, which so coalesce along the western border exposures into a general basement formation of sands that they are there usually inseparable.

As a whole these strata of the Trinity division may be subdivided into the following conspicuous formations and beds:

Paluxy formation.....	{ Upper sands. Thin limestones. Lower sands.
Glen Rose formation.	
Travis Peak formation.....	{ Hensell sands. Cow Creek bed. Sycamore sands.

The term Basement sands will be used as the equivalent of any of the above formations where they rest upon the underlying Paleozoic floor. The name Antlers sands will be applied to the equivalents of all these formations as they coalesce along the western border region north of Parker County.

FREDERICKSBURG DIVISION.

During the Fredericksburg subepoch the Cretaceous shore reached west and north approximately to a line extending from El Paso north into southwestern Kansas. The area lying south and east of this line, as far at least as the eastern border of the Black Prairie, as shown by the extent of the Edwards limestone, was a great arm of the sea, the bottom of which was covered with calcareous organisms as certain banks of the present West Indian seas are now covered. Over the entire area thus covered by the oceanic waters the sea deposited a mantle of arenaceous, argillaceous, and chalky sediments which now make the rocks of the Fredericksburg division. * * *

As a whole, these sediments thicken and become more calcareous seaward, away from the position of the old peripheral shore line at the close of the Fredericksburg epoch. * * * This thickening took place by the accretion of calcareous layers offshore and horizontally away

from the diagonal basement beds. * * * These changes in thickness were very gradual and can only be noted by comparing widely separated local sections. Hence the rocks of this division, as a whole, notwithstanding the variations to be noted, may be considered as presenting a remarkable example of uniformity of thickness and composition. In its entirety this division is composed of more calcareous rocks than the other divisions of the Comanche series. Although its interior margins ultimately pass into the Basement sands, this change mostly takes place beyond the borders of the east-central province, within which it is practically a great limestone formation (Edwards limestone), initiated by beds of clay (Walnut formation) at its base.

* * * The limestones of the Fredericksburg division thin toward the Rocky Mountains and the Ouachita uplifts to the north, and thicken southward or toward the Rio Grande, being in the neighborhood of 700 feet in the latter region and less than 30 along the southern foot of the Ouachita Mountains of Indian Territory. They ultimately pass into clays and sands around the western ends of the Ouachitas in southern Kansas and west of Texas in eastern New Mexico. * * *

In the area of its most typical if not greatest development, in the Grand Prairie region between the Brazos and the Colorado, as will be more fully set forth later, the limestone is further differentiable into two well-marked mappable subdivisions. In this region all sections of the Fredericksburg division present the following sequence:

1. At the base there are a few feet of calcareous clays intercalated with brecciated limestones, passing up into chalky layers, which become more numerous toward the top. These are the Walnut beds.

2. The chalky bands which begin to appear in the top of the Walnut clays are the beginning of a succeeding limestone formation (Comanche Peak limestone), which in this region is separated into two well-defined stratigraphic units. (a) The lowest of these is the Comanche Peak formation. This formation is composed of compact white rocks which on weathering shatter into numerous angular or conchoidal flakes, seldom weathering into ledges, and contain great numbers of casts of mollusks and echinoids. (b) Without break or apparent change in composition the rocks above the Comanche Peak begin to become harder, weathering into ledges often semicrystalline in character, and containing flint nodules and peculiar fossils of the types known as Requienia and Rudistes. These rocks form the Edwards limestone. The Comanche Peak beds are chiefly distinguishable from the succeeding Edwards limestone by the absence of flints and certain very peculiar fossils of the overlying beds, and by the fact that they weather into slopes instead of bluffs.

Stratigraphically there is no break between the various formations, and they pass upward or downward into one another by gradual transition. The marly lime of the upper portions of the Walnut formation grades into the chalky limestones at the base of the Edwards formation without demarcation.

The combined Comanche Peak and Edwards limestone thins out north of the Brazos, where it is no longer separable into individual beds [and is called the Goodland limestone]. On the other hand, it thickens south of the Colorado, where several distinct subdivisions could be made.

* * * * *

WASHITA DIVISION.

The Washita division has been defined as the uppermost of the three stratigraphic groups of the Comanche series. It is composed essentially of sediments laid down in a shallowing sea accompanying a regional uplift which followed the subsidence of earlier Comanche time. The Fredericksburg division ceases everywhere throughout its extent with the purer limestones of the Edwards formation. These limestones represent the deposition of the deepest waters of the Comanche epoch and the culmination of the subsidence which had been progressing since the beginning of Cretaceous time. The succeeding sediments of the Washita division within the east-central province are all of a less purely calcareous, [more] argillaceous, or arenaceous nature.

* * * * *

The beds of the Washita division in general are more varied in composition, of greater thickness, and more closely resemble shallow-water deposits toward the northern border region, extensive formations of ferruginous sands and bituminous clays occurring in that direction, which cease to the south. In general the strata of the Washita division, as a whole, become more calcareous to the south, but even this rule has its exceptions.

As a whole, the group decreases from about 400 feet in the Denison section on Red River to less than 175 feet in the Austin section, on the Colorado. This loss in thickness of the Washita division to the south is compensated for by a corresponding gain in that direction in the thickness of the Edwards limestone of the Fredericksburg division, so that the thickness of the Comanche series in its entirety is not impaired thereby.

The individual indurated beds of the Washita division seldom exceed a foot or two in thickness. The strata rarely extend through a hundred vertical feet without conspicuous lithologic or faunal changes. These individual beds are remarkably persistent in horizontal extension, especially when they are studied in large local areas, preserving their lithologic and paleontologic characters without any perceptible change for great distances. When the beds are traced through long distances, such as Texas provides, gradual important changes may be noted which can be appreciated only by comparison of widely separated minute local sections. What is a conspicuous clay formation in the Red River section may become a limestone when traced 300 miles south to the Colorado, or a formation which is a limestone upon Red River may be a clay on the Colorado.

Owing to these gradual changes in the character of the rocks the sections of the Washita division at the extreme ends of the area treated in this paper, as exemplified in the Denison and Austin sections, present entirely different lithological aspects and sequences, the relations of which would not be traceable were it not for the existence of certain well-determined paleontologic zones which persist regardless of the lithologic changes.

* * * * *

The Washita division presents several well-defined mappable units—eight, for instance, along Red River, and only three at Austin, on the Colorado.

In the region of its typical development as seen in the Red River section there are eight broad subdivisions: (1) Basement beds of bituminous clays rather abruptly succeeding the Edwards limestone; (2) beds of white, arenaceous, chalky limestone alternating with marls, which terminate with (3) a conspicuous limestone formation; (4) a group of beds of marls and shell conglomerates; (5 and 6) two groups of clays and sands separated by limestone; (7) an upper limestone; and (8) an uppermost lime marl.

These subdivisions, which are locally still further subdivided into conspicuous beds, may be named the Kiamitia, Duck Creek, Fort Worth, Denton, Weno, Pawpaw, Main Street, and Grayson beds. To the south, in the Colorado sections, only three lithologic members are recognizable—the Georgetown limestone, Del Rio clays, and Buda limestones. Each of these formations, although possessing very marked and important features in particular localities, loses its identity when traced through long distances, by coalescing with other formations.

I 14-15. NORTHERN TEXAS, SOUTHERN OKLAHOMA AND ARKANSAS, AND NORTHERN LOUISIANA.

Of the Lower Cretaceous of this region Veatch^{838b} writes as follows:

The lowest Cretaceous beds represent the near-shore deposits of the sea advancing over the old Jurassic peneplain and are, therefore, sandy and contain vegetable remains, as well as brackish-water shells. These are succeeded by limestone and marls, indicating deeper water, and these in turn are limited above by the great sand beds that represent the extreme shallow-water conditions which marked the beginning of the upper Cretaceous.

In Arkansas only the lowest of the series, the Trinity sand, is well developed, although near the Indian Territory line are good outcrops of the Goodland limestone, overlain by a series of marl and limestone beds, which, with the Goodland limestone, represent the other two grand divisions of the Comanche series, the Fredericksburg and the Washita.

The Trinity sand, the oldest and lowest formation of the Coastal Plain series in this region, outcrops in a narrow band 6 to 12 miles wide, which extends westward along the base of the Ouachita and Arbuckle mountains from Wolf Creek in Pike County, Ark., into Indian Territory to a point somewhat west of Ardmore, where it turns south toward Austin. Because of its extensive development about the headquarters of Trinity River in Wise, Tarrant, and Parker counties, Tex., it has been called the Trinity sand or Trinity formation.

South of Tishomingo and Atoka, in the Choctaw Nation, this formation consists of a fine yellowish pack sand, with irregular conglomerate beds at the base, and contains occasional lenticular masses of clays, the whole having an aggregate thickness of 200 to 400 feet.^a In this region it contains no fossils except occasional tree trunks, thought by Taff to be driftwood. Eastward these beds become more clayey in character and in southern Arkansas contain frequent thin layers of yellowish limestone, composed largely of the small oyster *Ostrea franklini* Coquand, together with other near-shore or brackish-water forms. Occasional thin beds of gypsum, like that at the Plaster or Gypsum Bluff on Little Missouri River near Murfreesboro occur. * * *

Above the Trinity formation is a thin bed of chalky limestone 15 to 25 feet thick, which, because of its whiteness and firmness, contrasts sharply both with the Trinity sand and with the series of marls with thin limestone layers that overlie it. Because of these features it is easily traced from its type locality, 2 miles north of Goodland, on the St. Louis & San Francisco Railroad, in the Choctaw Nation, Indian Territory, both eastward to Cerro Gordo, on Little River, in Arkansas, and westward past Oakland and Marietta, in the Chickasaw Nation. It is everywhere in this region characterized by peculiar fossils. South of Red River in Texas it increases gradually in thickness until it reaches a total of 700 feet on the Rio Grande,^b where it is composed of two members which are called the Comanche Peak and Edwards formations. * * *

Above the Goodland limestone, near Cerro Gordo, Ark., is a series of calcareous clays, containing thin beds of limestone and having a total thickness of over 250 feet.^c These beds have not yet been carefully studied, but Hill's reconnaissance in 1888 has shown that they may be regarded as the representatives of the Preston, Fort Worth, and Denison formations of the Texas section and of their equivalents in Indian Territory—the Kiamichi, Caddo, Bokchito, and Bennington formations of Taff [Washita group]. * * *

At the close of the lower Cretaceous there was evidently a considerable change in the depth of the ocean waters in the Texas and Arkansas areas, since overlying the marine deposits of the Washita series are sands and clays containing lignite and other remains of land plants of species very similar indeed to those of to-day, whose ancestors they probably were. In many places there is some evidence of slight erosion of the lower beds before these littoral deposits were laid down, and some portions of this area may have been dry land for a limited time.

I 16-17. ALABAMA, GEORGIA, AND SOUTH CAROLINA.

L. W. Stephenson has contributed the following notes:

The basal portion of the Cretaceous deposits in the region included between the Roanoke Valley in North Carolina and the Alabama Valley in Alabama is composed of highly cross-bedded arkosic sands, in general of coarse texture, with subordinate interbedded layers and lenses of light-colored clays of greater or lesser purity, reaching an estimated maximum thickness of 500 or 600 feet. These have been designated the "Cape Fear" formation in North Carolina by the writer^d and the "Hamburg beds" in South Carolina by Earle Sloan^e and have

been regarded as the eastward continuation of the Tuscaloosa formation (Upper Cretaceous), by the Georgia and Alabama geologists.^a

In the Carolinas these beds are separated from the overlying Black Creek formation by an unconformity. Likewise an unconformity separates them from the overlying Eutaw formation in the Chattahoochee and Alabama river regions in Georgia and Alabama. Geographically the belt in which the deposits occur is separated from the Cretaceous occurrences to the northward in Virginia by an overlap of Miocene beds. However, in all their physical characters they bear a close resemblance to the Patuxent formation, which forms the basal division of the Potomac group in Virginia and Maryland. On account of this physical similarity and because of their supposed buried connection with the Virginia Patuxent, the application of the name Patuxent has been extended to include these North Carolina arkosic beds. The apparent continuity of the North Carolina beds with the similar deposits to the south would, in the absence of known unconformities, seem to necessitate the adoption of the name Patuxent for all the beds in question in South Carolina, Georgia, and Alabama, unless biologic evidence indicating the incorrectness of this interpretation is forthcoming. With one exception no organic remains have been found in these arkosic beds south of the Virginia line. A few poorly preserved plant remains have been collected recently from an exposure in a bluff of Tallapoosa River at Old Fort Decatur, in Macon County, Ala. These were submitted to E. W. Berry, who expressed the opinion that the beds containing them are of Lower Cretaceous age. The meager paleontologic evidence thus afforded tends to confirm conclusions which Mr. Berry and the writer had previously reached, based on physical criteria alone. Unfortunately the poorly preserved condition of the leaves renders it difficult to determine satisfactorily the relation of the formation to the Patuxent formation of Virginia and Maryland. However, in Mr. Berry's opinion, the presence of large numbers of leaves, apparently dicotyledons, most of which are too poorly preserved to permit their specific or even generic determination, seems to justify doubt as to their being as old as the Patuxent formation, in which similar questionably identified dicotyledons are very sparingly represented.

I-J 13-14. EASTERN NEW MEXICO, OKLAHOMA, AND SOUTHERN KANSAS.

Portions of the Comanche series appear along the canyons which descend from the Tertiary of the High Plains to the "Red Beds." There are unconformities both above and below these incomplete sections, which constitute the northwestern occurrences of the Comanche series. Hill⁴⁴¹ describes in detail sections observed in Kansas, Oklahoma, and New Mexico, with comparative faunal lists, and under the title "Plains section" he summarizes the strata as follows:

Plains Tertiary.

"Dakota" sandstone.

Belvidere beds:

(b) Blue and black shale with fossils [the Kiowa shale of Cragin^{172,174}].

(a) Cheyenne sandstone grading upward into b.

"Red beds."

The fauna consists largely of typical Washita species with a few that range down into the Fredericksburg.

I-K 13. NEW MEXICO, COLORADO, AND WYOMING.

The Morrison formation of Wyoming and Colorado was formerly referred without question to the Jurassic on the evidence of its large vertebrate fauna. More recent studies of this fauna by Scott, Williston, and others favor its reference to the Lower Cretaceous, but this assignment of age is not yet unanimously accepted, and

^a Langdon, D. W., Variations in Cretaceous and Tertiary strata of Alabama: Bull. Geol. Soc. America, vol. 2, 1890, pp. 587-606. Veatch, Otto, Second report on the clays of Georgia: Bull. Geol. Survey Georgia, No. 18, 1909, pp. 82-106.

the formation is called Jurassic (?) in recent publications of the United States Geological Survey. Its relations to the Comanche series were traced by Stanton,⁷⁸¹ with W. T. Lee and C. W. Gilmore, and are expressed in the following comments and sections:

The beds now generally designated on United States Geological Survey maps as the Morrison formation have been a subject of interest and discussion since 1877, when abundant remains of dinosaurs were found in them. The first extensive collections of the vertebrate fauna were obtained in the neighborhood of Morrison near Denver, in Garden Park, near Canon City, Colo., and at Como or Aurora, Wyo. Since then the formation has been recognized by means of its fossils, its lithologic features, and its stratigraphic relations in the Black Hills, on the Laramie Plains, and elsewhere in Wyoming, in Montana, in western Colorado, in southeastern Colorado, and in adjacent parts of Oklahoma and New Mexico. * * *

The formation is nonmarine throughout, so far as known, and consists of variegated marls and shales with irregular beds of sandstone and sometimes thinner layers and lenses of siliceous limestone. The colors of the shales and marls are greenish gray, purplish, maroon, and red, very irregularly distributed, while the sandstones are usually gray, sometimes weathering brown or with small brown spots. The limestones are gray, in some cases weathering with a reddish tinge. The general appearance of the formation is remarkably uniform over large areas, and yet the individual elements are so variable that no two detailed sections are exact duplicates of each other. The total thickness is seldom more than 200 feet, though it is possibly more than 400 feet at Canon City.

Several geologists, particularly Hill and Lee, having suggested that the Morrison was a representative of some part of the Comanche series, Stanton examined its relations, as stated above, and found:

Section on Purgatoire River about 20 miles south of La Junta, Colo.

	Feet.
1. Benton shales, thickness probably not more than.....	200
2. Dakota sandstone.....	100
3. Dark shales and shaly limestones with Comanche fauna.....	50-100
4. Coarse gray cross-bedded sandstone.....	15-60
5. Variegated shales, marls, sandstones, and limestones of the Morrison formation, with Bron- tosaurus, etc.....	200
6. Gypsum and gypsiferous shales.....	70-125
7. Red Beds with Belodon near top, exposed.....	200-300

Section on Rio Cimarron east of Garrett post office, Okla.

	Feet.
1. Massive coarse cross-bedded gray and brown sandstone of the Dakota.....	150
2. Dark shales with layers of brown flaggy sandstone and bands of somewhat calcareous yellow sandstone with Comanche fauna.....	50-60
3. Coarse brown or gray cross-bedded sandstone with irregular bands of pebbles, apparently unconformable on the underlying stratum.....	4-15
4. Variegated shales, gray sandstones and bands of siliceous limestone, referred to the Morri- son, not well exposed. Thickness probably less than.....	100
5. Red Beds.	

The Comanche horizon has yielded a varied fauna which is clearly the same as the Washita fauna that has long been known as Mesa Tucumcari, New Mexico, in northern Texas, and in the Kiowa shales of southern Kansas. * * *

This horizon was traced with practical continuity westward up the Cimarron to Folsom, New Mexico, a distance of about 75 miles across the strike. Its lithologic features show little variation, and its thickness is never less than 50 feet nor more than 100 feet. Fossils gradually become less abundant in both species and individuals toward the west, until near Folsom only a small mactroid shell was found in considerable numbers. The most western point at which *Gryphæa corrugata* was collected is about 30 miles east of Folsom.

Along this line the coarse sandstone beneath the Comanche fossils is from 15 to 40 feet in thickness, and the variegated shales, sandstones, etc., of the Morrison increase to about 200

feet. Lithologically and stratigraphically this is identical with the Morrison beds seen on the Purgatoire, where characteristic dinosaurs were collected. Fragmentary, undetermined dinosaur remains were seen in it on the Cimarron near Exter, N. Mex.

Beneath the recognized Morrison some localities show 40 to 50 feet of gypsum and gypsiferous shales resting on a massive white or pinkish sandstone which Mr. Lee has described as the Exter sandstone. It varies greatly in thickness, the maximum observed being 80 feet. The Exter is separated from the red beds by a striking angular unconformity, wherever the red beds are folded in local uplifts. The red beds show the usual character and at Tod's ranch, 15 miles east of Folsom, they yielded fragmentary Triassic vertebrates.

Summing up the evidence presented by the sections quoted and also by those at Tucumcari and Canon City, Stanton says:

The question whether the Morrison formation is Jurassic or Cretaceous is still to be answered, and if a satisfactory answer is ever received it will doubtless be from vertebrate paleontology, aided by careful stratigraphic methods. If the Morrison is Cretaceous, the proof that it is so will not be by tracing it directly into marine Cretaceous strata. It has been shown that the beds supposed to be thus connected with it overlie it for more than 100 miles across the strike. But these overlying beds are by no means the earliest Cretaceous, and there is still room for the Morrison within that system if the fauna requires such a reference. On the other hand, there is ample space for it in the Jurassic ^a not otherwise represented in the region by sediments, and before the final decision is made the character of the flora in the Fuson formation of the Black Hills and in the Kootanie of Montana should be given due weight, and these formations should be closely studied and searched for other evidence.

I-K 17-18. ATLANTIC COASTAL PLAIN, MASSACHUSETTS TO NORTH CAROLINA, INCLUSIVE.

The following statement, prepared by William B. Clark, is an elaboration of a briefer article ¹⁴⁴ covering the northern part of the Atlantic Coastal Plain:

General conditions of occurrence.—The oldest deposits of the Atlantic Coastal Plain which outcrop at the surface are of Cretaceous age. Well borings at many points throughout the district have not afforded strata of earlier age, although such deposits may exist to the east, toward the margin of the continental shelf.

The deposits as a whole have been but little changed since they were originally laid down along the continental border, but the strata present much complexity due to the variation in the angle and direction of tilting during the successive oscillations of the sea floor during Cretaceous time. The sediments in general form a series of thin sheets which are inclined seaward, so that successively later formations are encountered in a journey from the inland border of the region toward the coast, yet at no place accessible to our study do we find a complete sequence of deposits, although sedimentation must have been continuous over a large part of the continental shelf. The incompleteness, therefore, must be regarded as a purely marginal condition due to the transgressions and retrogressions of the sea along the coastal border.

The Cretaceous formations are variously transgressed in the different areas by deposits of Tertiary and Quaternary age, these later formations in places reaching to the Piedmont border or beyond and entirely concealing the earlier strata along the outcrop. The full sequence of Cretaceous deposits can therefore be observed only at favorable points and chiefly along the main river channels, although even here the later formations are buried over many wide areas in consequence of the attitude of the strata to the present sea level.

The Atlantic Coastal Plain deposits afford representatives of both the Lower and the Upper Cretaceous, the former being most extensively developed in Maryland and northern Virginia and in North Carolina, the latter in New Jersey, whence the strata gradually thin out northeastward along the New England coast and southward through Delaware and

^a The marine Jurassic Sundance formation, characterized by *Cardioceras cordiforme* M. and M., etc., on which the Morrison rests in the northern area, does not represent the latest Jurassic according to European standards.

Maryland. In North Carolina the Upper Cretaceous reappears and covers a wide area to the south of the Hatteras axis.

Long Island and southern New England.—It has been long recognized that Upper Cretaceous deposits occur on Long Island and farther east, but although it has been apparent that the strata were the continuation of similar deposits in New Jersey, where their limits are better known, a satisfactory correlation of these deposits has never been made. It is apparent that the Raritan, the Magothy, and possibly the overlying Matawan are represented. The flora thus far studied is chiefly of the Magothy type, although the lower beds on Long Island contain forms that represent the Raritan, while the marine animal remains which have been found both in place and in reworked deposits on Long Island, Block Island, and Marthas Vineyard and at Marshfield, Mass., are of Matawan types so far as they can be determined. It is possible that they belong to beds in the upper Magothy, for marine fossils have been found in Magothy strata on the south shore of Raritan Bay, the fauna as a whole being similar to that of the Matawan.

Many contributions have been made to the knowledge of this region by those who have visited and studied it, among the more important being those of Newberry,^{610, 611} Shaler,^{728, 729, 730} David White,^{893, 894} Hollick,^{457, 458, 459} and Veatch.⁸³⁷

The strata consist of sands and clays, the former in places irregularly bedded and of varying degrees of fineness and more or less stained with iron, while the latter are plastic and locally lignitic. Sandy, more or less glauconitic clays have also been found.

New Jersey.—The deposits of Upper Cretaceous age are more extensively developed in New Jersey than elsewhere in the northern Atlantic Coastal Plain and may be regarded as forming the type section for that region. The major divisions can be more elaborately differentiated there than farther south and a much fuller classification has been proposed.

A study of the Cretaceous deposits of the New Jersey region began much earlier than in neighboring States and many contributions have resulted. Among those who have given a large amount of attention to the geology of this area are Morton,⁶⁰⁶ Cook,¹⁶⁹ Newberry,⁶¹⁴ Whitfield,⁹²⁵ Clark,^{142, 145, 146, 152} Weller,⁸⁸⁴ and Berry.^{72, 76, 78}

The following scheme of classification has been adopted for the New Jersey Upper Cretaceous:

- Manasquan formation.
- Rancocas group:
 - Vincetown sand.
 - Hornerstown marl.
- Monmouth group:
 - Redbank sand.
 - Navesink marl.
 - Mount Laurel sand.
- Matawan group:
 - Wenonah sand.
 - Marshalltown formation.
 - Englishtown sand.
 - Woodbury clay.
 - Merchantville clay.
- Magothy formation.
- Raritan formation.

The Raritan formation directly overlies the crystalline rocks or the Newark group, as the case may be, and consists of clays, sands, and gravels. It has been estimated to have a maximum thickness of about 300 feet at the outcrop, but it has been penetrated in well borings to a probable depth of 500 feet. An extensive flora has been described.

The Magothy formation unconformably overlies the Raritan formation and consists of dark clays and light sands. The clays are commonly lignitic. The deposits attain a maximum thickness of about 100 feet. An extensive flora quite distinct from and more recent than the Raritan flora has been found, as well as a marine fauna closely allied to that of the succeeding Matawan.

The Matawan consists chiefly of dark-colored clays, in places micaceous and glauconitic, in its lower part, and of sands, with an interbedded clayey member, locally highly glauconitic, in its upper part. It attains a total thickness of about 275 feet, although a thickness of 400 feet has been found in deep well borings east of its outcrop. It lies unconformably on the Magothy. The Matawan group contains an extensive fauna with subordinate faunules. It has been traced throughout the north Atlantic Coastal Plain and thence southward to the Gulf.

The Monmouth group consists of sands and clays, with an interbedded glauconitic division in the northern part of the area. Toward the south the upper sandy formation disappears. The greatest thickness of the group is about 150 feet. The Monmouth is conformable to the Matawan. It has an extensive fauna marked by the introduction of *Belemnitella americana* and other forms, representing a later fauna than the Magothy and Matawan fauna hitherto described. This fauna also has been traced southward through the north Atlantic Coastal Plain into the Gulf region.

The Rancocas consists largely of greensand marls and sandy calcareous beds which have a maximum thickness in southern New Jersey of about 125 feet. It is conformable to the Monmouth and is characterized by a fauna quite distinct from the preceding, including *Gryphæa vesicularis*, *Terebratula harlani*, and other forms.

The Manasquan formation consists of greensand marls and attains a thickness of about 50 feet. It is conformable to the Rancocas. It contains a marine fauna which has some forms in common with the Rancocas and others that are quite distinct.

Maryland and Delaware.—The deposits in Maryland and Delaware contain representatives of both the Lower and the Upper Cretaceous. The Lower Cretaceous also continues northward into Pennsylvania, where a few isolated outliers are found, and the basal formation of the Upper Cretaceous occurs as a narrow strip along the eastern border of that State. In Maryland and Delaware both divisions are extensively developed, the Lower Cretaceous attaining its maximum development in Maryland.

The Maryland area has been long studied and is discussed in an extensive literature. Among those who have been most actively engaged in the study of this region may be mentioned McGee,⁵⁶⁵ Clark,^{147, 148, 150} Bibbins,^{147, 148} Mathews,¹⁵⁰ Berry, and Miller.⁵⁹⁵

The following scheme of classification has been adopted for the Maryland-Delaware region:

- Upper Cretaceous:
 - Rancocas formation.
 - Monmouth formation.
 - Matawan formation.
 - Magothy formation.
 - Raritan formation.
- Lower Cretaceous (Potomac group):
 - Patapsco formation.
 - Arundel formation.
 - Patuxent formation.

The Patuxent formation consists mainly of sand, generally arkosic and in many places cross-bedded, with small masses of clay scattered through it. The formation attains a thickness of 350 feet. It has a well-defined early Cretaceous flora.

The Arundel formation consists chiefly of clays, which in places carry iron ore and are commonly lignitic. It has a thickness of about 125 feet. It is unconformable to the Patuxent. It has an extensive flora similar to that of the Patuxent and a fauna consisting chiefly of dinosaurian remains.

The Patapsco formation consists of highly colored and variegated clays and lighter-colored sandy clays and sands. It has a thickness of 200 feet and contains an extensive flora of "Mesocretaceous" types in which angiosperms constitute a considerable element. It is unconformable to the Arundel.

The Raritan formation consists chiefly of thick-bedded light-colored sands, with light-colored clays in the lower portion. The deposits have a thickness of about 400 feet. The Raritan overlies the Patapsco unconformably. It carries a distinctly Upper Cretaceous flora containing numerous dicotyledons.

The Magothy formation consists of alternating sands and clays, the latter in places lignitic. The maximum thickness of the formation is about 100 feet. The Magothy is unconformable to the Raritan. It contains an extensive flora of types more recent than those of the preceding formation.

The Matawan formation consists mainly of dark-colored micaceous sandy clays, the average thickness of the formation being about 50 feet. It carries an extensive marine fauna.

The Monmouth formation consists mainly of sands, more glauconitic in the upper part than in the lower. The deposits have a maximum thickness of about 100 feet on the eastern shore of Chesapeake Bay and gradually decrease in thickness until they thin out in the Potomac Valley. A fauna marked by the advent of *Belemnitella americana* and other forms is found in this formation.

The Rancocas formation consists chiefly of greensand marls, which are in many localities highly calcareous. The formation has a thickness of about 20 feet in central Delaware but gradually thins out toward the Maryland line.

Virginia.—The Cretaceous deposits which outcrop at the surface in Virginia are all Lower Cretaceous, although strata belonging without much doubt to the Upper Cretaceous have been penetrated in deep well borings to the east and have yielded a few fossils that indicate the presence of the Raritan, Magothy, and Matawan formations. The Lower Cretaceous deposits are limited to the Patuxent and the Patapsco, the Arundel formation not being recognized in Virginia.

Much study has been given to the Virginia area, the more important contributions having been made by Rogers,⁶⁷⁶ Ward,^{864, 866} Fontaine,³⁴³ Clark and Miller,¹⁵¹ and Berry.⁷⁷

The Patuxent formation is exposed in the principal drainage channels and consists chiefly of sands, cross-bedded, highly arkosic, and locally indurated, with clay beds in places lignitic and commonly chloritic. The thickness of the formation reaches about 300 feet. The Patuxent contains a large flora which is probably the most extensive known flora from the Lower Cretaceous.

The Patapsco formation consists of highly colored and variegated clays, in places lignitic, and sand beds, cross-bedded and locally indurated. The formation is limited to the northern part of the area, where it attains a thickness of about 150 feet and has an extensive flora of later types than those found in the Patuxent.

North Carolina.—The Cretaceous deposits of North Carolina belong in part to the Lower and in part to the Upper Cretaceous. In the northern part of the State the strata are confined largely to the main river channels, but south of the Hatteras axis they spread out and occupy a wide area.

The North Carolina deposits have not received as much attention until recently as the Cretaceous deposits farther north. Among those who have studied the region are Clark,¹⁴⁹ Stephenson,⁷⁹¹ and Berry.^{73, 74, 77, 79} The two latter have spent much time in recent years in a detailed field investigation, Stephenson giving his attention chiefly to the stratigraphy and marine invertebrate fossils and Berry to the fossil plants. Clark, who earlier studied the region, has devoted his attention to the interpretation of the deposits and faunas and their correlation with other areas.

The following scheme of classification has been accepted for the North Carolina area:

- Upper Cretaceous:
 - Peedee sand.
 - Black Creek formation.
- Lower Cretaceous:
 - Patuxent formation.

The Patuxent formation consists chiefly of sands and clays, the former locally cross-bedded and arkosic. Its thickness is about 300 feet. No flora or fauna has been found in it.

The Black Creek formation consists of light-colored sands and interbedded clays, the latter in places lignitic and generally thinly laminated. The thickness of the formation reaches about 700 feet. The Black Creek overlies the Patuxent formation unconformably. An extensive flora is found in it, the beds carrying the plant remains being interbedded with strata containing

marine invertebrate fossils in the upper portion of the formation. The fauna is extensive and is similar in type to that found farther north in the Magothy and Matawan formations and it has also been traced throughout the south Atlantic States to the Gulf.

The Peedee consists mainly of sands, commonly glauconitic, with subordinate beds of clay. The thickness of the formation reaches about 700 feet. The Peedee carries an extensive fauna of marine types, which is characterized by the introduction of *Belemnitella americana* and is similar to the Monmouth fauna farther north. It has also been traced through the south Atlantic and Gulf States.

General remarks.—The Cretaceous deposits of the Atlantic Coastal Plain form an irregular and interrupted belt along its western margin, resting for the most part on an irregularly eroded surface of ancient crystalline rocks, although the sandstones and shales of the Newark group intervene at some points. The slope of this floor is variable, but on the average it trends in an easterly direction at an angle of about 60 feet to the mile.

The thickness and angle of dip of the Cretaceous formations at the outcrop are extremely variable owing to the differential movements which have taken place along the landward margin of the Coastal Plain during the period of its building. The areas occupied by the outcrops of the several formations above described gradually diminish at varying rates from the point of their greatest development, until the formations finally disappear as outcropping deposits either because of the differential movements during Cretaceous time or because of the transgression of Tertiary and Quaternary sediments. The dip of the several formations is also variable but in general grows less with each succeeding formation, the dip of the latest Cretaceous strata being about 20 feet to the mile.

The correlation of the deposits within the limits of the northern Atlantic Coastal Plain is shown in the accompanying table, together with the approximate correlation of these deposits with the section hitherto recognized in the eastern Gulf region and in central Europe. L. W. Stephenson and E. W. Berry, under the direction of T. Wayland Vaughan, have greatly enlarged our knowledge of the stratigraphy and paleontology of the south Atlantic and Gulf States and the results of their work have been available for the comparisons with the southern districts south of North Carolina.

Cretaceous formations of northern Atlantic Coastal Plain.

	Approximate European equivalents.	Long Island and islands south of New England.	New Jersey.	Delaware and Maryland.	Virginia.	North Carolina.	Alabama.
Upper Cretaceous.	Danian.		Manasquan.		.		
			Rancocas.	Rancocas.			
	Senonian.		Monmouth.	Monmouth.		Peedee.	Ripley and Selma.
		Matawan.	Matawan.	Matawan.			Eutaw.
	Turonian.	Magothy.	Magothy.	Magothy.		Black Creek.	Tuscaloosa (western Alabama).
	Cenomanian.	Raritan.	Raritan.	Raritan.		 (?)
Lower Cretaceous.	Albian.			Patapsco.	Patapsco.	 (?)
	Urgonian.			Arundel.			Lower Cretaceous (eastern Alabama).
	Neocomian.			Patuxent.	Patuxent.	Patuxent. (?)

The Lower Cretaceous formations in the area under discussion constitute part of a belt of deposits of that age extending from Pennsylvania to eastern Alabama and are apparently embraced within a single geologic province. North of central Maryland, where the most complete sequence of the Lower Cretaceous strata is found, the Arundel and Patuxent formations are gradually transgressed by the unconformably overlying Patapsco formation, which in turn disappears by the overlapping of the Raritan formation in eastern Pennsylvania and in New Jersey.

Farther south, in Virginia, the Patapsco formation disappears near Fredericksburg and does not reappear except in a single occurrence still farther south, and the Arundel formation is not known to occur south of Potomac River. With the single exception above noted the Patuxent is the only Lower Cretaceous formation exposed in south-central and southern Virginia, where in the valley of James River some of the most fossiliferous beds of this formation have been found. Although separated at the surface from the deposits of the same formation farther north, through the transgression of the Tertiary and Quaternary formations, the continuity of the beds is assumed from the similarity of the flora, with its many identical species, as well as from the characteristic lithology.

Deposits formerly called the "Cape Fear" formation but now known to be a southward continuation of the Patuxent formation of Virginia are found in North Carolina. Here again the transgression of the Tertiary and Quaternary formations interferes with the continuity of the outcrop, although there is no reason to doubt that the deposits are continuous beneath the later strata. No fossils have thus far been discovered in the Lower Cretaceous deposits of North Carolina, but the strata occupy the same stratigraphic position at the base of the Coastal Plain Cretaceous here as farther north and are unconformably overlain by Upper Cretaceous formations. The deposits are also strikingly similar to those of the Patuxent formation in Virginia and Maryland and it seems to be a reasonable assumption that they constitute part of the same formation.

To the south of North Carolina similar deposits are known to extend through South Carolina and Georgia into eastern Alabama. The more southern occurrences of the Lower Cretaceous were long erroneously associated with the Tuscaloosa formation (Upper Cretaceous) farther west in Alabama and Mississippi, but they are entirely distinct from that formation both in stratigraphic position and in lithologic character, and they are separable everywhere by marked unconformities from the overlying Upper Cretaceous deposits. According to the evidence at present available, they are physically continuous with the Patuxent formation farther north, whether or not the same formational name is employed throughout the province. Notwithstanding the physical evidence in favor of a single formational unit at the base of the Coastal Plain Cretaceous all the way from Maryland to Alabama, it must be admitted that a transgressing sea throughout so extended a coast line might well have involved considerable time for its accomplishment and if the transgression proceeded from the north toward the south, as seems probable, the deposits in Alabama would necessarily be somewhat younger than those in Virginia and Maryland.

The Upper Cretaceous deposits within the area under discussion constitute part of a belt that is known to extend from Massachusetts through the islands off the New England coast and thence to the Gulf except at a few points where transgression or erosion has removed evidence of their presence. The most complete sequence of strata is found in New Jersey, north of which the later Upper Cretaceous formations are lacking, although the earlier formations continue through Massachusetts with their characteristic if somewhat incomplete faunas and floras. To the south the Raritan and Rancocas formations finally disappear in Maryland, but the intervening Magothy, Matawan, and Monmouth formations with their characteristic faunas and floras can be traced through Maryland, can be recognized in Virginia in the deep well borings to the east of the Cretaceous outcrops, and reappear in North Carolina in the Black Creek and Peedee formations. The boundary between the Matawan and the Monmouth in the north, as well as that between the Black Creek and the Peedee in the south, marks the division between the earlier fauna and the later *Belemnitella americana* fauna. The

lower fauna characteristic of the Magothy and Matawan and the Black Creek has been found in the lower part of the Ripley formation and in the Selma chalk, also in the Eutaw; the upper fauna of the Monmouth and the Peedee is found in the upper part of the Ripley and the Selma. The flora of the Magothy characteristic of the New England area and of New Jersey and Maryland is represented in the Black Creek and also in the Tuscaloosa of western Alabama and Mississippi.

The Cretaceous formations of the northern Atlantic Coastal Plain have been correlated with the recognized European subdivisions and the faunas and floras examined have led Clark and Berry to propose the approximate equivalents given in the table on page 612. The Lower Cretaceous floras are regarded as comprising the Neocomian to the Albian, the Patuxent flora being distinctly a Neocomian flora and the Patapsco an Albian flora. The Upper Cretaceous floras and faunas extend from the Cenomanian to the Danian, the Raritan flora containing a large Cenomanian element, while the Magothy and Black Creek floras are regarded as Turonian. The faunas which are found in succeeding beds are in the Matawan and Black Creek apparently Turonian, although regarded by some paleontologists as Senonian; those of the younger Monmouth and Peedee are unquestionably Senonian. The later Rancocas and Manasquan faunas of the northern part of the Coastal Plain are regarded as Danian and probably belong to the horizon of the Maestricht.

J 14. CENTRAL KANSAS.

Cragin¹⁷³ describes the occurrences of marine Lower Cretaceous in Saline County, Kans., in part as follows:

The Mentor beds, named from a small station in Saline County, Kans., within the area of their outcrop, are a terrane of variegated, earthy-textured marine shales, with intercalated beds of brown sandstone, resting in part conformably upon the Kiowa shales and in part unconformably upon the drab and purple-red laminated shales and impure limestones of the Permian, and succeeded above by the more heavily arenaceous fresh-water sediments of the Dakota. They were formerly considered by all geologists as constituting a part of the Dakota group, but are now known to belong to the upper part of the Comanche series. * * *

The shales of the Mentor beds are chiefly argillaceous, but they contain a greater or less admixture of sand, to which, as soft sandstones, they locally give place in certain horizons. They apparently contain some lime also, partly in the condition of sulphate. * * * Such outcrops of the shales as do occur present themselves either as limited, more or less steep-faced banks of marly-appearing clay, of white, ferruginous-yellow, red, or blue color, or particolored with two or more of these. Their coloring seems to be the result of the variable distribution of oxide, peroxide, and sulphates of iron.

The sandstone of the Mentor beds occurs in thin, local strata. While these are of slight consequence judged by the space they occupy, they are nevertheless of great stratigraphic importance, since it is from these alone that our knowledge of the geological age of the Mentor terrane has been derived. * * *

The thickness of the Mentor beds varies greatly, since that portion of the terrane that rests directly upon the Permian lies unconformably upon the latter and presents considerable differences in the elevation of its base. It probably nowhere greatly exceeds 50 or 60 feet.

* * * * *

The Mentor beds are thus seen to be characterized by a fauna related to that of the Denison beds and still more closely to that of the Kiowa shales. Their fauna is, in fact, especially related to that of the upper part of the latter.

The stratigraphic relation to the Kiowa shales is also close. While the Mentor beds generally rest upon the Permian in Saline County, they rest in part upon the Kiowa shales farther southward, as shown by the occurrence beneath them of black shales amongst some of whose fossils, submitted to the writer from a few miles west of Lindsborg by Prof. J. A. Udden, are *Modiola stonewallensis* nob. and *Sphenodiscus pedernalis* Roem.; but whether they are to be

considered as overlying all of the Kiowa or only a lower part of it, and whether or not they merge southward into the upper part of the Kiowa, are questions that remain still unanswered.

J-K 10. CALIFORNIA.

The general character and relations of the Cretaceous of the Pacific coast from southern California to British Columbia are ably discussed by Anderson,²⁷ who describes and correlates the separate sections and their faunas.

The Cretaceous of California is divided into the Shasta (Lower Cretaceous, comprising the Knoxville and Horsetown formations) and the Chico (Upper Cretaceous). They have been described as the "Shasta-Chico series" by Diller and Stanton,²⁸⁴ who give a comparative table of classifications according to Gabb's, White's, and their own observations, and state:

The Chico, Horsetown, and Knoxville beds have been found to grade into one another in such a way as to show that they are simply different phases of one continuous series of deposits extending without an important interruption of any kind from the bottom of the Knoxville to the top of the Chico. For this set of beds the term Shasta-Chico series has been proposed.^a

The type section of the "Shasta-Chico series" was measured on Elder Creek, in northern California, and originally stated in detail by Diller.²⁷⁰ The following is condensed from his statement:

	Feet.
Chico: Massive and thin bedded sandstone, with conglomerates.....	3,897
Horsetown: Sandstones, often thin bedded, and shales.....	6,109
Knoxville: Shales, with calcareous layers in the upper 10,000 feet, interbedded with sandstones below.....	19,974
Apparent total thickness of unaltered strata.....	[29,980]

The Chico (Upper Cretaceous), though generally conformable in the Valley of California to earlier Cretaceous formations where they occur, overlaps them in many localities. This is the case in the section on Chico Creek, in the northeastern part of the Valley of California, where the underlying rocks are metamorphosed auriferous slates.^{269, 27}

Lists of the faunas from different horizons of the "Shasta-Chico series" are given in the paper by Diller and Stanton²⁸⁴ already cited, but Stanton^{776, 778} discusses the faunas and also the stratigraphy in two later papers, of which that of 1895 assembles the facts of distribution and stratigraphic relations more comprehensively and clearly.

The remarkable thickness assigned to the Knoxville formation in Tehama County is in a measure borne out by the observations of Osmont⁶²⁴ in the region north of San Francisco Bay:

The eastern portion of both sections is largely made up of Cretaceous shales and sandstones, most if not all of which probably belong to the lower Cretaceous or Knoxville series.^b

This series consists of an enormous thickness of rather hard tawny-yellowish sandstone, interbedded in monotonous succession with dark-blue fissile shales, with occasional thin beds of dark-blue limestone. The sandstone strata are usually less than 2 feet thick, and almost never more than 10, while their regular alternation with soft shale made the bedding very distinct and characteristic.

^a Bull. Geol. Soc. America, vol. 4, pp. 205-224, 245-256. Since the papers referred to were written we have spent several months in the field, completely reviewing the Cretaceous of northern California. The results fully confirm our previous views.

^b Becker, G. F., Quicksilver deposits of the Pacific slope: Mon. U. S. Geol. Survey, vol. 13, 1888.

While standing at high angles, these beds do not show any important faulting along either of the sections. From near Knoxville, where they appear to overlie a large laccolith of serpentine, they extend in unbroken succession with steep northeasterly dip, to the head of Capay Valley, at Rumsey, where they are covered by Tertiary gravels and sandstones. The average angle of dip from Knoxville to Rumsey can not be less than 45° , which would give the series a thickness of 4 miles, and this does not represent the whole of the accumulation of sedimentary beds, since the upper limit is not exposed.

In the Coast Range south of San Francisco the Lower Cretaceous strata are less fully represented than they are to the north. In the Santa Cruz quadrangle⁹⁷ the Knoxville is but 100 feet thick and is bounded by unconformities above and below. (See Chapter XV, p. 669.) In the San Luis quadrangle^{325a} the relations are as follows:

Strata of Cretaceous age in California include three main groups—the Knoxville, Horsetown, and Chico. Two of these, the Knoxville and the Chico, are widely distributed throughout the Coast Ranges, and their representatives, the Toro and Atascadero formations, are found within this quadrangle. Nothing corresponding to the Horsetown group has been recognized here, and probably the horizon is represented by an erosion unconformity.

It has been thought that the Cretaceous sediments in California formed a conformable series from top to bottom, but, in the central Coast Ranges at least, this period was broken two or more times by igneous outbursts, with one long interval of elevation and erosion.

The Toro formation within the San Luis quadrangle consists of more than 3,000 feet of dark shale and thin-bedded sandstone. The formation is named from a creek which flows across it. The shale forms almost the whole of the bottom and middle portions. The sandstone is more abundant toward the top. The formation is not supplied with many fossils, for, excepting one specimen of an ammonite, the only species found is one belonging to the genus *Aucella*. This is very abundant through the middle and lower portions of the formation.

The Toro formation is the local representative of the Knoxville group, but it probably corresponds to a small part only of Knoxville time, the rest being represented by the unconformities above and below. It belongs to the lower Cretaceous or Shasta series.

The Cretaceous sequence on the west side of the Valley of California, near its south end, in the Coalinga district, is thus described by Arnold and Anderson:^{34a}

The next to the oldest terrane exposed in the Coalinga district is a thick series of strata of sandstone, shale, and conglomerate overlying the Franciscan formation and covering a wide belt for the most part west of the foothill region. It forms the high ridges bordering the Coalinga district on the west and may be easily recognized by the dark, thinly bedded, compact shale and sandstone of its lower portion and the massive drab concretionary sandstone of its upper portion. These strata are of Cretaceous age and comprise part or all of the two formations well known elsewhere on the west coast as Knoxville (Lower Cretaceous) and Chico (Upper Cretaceous). * * *

The Horsetown formation, which forms the middle portion of the Cretaceous in the standard Coast Range section, is not known to be represented in the Coalinga district, although it is not impossible that a portion of the great thickness of nonfossiliferous Cretaceous strata may be the equivalent of this formation. No evidence, however, has yet been found of its presence in this portion of the Coast Ranges.

A conservative estimate places the total thickness of the strata mapped as Knoxville-Chico at 12,800 feet. The maximum thickness is probably much greater. This succession of strata may be divided lithologically into three main divisions. The total thickness of the middle and upper divisions, which are probably to be referred together to the Chico formation, is at least 9,500 feet. A thickness of 8,300 feet is measurable in single sections, and even greater thicknesses may be found in single sections of the Knoxville-Chico as a whole. It is likely that

at least two unconformities separating the Knoxville-Chico beds into important stratigraphic groups will be made out on further study. * * *

A zone of coarse conglomerate varying in thickness from less than 100 to over 1,000 feet extends intermittently from the summit of Juniper Ridge, south of Los Gatos Creek, to a point south of Reef Ridge, in Big Tar Canyon. It is overlain and underlain, in appearance conformably, by the thin-bedded dark shale and sandstone of the lower half of the Knoxville-Chico. The portion of the terrane lying below this conglomerate is here classed by itself as the lower division. * * * The total thickness of the lower division as exposed in the Alcalde Canyon section is between 3,100 and 3,500 feet. * * *

Fossils of Knoxville (Lower Cretaceous) age, such as *Aucella crassicollis* Keyserling and *Belemnites impressus* Gabb, have been found in beds of dark shale in the Devils Den region not many miles south of the Coalinga district, and there is little doubt that the lower division of the rocks here described as Knoxville-Chico is at least in part the equivalent of the Knoxville formation. It is possible that the great beds of conglomerate mark the base of the Chico or Upper Cretaceous and that the whole of the lower division below this line of separation represents the Knoxville formation.

For reference to the views of F. H. Knowlton and James Perrin Smith on the Jurassic age of that part of the Knoxville which contains a Jurassic flora, see the next section (K 10).

For a general correlation table of the Mesozoic and Cenozoic formations of the Coast Range, see Chapter XVII (p. 818).

K 10. KLAMATH MOUNTAINS, OREGON AND CALIFORNIA.

In his published articles Diller ²⁷⁶ has recognized representatives of the Knoxville, Horsetown, and Chico of the California Cretaceous section in the Klamath Mountain section.

The strata of conglomerate, sandstone and shale, which are believed to represent these epochs, are comprised in the Myrtle formation. The strata are irregular, but shale predominates. The coarser detritus is derived from disintegrated granite. In the Roseburg quadrangle the thickness is estimated at about 6,000 feet. Fossils from the upper portion include *Pecten operculiformis* and *Trigonia æquicostata*, characteristic of the Horsetown epoch. *Aucella crassicollis* and *A. piochii* are found in the lower portion, the equivalent of the Knoxville. The Myrtle formation includes limestone lentils which contain *Opis californica* and *Hoplites dilleri* or a form closely related to it. These are also found in the Knoxville.

The Myrtle formation is bounded by very marked unconformities both above and below and is intruded by igneous rocks and metamorphosed. ^{274, 277}

The relations of the Myrtle formation to the Horsetown and the upper part of the Knoxville are apparently established beyond doubt by the common occurrence of *Aucella piochii* and *A. crassicollis* in similar stratigraphic relations in both areas, as well as by the abundant floras which have been found in both formations and which are intimately associated in Oregon with both species of *Aucella*. It is not clear, however, that the Myrtle formation includes older strata that should correspond to the middle and lower parts of the Knoxville. The Knoxville is 20,000 feet thick. The Myrtle, so far as known, is but 6,000 feet thick. Diller regards this known portion of the formation, which rests on a basal unconformity, as the thin

overlapping edge of the deposit and believes that the older sediments accumulated farther seaward. He says:^a

The lower portion of the Myrtle as exposed in Oregon corresponds only to the upper part of the Knoxville as exposed in California, yet it is quite correct to say that the Myrtle as a whole is the equivalent of the Knoxville and Horsetown (Shasta) as a whole, if it is admitted that the Myrtle includes beds which are older than any of the Myrtle yet seen in Oregon but which are believed to form the base of the overlapping strata. These basal beds of the Myrtle presumably occur farther west, beyond the present coast, but they may yet be found in Oregon.

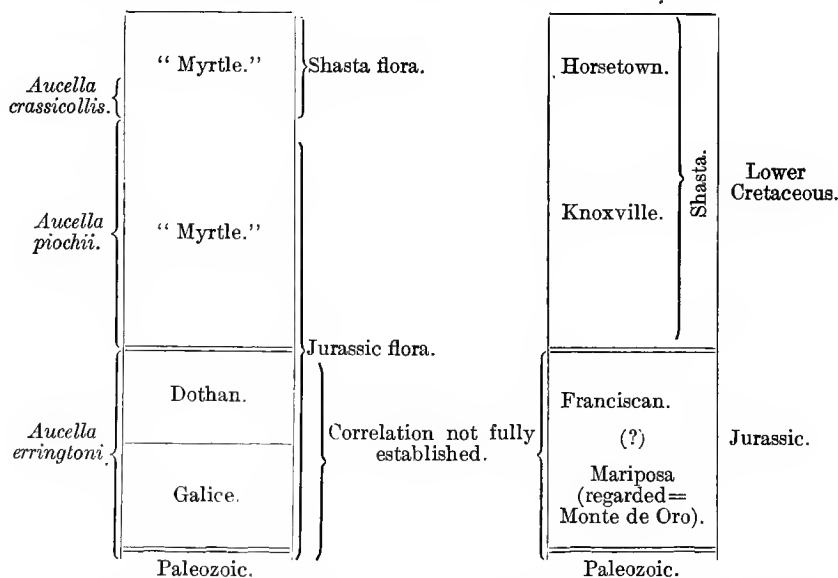

The age of the Myrtle formation is not yet satisfactorily determined, there being a difference of opinion between Stanton and Knowlton as to the correlation according to the faunas or the floras. The fauna as interpreted by Stanton is of Cretaceous age throughout. The floras as identified by Knowlton comprise a lower flora, of Jurassic age, and an upper flora, of Lower Cretaceous age.

We quote Knowlton's statement of the problem and the summary of his conclusions:⁵⁰⁹

In November, 1908, Mr. Diller published a paper under the title "Strata containing the Jurassic flora of Oregon,"^b the thesis of which he sets forth as follows: "Two fossil floras have been reported from the Mesozoic rocks of California and Oregon, the one Cretaceous and the other Jurassic. With the former the fauna is Cretaceous, but with the latter the fauna has been regarded as a matter of doubt. It is the purpose of this paper to remove the doubt by showing that in parts of Oregon and California the Jurassic flora * * * is in the 'Myrtle' and Knoxville beds, while elsewhere it extends down to the horizon of the Mariposa, and the general conclusion is reached that for the Pacific coast the line between the Cretaceous and the Jurassic is the great unconformity at the base of the Knoxville."

The major portion of Mr. Diller's paper is devoted to proof that the Jurassic flora occurs in the Knoxville formation—a point conceded by the present writer. It is to the placing of the Jurassic-Cretaceous line at the base of the Knoxville that exception is taken.

Mr. Diller's interpretation of the relations of the several formations concerned in this paper, together with his conclusion regarding the ranges of the floras and the supposedly characteristic invertebrates, is shown in the following diagram, which is taken from his paper:

^a Personal communication, February 15, 1910.

^b Bull. Geol. Soc. America, vol. 19, 1908, pp. 367-402.

THESIS OF THIS PAPER.

At variance with the conclusions above set forth, it will be shown in the present paper that the so-called "Jurassic flora of Oregon" is everywhere of true Jurassic age, that it is practically never ^a found in association with the acknowledged Cretaceous flora, and finally, that the line between the Jurassic and the Cretaceous of the region is to be drawn through the upper part of the Knoxville and not at its base.

* * * * *

SUMMARY.

1. The Lower Mesozoic strata of Oregon and California have afforded two floras, one of which is Cretaceous and the other Jurassic. These two floras, although sometimes occurring practically in the same section, have not been found commingling.

2. The Cretaceous flora ranges from the extreme upper part of the Knoxville formation through the Horsetown formation. It embraces about 60 species of plants and is regarded as being of Lower Cretaceous (Neocomian) age. It finds its closest affinity with the Kootenai of the Interior region, the Trinity of Texas, and the lower Potomac of the Atlantic coast.

3. Associated with the Lower Cretaceous flora is an invertebrate fauna regarded as being of Neocomian age, the plants and invertebrates thus being in agreement.

4. The Jurassic flora, which has been called the "Jurassic flora of Oregon," ranges from beds which have been referred to the Mariposa formation through the major portion of the Knoxville formation. It includes 100 species and finds its close affinity with the Lower Oolite floras of known position in other parts of the world. It is beyond question a true Jurassic flora.

5. Associated with the Jurassic flora is a meager, often poorly preserved invertebrate fauna of only seven species, including the two supposedly characteristic species of *Aucella* (*A. crassicollis* and *A. piochii*). This fauna, with the exception of *Aucella piochii*, is the same as that found in association with the Lower Cretaceous flora, and it is on account of this association that the Jurassic plant beds have been referred by some invertebrate paleontologists to the Cretaceous.

6. The age of the beds containing the "Jurassic flora of Oregon" thus hinges on the relative strength of the evidence afforded by the flora as compared with that of the associated fauna. It has been shown in this paper that of a total of 100 species of plants, 47 species are known also from known Jurassic of other, often widely separated parts of the world. Only one of these 100 species has been found in the Lower Cretaceous beds of the region. The total Knoxville fauna comprises 77 forms of invertebrates, only 7 named species of which have been found associated with the Jurassic plants. Of these 7 species of invertebrates, only a single species has been found outside the limits of the Oregon-California area, and it has been further shown that the invertebrate paleontologists are not in accord among themselves as to the interpretation to be given the age determination of the fauna. The conclusion is reached that the plants, being thoroughly consistent, afford the better criteria, and the beds are regarded as unquestionably of Jurassic age.

7. From the paleobotanical evidence which has been presented it follows that in this portion of the Pacific coast region the line between the Jurassic and Cretaceous is to be drawn through the upper part of the Knoxville formation, and not at its base. This line is fixed by the upper limit of the Jurassic flora.

In 1895 Stanton discussed the relation of the Knoxville fauna to the Volgian faunas of Russia, and after citing differences of opinion among the Russian geologists as to the Jurassic or Cretaceous age of the Volgian, he wrote: ^{776a}

It is evident, then, that even if it were possible to refer the Knoxville to definite horizons of the Russian *Aucella* beds its age might still be questioned. One important fact that should

^a The only possible exceptions are a scrap very doubtfully identified from the area near Riddles, Oreg., and a conifer of no stratigraphic value from California.

be borne in mind is that structurally and faunally, so far as known, the Knoxville is a unit. It is true that there is a gradual change in the fauna from the lower to the upper beds, but there is no distinct break that would justify the reference of one portion to the Jurassic and another to the Cretaceous. There are some elements of the fauna, such as *Belemnites tehamaensis*, *Hoplites storrsi*, and some of the Turbinidæ, that resemble Upper Jurassic types. *Aucella piochii* belongs to the same general type as *A. mosquensis*, which has usually been referred to the Jurassic, and it is somewhat closely related to the Aucellæ^a of the Mariposa beds, but Prof. Pavlow informs me that Aucellæ very similar to *A. mosquensis* occur in the Neocomian of Russia also. These resemblances, which will be more fully mentioned in the description of the species, are not considered of sufficient importance to counterbalance the evidence of the Cretaceous age of the entire series. Some Jurassic elements are naturally to be expected in the Lower Neocomian, and it is a well-known fact that in Europe several species of ammonites pass up from the Jurassic to the lowest Cretaceous beds.

Prof. Hyatt's opinion as to the Cretaceous affinities of the Knoxville ammonites has been cited on a previous page. That the Upper Knoxville beds containing *Aucella crassicollis* are Neocomian is shown by the resemblance of its fauna to that of the Petschora beds, now generally admitted to be Neocomian, and by its stratigraphic and faunal relations with the immediately succeeding Horsetown beds, which have been compared with the Gault by everyone who has studied their fauna.^b The few fossil plants that have been obtained from the Knoxville and the Horsetown also tend to show that these two formations are closely connected, and these plants are mostly either identical or closely related with species in the Lower Cretaceous Potomac formation of the eastern United States and in the Trinity beds at the base of the Comanche series in Texas.^c

From all these lines of evidence the conclusion is reached that the entire Knoxville series is of Neocomian age.

In 1910, as this manuscript is being finished, Stanton states orally that the preceding quotation expresses the views he stills holds.

J. Perrin Smith⁷⁶⁶ does not altogether agree with Stanton, as appears from the following statement:

The Cordilleran revolution began in the Great Basin sea in the middle of the Jurassic, when that body of water, after many vicissitudes, finally went dry, and has never since been covered by salt water, although in later ages Tertiary and Quaternary lakes have been scattered over its dead basin.

This elevation culminated, in late Jurassic time, in the upturning and metamorphism of the Triassic and Jurassic sediments of the Sierra Nevada and the Franciscan beds of the Coast Ranges. * * *

It is probable also that the Cordilleran revolution was something more than a mere orogenic disturbance, for it marks a change from the warmth of the Middle Jurassic, with its cycads and reef-building corals, to the cooler epoch of the Upper Jurassic, with its scanty boreal fauna. The Middle Jurassic was of tropical type, from Mexico to Alaska, and uniform up to Franz Joseph Land. The Upper Jurassic, on the other hand, was of boreal type from the Arctic region down as far as California, and for a short epoch in the Portland these conditions extended down as far as Mexico.

After this mountain-making epoch near the close of the Jurassic, the sea again encroached on the uplifted area, and the Knoxville sediments were laid down on the western border of the

^a See comparisons by Prof. Hyatt, Bull. Geol. Soc. America, vol. 5, pp. 404-407.

^b It is not probable that the limits of the divisions recognized in the California Cretaceous coincide exactly with those of the European subdivisions of the Cretaceous. It has been shown (Bull. Geol. Soc. America, vol. 5, pp. 445-449) that the Horsetown beds probably include the lowest Cenomanian, and at their base they may contain strata older than the Gault.

^c These plants are the only means by which the Lower Cretaceous of Texas and California can be compared. So far as known, their invertebrate faunas have nothing in common.

Coast Ranges. The lower Knoxville beds contain a fauna closely related to that of the Mariposa, still with Jurassic types of Aucella, and with the same poverty of other animals. But the upper Knoxville beds, while still retaining reminiscences of the boreal region in Aucella and a few other forms, show a preponderance of life characteristic of more favorable conditions. Aucellas of northerly habit mingle with cephalopods that did not belong in the boreal region, and on the near-by land cycads abounded. The line between Jurassic and Cretaceous should be drawn, not at the beginning of the Knoxville, but between the lower and the upper Knoxville beds; the former belonging to the Portland and Aquilonian, while the latter belong to the Neocomian.

L 10. JOHN DAY BASIN, OREGON.

Merriam^{589, 590} refers to exposures of conglomerate and sandstone on the west side of the John Day Basin, from which good collections of fossils were obtained. The outcrops appear to form opposite sides of a syncline, and include 3,000 or 4,000 feet of beds. The lower strata are said to "exactly duplicate" those of the Knoxville as it is usually developed in California and southern Oregon. Stanton has identified the Chico fauna in Merriam's collections.

L 12. SOUTHWESTERN AND CENTRAL MONTANA.

F. C. Calkins contributes the following notes from a manuscript for a folio on the Philipsburg quadrangle, Montana:

Both Lower and Upper Cretaceous are represented in the Philipsburg quadrangle, although they have not yielded very satisfactory fossils. The Lower Cretaceous is represented by the Kootenai formation, which may be described as follows:

The yellow-weathering beds of the Ellis formation are generally overlain by a heavy reddish sandstone, locally conglomeratic with well-rounded pebbles of quartzite like the Quadrant, which is taken to be the base of the Cretaceous. This bed is generally succeeded by argillaceous buff-weathering limestones, in the upper part of which have been found poorly preserved specimens of the fresh-water gastropod *Goniobasis* which, according to Dr. Stanton, tend to indicate a Kootenai age. Above these there are several hundred feet of maroon and gray-green sandstones and shales that have yielded no fossils. Near the top is a bed or several beds of gray limestone crowded with shells of fresh-water gastropods. These gastropod limestones, which are very conspicuous in the vicinity of Drummond, on the Northern Pacific Railway, seem to be very widespread and highly characteristic of this horizon. They are probably the same as those that in the Yellowstone National Park were referred to the Dakota. Above the gastropod limestones are a few feet of calcareous shale and sandstone. On Mount Princeton, in the Philipsburg quadrangle, there is a gradation to the black noncalcareous shales of the Colorado formation; elsewhere the transition is more abrupt.

These uppermost limestones have yielded two or more undescribed unios, one related to *U. douglassi* Stanton, *Goniobasis? increbescens* Stanton, and *Viviparus? sp.* The fauna is characterized by Dr. Stanton as probably upper Kootenai.

The total thickness of the beds referred to the Kootenai is about 1,500 feet.

The Cretaceous of the Great Falls coal field extends along the northern and northeastern flanks of the Belt Mountains. The Lower Cretaceous is represented by the Kootenai formation and the Upper Cretaceous by Colorado and Montana strata. The Morrison formation, which is doubtfully referred to the Jurassic by Stanton and others, is described under the Lower Cretaceous by Fisher,^{332a} who states:

The Morrison formation, which is extensively exposed along the Rocky Mountain Front Range in southern Montana and Wyoming, is also believed to occur along the northern base of

the Little Belt Mountains. In previous investigations in this field by Weed and others the Morrison formation has not been recognized, and the beds comprising it have been grouped with the Kootenai and included in the "Cascade" formation. During the last field season dinosaur bones provisionally regarded by C. W. Gilmore as of Jurassic age were found at one horizon in many different localities; and at one exposure in sec. 3, T. 16 N., R. 2 E., about 30 feet below the bone-bearing bed, a green shale containing a distinctly fresh-water fauna later than the Ellis formation was seen. These rocks, here provisionally regarded as constituting the Morrison formation, consist of sandstone and bright-colored sandy shale with scattered layers of impure limestone, many of them in lenticular form. The formation lies with apparent conformity on the Ellis and is overlain conformably by the Kootenai. The thickness ranges from 60 to 120 feet, but the exact limits of the formation are in many places difficult to determine. Fragments of bone have been found at different horizons throughout the overlying Kootenai formation, but thus far none that are sufficiently well preserved for specific determination have been discovered in this region. It is possible that future investigation may prove that the rocks here tentatively regarded as belonging to the Morrison constitute in reality a basal member of the Kootenai.

Section of supposed Morrison formation on the north side of Smith River, Montana.

	120

Fisher gives other sections of the supposed Morrison and states that the rocks have yielded invertebrate fossils which Stanton regards as "a fresh-water fauna later than the Ellis and suggestive of the Morrison."

In regard to the character and extent of the Kootenai, Fisher has the following to say:

The Kootenai, as determined by the present investigation, comprises the upper one-third of the Cascade and Dakota and the basal red shale included in the Colorado shale, as described by Weed in the Fort Benton folio. * * *

[This formation] consists of alternating layers of sandstone and shale, with the former predominating, especially in the lower half. The sandstones range in thickness from 10 to 60 feet and are more or less massive in character. In the upper part shales are more abundant and are interbedded with thin layers of impure sandstone. At Belt, on the east side of Belt Creek, where a complete section was measured, the basal member of the formation consists of a sandy shale interbedded with sandstone, the latter predominating, the whole having a thickness of about 60 feet. This member consists locally of firm, massive sandstone with only a small percentage of shale. It is overlain by coal, which here has a thickness of 6 feet, including a few thin partings. Above the coal there is a dark coaly shale 5 to 6 feet thick, covered by 38 feet of massive light-gray sandstone. This sandstone is overlain by 138 feet of beds, consisting in ascending order mainly of alternating layers of sandstone, red shale, and clay, with an occasional limestone lens in the lower part. Above this alternating series there is about 200 feet of red shale, which constitutes the topmost member of the formation. The total thickness is about 450 feet, which may be regarded as representative of the Kootenai formation as exposed along the Belt Creek valley. * * *

During the present investigation a number of detailed sections measured along Belt Creek proved conclusively that the stratigraphic interval between the base of the Ellis and the

Kootenai coal, to which Weed had assigned a thickness of 736 feet, is in reality only about 300 feet. According to the present classification the lower 120 feet of these beds has been assigned to the Ellis; an equal thickness immediately overlying, in which fresh-water invertebrates and land animals occur, to the Morrison; and the upper 60 feet, which is plant bearing, to the Kootenai. * * *

The Kootenai has the greatest areal distribution of all the formations outcropping within the area. It caps the surface for a great part of the district lying between Smith River and Belt Creek and is the surface formation of the high plateaus south of Otter Creek. Beyond Otter Creek it is exposed as a band of varying width which narrows toward the east.

Fisher gives columnar sections measured along the Belt Creek valley which show the character and thickness of the several formations. As to fossil evidence and correlation he states:

The Kootenai formation of the Great Falls district carries an abundant fossil flora of Lower Cretaceous age. Fossil plants of Kootenai age were first discovered in the Great Falls coal field in 1889 by J. S. Newberry. From these fossils, which consisted of only a few species, it was possible to correlate the rocks of the Great Falls region with the Kootenai north of the international boundary line, described by George M. Dawson. * * *

During the present investigation fossil plants, all of which were studied and reported on by F. H. Knowlton, were collected from five different horizons—15, 60, 70, 150, and 300 feet above the base of the Kootenai formation. * * * The collection * * * is not large, but it is of unusual interest in that it contains a number of species before unknown in the Kootenai beds of this age; it contains also a species of the genus *Protorhipis* not previously found in North America, as well as some believed to be new to science.

In addition to the plants, some fresh-water invertebrates were collected from the upper part of the Kootenai during the investigation. * * * These fossils are too imperfect for positive identification, but the species with which they are compared occur a few miles south of Harlowton, Mont., in beds that belong to either the Kootenai or the Morrison.

M 10. WASHINGTON AND BRITISH COLUMBIA.

A belt of Cretaceous strata crosses the international boundary from Washington into British Columbia. The rocks were described by George Otis Smith^{757a} in 1904 and by Camsell¹²⁹ in 1907. The following is quoted from Smith's account of the eastern belt on Pasayten River. Camsell's description is briefer and to the same effect.

Prof. Russell, in his reconnaissance of 1901, examined an assemblage of folded sedimentary strata in the neighborhood of Barron and Crater Pass.^a From these rocks he collected fossils which are commented on in the following extract from his report:

"A thick bed of bluish sandstone at the base of Gold Ridge, penetrated by the tunnels of the St. Paul and Minneapolis mines, contains fossil ferns and nearly upright tree trunks. One sample of fern collected has been determined by F. H. Knowlton as approaching closely *Dryopteris arstedii*, from the Cretaceous rocks of Greenland. A siliceous limestone in the same ridge, but several hundred feet higher in the series and extending southward to the border of Crater Pass, is abundantly charged with bivalve shells, which, as determined by T. W. Stanton, are of a species of *Actæonella*. The evidence furnished by the fossils just mentioned indicates a Cretaceous age."

The authors of this paper found that these Cretaceous beds extended eastward along their route to the Hidden Lakes and were very extensively developed to the north, and believe that they extend west to a point not far above the mouth of Granite Creek. In this, however, they differ from Prof. Russell, who believes that the slaty rocks with steep dips exposed along lower

^a Russell, I. C., *Geology of Cascade Mountains: Twentieth Ann. Rept. U. S. Geol. Survey, pt. 2, 1900, pp. 114-117.*

Slate Creek and Ruby Creek are much older than the Cretaceous.^a * * * The authors do not consider that the assumption of the pre-Cretaceous age of these beds is justified and have provisionally considered them as belonging in the same formation with those at Barron.

To the rocks of this locality which he recognized as Cretaceous Prof. Russell provisionally applied the name Similkameen formation.^b This name was, however, applied ten years earlier by Dawson to a Miocene formation in British Columbia.^c * * *

The Pasayten formation is composed of sedimentary rocks without contemporaneous volcanic materials. East of the main fork of Pasayten River sandstone appears to be the dominant rock. * * * The lowest part of the section, as seen along the crest of the Hozomeen range, includes at least 1,000 feet of black shale. Above this shale is a sandy conglomerate, with pebbles from 1 to 8 inches in diameter. * * * Sandstone overlies the conglomerate and is succeeded by more black shale. The steep dips here indicate the presence of a great thickness of these rocks, * * * so that 6,000 feet would appear to be a very conservative estimate for the thickness of the Pasayten formation.

There are a few thin and discontinuous beds of limestone in the Pasayten formation, but they constitute only an insignificant proportion of its total volume. Along the lower portion of Slate Creek the supposed Cretaceous rocks are mainly black indurated shales with nearly vertical dips.

The argillaceous portions of the Pasayten formation are generally dark-colored, distinctly bedded shales. They are often siliceous and in general more or less indurated, and are popularly referred to as "slate." * * *

The sandstones, while occasionally quartzitic, are more commonly gray or greenish gray in color, and evidently composed in large part of feldspar and rock fragments. The conglomerates contain a variety of pebbles, including several granitoid rocks, gabbro, diabase, metamorphosed volcanics, chert, quartzite, and vein quartz, illustrating the character of the pre-Cretaceous formations of the region.

The whole series has undergone a considerable degree of "static" metamorphism, as shown by the generally thorough cementation of the sandstones and the presence of joints in all the varieties of rocks. Both these phenomena are exemplified strikingly in the conglomerates, which often are divided into great blocks whose faces are nearly as smooth as if made by a saw that had cut indifferently through the pebbles and their compact matrix.

The series is cut by many dikes and sheets of igneous rock; these are especially numerous along the main divide, where they must add materially to the volume of the formation. At three localities there are exposures of granitoid rock, apparently intrusive in the Pasayten formation.

M 11-12. CANADIAN ROCKIES, ALBERTA AND BRITISH COLUMBIA. ^d

The Cretaceous areas in the Canadian Rockies are best known as the Cascade and Crows Nest Pass coal fields. Dawson stated that in this region dark Cretaceous shales in apparent conformity succeed Carboniferous shales, which are lithologically similar, but the Fernie shale (Jurassic) has since been distinguished. The Cretaceous consists of shales, sandstones, conglomerates, and coals, to a total thickness of 12,000 feet or more. It comprises the Kootenai formation (Lower Cretaceous), a local volcanic intercalation, and Upper Cretaceous strata. Dawson's original description ^{255a} runs in part:

Over the area of the Great Plains, both in the United States and Canada, and in the Rocky Mountain region south of this district, the lowest rocks of the Cretaceous series developed are those of the Dakota, of Middle Cretaceous age. In the vicinity of the west coast Lower Creta-

^d For the Cretaceous of the plains in this latitude see p. 695.

ceous rocks are found, and in this part of the mountains we appear to enter upon the edge of the area of deposit of the Lower Cretaceous, the beds here named the Kootanie series occupying that horizon. The geological horizon of the Kootanie series is determined by its position relatively to the higher members of the Cretaceous series, and by the fossil plants which it has yielded. * * * The plants "consist of ferns, cycads, and conifers, some of them identical with or closely related to those of the Jurassic of the Amur country in Siberia, and others similarly related to the Lower Cretaceous of Greenland, as these floras have been described by Heer. This group undoubtedly represents the flora of the Lowest Cretaceous, which has not hitherto been recognized in western America." * * * That the series characterized by these plants is a widespread and important one is shown by the fact that one of the species (*Pinus suskwaensis*) had previously been found on Suskwa River, in northern British Columbia, at a distance of 580 miles northwest of the most northern locality here referred to.

* * * * *

No complete section can yet be given of the Cretaceous rocks of the mountain region, nor of those of the adjacent foothills. * * * Two horizons appear, however, to be fixed with considerable definiteness in the lower part of the Cretaceous of the mountains—that of the most important and persistent coal seams and that of the volcanic intercalation. The first of these is fixed in part by the similarity of appearance and character of the coal and beds near them, but chiefly by the very similar group of fossil plants which is found in association with these coal seams.

* * * * *

The thickness of the rocks of the Kootanie series below this coal-bearing horizon was estimated on the Crow Nest Pass and near the west summit of the North Kootanie Pass at about 7,000 feet, which may be taken as a minimum estimate of the greatest observed development of this part of the series. The beds are chiefly shales and sandstones of very varied texture and appearance.

The volcanic ash beds and agglomerates of the Cretaceous, in this region, are evidently due to local eruption, which had its center in the latitude of the Crow Nest Pass. These volcanic rocks have, however, been traced north and south from this point over a total length of 45 miles, and may probably have at one time had as great an extension east and west, though this has subsequently been diminished by the folding together of the beds. The volume of the strata between the coal-bearing horizon and the base of the volcanic rocks on the Crow Nest Pass was estimated approximately at 3,350 feet, on the South Kootanie Pass at 2,400. The mean of these approximations, 2,750 feet, may for the present be adopted as a probable result. The volcanic rocks themselves, on the Crow Nest Pass, where they attain their maximum, have a volume of about 2,200 feet, but thin out very rapidly to the north and south.

The summit of the Kootanie series is not yet precisely defined but is situated between the apparently constant coal-bearing horizon and the base of the volcanic beds, as, on the Northwest Branch of the North Fork, fossil plants believed to represent the horizon of the Dakota are found a few hundred feet below these volcanic beds.

(See also M 11, Chapter XIII, p. 574.)

M 10, N 9-10, O 9. WESTERN BRITISH COLUMBIA.

The Jackass Mountain group, so called by Selwyn from the locality of that name on Fraser River (near the mouth of the Thompson?), is described in his report⁷²⁴ as consisting of "hard, close-grained, and thick-bedded greenish sandstones or quartzites, green and black shales, and, above these, massive, thick-bedded pebble conglomerates, dipping generally at low angles in various directions; some of the inclosed pebbles are of rocks belonging to the Cache Creek series."

In 1875 Dawson^{249a} identified these rocks on Tatlayoco Lake (longitude 124° 30', latitude 51° 30'), where they have the character of the strata on Jackass Moun-

tain, and he found fossils by which the age was "determined as lower Cretaceous of the horizon of the Shasta group of the California geologists." He says further:

Along the eastern shore of the lake these rocks, as already mentioned, appear to overlie those of the Porphyrite series. * * * The series is no doubt conformable throughout, the upper beds * * * showing, however, a greater development of conglomerates. The rocks may be described as being compact bluish-gray quartzites or hard sandstones and conglomerates of all grades in regard to size of particles, associated with blackish or dark-colored slaty and shaly beds, which recur frequently at different horizons. Great fragments of highly fossiliferous quartzite strew the lower slopes in some places, but fossils were only observed in situ about 2,000 feet above the lake, where they are found not only in the quartzite but in black shaly beds. * * * It is highly probable that softer shaly beds may bear a larger proportion to the quartzites than now appears, as there are extensive hollows following the strike in which no exposures occur. Many of the beds are somewhat calcareous, and some of the shales are dark colored from carbonaceous matter. Together with the marine fossils, in some layers surfaces are found covered with obscure plant impressions, like fragments of stems or bladelike leaves. No indications of coal were, however, observed. The thickness of the entire series, as shown on the east side of Tatlayoco Lake, probably does not fall short of 7,000 feet.

In 1877 Dawson²⁵¹ reexamined the Jackass Mountain rocks in the type locality and found "*Syncyclonema meekiana* Wh., *Ancyloceras percostatus* Gabb, *Crioceras latus* Gabb, *Pleuromya* n. sp. allied to *P. papyracea* Gabb, an *Arca* * * * and a badly preserved cast of a *Cucullæa*." These fossils confirm the correlation with the rocks on Tatlayoco Lake.^a

The small basin of the Jackass Mountain occurrence, above described, is crossed by the fiftieth parallel. That of Tatlayoco Lake is the south end of a large area which widens toward the north and extends nearly to latitude 58°. A section along Skeeha River and across the mountains to Babine Lake, near the fifty-fifth parallel, is described by Dawson.²⁵³ Referring to the rocks cut by the Skeena and its tributaries, he notes that they are chiefly feldspathic rocks of purplish, grayish, greenish, or bluish tints. They "are sometimes brecciated, and the breccias occasionally pass into water-formed conglomerates, with well-rounded fragments, the finer materials graduating into ordinary quartzites, sandstones, and argillites by intermediate varieties. Fossils were found in some abundance in a bluish feldspathic rock. * * * They include belemnites, a *Trigonia*, with other mollusks and a branching coral."

Near Kitsequecla the rocks change somewhat in character. The sandstones are not highly indurated, as before, but rather soft, and associated with carbonaceous shales, which occur at different stages in the formation and are sometimes 10 or more feet in thickness. At a little distance these quite resemble coal seams, and on closer examination are in fact found to include films and small lumps of a material, which, though very impure and ashy, may be called true coal. Ironstone in nodules and sheets occurs in abundance in some parts of the formation, and obscure plant impressions were observed in the sandstones. The rocks have been irregularly deposited in many instances, the carbonaceous shales in particular showing a tendency to lenticular forms. * * *

It will have been observed that while the porphyrite and other feldspathic and often brecciated rocks prevail toward the western margin of the region, comparatively soft sandstone, argillites, and carbonaceous argillites characterize the eastern, the intervening region showing rocks more or less intermediate in lithologic character and degree of induration. * * *

^a This list indicates correlation with the Horsetown of California.—T. W. Stanton.

In proceeding eastward from the forks to the northern end of Babine Lake, across the intervening mountain region, similar rocks continue to prevail. Sandstones are most abundantly represented but contain in some places carbonaceous shales and toward the summit of the pass become associated with rocks of volcanic origin like those before described. These occasionally seem to form fully one-half the thickness of the beds represented. In one place 5 miles up the Suskwa River a few impressions of leaves were found. Some of these appear to be coniferous. There is one narrow angiospermous leaf and several grasslike blades. Not far from the summit numerous fragments of silicified wood were obtained, with a few specimens of a mollusk which, according to Mr. Whiteaves, who has examined the specimens, is a *Thracia* of the section *Corimya*. The species is probably undescribed, but it is identical with one from the coal-bearing rocks of the Queen Charlotte Islands.

In 1875 Dawson²⁴⁹ distinguished in southwestern British Columbia a great body of volcanic rocks and pyroclastic tuffs under the name "Porphyrite group." He says:

Porphyrite group.—This name may be provisionally employed to designate a series of rocks, chiefly feldspathic and often porphyritic, though also including diorites of varied texture, the reference of which to any of the groups formerly defined seems uncertain. They are best seen about Tatlayoco Lake, where they overlie unconformably the Cascade crystalline rocks and appear to underlie the beds of the Jackass Mountain series. The whole of the rocks of this group seem to be of igneous origin, though some of them may owe the arrangement of their material to water.

After the field work of 1876 Dawson²⁵⁰ wrote:

It may now, however, be affirmed with considerable certainty that the rocks called the Porphyrite series in last year's report underlie, probably conformably, the fossiliferous series of Tatlayoco Lake and consequently bear the same relation to the Jackass Mountain beds of the preliminary classification. This inference is chiefly based on the fossils discovered on the Iltasyouco River, described by Mr. Whiteaves in an appended note.

* * * * * * * * *

The most interesting and typical sections of these rocks examined last summer are those in the vicinity of Iltasyouco and Islaho or Salmon rivers. The rocks here seen represent those described last year on Tatlayoco Lake, and though they have not been again observed in contact with the upper arenaceous and conglomerate beds of the Tatlayoco Lake sections, the discovery of fossils on the Iltasyouco River, of a horizon close to though probably lower than that of the Jackass Mountain group, together with additional evidence tending to show the blending of the ordinary aqueous sediments of the upper part of the Jackass Mountain series with the igneous products of the Porphyrite series, leaves little room for doubt that the latter is the downward continuation of the former, and that the whole constitutes a formation, bridging to some extent the gap ordinarily found between the Cretaceous and Jurassic.

Detailed sections and descriptions of these rocks, which exceed 2,000 feet in thickness, are given on pages 59 to 72 of Dawson's report.

Whiteaves⁹¹¹ reports on the fossils from the "Porphyrite group" of Iltasyouco River and closes with the following comment on correlation:

The fossils above enumerated are of much interest as affording the first instance yet observed of the occurrence of a well-marked fauna of Jurassic age in British Columbia. It is true that fossils, probably from a very similar geological horizon, were collected by Mr. Selwyn in 1875, at Rock Island Gates, below Hudson's Hope, on the Peace River, but these specimens, which were described in the report of progress for 1875-76, are very few in number and so imperfect that none of the species could be satisfactorily determined.

If the identifications in the present paper be correct, it would appear that nine of Meek and Hayden's species, from the Jurassic rocks of Dakota, are found also in the Coast Range of British Columbia. These are:

Gryphaea calceola var. nebrascensis.	Grammatodon inornatus.
Camptonectes extenuatus.	Astarte fragilis.
Eumicrotis curta.	Pleuromya subelliptica.
Modiola (Volsella) formosa.	Planorbis veterenus.
Modiola (Volsella) pertenuis.	
* * * * *	* * * *

Trigonia dawsoni and *Astarte ventricosa*, from the Itasyouco River, are also found in the Jurassic rocks of the western slope of the mountains in Nevada; and it may be that there is no physical or geographical break between the coast range of British Columbia and the Sierra Nevada. Mr. Gabb has pointed out that the Jurassic fossils of Nevada are probably of the age of the Lias, and some of the Itasyouco lamellibranchs, as has already been stated, are barely distinguishable from European Liassic species. On the other hand, the few ammonites collected by Mr. Dawson, so far as very fragmentary specimens enable one to judge, appear to be conspecific for the most part with well-known forms from the English Inferior Oolite, though one, which has been doubtfully referred to *Perisphinctes anceps*, may indicate a horizon as high as the Oxford Clay or Coral Rag. On the whole, however, the evidence, as far as it goes, is in favor of the supposition that these fossils from British Columbia belong to the lower rather than to the upper part of the Jurassic series.

Subsequently Whiteaves⁹¹⁸ modified this conclusion in favor of a later age for the rocks in question. He says:

Certain rocks described by Dr. Dawson in the report of progress of the Geological Survey of Canada for 1876-77, and there referred to as the "Porphyrite series," occur on Sigutlat Lake and the Itasyouco River, which flows from Sigutlat Lake into the Dean or Salmon River. The fossils collected from these porphyrites were reported upon provisionally by the writer in an appendix to Dr. Dawson's report. They were then regarded as possibly of Jurassic age, on account of their resemblance to the fossils of the so-called Jurassic rocks of the Black Hills of Dakota, but are now believed to be Cretaceous.

The collections of fossils that have been made from the Cretaceous rocks at Quatsino Sound, Vancouver Island, in 1878 and 1885, and at various localities off the coast or on the mainland of British Columbia between 1875 and 1888, have led to the conclusion that the Aucella-bearing rocks and Jackass Mountain series of that province are not older than but of about the same age as the Queen Charlotte Island formation, and that the porphyritic rocks of Sigutlat Lake and the Itasyouco River are of the same age and not altered Jurassic sediments.

N 8-9. QUEEN CHARLOTTE ISLANDS.

The Cretaceous or coal-bearing rocks of Graham Island, the northern member of the Queen Charlotte group, are described by Ells,^{316b} who, however, confines his account largely to local details and refers to Dawson for a general discussion. Dawson,^{252b} following Richardson,^{671a} distinguished the following strata:

	Feet.
A. Upper shales and sandstones.....	1,500
B. Coarse conglomerates.....	2,000-3,000
C. Lower shales with coal and iron ore.....	1,800-5,000

To these he added:

	Feet.
D. Agglomerates of volcanic origin.....	3,500
E. Lower sandstones.....	1,000?

The upper shales (A) are generally arenaceous and interstratified with sandstones from 3 to 6 inches thick. A bed of sandstone 30 feet thick occurs 70 feet above the base, and the lowest shales are interstratified with reddish-weathering, grayish-brown dolomite, which constitutes the chief part of the mass and seems to form a passage to the underlying conglomerates. The shales have yielded but one recognized fossil, "*Inoceramus problematicus*."^a

The conglomerates (B) include for the most part well-rounded pebbles, in some layers several inches in diameter, derived from the more or less crystalline pre-Cretaceous rocks; rounded shaly fragments of the next underlying Cretaceous are also found, indicating slight erosion, but no true unconformity, during the deposition of the conglomerate. Gray and yellow sandstones are interbedded and the upper part of the conglomerate is dolomitic.

The lower shales and sandstones, at the base of which the anthracite coal is found, consist of blackish or gray shales, interbedded with gray or yellowish-gray sandstones and numerous layers composed of sandy argillaceous material, intermediate in character between shale and sandstone. The bedding is generally regular and certain zones are characterized by large calcareous nodules, generally lenticular, and occasionally several feet in diameter or even coalescing to form sheets of calcareous matter. Layers so coarse as to be called conglomerates scarcely occur. The beds immediately underlying the conglomerates of subdivision B are generally gray shales, very regular in their bedding, and quite hard. Below these is a considerable thickness of strata in which shaly beds usually preponderate, while toward the base of the subdivision sandstones are more important. The lowest beds are of interest as being those in association with * * * the coal. * * *

Subdivision C rests on a series of volcanic rocks constituting subdivision D, which apparently forms a member of the same formation. The upper surface of the agglomerate and ash rocks of D must, however, have been an irregular one, and to its undulations the lower beds of C more or less closely conform. The appearance at the junction of subdivisions C and D is therefore that of an unconformity more or less marked. * * * This partial unconformity is, however, believed to be essentially unimportant and only such as might be anticipated at the junction of two classes of deposits so dissimilar. * * * The occurrence of fossils identical with those of subdivision C in beds below the volcanic horizon, with the inclusion of marine forms in some parts of the upper portion of the rocks of volcanic origin (at points on the east side of Alliford Bay), serve to show the continuity of the conditions of deposit.

The passage beds have been observed in a number of localities to be coarse feldspathic or tuffaceous sandstones, generally pale in color and formed apparently by the rearrangement of the still unconsolidated materials of the upper beds of D. These vary in thickness but are generally associated with black carbonaceous argillites, which are sometimes shaly and at the Cowgitz mine hold the seam of anthracite coal.

* * * * *

[The agglomerates which constitute subdivision D] are almost exclusively of volcanic origin, though some layers show traces of water action in the rounding of fragments. Some beds may have been flows of molten matter, but most are of a fragmental character, either agglomerates or tuffaceous sandstones, of greenish, grayish, brown, or purple tints. * * * The material is almost everywhere predominantly feldspathic, and some specimens resemble typical porphyrite of rather coarse grain. At the east side of the point north of Alliford Bay, hard dark tuffaceous sandstones are found graduating into agglomerates, some of which, however, have their fragments so well rounded as to be more appropriately designated conglomerates.

^a *I. labiatus*.—T. W. Stanton.

Many layers here become calcareous from the inclusion of organic remains, of which some are evidently shells, though too poorly preserved for recognition, except in the case of one or two specimens, which appear to be *Ostreæ*.

The base of the Cretaceous consists of tufaceous beds with ordinary sandstones and calcareous layers that contain many fossils. "These, while in some cases specifically identical with those of subdivision C, include a few species not yet found in that part of the section, and thus present a general facies somewhat different from it."

The fossils from the Cretaceous of the Queen Charlotte Islands are described by Whiteaves.⁹²³

Dawson discussed the relations of the Queen Charlotte group and the Kootenai (Lower Cretaceous) of British Columbia, and reached the conclusion that "The very important fact is established of the existence of an identical earlier Cretaceous horizon on the west coast, and in and even to the east of the eastern range of the Cordillera system."

Stanton states (orally) that Dawson's reasoning was based chiefly on marine mollusks occurring below the plant-bearing beds of the Kootenai, in the Fernie formation, which is now assigned to the Jurassic. (See Chapter XII, under N 8-9, table of formations by Dawson, p. 540.)

N 9. TELKWA RIVER DISTRICT, BRITISH COLUMBIA.

Near the center of the large area mapped as Lower Cretaceous in British Columbia is Telkwa River, which traverses a district surveyed by Leach,⁵²⁷ who thus describes the rocks of Dawson's "Porphyrite group" and the overlying coal-bearing strata:

Rocks of the Porphyrite group occupy by far the most extensive area in this map sheet. They consist of a great series of volcanics, composed of tuffs, andesites, agglomerates, etc., more often occurring in sheets as volcanic flows but frequently showing evidences of deposition under water, more particularly toward the top of the series, and are all more or less regularly bedded.

* * * * *

The rocks of this group vary greatly in appearance in different parts of the field, in color ranging from light greenish grays to dark purplish reds. Generally speaking it may be said that red colors predominate toward the top of the series, the beds consisting of reddish andesites, breccias, and tuffs, in many cases amygdaloidal, with inclusions of calcite and zeolites. Green is the characteristic color toward the base, the beds being composed largely of fine-grained greenish feldspathic rocks, often amygdaloidal and containing much calcite and epidote. * * *

Immediately overlying these rocks, and possibly unconformable to them, although both have been subsequently folded and faulted to such an extent that their immediate relationship to one another is somewhat doubtful, occurs a series of beds composed chiefly of clay shales and containing a number of important coal seams. The lower member of these beds consists of a coarse, loosely cemented conglomerate, mainly composed of pebbles from the underlying volcanics, in places shading into a coarse grit and not more than 60 feet in thickness in any place seen. * * * This is followed by some thin-bedded clay shales with a few soft, thin, crumbly beds of light-colored sandstone, succeeded by more clay shales and coal, carrying numerous yellow-weathering clay-ironstone nodules. These are the youngest sedimentary rocks represented in the district, and [are] not of great thickness (in no case seen showing more than 300 feet in all). * * *

A few fossil plants were collected from the coal-bearing beds of Goat Creek, [among] which * * * Prof. Penhallow [identified] * * * *Gleichemia gilbert-thompsoni* Fontaine. Along the international boundary line, on the Skagit River, * * * Daly obtained the same species [which is thought to indicate a Lower Cretaceous age].

N-O 4. ALASKA PENINSULA.

The Mesozoic area in the Alaska Peninsula includes Cretaceous as well as earlier Mesozoic rocks. Stanton and Martin summed up their general conclusions as quoted on page 574, Chapter XIII. Their statement in regard to the Cretaceous⁵⁷⁵ is as follows:

The presence of the Russian type of Lower Cretaceous on the Alaska Peninsula is suggested by the occurrence of *Aucella* related to *A. crassicollis* at Port Möller and Herendeen Bay, where Jurassic types of *Aucella* also occur in other beds, but the details of the stratigraphy are unknown. These beds, with *Aucella* cf. *crassicollis*, comparable with the Upper Knoxville beds of California, are widespread in Alaska, though we found no indication of them at any localities studied by us. The species was obtained by Mendenhall on Bubb Creek, a branch of the Taxlina, in the Matanuska series; by Spurr in the Oklune series on the Kanektok near the mouth of the Kuskokwim; by Schrader in the Koyukuk and Anaktuvuk series in northern Alaska, and by Wright on Admiralty Island, southeast Alaska, where *Aucella piochi*, another Lower Cretaceous species, was found at a neighboring locality. It also occurs in the Mission Creek series on the Yukon. The geographic distribution of these Cretaceous *Aucella* beds is thus seen to differ radically from the distribution of the Naknek formation with its Jurassic *Aucellæ*, and this is regarded as evidence of a probable unconformity between them.

On Chignik Bay Upper Cretaceous rocks, closely associated with plant-bearing Kenai beds, occur on the lagoon 1 to 2 miles northeast of the Alaska Packers Association cannery and on Whalers Creek, 5 miles west of the same place, where they apparently include a workable coal bed. The exposures at the first locality consist of several hundred feet of shales and sandstones with some thick beds of coarse conglomerate in the middle portion. The beds beneath the conglomerate contain great numbers of fossil plants, a collection of which yielded * * * Upper Cretaceous species identified by Dr. Knowlton.^a * * *

The shales above the conglomerates yielded * * * fossils [which] indicate correlation with a horizon in the Chico as developed in California and Vancouver Island, which includes practically all of the Upper Cretaceous, but the beds at Chignik are probably not older than basal Senonian.

Beds of possibly the same age occur on the north shore of the small bay north of Aievak or Douglas village, where there is a series of shales and sandstones with an estimated thickness of 2,000 feet. * * *

The Cretaceous beds at Chignik may be directly correlated with those on the Yukon near Nulato, and less certainly with those on the Anaktuvuk, in northern Alaska, which are the only occurrences of Upper Cretaceous hitherto reported in the Territory.

It is probable that more detailed study will reveal considerable areas of Upper Cretaceous rocks on the Alaska Peninsula, but their recognition in rapid reconnaissance is made difficult by the fact that lithologically they resemble the Eocene Kenai beds of the same region, which, like the Upper Cretaceous, are coal-bearing and contain fossil plants of similar general types. * * * There are doubtless unconformities both below and above the Upper Cretaceous of this region, since all of the Lower Cretaceous is lacking at most localities, and at some places the Kenai rests directly on the Jurassic.

^a For list of species see the work cited.—B. W.

Atwood^{42a} reports on the Jurassic and Cretaceous of the Alaska Peninsula as follows:

Geologic sequence in western part of Alaska Peninsula.

Age.	Geographic distribution.	Lithologic character.	Thickness (feet).	Remarks.
Upper Cretaceous....	Chignik and Herendeen bays.	Conglomerate, sandstone, and shales, with coal seams.	600+	Contains valuable coal beds at Chignik and Herendeen bays.
Lower Cretaceous....	Herendeen Bay.....	Shale, sandstone, and calcareous sandstone.	1,800+	
Upper Jurassic.....	Chignik and Herendeen bays.	Sandstones, conglomerates, and arkose.	1,000+	

The Upper Jurassic sediments are * * * dense, fine-grained sandstones of bluish color, conglomerates, shales, and arkose. They are the oldest sedimentary rocks exposed in either the Chignik or the Herendeen Bay districts. * * * The Chignik localities have yielded several collections of invertebrate fossils whose age has been determined by Stanton.

The Upper Jurassic beds in Pinnacle Mountain, Herendeen Bay, are overlain by Cretaceous rocks and both have been folded, truncated, and in part covered by volcanic material, which issued from the summit of Pinnacle Mountain. The exposures on the west shore of Herendeen Bay * * * consist chiefly of fine-grained blue sandstones. [The fossils have been examined by Stanton], who reports that within the Upper Jurassic of Herendeen Bay two horizons are represented. At the upper horizon are forms related to *Aucella pallasii*. * * * At the lower horizon are forms related to *Aucella bronni*. * * *

Among the collections procured from the Chignik Bay region there are no fossils of Lower Cretaceous age. In parts of this region, at least, the Upper Cretaceous beds unconformably overlie the Upper Jurassic, and it may be that there is no Lower Cretaceous in the region. In the Herendeen Bay district the Lower Cretaceous appears in three belts extending through the Herendeen Bay coal field, coming to the surface on the flanks of the folds. The fossils * * * from these formations indicate that there are two horizons within the Lower Cretaceous. At the upper horizon are forms related to *Aucella crassicolis*, and at the lower are forms related to *Aucella piochii*. * * * The sediments * * * consist of sandstones, shales, and conglomerates.

O 8. SOUTHEASTERN ALASKA.

The Cretaceous rocks of southeastern Alaska comprise *Aucella*-bearing beds, which are Lower Cretaceous or possibly Jurassic, and a higher terrane, apparently unconformable to the *Aucella*-bearing beds, but conformable to the overlying Kenai formation (Eocene) and containing plant remains. Brooks¹⁰¹ thus sums up the known facts:

The recent studies of Wright have revealed the presence of the *Aucella*-bearing beds along the eastern coast of Admiralty Island in a series of conglomerates, graywackes, and slates. Stanton makes the following statement in regard to the fossils from these beds:

"The specimens of *Aucella* from Pybus Bay, Admiralty Island, are apparently referable to species that in California and adjacent States are characteristic of the Lower Cretaceous, *Aucella piochii* occurring in a lower zone than *Aucella crassicolis*. The Alaskan specimens probably also come from the Lower Cretaceous, although strict correlation is rendered somewhat hazardous by the fact that the genus *Aucella* with similar specific forms ranges down into the upper Jurassic."

Wright has also found a conglomerate sandstone and shale series on Kupreanof Island, a few miles south of Admiralty Island, which carries plant remains assigned to the Upper Cretaceous. Knowlton reports on these fossils:

“These plants indicate beyond question that the age is Cretaceous, and I would place them in the lower part of the Upper Cretaceous, or approximately of Cenomanian age.”

It appears that these Upper Cretaceous beds are discordant to Aucella-bearing terranes of the adjacent region, and that they are conformably succeeded by the Kenai (Eocene) rocks, with which they are lithologically identical.

Later information by Wright ⁹⁵³ is as follows:

[Part of] stratigraphic column in southeastern Alaska.

Age.	Character of rocks.	Thickness (feet).	Structural characteristics.
Eocene to Upper Cretaceous.	Basalts, andesites, rhyolite tuffs, breccias, conglomerates, sandstones, and coal seams, with fossil plants. Conformity.	1,500 ±	Flat-lying, slightly tilted, covering wide areas.
	Conglomerates, sandstone, shale, and coal seams, with fossil plants. Unconformity.	1,000+	Tilted, slightly folded, unmetamorphosed, occupying local basins.
Lower Cretaceous to Jurassic.	Shale, conglomerate, and black limestone with fossils. Conformity.	500+	Folded and faulted, with steep dips and variable strikes, slightly metamorphosed, occurrence local.
	Gray limestone, Aucella beds..... (?)	200+	Same as above.
	Graywackes, slates, and conglomerates, carrying granite cobbles; lava conglomerates, and sandstones; no fossils. Conformity.	2,000 ±	Folded and faulted, indurated, variable strike and dip, distribution limited.
	Andesite lavas, tuffs, breccia, conglomerate, and sandstone overlying granite intrusives; no fossils.	1,000 ±	Steeply tilted and folded with general northwesterly strike and variable dip, metamorphosed and reundered slightly schistose; distribution limited.

O-P 4. LOWER YUKON AND KUSKOKWIM BASINS, ALASKA.

The so-called Cretaceous of the Kuskokwim basin, represented as Lower Cretaceous on the map, comprises both sedimentary and volcanic rocks which constitute three different series, according to Spurr, and which may be older than Cretaceous, according to Brooks.¹⁰¹³

Spurr subdivided the Mesozoic rocks of the Kuskokwim Valley into three series, all Cretaceous, of which the Holiknuk and Kolmakof series are supposed to be synchronous, while the stratigraphic relation of the third—the Oklune series, which is Jura-Cretaceous—to the others is unknown. The Holiknuk series is made up of alternating sandstones, argillaceous and siliceous limestone containing fragmentary Cretaceous fossils, and shale and arkose, all thrown up in broad open folds. An unconformity determined the line of demarcation between these beds and the underlying Tachatna series (Devonian).

A succession of volcanic rocks of various types occurs to the southwest, and these, together with some intercalated tuffs, shales, impure limestones, and arkoses, form Spurr's Kolmakof series, supposed to be synchronous with the Holiknuk beds. A group of sediments, including shales, impure limestones, with some arkoses, received the name "Oklune series," from the mountains where they are typically exposed. These beds are referred to the Jura-Cretaceous on the evidence of some fragmentary fossils. As far as the facts presented can be interpreted, all three of these series may belong to the same horizon. All three exhibit about the same amount of deformation and are intruded by igneous rocks of various kinds. If they are not of

the same age, it is probable that the Holiknuk belongs to the Jurassic or the Triassic and that the others are younger.

Maddren⁵⁶⁹ gives the following description of the Cretaceous in a generalized table of stratigraphic sequence in the central Kuskokwim, Innoko, and lower-central Yukon region:

Conglomerates, arkoses, and shales, with some coal beds on the Yukon. Contains acidic dikes and sills on lower Kuskokwim and also basic volcanic material. Fragmentary plant remains and marine shells. Probably includes both Upper and Lower Cretaceous. Occurs throughout the lower Kuskokwim Mountains, southeast side of the Innoko Valley, northwest side of lower Yukon Valley, lower Koyukuk Valley, and upper part of central Kuskokwim Valley.

O-P 8. SOUTHERN YUKON TERRITORY AND BRITISH COLUMBIA.

In the vicinity of Lake Bennett (near latitude 60°, longitude 135°) the porphyrite and tuffaceous rocks of the middle and later Mesozoic are developed with the typical characters of the "Porphyrite group." The description by Cairnes¹¹⁴ is in part as follows:

Newer than these Coast granites is a series [Windy Arm] chiefly consisting of porphyrites, diabases, andesites, tuffs, and basalts which cut through and overlie them, by far the greater part of the rocks being porphyrites which are generally fine-grained and greenish in color and present a fresh, unaltered appearance.

Following an account of the petrographic character and eruptive relations of the porphyrites, Cairnes continues:

There have been great showers of ashes and finer material which have consolidated into generally fine-grained greenish rocks showing bedding structure which is often quite pronounced, giving the rocks the appearance of fine-grained sandstones and shales. In places these particles have fallen into water and show to some extent water-sorting action and are mixed with argillaceous and other sedimentary materials. These rocks seem to grade into true sediments as shales, conglomerates, bedded cherts, cherty quartzites, etc., which carry coal seams. * * * The true sediments with some of the upper bedded ash rocks and tuffs are included in the Tutshi series described below. The rest are included in the Windy Arm series. The whole series appears to correspond to Dr. Dawson's Porphyrite series. * * * This Windy Arm series also corresponds, in all probability, to the rocks of division IV on Mr. Gwillim's Atlin map * * * and includes the corresponding representatives of the greenstones of his gold series division VI, which are newer than the granites. The corresponding representatives of the other members of division VI, which are older than the granites, have been included in this report, and on the map in the Lower Cache Creek series. * * *

Tutshi series.—This name was given by Mr. McConnell to include the "argillites, tuffaceous sandstones, conglomerates, etc.," of the Windy Arm district, and the writer has adopted the name for all rocks in the area that appear to belong to this same series. These Tutshi rocks, which in all probability * * * correspond to the rocks of Mr. Gwillim's division III on his Atlin map, belong, as well as the Windy Arm series, to Dr. Dawson's Porphyrite series and correspond lithologically and stratigraphically with his Jackass Mountain series. * * * This latter consists chiefly of igneous products, and the Jackass Mountain series resembles rocks of ordinary aqueous origin. * * * All rocks, therefore, which are of aqueous origin, and all those associated and interbedded with them, are placed in this Tutshi series, as water action has had more or less effect on all of them and has not affected the rocks of the Windy Arm series. Dr. Dawson considered the Porphyrite series to be probably a link between the Jurassic and Cretaceous, making the Jackass Mountain beds Lower Cretaceous. The fossils found this season in these Tutshi beds, being all typically Lower Cretaceous, further bear out this correlation.

The fossils identified by Whiteaves from the Tutshi series of McConnell comprise:

Trigonia, small, arcuate, and beaked species. Two other Pelecypoda, imperfect and undetermined. Shales with numerous valves of an *Estheria* or of very young specimens of *Inoceramus*. Also two crushed fragments of a small ammonite, apparently referable to *Prionocyclus woolgari*. These are all placed under the head "Cretaceous" and are probably lower Cretaceous as described above.

Stanton's comment^a on the above identifications is that the only specific name mentioned is characteristic of the Upper Cretaceous.

Q 4-5. KOYUKUK BASIN, ALASKA.

The Koyukuk "series" is a Lower Cretaceous or possibly Jurassic terrane, consisting of impure limestone, slate, and some sandstone, associated with igneous rocks. It carries *Aucella crassicollis* Keyserling. It occupies a large area in the lower Koyukuk basin, where it was first distinguished by Schrader.¹⁰¹¹

Q 7. UPPER YUKON, ALASKA.

The latest report on the upper Yukon, that of Brooks and Kindle,¹⁰³ gives the following section of the later Mesozoic rocks (post-Triassic):

Provisional stratigraphic table.

System.	Series.	Lithologic character.	Locality.
Cretaceous.	Upper Cretaceous.	Conglomerates, sandstone, slate, and shale, cut by granite. Invertebrate fossils.	Wolverine Mountains, Quail Creek, near Rampart.
	Lower Cretaceous or Upper Jurassic.	Unconformity. Siliceous slate and quartzites, with some tuff and a little limestone, cut by basic dikes. Invertebrate fossils. Unconformity.	Upper Yukon River, between Fourth of July and Coal creeks.

The only member of the Mesozoic extensively developed along the Yukon is the so-called *Aucella* beds, which may be either Jurassic or Lower Cretaceous, but may here for convenience be assigned to the latter system. These Lower Cretaceous beds form a practically continuous belt along the Yukon from about the mouth of Fourth of July Creek to Coal Creek. There may be, however, some of the younger Tertiary beds included within this area which were overlooked in the hasty examination.

The Lower Cretaceous of the upper Yukon comprises a series of closely folded rocks characterized by a large amount of silica. They included primarily siliceous slates, slaty sandstones, and quartzites, with which are associated some argillites and pyroclastics. One heavy bed (50 to 70 feet thick) of massive tufaceous conglomerate was observed within the Mesozoic area about 5 miles below Washington Creek, but may be an infolded older or younger terrane. The pebbles of this conglomerate, which are chiefly limestone, are well rounded, and some are 2 feet in diameter. The dominating rock type of the Lower Cretaceous is a siliceous slate or quartzite, sometimes interbedded with a clay slate. These rocks are usually pyritiferous and iron stained when weathered. Three miles below Washington Creek there is a series of beautifully banded slates and quartzites. * * *

These rocks in a general way strike easterly and northeasterly, but there are many local variations. They are usually closely folded, and no determination of thickness, which probably does not exceed a few thousand feet, could be made. On Washington Creek they appear to rest unconformably on the Devonian and in turn are unconformably overlain by the Tertiary

^a Personal communication.

beds. Near Coal Creek the Aucella-bearing beds seem to underlie the Upper Carboniferous limestone, which has apparently been thrust over them.

R 3. CAPE LISBURNE, NORTHWESTERN ALASKA.

Collier^{165c} found a thick sequence of strata apparently overlying the Corwin formation (Jurassic), and in the absence of fossils assigned it provisionally to the Lower Cretaceous. He describes it as follows:

Southwest of the area occupied by the Corwin formation, and lying between it and the Carboniferous rocks exposed at Cape Lisburne, there is a series of beds which, though they resemble the Corwin Jurassic rocks, are easily differentiated from them on lithologic grounds. These rocks outcrop along the coast from a point 2 miles west of Corwin Bluff to within 3 miles of Cape Lisburne and extend inland in a southeasterly direction. * * * The exact contact of this formation with the Corwin was not exposed, or if observed its significance was not understood, though the field relations of the two formations are definitely known at a number of localities. Continuous sedimentation and conformity between the formations are indicated, though the possibility of thrust faulting along the contact should not be overlooked. This formation is therefore provisionally regarded as overlying the Corwin and constituting an upper member of the Mesozoic series. * * *

Lithologically this formation consists of sandstones and shales, with the former in the ascendant. The sandstone beds range in thickness from a few inches to 20 or more feet. They resemble the sandstones of the Corwin formation, but taken as a whole are probably somewhat less gritty and contain no conglomeratic material. The shales which are interbedded with the sandstones are dark colored and sometimes micaceous, so that they have a silvery sheen on the bedding faces. In a few instances ripple marking was observed on shaly beds.

No definite fossils were found, after a diligent search, either in the sandstones or the shales, though indistinct impressions of vegetable fragments, probably detrital material, were found in some of the beds. The structure of the formation, while it consists of simple open folds near its boundary with the Corwin, becomes increasingly complicated as the fault at the contact with the Carboniferous rocks is approached. Overturned folds and minor thrust faults with axes extending in a general way northwest and southeast are typical features. * * *

Owing to the complex structure of this formation, it was impossible to definitely measure its thickness, but from the imperfect evidence obtained it is believed to be not less than 5,000 nor more than 15,000 feet, and for the purposes of this report it is estimated at 10,000 feet. Since no direct paleontologic or paleobotanic evidence was obtained, the age of the formation can only be inferred from its relation to the Jurassic Corwin formation, which it overlies. It is therefore provisionally assigned to the Lower Cretaceous. On Anaktuvuk River, 400 miles east of Cape Lisburne, Schrader found a formation somewhat similar to this, both in its lithology and in its topographic relations to the Lisburne formation, which he called the Anaktuvuk series^a and which contains Lower Cretaceous fossils. If the above assignment is correct, the upper Mesozoic formation of the Cape Lisburne region should be correlated with the Anaktuvuk series.

R 5. NORTHERN ALASKA, ARCTIC SLOPE.

According to Schrader¹⁰¹¹ the Cretaceous which he crossed in descending the Colville may be divided into two groups, which are unconformable—"the Anaktuvuk (Lower Cretaceous) and the Nanushuk series (Upper Cretaceous)."

The Anaktuvuk is made up of fine, heavy-bedded sandstones, or arkose—sometimes a grit, with little conglomerate—the whole aggregating at least 2,000 feet. Resting unconformably on these are sandstone, impure limestone, slate, quartzite, and chert, which make up the Nanushuk series. The Anaktuvuk carries *Aucella crassicolis* Keyserling, making it Jurassic-Cretaceous, while the Nanushuk has yielded Upper Cretaceous fossils. The Nanushuk, like the Upper Cretaceous of the lower Yukon, contains coal seams of excellent quality.

^a Schrader, F. C., Reconnaissance in northern Alaska: Prof. Paper U. S. Geol. Survey No. 20, 1904, pp. 74-76.

CHAPTER XV.

UPPER CRETACEOUS.

Color, light green.

Symbol, 7.

Distribution: South America and West Indies; present but not distinguished in Mexico from Lower Cretaceous; Atlantic and Gulf coasts from Mexican boundary to New England; the Interior province, New Mexico to Mackenzie; Pacific coast, Lower California to Alaska; the Arctic coastal plain of Alaska; and the west coast of Greenland.

Content: Marine and coastal-plain deposits of the Atlantic and Gulf coasts and West Indies, comprising Raritan to Manasquan, New Jersey; Black Creek ("Bladen") and Peedee ("Burches Ferry"), North Carolina; Tuscaloosa to Ripley, Alabama; and the Gulf series—that is, Woodbine to Navarro—of Texas and Louisiana. In Mexico included on map with Lower Cretaceous (8). Marine and coastal-plain deposits of the Interior, Dakota to Fox Hills, inclusive, and equivalents. Marine deposits of the Pacific coast, Chico and its equivalents. Laramie and coal-bearing portion of the Montana of the Rocky Mountains and Great Plains mapped separately.

MONTANA, COAL-BEARING PORTION.

Color, olive-green.

Symbol, 7a.

Distribution: Rocky Mountains and northern Great Plains of the United States and Canada.

Content: Middle Montana, generally coal bearing; Mesaverde of New Mexico, Colorado, and southern Wyoming; Eagle, Claggett, and Judith River of northern Wyoming and Montana and their equivalents in Canada.

LATE UPPER CRETACEOUS, LARAMIE.

Color, yellowish green.

Symbol, 6.

Distribution: Rocky Mountains of the United States, southern Wyoming to New Mexico.

Content: Late Cretaceous coal-bearing formations; Laramie of the Denver Basin; "Lower Laramie" of southern Wyoming; and coal-bearing equivalents in Colorado and New Mexico.

Upper Cretaceous areas.

D 19. CURACAO, ARUBA, AND BONAIRE.

The little islands of Curacao, Aruba, and Bonaire, in the Dutch West Indies, were mapped by Martin.⁵⁷⁶ He identified the Upper Cretaceous (Rudistenkalk), which on Curacao consists of a fine-grained crystalline limestone, of dirty blue or yellow-white color, that resembles a Paleozoic rock. The strata are rich, however, in remains of *Rudistes radialites* Lam., which are identified by Stanton on the basis of Martin's illustrations as of Upper Cretaceous age. There is also a siliceous slate formation with which the limestone occurs in immediate and conformable contact.

E 18. JAMAICA.

Hill's work on the geology of Jamaica^{443a} is the basis of the mapping of that island and affords the following excerpts. Many details of the original work are necessarily omitted. Hill classifies the geologic formations of Jamaica into four great categories, as follows:

1. A fundamental series of stratified shales and conglomerates (of terrigenous origin), tuffs and other débris of volcanic material (whose source is not apparent), and, rarely, marine limestones and marls, all of which have suffered great displacement and deformation. This series characterizes the higher mountains and forms the nucleus of the island structure upon or around which all subsequent formations have accumulated.

2. A series of organically derived oceanic material—marls and limestones—which rest unconformably against and upon but do not completely overlap the more elevated outcrops of the first-mentioned series. It constitutes piedmontal formations of great thickness around bases of the higher mountain summits.

3. Laccoliths, dikes, and sills of igneous rocks, which penetrate the first series and the lower portion of the second and are, therefore, of later age than both.

4. Certain deposits of alluvium, oceanic marls, and coral reef rock, which are adjacent to the present coasts and represent fringing reefs and other accretions around the island's border after it had almost attained its present area and outline.

These four series of rocks are unconformable to one another and are the products of the greater events in the geologic history of the island. •

Hill gives a tabular summary of the geologic history of the island, of which the following is a part:

Geologic formations on Jamaica.

Time.	Series.	Formation.	Material.	Fossil remains.
Late Pleistocene and Recent.	Coastal.	Bogue Island.....	Mangrove mud.	Marine Mollusca, reef coral, etc. Reef coral. Reef coral. Reef coral.
		Montego.....	Alluvial.	
		Falmouth.....	Littoral marl.....	
		Coast Soboruco.....	Elevated reef rock.....	
		Barbican.....	Elevated reef rock.....	
		Hopewell.....	Elevated reef rock.....	
Pliocene.		Manchioneal.....	Littoral marl.	Marine Mollusca, Foraminifera, Brachiopoda.
		Kingston.....	Old aggradational material.	
Miocene or late Oligocene.	Bowden.	May Pen.....	Impure lime.....	Marine Mollusca, echinoids, simple corals, Foraminifera, and Bryozoa. Same as above, and fresh-water shells.
		Bowden.....	Conglomerate and marl...	
Middle Oligocene.		Break.		
Early Eocene to early Oligocene.	Oceanic.	Cobre.....	White limestone and marl.	A few mollusks and simple corals. Foraminifera and Radiolaria. Mollusca, corals, echinoids, and Foraminifera. A few mollusks and corals.
		Moneague.....	White limestone.....	
		Montpelier.....	White chalk with flints....	
		Chapelton.....	Yellow-white limestone...	
		Catadupa.....	Nodular limestone in clay.	
		Richmond.....	Alternation of clay and sandstone.....	
Late Cretaceous.	Blue Mountain.	Minho.....	Volcanic tuffs.	Rudistes, corals, and mollusks. Rudistes, corals, and mollusks. Rudistes, corals, and mollusks.
		Ballard.....	Black bituminous shale...	
		Logie Green.....	Yellow marls.....	
		Jerusalem.....	Irregular beds of limestone.	
		Frankenfield.....	Irregularly bedded lavas, tuffs, and conglomerates of hornblende andesites.	

In his table Hill placed the line between the late Cretaceous and early Eocene above the Richmond. In copying the table it has been moved to a position below the Richmond, on recommendation of T. W. Vaughan and in accordance with the text of Hill's work, which shows clearly that he regarded the Richmond as early Eocene.

The late Cretaceous rocks of Jamaica are called Blue Mountain series, of which Hill says:

This series comprises the oldest rocks of the island. It consists of loose or slightly indurated beds of gravel, clay, boulders, and tuffs, with exceptional beds or bosses of hard indurated

limestones and yellow clay. The rocks are usually of dark color (black, blue, or dull chocolate), in strong contrast to the glaringly light colors which characterize the succeeding formations of the Oceanic and Coastal series. The material, with the exception of occasional limestone beds and a few outcrops of clay marls, can be traced to igneous rocks; it was first volcanic ejecta and subsequently and successively underwent various degrees of attrition and sedimentation from coarse boulders and tuffs to finely triturated impure clay shale, a process indicating extensive working over. These rocks are the material of the Central Mountains, composing the eminences above 3,000 feet, such as the Blue Mountain Ridge. They undoubtedly underlie the surface rocks of the rest of the island, as occasionally revealed by erosion through the white limestone which veneers them, as seen in some of the central basin valleys, the canyons of the marginal streams, and certain bluffs of the back coast border along the northwest coast.

Nowhere on the island can all the beds of the series be seen in continuous exposure. As has been noted concerning the rocks of the Blue Mountain district, "the strata are so excessively disturbed, so traversed and semimetamorphosed by dikes of syenite and mixed up with porphyritic masses, that it is impossible to observe the intricacies of the stratification or to determine the sequence of the beds inter se without a lengthened and detailed investigation." Sufficient is known to state that it probably exceeds 5,000 feet.

Previous attempts to classify the rocks which are collectively arranged in this series have been confusing and unsatisfactory. * * *

While it is still impossible completely to differentiate all the beds of the Blue Mountain series, our observations have enabled us to make a more accurate classification of them than any hitherto presented, which may be stated as follows:

Blue Mountain series:

Upper division (Eocene): Richmond beds.

Lower division (Upper Cretaceous):

Minho beds.

Ballard beds.

Logie Green beds.

Frankenfield beds.

Jerusalem beds.

Yallahs beds.

[In classifying the basement beds the chief difficulty] is the complex folding and partial concealment which make it impossible to determine the exact base of the series. The Jamaican reports present conflicting conclusions on this subject, inconsistently stating in different places, that the base of the section is composed of igneous rocks, Cretaceous limestones, and a formation termed the "Metamorphosed series."

Hill quotes various opinions and states that the visible base of the section is a great series of tuffs and conglomerates in which the fossiliferous Cretaceous beds constitute local occurrences. The limestones are certainly the oldest rocks paleontologically identifiable, but they are clearly intercalations in vast beds of igneous débris. He searched with care but in vain for evidence of some older or lower-lying rocks beneath the Blue Mountain series.

Referring to the lower division or Upper Cretaceous of the Blue Mountain series, Hill says:

All beds of the lower subdivision, taken collectively, represent the product of disturbed conditions, such as active volcanism accompanied by the piling up and contemporaneous degradation of vast quantities of igneous material much of which was deposited below the sea level, alternating with short periods of quiescence, when shales and marls were permitted to accumulate and sparse faunas to gain temporary foothold. The alterations of shale and igneous material in the Blue Mountain series indicate alternating conditions of sedimental placidity

and volcanic extrusion, and a conflict between disturbed and quiescent conditions of deposition which finally culminated in the establishment of the latter in the succeeding Richmond epoch.

For a description of the Richmond and later beds of the early Tertiary, see Chapter XVI (pp. 717-721).

E 19. SANTO DOMINGO.

The Sierra group of Santo Domingo was described by Gabb as of Cretaceous age. His account of the rocks shows them to be highly metamorphosed and varied in character, and generally unfossiliferous. For this reason the major part of the terrane is mapped as Paleozoic undivided, and his description is quoted in Chapter VII (pp. 345-347). The description of the limestone which contains Cretaceous fossils is as follows: ^{352a}

On the Nigua River the limestone acquires its greatest development. Here the metamorphic action has been unusually well marked and the formation is represented mainly by limestones and jaspers. The stratification also is unusually well preserved, so that a good section is attainable. The lime strata of the Ocoa are apparently all repeated on the Nigua, and the conglomerates are replaced by beds containing but few pebbles, the matrix being either a pure or more usually an earthy limestone. This latter rock, at two localities on the river, yields fossils, in a bad state of preservation for extraction, although occasionally recognizable. The shell substance is completely crystallized, so that it is next to impossible to extract a thick shell in such a manner as to expose its surface. Of hundreds of attempts to obtain a specimen of a very common *Trigonia* I have only succeeded once or twice in obtaining a little piece of the surface; the fracture always taking place among the crystals of calc spar into which the shell has been cemented. The univalve shells invariably break across and, in a word, the collector has to content himself with the few imperfect fragments found weathered out. Nowhere else have fossil Mollusca been discovered in this formation in Santo Domingo, and only in one other instance have I found any other fossil in it. Three or four miles west of San Jose de las Matas I was fortunate enough to discover two fragments of the same limestone, being of a dark bluish-gray color, on the surface of which can be detected, faintly marked, the stars of a coral. Doubtless by means of polishing they can be brought out. These are of especial value, being the only traces of corals yielded to us by the formation; unless indeed a stray pebble, found on the surface of the ground near Bani, also containing corals, may belong to the same group. On the peninsula of Samana the limestones are highly metamorphosed, and here occurs a very curious mixture. In some cases the limestone has a few scattered scales of mica embedded in it; in others the mica is so abundant as to form layers, while not infrequently, especially in the eastern part, mica slate, alternating with the limestone, is not an unusual feature. This is the more remarkable since it occurs nowhere else on the island, and in only one other locality is mica found, and there in hardly noticeable quantities.

With so few data it would seem hazardous to venture a determination of the geological age of the group of rocks in question. But a careful study of the scanty material at my disposal reveals the existence of a serrated oyster, a *Trigonia*, a *Turritella*, shells resembling *Ancillaria*, *Natica*, *Pugnellus* (?), and *Mactra*, besides a fusoid, one fragment that seems to belong to the group of *Pterocrea*—at least it is an alate shell—bivalves that may prove to be *Cucullæa* and *Lima*, and better than all else a beautiful little ammonite in perfect preservation, and a fragment that I think more careful study will decide to be a piece of a baculite. From the above list it will be seen that there can be no possible doubt of the secondary age of the rocks. The ammonite restricts it so far. The style of the ammonite besides confines it to the two groups of Jurassic and Cretaceous, a determination corroborated by the *Trigonia*, which further belongs to a type much more common in the latter than in the former formation, resembling *T. emoryi* Con., *T. evansana* Meek, and *T. mooraena* Nob. (*T. crenulata* Roem.,

not Lam.). In fact I am not sure but that the second of these species is also found in New Grenada, whence it was previously described by Mr. Lea as *T. tocaimana*, and that the present one may have to be included under the same name. The gastropodous shells are of but little real assistance, although the *Ancillaria* belongs to a type as yet only known by one of two species high up in the Cretaceous; the oldest members of the family being in that horizon. The naticoid of course has but little weight, while my generic determination of the (?) *Pugnellus* is not sufficiently sure to warrant me in availing myself of this really valuable aid.

The *Maetra* is not of any great stratigraphical value, and the other bivalves are of still less importance. The baculite, if it should prove to be such, is a little fragment so embedded in the matrix that it will have to be developed by grinding or polishing, since any other process would inevitably destroy it. It will be thus seen that the formation is either Cretaceous or Jurassic, and the preponderance of evidence is in favor of the Cretaceous. This receives additional weight from the results of the labors of other geologists in the Caribbean region. * * *

Dr. P. Martin Duncan has elaborately studied and described the fossil corals of the West Indies, having had large collections from nearly all of the islands at his disposal. He is quoted by Mr. Etheridge as anticipating the discovery of Cretaceous rocks in Santo Domingo on account of some corals from the Miocene of the Cibao, which seemed out of place in that formation.^a

F 17-18. CUBA.

T. W. Vaughan has contributed the following original notes to this work:

Cretaceous formations possess an extensive development in Cuba. In the Province of Havana calcareous strata containing Upper Cretaceous fossils occur at Santiago de los Baños. Lying between the Tertiary limestones and the serpentine protaxis in the vicinity of Havana are glauconitic limestones, somewhat earthy in composition, and magnesian marls, which have been referred by Salterain to the Cretaceous. We consider the age of these beds as doubtful, as neither the paleontologic nor the stratigraphic evidence is sufficient to warrant a positive conclusion.

Occurring below the lowest observed fossiliferous Tertiary strata in the vicinity of Matanzas are limestones, sandstones, and shales which occupy the same relative stratigraphic position as the supposed Cretaceous of the region near Havana and may be referable to this geologic period. Cretaceous formations occupy extensive areas in the central portion of the Province of Santa Clara, where such typically Cretaceous fossils as *Barrettia*, *Requienia*, etc., were collected. The basement beds consist of an unfossiliferous arkose, composed very largely of material derived from the underlying serpentine and granite. Above these basement beds lies a hard grayish limestone replete with the remains of organisms characteristic of the Cretaceous period. Formations of the same age occur also in the vicinity of Cienfuegos, and Cretaceous strata of calcareous composition occupy extensive areas in the central portion of the Province of Camaguey. Strata have been referred to this age in the literature on Oriente Province, but as no fossils have been listed there is doubt as to the extent of the area underlain by the Cretaceous in this portion of the island. Coal-bearing sandstones of no economic importance occur at various places in eastern Cuba and are perhaps of Cretaceous age.

In the Province of Pinar del Rio, between Viñales and the city of Pinar del Rio, there is a hard grayish limestone overlying the schists. No paleontologic evidence as to the age of this limestone was obtained, but from its stratigraphic position and general lithologic character it is referred provisionally to the Cretaceous period.

^a Etheridge (Geological report of Jamaica, Appendix V, 1869, p. 308) says: "Dr. Duncan has also stated his belief that 'the Hippurite limestone exists in the neighboring island of Santo Domingo, basing this opinion upon the fact that corals having very decided lower Cretaceous affinities were noticed in Miocene strata' in that island. He noticed having found the European lower chalk coral *Astrocenia decaphyllia* in the Jamaican Miocene; *Phyllocenia sculpta*, from the Gosau and Uchaux beds, was also found in the Nijavi shale in St. Domingo, associated with four other species of Turonian affinities in the same shale."

F-G 13-14. MEXICO.

The Upper or Neo-Cretaceous of Mexico is described in general terms by Aguilera,^{9c} as follows:

The Neo-Cretaceous is encountered principally in the northern part of the Republic and commences with shales of the lower Turonian characterized by *Inoceramus labiatus* of the Ligerian substage. This substage occurs at Cerro Prieto, at the foot of Cerro Muleros, near the city of Juarez. It is also known in the north of Zacatecas, at Mazapil; in Coahuila, at Parras and Peyotes, and in the latter locality it contains, besides *Inoceramus labiatus* Schlotheim, *Ptychodus mortoni* Mantell, *Ptychodus* cf. *whiplei* Marcou, *Ceratodus* sp., *Tryonix* sp., and many teeth of fishes, etc.

The upper Turonian or the Angoumian and the Emscherian or lower Senonian have not as yet been found in Mexico characterized by their fossils. The rocks of this age in general are shales interbedded with occasional layers of limestone and are unfossiliferous. * * *

The Aturian is well represented at Cardenas and at Santa Catarina, in the State of San Luis Potosi, between the capital and Tampico, by a fauna very rich in lamellibranchs: *Gryphæa vesicularis* Lamarck, *Coralliochama G. Boehmi* Böse, *Biradiolites cardenasensis* Böse, *Radiolites austinensis* Roemer, *Exogyra costata* Say; and containing also gastropods—different species of *Cerithium*, *Turritella*, *Actæonella*, *Nerinea*; one finds also *Orbitoides* and a large number of corals. An *Actæonella* fauna is found, likewise in the environs of Monterey, in Nuevo Leon, but on approaching Coahuila *Actæonella* disappears and *Exogyra costata* Say, *Exogyra ponderosa* Roemer, *Ostrea glabra* var. *wyomingensis* Meek and Hayden are predominant. The Senonian is found at Las Esperanzas, in Coahuila, where it is formed of calcareous and marly sandstones which alternate with shales, and is terminated in the upper part by glauconitic sandstones characterized by *Sphenodiscus lenticularis*, lamellibranchs, and gastropods. * * * In the south of Mexico the Senonian has not yet been encountered, and it is probable that erosion has destroyed it in certain places where it may have occurred.

Sapper described Upper Cretaceous strata of the Province of Chiapas, but they have been assigned to the "Meso-Cretaceous" (Comanche) by Böse. (See Chapter XIV, p. 589.)

Regarding the Upper Cretaceous of Mazapil, see quotation from Burckhardt in Chapter XIII (p. 554).

Local descriptions of the Upper Cretaceous of Mexico and its relations to the Lower Cretaceous strata will be found, together with lists of fossils and correlations with European divisions, in the "Guide des excursions"⁸ of the tenth international geological congress, at Mexico, in the following sections:

- No. 29. Environs de Monterrey et Saltillo.—Böse.
- No. 26. Géologie de la Sierra de Mazapil et Santa Rosa.—Burckhardt.
- No. 24. Géologie de la Sierra de Concepción del Oro.—Burckhardt.
- No. 23. Excursion dans les environs de Parras.—Böse.
- No. 27. Les gisements carbonifères de Coahuila.—Aguilera.

G 12, H 11. LOWER CALIFORNIA.

The "Mesa sandstones" of Lower California, which were described by Gabb on very slight evidence as possibly Miocene, are here assigned to the Upper Cretaceous on the evidence of their similarity to the sandstone of that age which occurs at Ensenada. (See p. 647.) From Gabb's account of the peninsula³⁵⁰ we quote as follows:

The three geographical divisions into which I have separated the peninsula are dependent for their peculiar features on their geological structure. The rough mountains of the south are

almost wholly granite, the table-lands of the middle are made up of nearly horizontal sandstones and volcanic rocks, while the more northern portions combine the ragged and irregularly disposed ridges of the south with occasional flat-topped mountains, capped by rocks of sedimentary or eruptive origin.

All of the higher ridges of the southern extremity of the Territory are made up of granites and syenites, and formed, during the deposition of the heavy bedded Mesa sandstones, an island of considerable height and very irregular outline. The structure of these mountains is so simple that a further description is unnecessary. It is not until within half a mile south of the mining town of San Antonio that any change in the geology occurs. Here mica slate is encountered for the first time, and forms a belt several miles wide, and running from Todos Santos, on the southwest, past San Antonio and Triunfo, northeast. It probably extends into the Cacachilas Range and forms there, as at the other mining districts, the country rock of the metalliferous veins. Beyond the mica slate again, on the road between Triunfo and La Paz, granite is encountered, making the face of the range and extending to near the latter town.

In all of the valleys scattered through these mountains and in some of the lone hills on the east side of the peninsula are sedimentary formations of a comparatively late geological age. At Santiago I was informed that 3 miles northeast of that place is a locality where large fossil oysters occur in great abundance, and that they are collected and burnt for lime. I had no opportunity of visiting the locality, a circumstance which I have regretted ever since. A short distance farther northeast, near the coast, at a rancho called Los Martyres, is a high hill of sandstones, without fossils, dipping to the westward at an angle of about 15° . From its general appearance it is, in all probability, of the same age as the sandstones which make up the mesas above La Paz. In none of these sandstones have I ever succeeded in finding fossils by which to obtain a clue to their geological age. They probably, however, belong to the same group as the Miocene sandstones of Upper California. They have in many respects the same lithological characters and bear the same relations to the granites that those rocks hold where we have had an opportunity of proving their age. Besides this very doubtful testimony, there is still another item of evidence which, in the absence of any better, should have some weight. Mr. John Xantus, an able collector, sent from Cape San Lucas to the Academy of Natural Sciences of Philadelphia a few fossil oysters, which, if my memory does not deceive me, belong to a species very characteristic of the Upper Californian Miocene—*O. titan* Conrad. Should I be correct, this is important, though half a dozen years is a long interval, particularly if one had never devoted any especial attention to the specimens remembered.

With so little evidence of their age, therefore, I have hesitated about pronouncing a decided opinion, preferring to leave it an open question, trusting that some future explorer will be more lucky than myself and discover fossils from which these rocks can be assigned to their proper place in the geological scale. In consequence of the difficulty I have adopted the provisional name of Mesa sandstone in speaking of the formation.

After leaving the granitic ranges south of La Paz the whole appearance of the country changes, and with it the geological structure. The granite itself has disappeared, only to show itself as one or two insignificant outliers, and in its place come enormous deposits of sandstones forming flat-topped mountains, ragged and precipitous along the east coast but sloping off so gradually toward the Pacific as to merge insensibly into the broad, low plains of the west. Pretty regularly bordering the west coast and occurring occasionally along the gulf are deposits of post-Pliocene age, in places filled with and almost made up of the casts or shells of Mollusca, still living in the adjoining waters. Penetrating both these formations, and often capping one or the other or both indiscriminately, are deposits of volcanic origin. These volcanic rocks usually occur as dikes or broad superficial sheets which have been spread over the top of the mesa subsequent to the deposition of the post-Pliocene, and are by no means uniform either in thickness or in the manner of their distribution. Very few volcanic cones exist. Almost the only ones are the volcano of the Virgines, north of Moleje, and a series of cones and ridges extending westward to near San Ignacio. Elsewhere the eruptions appear to have taken place in the

form of long fissures, forming dikes, which, having spread their surplus over the surrounding plains, have closed, never again to reopen. In this manner immense areas have been covered with caps of eruptive rocks often 100 feet thick, the source of which is now entirely hidden, an occasional hint only existing in the denuded section of some bluff where the dike has been cut through by the agency of running water.

The post-Pliocene rocks usually lie on the lower margins of the mesa in such a manner as to show that they were deposited during the period of elevation of this portion of the peninsula. The older Mesa sandstones are usually so little disturbed that the two formations seem conformable, though sufficient evidence exists to prove that the elevating force had been acting for a long time before the oldest beds of the newer formation were deposited. This later series consists of fine-grained argillaceous sandstones and shales, some coarser light-gray sandstone, and lastly a thin bed, highly fossiliferous, as are also some of the earlier strata, but the latter highly calcareous. Where the series remains unbroken, this last stratum is always the highest, and it is nearly made up of the casts of living species of shells, *Ostrea cummingii* being almost the only one retaining its structure. At Purissima, on the west slope, the Mesa sandstones have been folded in a series of long and graceful undulations, the tops denuded to a nearly straight line and the post-Pliocene lies unconformably capping the surface. On the opposite side of the mountains bordering the gulf there are still more marked instances of unconformability, which will be described in their proper place.

The Mésa sandstones are easily distinguished from the overlying rocks by their coarser grain, greater compactness, and above all by their being highly metamorphosed along the greater part of their eastern margin. Another marked feature is the presence of large quantities of bowlders and pebbles of volcanic rocks embedded in them, sometimes to such an extent as to form even a preponderance of the bulk of some strata. These bowlders are uniformly small and very much rounded near the west coast wherever the rock is encountered, and increase in size toward the vicinity of Loreto, or rather toward that part of the coast a little below Loreto, in such a manner as to point unmistakably to this region for their origin. Not only does the size increase, but in the same ratio is the increase in number and the decrease in the amount of attrition to which they have been subjected. The lithological characters vary markedly from those of any eruptive rocks encountered in place on the peninsula; no similar rocks have been discovered between the Mesa sandstones and the underlying granite, and the only reasonable conclusion which can be arrived at is that they must have been derived from a body of land which formerly lay in that region now occupied by the gulf, and somewhere in the vicinity of or a little south of Carmin Island.

Another striking feature of this region is the peculiar manner of the elevation of the mesa. It has not been lifted by an evenly distributed force; not, like most mountain chains, by a folding along a given axis. The eastern side seems to have felt this force almost alone, the elevation of that portion lying to the west seeming to be due almost as much to the rigidity of the rocks as to the extension westward of the uptilting power. More properly speaking, the great force was exerted very nearly parallel with what is now the coast line of the gulf, and from there toward the Pacific this agency diminished so gradually as to produce no breaks or even foldings worthy of mention. We thus have the whole width of this portion of the peninsula tilted up by its edge from coast to coast, so that traveling eastward one can hardly realize the rise until, within 15 or 20 miles of the coast, he finds himself on the verge of a precipitous descent of from 2,000 to 3,000 feet in height. This eastern escarpment extends from near La Paz to near Moleje, with but few interruptions, and exhibits nearly everywhere the projecting edges of nearly horizontal beds of sandstone, sometimes unaltered, but usually metamorphosed.

The preceding description of the peninsula by Gabb should be supplemented by consulting the articles by Lindgren, and by Emmons and Merrill. Lindgren's account is quoted below and the map follows his inference in placing the "Mesa sandstones" in the Cretaceous.

Emmons and Merrill³²³ sum up the work of previous writers and give their own observations in latitude 30°. The section which accompanies their article has been compiled in the map of North America, as is shown by the details of distribution of granitic and metamorphic rocks in that latitude. If we knew the distribution, the great mass of granite which is shown as the backbone of the peninsula would undoubtedly prove to be broken up by areas of metamorphic rocks of greater or less extent, which are presumably to be assigned to the Mesozoic or Paleozoic, and by patches of the "Mesa sandstones" and volcanic rocks which overlie the intrusive and metamorphic rocks that cap the peaks and ranges.

Lindgren⁵³⁶ gave the following account of Cretaceous strata at Ensenada:

The first evidence of the existence of Cretaceous strata in Lower California was furnished by a few fossils sent to the National Museum by Mr. C. R. Orcutt, of San Diego, who found them at the southern shore of Todos Santos Bay.

Dr. C. A. White has mentioned and described those fossils. * * * The exposures are not very extensive; they are, in fact, limited to a patch about 3 miles long east and west and 1 mile north and south, on the northern side of Punta Banda. This promontory consists mainly of old porphyritic rocks, against which the Cretaceous strata have been deposited; they form a perpendicular sea cliff about 50 feet high and extending for about 2½ miles along the shore; in most places post-Pliocene gravel and sand cover the top of the cliff, but Cretaceous exposures may be found a little higher up, protruding from the later, covering beds.

The strata consist of a series of yellow coarse sandstones, interstratified with heavy conglomerates of well-rolled pebbles up to a foot in diameter, evidently petrographically identical with the massive rocks forming the peninsula and derived from them. * * *

In these heavy sandstones, generally void of fossils, there are at intervals strata 2 to 4 feet thick composed entirely of the calcareous shells of *Coralliochama*, accompanied by a small specimen of *Cerithium*. The fauna is decidedly monotonous, and but a few new forms were found.

There are strong reasons for believing that this isolated Cretaceous mass is but the first of a series of similar strata farther south, and I only regret that I could not extend my trip in that direction. On Todos Santos Island, about 12 miles from the coast, there appears to be an exposure of sandstone similar to that of Punta Banda. At the harbor of Santo Tomas, 40 miles south of Ensenada, a steep sandstone cliff, containing many and large pebbles, is said to form the coast. Similar sandstones occur at Cape Colnett, about 70 miles south of Ensenada. From here it is not very far to where the Mesa sandstones begin, and it appears to me quite probable that these also will eventually be found to belong to the Cretaceous period. Gabb has followed the sandstones more carefully on the eastern than on the western coast and states expressly, regarding the former, that they continue to skirt the coast for a long distance north of the end of the second or middle division, where they occupy the whole peninsula. His description of the appearance of the sandstone corresponds very well indeed with the Todos Santos occurrence. It must be remembered that Gabb did not determine the age of the Mesa sandstones, but only conjectured, based on a very slight clue, that they were Miocene. At the same time he describes the quite extensive metamorphism which has affected the strata in certain regions. This fact can not well be brought into accord with such a comparatively recent age as that to which he assigns the rocks. At least nothing has been observed in Upper California indicating that any extensive metamorphism has occurred so recently.^a

The strata which occur at Todos Santos Bay were placed in the Wallala group of White, which has since been recognized as lower Chico.

^a The character of the Miocene series recently found in the southern part of the peninsula at Boleo * * * appears to be very different from the Mesa sandstones and from the Todos Santos occurrence; it also incloses volcanic materials of andesitic and basaltic character. It is probable that the shells referred to above (*Ostrea*) came from a series equivalent to this and not from the Mesa sandstone.

G-H 13-14. COAHUILA AND ZACATECAS, MEXICO.

The Upper Cretaceous of northeastern Mexico contains important coal measures. The stratigraphy and structure of the State of Coahuila have been described by Aguilera,¹⁰ who tabulates the stratigraphy as follows:

Stratigraphy of Coahuila, Mexico.

Series.	Stage.	Substage.	Division.	Plains.	Sierra de Santa Rosa.	
Pliocene.			Uvalde.. Reynosa.	Conglomeratic limestone. Yellowish limestone.		
Eocene.				Oyster beds in shales. Variegated shales	Removed by erosion. Do.	
Neo-Cretaceous.	Laramie.		Las Esperanzas.	Glauconitic sandstones with impressions of plants and silicified wood.	Do. Exposed only in moderate thickness in a few places at foot of the Sierra.	Danien.
	Montana.	Eagle Pass.		Shales with workable beds of coal.	Carbonaceous shales on the slopes; of slight thickness.	Aturien.
		Fox Hills and Fort Pierre.		Yellowish fossiliferous calcareous sandstones, with thin beds of shale and limestone, also fossiliferous.	Calcareous shales with <i>Erogyra costata</i> on the summit of the Sierra. Fossiliferous shales of Muzquiz (Montana and Colorado).	Emscherien (?).
			Barroterán.	Bluish shales without fossils.		
		Colorado.	Niobrara. Benton.	Peyotes.	Calcareous shales with <i>Inoceramus labiatus</i> , <i>Ptychodus Whitley</i> .	
Meso-Cretaceous.	Edwards limestone.			Santa Rosa.	Compact ash-gray limestone.	Cenomanien.

In describing the strata Aguilera says:

The sedimentary rocks are marly sandstones, of bluish and reddish colors, and also limestones of various tones of gray, including argillaceous shales that are gray and black in the upper part and bluish in the lower part of the entire mass of the formation. The sandstones are in general of fine grain. There is a bed, varying in thickness from 5 to 30 meters, which consists of conglomerate of large limestone pebbles.

* * * * *

Throughout the broad region in which the coal-bearing strata of the Cretaceous are developed in Coahuila, one may distinguish the following divisions: At the base the Barroterán, and then, following in succession upward, the Esperanzas formation comprising the fossiliferous beds of Esperanzas, Muzquiz, and other places upon the slopes of the mountains; the Sabinas, consisting of the glauconitic sandstones of the village of Sabinas, and topped by the shales which contain a bed of *Ostrea cortex*; the Arroyo Tulillo for the beds of *Ostrea glabra* Meek. To these may be added the Peyotes division with beds containing *Inoceramus labiatus* Schlotheim, etc.

Burckhardt¹⁰⁹ has classified and described the Jurassic and Cretaceous of the Sierra de Mazapil district, in the States of Zacatecas and Coahuila, in the "Mesa Central" of Mexico. (See table in Chapter XIII, pp. 552-553.)

H 14. SOUTHERN TEXAS.

In describing the Upper Cretaceous of the Rio Grande section near Eagle Pass, Vaughan^{832a} adopted with slight modifications the classification of Dumble²⁹⁴ and distinguished the Eagle Ford formation, Austin chalk, Upson clays, and Eagle Pass formation. The Eagle Ford rests upon the Buda limestone of the Comanche series. It is composed of flaggy argillaceous limestones, in places separated by calcareous shaly layers. The thickness is 250 feet or more.

The Austin chalk is a soft, chalky, argillaceous white limestone, composed in part of Foraminifera. Its thickness is undetermined but was estimated by Dumble at 1,500 feet.

The Upson clays are described as yellow at the base and as containing calcareous septaria; the upper portion is a clay shale. The thickness was estimated by Dumble at 700 feet.

The Eagle Pass formation is described as comprising three members, called San Miguel beds, Coal series, and Escondido beds. These consist of sandstone and clay with coal beds, of which Vaughan gives many detailed sections. An artesian well near Eagle Pass penetrated 1,512 feet of strata, of which Vaughan assigns 767 feet to the San Miguel beds and 745 feet to the Coal series. A summary of the formation is given as follows:

Résumé of characters and thickness of the Eagle Pass formation.

Escondido beds, composed of sandstones and clays, with many fossiliferous horizons, exposed for 26 miles below Eagle Pass.....	Feet. 2,600
Coal series, as determined by artesian well bore, which begins in the uppermost bed.....	900
San Miguel beds, the lower 600 feet of the artesian well bore and the thickness of sandstone exposed in the hills north of the Carter ranch, 15 miles above Eagle Pass (200?).....	800
	4,300

Aguilera^{10a} has divided the Upper Cretaceous in the coal-bearing area of northern Coahuila, south of Eagle Pass, into the Sabinas, Las Esperanzas, Barroterán, and Peyotes formations.

In the Uvalde area, Texas (99° 30'–100° west longitude and 29°–29° 30' north latitude), according to Vaughan,^{833a} the Upper Cretaceous rests upon the Buda limestone and exhibits the following divisions:

Generalized section of Upper Cretaceous sedimentary rocks of Uvalde quadrangle, Texas.

	Formation.	Thickness (feet).	Character of rocks.
Gulf series.	Pulliam formation.	100–200	Coarse and fine grained yellowish and brown sandstones and clay; asphaltum horizon near top. Bed of <i>Ostrea cortex</i> Conrad at top. <i>Sphenodiscus pleurisepta</i> (Conrad) also occurs near the top.
	Anacacho formation.	300–400	Yellow, usually argillaceous but sometimes arenaceous limestones, with beds of yellow marl or clay. The limestones are more developed in the western portion of the quadrangle and the clay in the eastern portion. Fossils: Radiolites sp., Sphærolites sp. <i>Exogyra læviuscula</i> Roemer, <i>Exogyra ponderosa</i> Roemer, <i>Gryphæa vesicularis</i> Lam., Baculites sp.
	Austin chalk.	350–400	White and yellowish chalk, with some marly beds. Fossils: <i>Gryphæa aucella</i> Roemer, <i>Inoceramus</i> cf. <i>digitatus</i> Sowerby, <i>Mortonicerias texanum</i> (Roemer), <i>Pyrina parryi</i> Hall.
	Eagle Ford formation.	75+	Argillaceous and calcareous flags.

H-I 14. NORTHEASTERN TEXAS.

According to Hill,^{445a} the Upper Cretaceous of northeastern Texas is characterized as follows:

The upper Cretaceous or Gulf series rests unconformably upon the Comanche series and may be divided into five conspicuous formations, the beds of which grade into one another by imperceptible transition. The lowest of these north of the Brazos, the Woodbine, consists of ferruginous sands and clays. Above this is a formation characterized by bituminous clays, the Eagle Ford. Then follows a conspicuous formation of chalk, the Austin chalk. Succeeding this is a formation of marly clay, the Taylor marl. The uppermost formation, the Navarro, is composed of unindurated beds of glauconitic sands, clays, and a little chalk, as will be described later. There is no sedimental break between these formations, the whole series being practically continuous. All are characterized, with certain exceptions, by their general lack of consolidation, little or no hard rock being found. The beds grade into one another so gradually that partings are mappable only with the greatest difficulty. * * *

The Woodbine formation apparently rests unconformably upon the Grayson marls and Main Street limestones of the Denison beds of the Washita division, at the top of the Comanche series. The upper beds pass, by inseparable transition, from sands into sandy clays and finally into the bituminous clays of the Eagle Ford formation. This transition is so gradual that no exact line of separation can be drawn between the Woodbine and Eagle Ford formations. The parting is arbitrarily established at the zone of *Exogyra columbella*, which is considered as the top of the Woodbine formation.

The formation has a thickness of at least 600 feet in the northern section and diminishes southward until it disappears by thinning out and overlap at the Brazos. On Aquilla Creek north of Waco the formation is 45 feet thick. According to Taff, it is 200 feet thick in the Cleburne section. On Cottonwood Creek northwest of Hillsboro it is 95 feet thick. In the Fort Worth section its thickness is about 300 feet and in the Denison section about 500 feet.

* * * * *

The Eagle Ford formation is essentially a bituminous clay, accompanied in places by thin laminated clay limestones and nodular septaria of blue limestone. These clays are notable in the Texas section, where the other clay formations are mostly of a marly nature by reason of their bituminous character, resembling the shales of the Cretaceous formations of the Rocky Mountain region and the northern part of the Great Plains. Even these dark-blue clays become more calcareous in the upper layers and in the extension of the beds south of the Brazos, but north of that stream they form most of the medial and lower portion of the beds. From Dallas north the nodular septaria are of large size and abundant. In age these beds are identical with the Benton formation of the Meek and Hayden section. On Red River, in the Paris section, their thickness is estimated at 600 feet; in the Sherman section, 600 feet; in the Dallas section, about 480 to 500 feet; near Midlothian, 350 feet; in the Waco section, south of South Bosque, 200 feet; in the Austin section, 30 feet; on the Nueces, 200 feet.

* * * * *

The Austin chalk consists of beds of impure chalk containing 85 per cent or more of carbonate of lime, interstratified with softer beds of marl. It is usually of an earthy texture, free from grit, and when freshly exposed easily cut with a handsaw. Under the microscope the material shows calcite crystals, particles of amorphous calcite, and the shells of foraminifers, mollusks, echinoids, and other marine organic debris, such as usually constitute chalk formations.

* * * * *

Throughout the area included in this report the Austin chalk rests upon 5 to 10 feet of finely laminated and usually arenaceous, calcareous, argillaceous yellow to bluish material constituting the top of the Eagle Ford formation and ordinarily termed the Fish beds. The formation passes upward into the Taylor marls without stratigraphic break. Southeast of Waxahachie, at the upper contact or parting between the Austin chalk and the Taylor marl,

the marl rests directly on the massive upper strata of the chalk, the transition being very abrupt; but south of Waxahachie there are several feet of calcareous arenaceous marl intervening between the two divisions which are included with the chalk.

The thickness of this formation is difficult to determine with accuracy. Southeast of McKinney it is 625 feet; at Waxahachie, 550 feet; and southeast of Sherman, Dallas, and Waco it is estimated to be very nearly 600 feet thick. At Austin, according to the log of the Manor well, it is about 410 feet thick, but the exact thickness has not been determined.

* * * * *

The Cretaceous section above the Austin chalk in the Black Prairie region of Texas is composed almost entirely of unindurated layers, firm rock strata being very few and exceptional. The beds are principally calcareous clays which weather so rapidly into a mantle of thick black soil that continuous sections of them can not be seen or measured with accuracy, and hence their thickness, sequence, and general character must be judged largely from well holes. These unindurated uppermost Cretaceous strata in places, as at Corsicana, are fully 2,000 feet thick. They can be differentiated, after a manner, into two general formations, the lower of which may be termed the Taylor and the upper the Navarro. In some places, notably in the north-eastern corner of the State, the upper formation, which will be described later, is separable into several members.

* * * * *

The Taylor formation consists of calcareous clay marls which are locally known as "joint clays." These are blue-black in the substructure but weather into a deep regolith consisting of a whitish-yellow subsoil and a dense black soil which characterizes the main "black waxy" belt of the Black Prairie. The regolith is jointed, laminated, and friable throughout, having a crackled appearance when dry. Because of their rapid surface disintegration the character of the unaltered beds is seldom seen except when their material is brought up by the well digger or is exposed in freshly cut ravines or creeks. To the eye this clay marl is generally lacking in siliceous material, although a portion may be detected by chemical analysis. The bituminous matter which characterizes the Eagle Ford formation and the grains of glauconite which are found in the rocks of the overlying Navarro beds are also less notable. Their accessory constituent is lime, in a chalky condition. The marls are of fine consistency, compact, and apparently massive until their laminated character is developed by exposure.

* * * * *

Owing to lack of outcropping sections for measurement it is difficult to ascertain the exact thickness of this formation or to separate it from the overlying Navarro formation. In the latitude of Austin, as determined from the well at Manor, the beds are about 650 feet thick. In north Texas we have no reliable records by which to estimate their thickness. At Corsicana there are at least 1,500 feet of clays above the Austin chalk, a portion of which belong to the Taylor marls. Taff gives the Taylor marls nearly 1,000 feet in Williamson County, but this is probably overestimated.

* * * * *

The Navarro formation includes the highest beds of the Cretaceous which outcrop along the eastern portion of the Black Prairie region and of the northern margin of the Rio Grande Plain. This formation is the upward continuation of the Taylor marls, the one passing into the other by gradual transition. The chief lithologic differences are that the clays, chalks, and sands composing the Navarro formation contain more or less sand and glauconite, while the Taylor marls are apparently free from those substances. Besides these lithologic differences, there are conspicuous changes in the fossils. The latter become more plentiful in the Navarro formation and have the same character as those of the Upper Cretaceous of the New Jersey and Alabama regions, of which they are the equivalent and continuous beds, being especially marked by *Gryphæa vesicularis*, *Exogyra costata*, *Ostrea larva*, *Sphenodiscus lenticularis*, and numerous other forms.

* * * * *

In the southwest corner of Arkansas and in the Red River counties the uppermost Cretaceous beds show considerable stratigraphic differentiation, consisting of beds of glauconitic

clay marl, chalks, and glauconitic sands. South of the Sulphur Fork of Red River to the Colorado the beds consist almost exclusively of glauconitic sand and clay marls, there being only a few local occurrences of secondary limestone or arenaceous flags.

I 15. NORTHEASTERN TEXAS, ARKANSAS, AND LOUISIANA.

According to Veatch ^{838c}—

The upper Cretaceous of Arkansas is composed of the following members, beginning with the lowest:

1. Sands with bituminous laminated clays containing leaf impressions and lignite beds—the Bingen formation.
2. Blue calcareous clay with *Exogyra ponderosa*—the Brownstown formation.
3. White chalk—the Annona chalk.
4. Calcareous clay or clayey chalk, with considerable greensand—the Marlbrook formation.
5. Indurated sand, with thin calcareous and quartzitic layers locally called “water rocks,” glauconitic in part—the Nacatoch sand.
6. Dark calcareous clays, fossiliferous below, which pass upward without a sharp break into the sandy, lignitiferous lower Eocene beds—the Arkadelphia clay.

The near-shore character of the Bingen sand is in such contrast to the overlying and underlying Cretaceous marls and in the outcrop is so similar to the overlying sandy surficial deposits of the late Tertiary that in Arkansas it has heretofore, with the exception of a limited outcrop near Morris Ferry, either been confused with the surficial deposits or been regarded as an outlier of the Lower Eocene beds, which it closely resembles lithologically.^a

This formation consists of white or brown sands and clays containing some greensand and considerable lignite or lignitiferous matter, in which respect it differs from the overlying formations.

* * * * *

To the west and south the beds below the Brownstown and Taylor marls thicken rapidly, and the various sand beds encountered together in southern Sevier and Howard counties, Ark., become greatly separated by layers of clay. * * *

The Bingen sand, while the lithological counterpart of the Woodbine formation, is apparently the time equivalent of all the beds of the lower [upper] Cretaceous below the Brownstown and Taylor formations.

* * * * *

The Brownstown formation, into which the Bingen sand gradually grades, is well developed in the southern part of Sevier County, Ark., about Brownstown, from which place it takes its name. It is a blue or gray calcareous clay containing many fossil oysters and is characterized by the presence of the large oyster *Exogyra ponderosa*, whence it has sometimes been called the *Exogyra ponderosa* marl. * * * It is limited above by the Annona chalk and has a total thickness of 150 feet in the eastern part of the area and 600 feet in the western.

* * * * *

The White Cliffs chalk,^b [so named] from the bluffs and village of that name on Little River, in the northeastern part of Little River County, Ark., was renamed the Annona chalk^c from the town of Annona, Red River County, Tex., because it was found that White Cliffs as a formation name had been applied by Powell^d to certain Juratrias beds in Utah. It consists of white chalk, which at White Cliffs has a thickness of over 100 feet, but thins out rapidly to the east, disappearing entirely before reaching Okolona, where Taff has found only the chalky marl which, at the type locality, underlies it.

^a Hill, R. T., Ann. Rept. Geol. Survey Arkansas for 1888, vol. 2, 1888, pp. 56–58; Bull. Geol. Soc. America, vol. 5, 1894, p. 309, Pl. XII; Twenty-first Ann. Rept. U. S. Geol. Survey, pt. 7, 1901, p. 195, fig. 21.

^b Hill, R. T., Ann. Rept. Geol. Survey Arkansas for 1888, vol. 2, 1888, pp. 87–89.

^c Hill, R. T., Bull. Geol. Soc. America, vol. 5, 1894, p. 308; Twenty-first Ann. Rept. U. S. Geol. Survey, pt. 7, 1901, p. 340. Hill's spelling Anona has been changed to Annona, the spelling used in the Postal Guide and on Hill's map of the Black and Grand prairies of Texas, 1899 (Twenty-first Ann. Rept. U. S. Geol. Survey, pt. 7, 1901, Pl. LXV).

^d Geology of the Uinta Mountains: U. S. Geol. and Geog. Survey Terr., 2d div., 1876, pp. 41, 51, 151.

The Annona chalk is succeeded by a series of blue, chalky, somewhat glauconitic marls, in places impure chalk [the Marlbrook formation]. * * * About 200 to 300 feet above the base of this formation is a very chalky layer 20 to 50 feet thick, which has been called the Saratoga chalk marl or the Saratoga formation.^a * * * The thickness of the Marlbrook formation ranges from 750 feet at Texarkana to 50 feet or less at Arkadelphia.

Above the Marlbrook marl is a series of sandy beds which are of vast economic importance to a strip of country along the Iron Mountain Railway between Arkadelphia and Texarkana, since they are the source of the main water supply of that region. Like the other sandy beds of the Cretaceous, at the outcrop they are distinguished with difficulty from the surficial sands that mantle the region. * * *

The outcrop at Nacatoch Bluff, on Little Missouri River, in Clark County, is one of the most complete exposures occurring along this belt and shows the calcareous and quartzitic rocks which, when encountered in wells, are called "water rocks."

Section of Nacatoch Bluff on Little Missouri River, Clark County, Ark.

	Feet.
1. Slope not well exposed; seems to be composed entirely of chert and quartz gravel.....	20
2. Ledge of fossiliferous arenaceous limestone, containing many large fossil shells: <i>Exogyra costata</i> , <i>Pectunculus</i> sp., and <i>Ostrea subspatulata</i>	1
3. Sand.....	10
4. Very impure sandy limestone or calcareous sandstone, with many imperfect fossils.....	.1
5. Sand.....	4
6. Hard fossiliferous calcareous sandstone.....	.5
7. Sand.....	5
8. Slope on which landslip masses render positive determination difficult; seems to be composed of sand.....	25
Level of Little Missouri River.	
* * * * *	

The dark laminated clays which overlie the Nacatoch sand and form the "blue dirt" of the well drillers along the line of the Iron Mountain Railway from Arkadelphia to Texarkana were named by Hill in 1888 the Arkadelphia shales, from the outcrops at Arkadelphia, Clark County.^b These beds contain uppermost Cretaceous fossils for 100 to 200 feet above the Nacatoch sands, the fossil-bearing beds being well developed on Yellow Creek 3 to 4 miles northwest of Fulton, 5 to 6 miles north of Hope, north and northwest of Emmet, and at Arkadelphia. Thus far no fossils have been found in the upper portion of this formation, which extends without any apparent break to the Eocene sand beds forming the sandy hills (the crest of the Sulphur Wold) south of the Iron Mountain Railway. This absence of fossils, together with the fact that the Midway (Eocene) formation, though commonly characterized by limestones, contains dark-colored clays, makes the exact determination of the top of the Cretaceous in this section particularly difficult.

The total thickness of the Arkadelphia clay, excluding the beds which appear to be stratigraphically Eocene, is from 200 to 300 feet at Arkadelphia, 500 feet at Lanesburg, 500 to 600 feet at Hope and Spring Hill, and 500 feet at Texarkana and Shreveport.

I 16. WESTERN TENNESSEE.

The Cretaceous of western Tennessee comprises the Coffee sand member of the Eutaw formation, the Selma chalk ("Rotten limestone"), and the Ripley formation. The deposits are described by Safford^{687c} and Glenn.³⁶⁸ The section does not differ materially from that in Mississippi.^{891a} (See p. 654.) According to recent field studies by L. W. Stephenson the Coffee sand member represents all of the Eutaw formation that is present in western Tennessee.

I 16-17, J 16. EASTERN GULF REGION, GEORGIA, AND SOUTH CAROLINA.

As a result of the recent studies of the Coastal Plain of the United States, conducted in cooperation between the Federal and the State geological surveys, data have been procured on the stratigraphic and age relations of the several Cretaceous formations. L. W. Stephenson contributes the following review of the literature and discussion of the subject:

C. A. White⁸⁹¹ in 1891 published a résumé of the literature on the Cretaceous of these areas to that date. The more important previous investigators were Tuomey,⁸¹² Winchell,⁹⁴³ and Smith and Johnson⁷⁵⁰ in Alabama, Hilgard^{438, 439} in Mississippi, Safford^{688, 687} in Tennessee, and Ruffin⁶⁸² and Tuomey⁸¹¹ in South Carolina.

The principal contributions to the geology of these regions, since the publication of those enumerated by White,⁸⁹¹ have been by Langdon,⁵²⁰ Smith, Johnson, and Langdon,^{751a} Crider,^{178a} Glenn,^{369a} Sloan,^{743, 744c} and Veatch.⁸⁴²

A table which sets forth in condensed form the present writer's views regarding the age relations of the lithologic divisions heretofore recognized in the region is inserted opposite to enable the reader to understand more clearly the following discussion of past and present interpretations.

In 1860 Eugene W. Hilgard,^{438a} State geologist of Mississippi, differentiated four major divisions in the Cretaceous deposits of that State. These were, in ascending order, the Eutaw group, Tombigbee sand group, Rotten limestone group, and Ripley group.

His Eutaw group rests upon Carboniferous rocks and includes all the Cretaceous deposits below the Tombigbee sand. These deposits consist of "bluish-black or reddish laminated clays, often lignitic, alternating with and usually overlain by noneffervescent sands, mostly (though not always) poor in mica, and of a gray or yellow tint. Contains beds of lignite, very rarely other fossils."^{438b}

Hilgard's reason for adopting the name "Eutaw group" is given in the following quotation: "I adopt this name in view of these beds having been first examined in detail and recognized as being of Cretaceous age, by Tuomey,^a near Eutaw, Ala., where they are characteristically developed."^{438c}

The type region of the Tombigbee sand is in the vicinity of Columbus, in Lowndes County, Miss., where the beds are mapped as a belt 15 or 18 miles wide. The type exposures occur in bluffs of Tombigbee River. To the north of Lowndes County the Tombigbee belt is represented as narrowing down to a strip 2 to 4 miles wide, with a corresponding widening of the Eutaw area. By thus narrowing the Tombigbee belt, what Hilgard actually did was to run his Eutaw-Tombigbee boundary line obliquely across the strike of the beds so that to the north of the line he represented as belonging to the Eutaw a thickness of strata which correspond in age and stratigraphic position to the lower two-thirds or three-fourths of the Tombigbee as mapped south of the line; indeed the sections given as typical of the Eutaw are within these northward Tombigbee representatives.

In 1887 Eugene A. Smith, State geologist of Alabama, and Lawrence C. Johnson^{750a} published a classification of the Cretaceous deposits of Alabama, the divisions recognized being, in ascending order, the Tuscaloosa formation, Eutaw formation, Rotten Limestone, and Ripley formation. They described the Tuscaloosa formation as consisting of at least 1,000 feet of "purple and mottled clays interstratified with white, yellowish-white, pink, and light-purple micaceous sands, and near the base of the formation dark-gray, nearly black, thinly laminated clays, with sand partings." The Eutaw formation is described as "a series of laminated sands and sandy clays at least 300 feet in thickness."

If only those parts of the area in Mississippi immediately west of the Alabama line, mapped by Hilgard respectively as Eutaw and Tombigbee, are considered, his Eutaw division corresponds almost exactly to the Tuscaloosa formation of Smith and Johnson, and the Eutaw divi-

^a Tuomey's account of the beds near Eutaw to which reference is made is given in First Bienn. Rept. Geol. Survey Alabama, 1850, pp. 118-120.—L. W. S.

Correlation of the Cretaceous deposits of the eastern Gulf region and of the Carolinas.^a

^b A series of nonchalky equivalents of the Selma chalk referred by Langdon to the Ripley.

^c Included by Langdon in his Ripley group.

^d Correlated by Safford and subsequent investigators with the Eutaw formation, but now considered to represent only the upper part of the Eutaw.

^e The stratigraphic position of the base of the Black Creek formation with reference to the eastern Gulf section has not been established with accuracy.

^f Correlated by Langdon and others with the Tuscaloosa formation (Upper Cretaceous) of central and western Alabama, but on the evidence of fossil plants now referred to the Lower Cretaceous. It has not been proved that this division is synchronous with the Patuxent ("Cape Fear") formation of the Carolinas, as indicated in the table.

^g Correlated with the Patuxent formation on physical evidence only. Since the extension of this name to include the "Cape Fear" formation of North Carolina some doubt has arisen as to the correctness of the correlation.

~~~~~ Unconformity. . . . . Line of separation between members of a formation.

sion of those authors corresponds to the Tombigbee sand of Hilgard. However, the sections of the Eutaw described by Hilgard, all of which are north of Columbus in Mississippi, do not correspond to the Tuscaloosa formation but, as previously stated, represent a part of the northward extension of the Tombigbee division as mapped and hence correspond in stratigraphic position to a part of the Eutaw of Smith and Johnson.

The essential difference between the Tuscaloosa and Eutaw divisions of Smith and Johnson may perhaps best be stated as follows. The Tuscaloosa consists of a series of sands, clays, and gravels in large part of shallow-water origin, characterized by irregularity of bedding and, where the conditions for their preservation were favorable, by the presence of fossil leaves. The Eutaw consists predominantly of glauconitic sand of marine origin which in approximately the lower two-thirds or three-fourths of its thickness contains subordinate lenses of dark clay and exhibits fine cross-bedding and in its upper one-third or one-fourth is made up of massive beds of glauconitic sand with calcareous sand beds in its upper part. So far as known no structural break exists between the Tuscaloosa and Eutaw formations, sedimentation apparently having been continuous from the one to the other. Nor has it been possible to recognize any sharp lithologic line of separation between them, the change from the one kind of sedimentation to the other having been transitional.

Beds representing the Tuscaloosa formation extend from western Alabama northward, occurring in a wide belt that includes the northwestern part of Alabama and a relatively narrow area in the adjoining northeastern part of Mississippi. The formation as a whole, however, becomes much thinner toward the north and disappears in the vicinity of the Tennessee State line. It is doubtful if, in the region of their outcrop, the Mississippi representatives of the division exceed a maximum thickness of 400 feet. Hilgard did not differentiate these lower beds of shallow-water origin from the higher beds of marine origin but included them in his Eutaw formation, as shown by the map accompanying his report.

The Mississippi representatives of the Eutaw formation of Smith and Johnson include, as previously stated, all of the Tombigbee sand and a part of the Eutaw group of Hilgard. Although the width of the Tombigbee belt as mapped by Hilgard immediately west of the Alabama line is 15 or 18 miles, corresponding to a thickness of 400 or 500 feet, the actual sections given by him in this part of the area are all near the western border of the belt and probably include only about the upper 150 or 200 feet of the strata mapped. Farther north in Mississippi beds which correspond in stratigraphic position to the lower two-thirds or three-fourths of the Tombigbee as mapped in Lowndes County are included by Hilgard in his Eutaw group, and among these are the sections which he indicated as typical of this division in Mississippi. These correspond in age and position to a part of the Eutaw division of Smith and Johnson, although in the intervening area in Lowndes County beds of the same age were mapped as Tombigbee. This confusion was due apparently to the fact that Hilgard failed to find in Lowndes County any of the beds of dark clay corresponding in position to those farther north, upon the basis of which he seems to have differentiated his Eutaw group. These clays are of a resistant character and where they occur in stream bluffs form rather conspicuous exposures; but when the division as a whole is considered they constitute subordinate lenses only of deposits made up in the main of glauconitic sands. Such clay beds, however, do occur in Lowndes County, being exposed in the banks of Floating Turtle Creek a short distance east of Columbus.

From the facts brought out in the above discussion it is apparent that a readjustment of the nomenclature as applied by Hilgard to the beds subjacent to the Selma chalk in Mississippi is necessary. The classification of the corresponding deposits in Alabama by Smith and Johnson is based on essential physical differences, namely, those depending on origin. In Mississippi these differences were not recognized. It would appear, therefore, that the Alabama nomenclature is the more logical. For this reason, in the opinion of the writer, the name Tuscaloosa, which stands for the lower shallow-water portion of the series, should be extended to include the corresponding deposits in Mississippi. The name Eutaw, which in Alabama stands for the upper or marine portion of the series, can appropriately be extended to include the corresponding beds

in Mississippi, although this will mean the expansion of the term as Hilgard used it, to include the Tombigbee sand above, and its contraction with reference to the Mississippi representatives of the Tuscaloosa formation below.

The name Tombigbee sand, however, if applied to the actual type sections of the division described by Hilgard and their equivalents, is expressive of a natural phase or subdivision of the Eutaw formation and is eminently worthy of preservation in the literature. If we disregard Hilgard's imperfect mapping, the sections of the Tombigbee sand described by him are all included within a thickness of strata which probably does not exceed 150 or 200 feet. Thus limited the division includes the uppermost massive, more or less calcareous and phosphatic beds of the Eutaw formation, as distinguished from the more irregularly bedded and more argillaceous portion of the formation beneath it. These upper, massive beds are traceable for many miles to the north of Lowndes County in Mississippi and they extend eastward, with certain modifications, entirely across the State of Alabama into Georgia. They were recognized by Smith and Johnson, who spoke of them as the "upper member of the Eutaw formation." This member, however, can not be sharply differentiated from the remainder or lower member of the formation, for massive lenses of glauconitic sand of greater or less extent occur in places at lower levels than the Tombigbee member proper, and where these appear in small exposures they are not distinguishable from that member.

The Eutaw formation as thus defined (including the Tombigbee sand member) extends from Alabama northward through Mississippi to the vicinity of the Tennessee State line, where it ends against the unconformably subjacent Paleozoic rocks.

The term "Rotten limestone" was introduced by Alexander Winchell <sup>943a</sup> in 1857. This name was the commonly accepted designation of this great body of chalk rock until 1894, when Smith, Johnson, and Langdon <sup>751b</sup> proposed the geographic appellation Selma chalk, as a coname with "Rotten limestone," and since that time the geographic term has been the accepted designation. It has been found that the Selma chalk makes up all of the Upper Cretaceous strata above the Tombigbee sand member in western Alabama and east-central Mississippi, where it has an approximate thickness of 1,000 feet, the terrane being overlain unconformably by Eocene strata carrying characteristic fossils from the eastern part of Marengo County, Ala., to the northern part of Noxubee County, Miss. To the north in Mississippi and to the east in Alabama the Selma chalk as such becomes thinner and in each direction finally disappears. The thinning of the formation is due, not to the actual thinning or disappearance of the beds, but to their replacement along the strike by nonchalky materials (sands, clays, marls, etc.) having the same age and stratigraphic position. In the region of its fullest development the formation is divisible on paleontologic grounds into two parts; the lower, embracing approximately the lower half of the formation, is most conspicuously characterized by the presence of *Exogyra ponderosa* Roemer; the upper, embracing the remainder of the formation, is characterized by the presence of *Exogyra costata* Say, and carries a fauna which corresponds in a general way with that of the Ripley formation of northern Mississippi, though it contains fewer species.

The Ripley formation, which in its type region in northern Mississippi conformably overlies beds of the Selma chalk, is not younger than the youngest of the Selma chalk beds where the latter are most completely developed in western Alabama and east-central Mississippi; on the contrary, it is of the same age as the upper 300 or 400 feet of the Selma, the nonchalky, sandy, and argillaceous beds of the Ripley being the representatives in northern Mississippi of the upper part of the Selma chalk. To the north in Tennessee both the Selma chalk and the Ripley eventually lose their distinguishing lithologic characters, the former merging into marine and estuarine equivalents and the latter into shallower-water equivalents, probably largely of estuarine origin. The Ripley formation with these lithologic modifications is traceable northward through Kentucky to the head of the embayment region in southern Illinois, to which limit the beds maintain their shallow-water characteristics.

What has been said thus far applies more especially to the Cretaceous beds of the eastern Gulf region between central Alabama and Mississippi River. The conditions of deposition which

prevailed in the region of the Chattahoochee Valley in eastern Alabama and western Georgia were, during much of Cretaceous time, markedly different from those existing farther west.

The lowest Cretaceous division of the Chattahoochee region, the Tuscaloosa group of Langdon,<sup>520</sup> was supposed by that author to represent the eastward extension of the Tuscaloosa of Smith and Johnson. The physical aspects and relations of these deposits, and the paleontologic evidence furnished by a collection of poorly preserved fossil plants from Old Fort Decatur, on Tallapoosa River, studied by E. W. Berry, have led both Mr. Berry and the writer to doubt the correctness of this correlation. It is believed that they are of Lower Cretaceous age and hence older than the Tuscaloosa formation.

The Eutaw group of Langdon in the Chattahoochee region is approximately the eastward extension of the Eutaw of Smith and Johnson except that in the opinion of the writer, based on paleontologic evidence, it should have included at least 120 feet of the overlying beds which Langdon referred to the base of his Ripley group. The beds of the division exposed on Chattahoochee River are in the main of marine origin, although in places they exhibit in part the characters of shallow near-shore or estuarine deposits. To the northeast in Georgia they pass into shallow-water equivalents and eventually end unconformably against the underlying older terrane (Lower Cretaceous).

The conditions which favored the deposition of chalklike rocks in central and western Alabama were entirely lacking in the Chattahoochee region, and we have in place of the chalk a series of marine sands and clays which as a whole are synchronous with the fully developed Selma chalk of western Alabama. The conditions unfavorable to the deposition of chalk, which at the beginning of Selma time existed only from Macon County eastward, gradually spread westward as Upper Cretaceous time proceeded, ending, so far as the record has been preserved, a short distance east of Tombigbee River in Marengo County, Ala. These nonchalky deposits of the Chattahoochee region were by Langdon referred in their entirety to his Ripley group. Recent studies by the writer in this region have shown that Langdon's Ripley group of the Chattahoochee region is divisible on paleontologic grounds into two parts—a lower part carrying a number of species restricted to the lower one-third or one-half of the formation, and an upper part carrying a large number of species that do not range lower than the upper one-half or two-thirds of the formation, and characterized especially by the presence of *Exogyra costata* Say. These two parts, with the exception of the Tombigbee representatives at the base of the lower one, correspond to the two parts recognized paleontologically in the Selma chalk. There are, however, in the Chattahoochee region, a large number of wide-ranging species common to both the lower and upper divisions noted.

Northeastward from Chattahoochee River in Georgia the equivalents of Langdon's Ripley group pass first into a series of alternating marine and shallow-water beds, and finally, still farther to the northeast, into irregularly bedded sands and clays of shallow-water origin. The latter are overlapped and concealed in central and eastern Georgia by Eocene beds.

The classification of the Georgia Cretaceous deposits adopted by Otto Veatch<sup>842</sup> in 1909, is essentially the same as that of Langdon, except that Veatch subdivided the Ripley into four parts on the basis of the alternation of beds of marine and shallow-water origin recognizable in a part of the area. These subdivisions are, in ascending order, the Blufftown marl, Cusseta sand, Renfroes marl, and Providence sand.

The lower part of the "Blufftown marl" is probably synchronous with the Tombigbee sand member. The upper part of the "Blufftown marl," the Cusseta sand, the so-called Renfroes marl, and the Providence sand together are the equivalents of the Selma chalk where that formation is most fully developed in western Alabama and east-central Mississippi.

As regards the correlation of the Upper Cretaceous deposits of the eastern Gulf region with deposits in regions outside of this area, the following may be said: That part of the series characterized by the presence of *Exogyra costata* Say, which includes the Ripley formation of northern Mississippi; about the upper half of the Selma chalk where most fully developed; and the upper one-half or two-thirds of the Ripley formation as developed in the Chattahoochee region are

correlated on the evidence of the invertebrates they contain, with the Peedee sand of the Carolinas and with the Monmouth formation of Maryland and New Jersey.

The invertebrates present in that part of the Chattahoochee section lying below the beds characterized by the presence of *Exogyra costata* Say and above the top of the Eutaw formation indicate synchronicity with the upper marine invertebrate-bearing beds of the Black Creek formation of the Carolinas; the few species of plants found in the same beds offer no evidence in contradiction of this correlation. The invertebrates also point to synchronicity with all but the lowermost beds of the Matawan formation of Maryland and New Jersey. This portion of the Chattahoochee section is believed to correspond approximately to the lower one-half of the Selma chalk where the latter is most fully developed. No paleozoologic data have been obtained for a direct comparison of the Eutaw formation with the Black Creek formation; however, the invertebrate fauna present in the upper part of the Chattahoochee representatives of the Eutaw ("Blufftown marl") includes a considerable number of Black Creek species which do not range up into the beds carrying *Exogyra costata* Say. On account of this close faunal relationship it is believed that the Eutaw is represented in North Carolina by an undetermined portion of the Black Creek formation lying immediately beneath the invertebrate-bearing beds of that formation. There is evidence for considering the upper part of the Eutaw (Tombigbee sand member) as corresponding to the lowermost beds of the Matawan group (Merchantville clay) of New Jersey.

Fossil plants have been collected from the Chattahoochee representatives of the Eutaw formation, and on the evidence thus furnished the beds have been correlated by E. W. Berry with the Black Creek formation of the Carolinas, no particular horizon in that formation, however, being designated, and with the Magothy formation of Maryland and New Jersey. The Tuscaloosa formation in Alabama has furnished an extensive flora which Berry considers in part contemporaneous with the Black Creek flora, in this case likewise the reference being made to no particular horizon in the Black Creek formation, and in part contemporaneous with the Magothy formation.

In this connection it may be stated that in an unpublished manuscript on the Cretaceous flora of South Carolina Berry admits the possibility of the Magothy flora having persisted during the time of deposition of the Matawan equivalents in the Carolina and Chattahoochee regions.

The question of the correlation of the eastern Gulf Upper Cretaceous with the Cretaceous of the western Gulf and western interior region is at the present time under investigation. As regards the age relations of the beds toward the lower part of the series the two classes of biologic evidence, plant and animal, have led to certain differences of opinion between the students of each class. Until further facts have been obtained and a closer comparison of the species in the two regions has been made, it seems inadvisable to attempt a statement of exact correlation. As regards that portion of the eastern Gulf Cretaceous, however, characterized by the presence of *Exogyra costata* Say, there is general agreement that it corresponds approximately to the Navarro formation of Texas and to an undetermined upper portion of the Montana group of the western interior region.

The Upper Cretaceous deposits present in South Carolina belong regionally with the deposits of the same age in North Carolina, the former being the southward continuation of the latter. The Carolina Upper Cretaceous is separated, geographically, from the corresponding Gulf Cretaceous deposits by a great overlap of Eocene strata. The two formational units recognizable in North Carolina, the Black Creek and Peedee formations, are also easily distinguishable in South Carolina.

The Black Creek formation, the older of the divisions, received its name from Black Creek, South Carolina, along whose banks and valley sides it is best exposed in this State.<sup>743a</sup> Better exposures occur, however, in the bluffs of Cape Fear River, in Bladen County, N. C.

The deposits typical of the formation consist of an estimated thickness of 500 to 700 feet of irregularly bedded, laminated carbonaceous clays and thin laminae and lenses of sand, the whole being more or less lignitic and pyritiferous. The sand lenses and laminae are slightly

glaucinitic in places throughout the formation, and toward the top occur rather massive interbedded layers of glauconitic sand some of which bear marine invertebrates. The clays carry fossil leaves in various stages of preservation. The sands and clays are believed to be in part of estuarine and in part of marine origin. An Upper Cretaceous terrane which has not been differentiated in North Carolina but which is developed in South Carolina from Chesterfield County southwestward consists mainly of light-colored clays and coarse arkosic sands. These beds, designated the Middendorf beds by Sloan,<sup>744b</sup> although lithologically different from the Black Creek, and evidently of shallower-water origin, are regarded by E. W. Berry, on the evidence of fossil plants, as contemporaneous with the lower portion of the Black Creek formation, and they are treated as a member of the Black Creek under the name Middendorf arkose member.

The Black Creek formation rests unconformably upon the Lower Cretaceous deposits of the region and is overlain by the Peedee sand. The typical beds of the Black Creek formation occur in the valley of Peedee River and its tributaries in parts of Marion, Florence, Marlboro, and Darlington counties, and the Middendorf arkose member appears in a relatively narrow area from Chesterfield County southwestward to Aiken County. The failure of the upper part of the Black Creek formation to appear at the surface to the south and the narrowing down of the Middendorf member in that direction are due to an overlap of Eocene beds from the southeast. Over much of the area of its occurrence the formation is concealed at the immediate surface by thin surficial deposits of late Tertiary or Pleistocene age.

The Peedee sand received its name from Peedee River, South Carolina.<sup>682</sup> It was later designated by Sloan<sup>743,744c</sup> the "Burches Ferry marl." The formation consists of 800 feet or more of marine sands and clays, more or less calcareous and glauconitic, carrying marine invertebrates. It appears at the surface in bluffs of Peedee River and its tributaries in Florence, Williamsburg, Georgetown, Marion, and Horry counties and is present in considerable areas in these counties beneath thin patches of Tertiary deposits and beneath a thin but almost continuous covering of Pleistocene and Recent deposits. Southward from this area the formation is overlapped and completely buried by Eocene strata.

As previously stated, the Upper Cretaceous formations of this State constitute the southward continuation of deposits which have their most extensive areal distribution in North Carolina. More complete collections of fossil leaves and invertebrates have been made in that State than in South Carolina, and it is largely on the results of paleontologic investigation carried on in North Carolina that the following attempt at correlation with Cretaceous deposits in outside regions is based. The plants have been studied by E. W. Berry and the invertebrates by the writer.

The invertebrates present in the upper part of the Black Creek formation indicate a pre-Peedee, or, in terms of the Maryland-New Jersey section, a pre-Monmouth age of the beds containing them. This part of the formation would appear, therefore, on this evidence to be synchronous with a part of the Matawan formation. The plants which occur throughout the vertical extent of the formation, being interbedded with the invertebrates in the upper part of the terrane, constitute a flora, according to Berry, analogous with that contained in the Magothy formation of Maryland and New Jersey, the Matawan formation in these States not having yielded any considerable flora. The Black Creek beds below the invertebrate-bearing beds of the formation are doubtless referable, therefore, in part or in whole to the Magothy formation, but the presence of the flora in supposed Matawan equivalents in the Carolinas would seem to indicate its persistence here to a later time than the record preserved in the New Jersey-Maryland deposits would indicate.

Referred to the Upper Cretaceous deposits of the Chattahoochee region (Georgia-Alabama) the invertebrates in the upper beds of the Black Creek indicate close synchronicity with the beds exposed along Chattahoochee River from Roods Bend, in Stewart County, northward to the vicinity of Florence, in the same county, or to that part of the Ripley formation below the beds characterized by the presence of *Exogyra costata* Say. Fossil plants referable to the Black Creek flora have been found at several horizons from beds at the extreme base of the Upper Cretaceous deposits (Eutaw formation) of the region up almost to the base of the beds carrying

*Exogyra costata* Say. The Black Creek would appear, therefore, to represent all the Upper Cretaceous deposits of the Chattahoochee region subjacent to the beds carrying the above-named species. This would mean the correspondence of the Black Creek to about the basal one-half of the Selma chalk, where that formation is most fully developed in western Alabama and east-central Mississippi, and to all of the Eutaw formation of the same region. According to Berry, on the evidence of the plants, the Black Creek includes also representatives of at least a part of the Tuscaloosa formation of Alabama, which forms the basal division of the Cretaceous in central and western Alabama and northeastern Mississippi.

The Peedee sand is correlated, on the evidence furnished by invertebrates, with the Monmouth of the Maryland-New Jersey Cretaceous, with the beds of the eastern Gulf region carrying *Exogyra costata* Say (which would include the upper one-half or two-thirds of the Ripley formation of the Chattahoochee region, the upper half of the Selma chalk, and the Ripley formation of northern Mississippi), and with the Navarro formation of Texas.

#### I-J 13. COLORADO AND NEW MEXICO.

Concerning the Cretaceous of southwestern Colorado, Cross<sup>187</sup> states:

The lowest Cretaceous formation recognized is the Dakota, which alone, of all the divisions, has the lithologic character common in other parts of the Rocky Mountain region.

Succeeding the Dakota comes a very homogeneous clay shale formation more than 1,000 feet thick, which from the invertebrate fossils found at several horizons must be supposed to represent the Benton, Niobrara, and a part of the Pierre formations as distinguished at the eastern base of the Front Range in Colorado. But the fossil-bearing strata are neither sufficiently numerous nor well enough developed to serve as horizons for a satisfactory subdivision of this shale formation, which was named the Mancos shale in the Telluride folio.

The next higher distinguishable series in the Cretaceous section is the variable complex whose more massive sandstones cause the principal scarps of the Mesa Verde. Holmes named this series after the Mesa Verde in the Hayden reports and his designation is here accepted. It was not used, however, on the Hayden map. The Mesaverde formation consists of alternating sandstones and shales with several seams of excellent coal. The invertebrate fossils, which are not uncommon at several horizons in the shales and sandstones, range throughout the Montana group, and hence give no ground for a reference of the Mesaverde strata to the Fox Hills, as was done on the Hayden map.

Above the Mesaverde formation occurs another formation of clay shale, reaching an observed thickness of nearly 2,000 feet, which is very much like the Mancos shale but contains fewer fossils. The only identifiable form thus far found in this shale occurs also in the Mancos shale, so that this division is still apparently below the true Fox Hills. This formation is called the Lewis shale. Holmes designated it the "Sand Shale group."

Still above the Lewis shale is a second series of sandstones, shales, and coals, bearing some resemblance to the Mesaverde formation but differing in detail. The lowest member of this complex is the "Pictured Cliff sandstone" of Holmes's San Juan section, which he placed in the Fox Hills upon the evidence of invertebrate remains. The remainder was referred by Holmes to the Laramie, but without fossil evidence. The present survey has also failed to bring to light valid ground for assigning any of the beds in question to the Laramie, while there is some reason to believe that more than the lower sandstone belongs to the Montana group.

Between the uppermost quartzose sandstones of the Cretaceous and the Puerco marls (Eocene), which are well developed below Durango on the Animas, there occurs a series of beds not recognized by Holmes. These strata are composed mainly of andesitic débris, tuffs, or conglomerates, and it has been proposed by the writer to call them the Animas beds or formation. The fossil plants obtained from the tuff layers clearly indicated that the beds may be correlated with the Denver, Middle Park, Livingston, and other post-Laramie formations, which paleontologists refer to the Mesozoic, although they are stratigraphically shown to be later than the great revolution which terminated the conformable succession of Cretaceous sediments.

The strata thus described by Cross extend southward in New Mexico around the east side of the San Juan basin, where they have been traced by Gardner:<sup>358</sup>

The San Juan coal region is a basin of more or less circular outline, with an area of about 13,500 square miles, about one-seventh of which lies in Colorado and the remainder in New Mexico. The region receives its name from San Juan River. The two chief coal-producing localities are Durango, in the extreme southwestern part of Colorado, on the Denver & Rio Grande Railroad, and Gallup, in New Mexico, on the Atchison, Topeka & Santa Fe Railway.

The formations known to occur in the San Juan district are as follows:

*Generalized section of rocks in coal field between Gallina and Raton Spring, N. Mex.*

|                 | { Dakota sandstone.        |                   |

The Dakota or basal formation of the Cretaceous throughout the San Juan region \* \* \* consists chiefly of hard quartzite with intercalated shale toward the top but near the base is made up of reddish sandstone and yellowish shale that grade gradually into the Jurassic-Triassic rocks below. No signs of coal beds were observed in the Dakota, but they are known to occur in other parts of the basin.

The Mancos shale rests conformably upon the Dakota. In the type-locality at Mancos, Colo., the formation is all shale, but in New Mexico there are transitional sandy beds toward the top. At a point 10 miles north of Gallina a part of the formation becomes arenaceous and forms a hogback in the shale valley. This sandy bed is about 30 feet thick and about 275 feet below the top of the formation. It is no doubt the beginning of the sandstone and shale formation that increases in thickness toward the south and is coal bearing on the south side of the basin. In the vicinity of San Miguel, 12 miles down Rio Puerco from Cuba, the writer observed a thickness of 300 feet of argillaceous sandstone and sandy shale in the Mancos, grading upward through a transition zone to the Mesaverde.

The Mesaverde is the most important coal-bearing formation in the area, as well as throughout the San Juan region. It forms a prominent hogback across the east side of the Gallina-Raton Spring field. \* \* \* Coal beds occur at varying intervals between a prominent basal and a capping sandstone. The main coal bed of the area is just below the top sandstone.

The Lewis is much like the Mancos in appearance. It changes notably in thickness across the field. From about 2,000 feet north of Gallina it thins to 250 feet on the Arroyo Torrejon and in the vicinity of Raton Spring. It may be, however, that the lower part of the shale in that region is replaced by sandstone which has heretofore been considered Mesaverde.

The Laramie is without workable coal beds at the north limit of the field. In fact, Schrader<sup>a</sup> maps the entire area northward to the Colorado State line as barren. West of Gallina the Laramie and underlying Lewis shale disappear beneath unconformable Eocene beds. The next

<sup>a</sup> Schrader, F. C., The Durango-Gallup coal field, Colorado and New Mexico: Bull. U. S. Geol. Survey No. 285, 1906, p. 243.

point to the south at which the Laramie shows is where it emerges from beneath the Puerco, about  $10\frac{1}{2}$  miles southwest of Cuba. The Laramie strata exposed between this point and Raton Spring are coal bearing, the coal beds increasing in thickness and number toward the west.

The section given by Gardner applies in a general way to the region originally described by Holmes in the valley of San Juan River and may be compared with that observed by Dutton in the Zuni Plateau farther south. Sections by both Holmes and Dutton are given in the latter's report.<sup>301c</sup>

South of Santa Fe, N. Mex., Lee<sup>a</sup> observed the following section. The lower 555 feet of the section was measured about 2 miles north of Galisteo Canyon; the upper part about  $1\frac{1}{2}$  miles south of Galisteo.

*Section of rocks exposed in Galisteo Canyon, south of Santa Fe, N. Mex.*

The Cretaceous of the western Great Plains near the southern boundary of Colorado is described by Hills,<sup>450, 451</sup> from whose account the following notes are derived.

The lowest Upper Cretaceous in the Elmore quadrangle is the Dakota sandstone, the base of which is not there exposed. On Purgatoire River, farther east, it rests upon the Comanche series and, as described by Stanton,<sup>781a</sup> is a gray and brown, mostly massive cross-bedded sandstone about 100 feet thick. On the same stream in the Elmore quadrangle Hills measured 300 feet and estimated the total

<sup>a</sup> Lee, W. T., unpublished notes.

at 375 feet, but it is probable that he included in the Dakota some Comanche strata which had not at that time been recognized in the region. Hills says:<sup>450</sup>

The lower two-thirds of the Dakota consists of sandstones, with fine conglomerates, imperfectly stratified or cross-bedded, and the heavy layers which make up this part of the formation are separated from one another by thin bands of finer, shaly material. The upper one-third also consists of sandstone layers parted from one another by thin bands of shale, but the individual beds are not so thick and the shale partings are more numerous. These two portions are separated from each other by a prominent bed of hard shale—fire clay—the position of which, in cliff exposures, is often indicated by a narrow shelf or terrace immediately below it.

The color of the upper sandstone is generally grayish white, the lower somewhat darker, with yellowish and brownish weathered surfaces. The pebbles of the coarser layers are quartzite, quartz, and chert. The finer-grained layers are made up of quartz grains, among which white, kaolin-like specks are included. The lower sandstone is of an open, porous texture and more loosely aggregated than that lying above the fire-clay stratum. But the texture of any particular layer varies from place to place, and the same is true of the thickness of the individual beds, so that the only constant features are the fine-grained, compact sandstone above and the coarser, porous sandstone below the persistent bed of fire clay separating them.

The Dakota is followed in succession by the Graneros shale, the Greenhorn limestone, and the Carlile shale, which constitute the Benton group. Of these formations Hills says:

The Graneros formation, which marks the beginning of the marine conditions following the subsidence that terminated the Dakota epoch, consists of dark-gray clay shale, from 200 to 210 feet in thickness, darker near the center than elsewhere, resting on the Dakota sandstone and graduating rather abruptly into it. Large limestone concretions are not uncommon in the upper half but are not a distinguishing feature, as similar concretions are met with in the other shale formations of the district. At a distance of about 30 feet above the base there is a layer, from 1 to 2 feet thick, of hard concretionary limestone, weathering an orange tint, which is noticeable and characteristic.

The Greenhorn formation is made up of layers of dove-colored limestone, usually less than 12 inches thick, separated from one another by somewhat thicker layers of shaly material. It graduates into the Graneros shale below and the Carlile shale above. Fossil shells are abundant in the limestone layers, especially the flat, oval, concentrically ridged *Inoceramus labiatus*. The coiled ammonite *Prionocyclus* is sometimes present. The thickness varies from place to place, owing to the thickening or thinning of the shaly layers. At the same time the graduation into the Graneros and Carlile formations is more abrupt in some places than in others, thus rendering it doubtful at times where to draw the line. The maximum thickness occurs in the northeastern part of the quadrangle, where it is often 50 feet. In the southeastern part the exposed sections are not so complete and it is thought that in some places the thickness may not exceed 30 feet. \* \* \*

The Carlile formation consists of about 180 feet of dark-gray shale, the middle portion the darkest, overlain by from 10 to 15 feet of soft, shaly yellowish-gray sandstone, into which it graduates through a varying thickness of more distinctively shaly material. A thin band of purplish bituminous limestone containing large numbers of coiled ammonites is persistently present capping the formation. Concretionary nodules several feet in diameter and seamed with lime spar are rather common, especially in the upper half of the beds.

Overlying the Benton group is the Niobrara group, concerning which Hills says:<sup>451a</sup>

The Timpas and Apishapa formations, both of which are characterized by the presence of limestone strata, or of shale containing a considerable proportion of lime, constitute a Niobrara

group and are elsewhere mapped undivided as the Niobrara formation. The Niobrara beds are distinguishable by their limy character from all other Cretaceous formations, except the Greenhorn limestone of the Benton group, from which, however, the limestone of the former is readily distinguished by its color and fracture.

The Timpas formation comprises about 200 feet of strata, of which the lower 45 to 50 feet is limestone and the remaining 150 feet calcareo-argillaceous shale interrupted by thin limestone bands, which become prominent toward the top. The limestone at the base is made up of layers, usually less than 12 inches thick, which are separated from one another by very much thinner layers of calcareous shale. The fracture is conchoidal and rudely parallel with the bedding planes, and the grayish-white weathered surfaces break off naturally into thin conchoidal flakes. As the Greenhorn limestone is dove colored and has a cross fracture, the two are easily distinguished. The only fossil at all noticeable is the large oval, concentrically ridged shell *Inoceramus deformatis*, characterized by the excessive bulge of the ventral valve. The limestone itself, however, consists largely of the skeletons of foraminiferal organisms, readily seen in thin, transparent sections under the microscope. The middle and upper portions of the formation consist mainly of bluish or dove-colored shale, with thin bands of limestone at intervals. There are three of these bands from 1 to 3 feet thick in the upper 40 feet of the section, and one of these marks the top of the formation. \* \* \*

The total thickness of the Apishapa approaches 500 feet. The lower portion for about 40 feet consists of dark-gray or blue-gray shales, followed by rotten shales of paper-like lamination about 90 feet thick, which grade through blue sandy shale into calcareo-arenaceous shales. The latter become coarser and flaglike toward the middle of the formation and constitute about one-third of it. The upper 100 feet resembles the basal portion, but includes two and at times three thin layers of limestone and usually lens-shaped concretions of similar but more impure material. The middle zone is always more or less bituminous and fairly constant in character. The remainder of the formation varies considerably except in its general shaly features and the presence of limestone strata near the top. The fossil remains consist of fish scales, which are generally abundant in the shales and sometimes in the coarser flaglike layers. In the sandy shales at the base of the middle zone the tracks of what was probably a small crustacean are characteristic. These tracks appear as a double row of short, straight lines, those on one side inclined toward those on the other.

The Pierre shale succeeds the Apishapa formation of the Niobrara group, and of it Hills says:

The beds of the Pierre epoch consist of argillaceous shales throughout. The thickness is estimated at from 1,300 feet at the southeast extremity of the outcrop to 1,500 feet at the northwest extremity, the changing dip and small number of exposures making accurate measurement very difficult, if not impossible. The shales vary much in appearance. The basal and upper zones weather to a yellowish-green color; the middle zone is dark gray to lead-gray, occasionally almost black. The latter zone contains an abundance of lime-iron concretions that break up readily and impart a rusty tint to the surface. They are always arranged parallel with the bedding.

The Trinidad sandstone follows the Pierre shale. According to Hills it represents—

some part or possibly the whole of the Fox Hills group, but on account of its relation to the Laramie and the thickening of the lower zone of the formation northward it is presumably the upper portion only. In the Spanish Peaks quadrangle the total thickness is about 150 feet in the vicinity of Trinidad and 170 feet toward the north boundary. As elsewhere the formation consists of a basal zone of thin-bedded, fine-grained dark-gray sandstone layers, separated from one another by thinner partings of shale; and an upper zone of massive light-gray sandstone, capped by a few feet of brown sandstone in contact with the overlying Laramie. \* \* \*

The marine Cretaceous ended with the Trinidad. The conditions of the succeeding Laramie epoch were shallow waters connected with the ocean. \* \* \*

Owing partly to a certain amount of erosion preceding the deposition of the succeeding Eocene formation, though mostly to the general thinning out of the measures toward the north, the thickness of the Laramie varies considerably. Thus, along the southwestern border of the district and in the Raton Mountains near the southern border it is not less than 2,000 feet, and doubtless exceeds this amount near the crest of the high ridge immediately south of the line; while in the central and northern portions it does not exceed 1,700 feet, and is even less than this in the northeastern area near the north boundary, where it is about 1,500 feet.

The sections of the Laramie in different parts of the district vary but little in their general features. There is always an alternation of massive or thick-bedded gray sandstone beds with thick shaly beds. The latter predominate toward the base of the group, the former toward the top. The shaly beds of the upper half of the group are shale or clay shale, but in the lower half, noticeably in the lower portion of it, they consist of sand shale—that is, thin layers of greenish-gray fine-grained sandstone with partings of shale of the same color. The lower shaly beds are occasionally interrupted by bands of sandstone a few feet in thickness and by beds of clay shale associated with seams of coal, which may occur toward the center of the shale bed or entirely above it and may equal the latter in thickness. Some of the upper sandstone beds are disposed to weather into cavernous forms, and some of the alternating beds associated with them consist of fine-grained greenish-gray fissile sandstone instead of shale. But aside from the general features the sections possess little in common. It is only the lower, main sandstone bed and the shaly beds above and below it that are really persistent throughout the district. \* \* \*

The group is characterized by a rich semitropical flora, very similar to what is found in the Gulf States to-day, and leaf imprints of certain species of oak, fan palm, fig, poplar, willow, and tulip tree are of common occurrence in the thin-bedded sandstone and lower shaly beds.

Lee's recent work in southern Colorado and northern New Mexico<sup>529</sup> throws doubt on the Laramie age of the coal-bearing rocks of this region, or at least of the upper part of them.

The Cretaceous of the Denver district was described in great detail by Eldridge<sup>322</sup> in the Denver monograph. The original description should be consulted. Fenneman<sup>328a</sup> has published a report on the Boulder quadrangle, which lies partly in the Denver Basin, and his descriptions are here abstracted as follows:

Above the Jurassic [Morrison] comes the prominent Dakota formation, easily recognized and well known in the great hogback which parallels the Front Range for hundreds of miles. It is a firm sandstone that is often quartzite, is generally thick bedded, and is characterized by frequent cross-bedding and ripple marks. \* \* \* At its base, though not everywhere present, is a pebble conglomerate. The constituent pebbles include "abundant limestones, quartzites, clays, flints, jaspers, and rocks of granitic composition, together with the separate mineral constituents of the last." The whole is so firmly cemented that, where unweathered, the rock fractures in broad planes which pass through the pebbles. Frequently a series of thin pebble beds in a mass of sandstone takes the place of the continuous conglomerate. This alternation of beds makes the thickness of the basal zone indefinite, but there are few pebble beds above the first 20 or 30 feet. Considerable variation may be discerned in the sandstone, but with the exception of the basal conglomerate no one bed has a constant position in the column. Generally the sandstone is composed of quartz grains, with a siliceous cement, and is gray or yellowish gray. With increase of iron oxide the sandstone exhibits striking features of differential coloring. \* \* \* At intervals between the stronger ridge-making ledges occur layers of thinly laminated shaly sands, aggregating in thickness only a few feet. \* \* \* The line between the Dakota and the overlying Benton shales, while very distinct in a large way, is not so easily located in detail. Alternations of sandstone and shale occur over a zone of 50 feet or more. The thickness of the Dakota at Bear Canyon is about 320 feet, and at Fourmile Canyon a little greater.

The Benton shales have a thickness of more than 500 feet at the north end of the field. They are somewhat thinner at the south end and taper uniformly from both ends toward Boulder Creek, where the formation almost disappears. The great body of the shale is dark. There are frequent layers a few inches thick which are strongly impregnated with iron. The formation is calcareous in varying degree. At many places some beds are composed of a black limestone showing a crystalline surface when broken and having a strong bituminous odor. \* \* \* As the summit is approached the blackness disappears and the last 75 feet (observed near the north end of the field) show light-colored limestone, shale, and sandstone. North of Sixmile Canyon these beds, which may be regarded as transitional to the Niobrara, show the following section:

*Section of upper part of Benton formation north of Sixmile Canyon.*

|                                                      | Feet. |
|------------------------------------------------------|-------|
| Greenish sandstone, calcareous in upper third.....   | 15    |
| Shales, blue to yellow, noncalcareous.....           | 15    |
| Sandstone, noncalcareous, firm, rather purplish..... | 10    |
| Shale, iron stained at intervals.....                | 10    |
| Shale, calcareous (or calcareous at top).            |       |

Below these beds is a limestone of variable thickness strongly resembling the basal Niobrara. It occurs in lenses only. The greenish sandstone at the top is found below the basal Niobrara wherever the latter is exposed in this district. It is generally 10 or 15 feet thick and is not calcareous except in the upper portion. As it is often very much fractured and the cracks are abundantly filled with carbonate of lime, this calcareous character may be due to infiltration from the limestone above. The blue and yellow shales below are also seen wherever the base of the greenish sandstone is exposed.

The Benton is succeeded by the Niobrara, whose prominent characteristic is its calcareous nature. It is composed in small part of true limestones, but the greater mass is made up of calcareous shales, while considerable portions are of intermediate character. Its thickness at Fourmile Canyon is a little more than 400 feet. The basal stratum of compact limestone rests upon the greenish sandstone which is at the top of the Benton. Occasionally a foot or more of light-colored marl intervenes. Below the Niobrara, as pointed out above, are occasional beds of similar limestone and calcareous shales interbedded with noncalcareous sandstones.

Above the Niobrara are the Pierre shales, which are more than 5,000 feet thick. They are slate colored, leaden gray, dark brown, and sometimes nearly black. \* \* \* While in general noncalcareous, the Pierre has local limy beds. At places these form continuous strata, as, for example, 4 miles north of Boulder, one-half mile east of the contact with the Niobrara. Here, for a thickness of nearly 40 feet, strong limestone beds are so closely grouped as to give the outcrop the appearance of the basal Niobrara. At other places the limestone beds are smaller and more isolated or are divided into concretionary masses often containing fossils. Less prominent calcareous masses may be found at any horizon, either in beds or in more or less perfect concretions. Concentrations of iron occur in similar but less massive forms, ranging from clear-cut beds to well-formed nodules. The lime and the iron may or may not occur in the same concretionary mass. Many of the calcareous nodules mentioned contain much iron carbonate, which, in progressive oxidation toward the center, gives rise to sharply marked concentric shells differing in color. Sandy beds may occur at any place in the section. The most prominent and persistent of these is about one-third way up from the base, or a little higher. \* \* \* From pure sands at one extreme to pure clay shales at the other, the Pierre shows all gradations in composition. The sandy layers are generally firm and gritty, almost as dark colored as the shales themselves, and not very porous. In rare instances light-colored, friable sands are encountered in drilling oil wells. The thickness of the sandy beds is as variable as their constitution, while the lateral extent of such beds, as indicated by occasional outcrops and by the records of wells, is, in a large majority of cases, a small fraction of a mile. Some of these beds may be lenses, but doubtless the more common mode of lateral limitation of the sands is by a gradual change in composition of the beds into the shales.

Within the limits of this area the great body of the Fox Hills is but indefinitely distinguished from the Pierre. In mild contrast with the latter its shales are yellowish instead of slate colored and are also more arenaceous. \* \* \* The topmost stratum of the Fox Hills is, however, a very definite feature in the stratigraphy. For many feet below it there are occasional sandstone beds, and the intervening shales are highly sandy, but at the top is a continuous bed of sandstone 40 feet thick.

The Laramie outcrops in the southeast corner of the area. Within the limits here defined this formation consists essentially of (1) sandstones at the base, (2) sandstones alternating with shales and coal overlying, (3) sandstones above the coal, and (4) clays, containing isolated sandstone beds and lignitic streaks. \* \* \* The basal sandstones are exposed at various places in the Marshall coal field, but best of all at White Rocks, on the eastern border of the area, mapped. Here the bold sandstone escarpment comprises two distinct and massive beds, whose topographic effect, however, is that of a single stratum continuous with the Fox Hills sandstone beneath. The lower Laramie sandstone is 40 feet thick, equaling the underlying Fox Hills sandstone, while between the two are a few feet of thinly laminated sandstones, varying to a lignitic shale. The second and thicker stratum of Laramie is separated from the first by gray shaly sands, inclosing 10 inches of lignitic shale and above 10 inches of coal. Both Laramie beds are clearly distinguished from the Fox Hills by their gray or white color and coarser grain. They are composed of coarse quartz sand and in addition always show some black specks of an undetermined mineral. The two sandstones differ in the following respects: The upper is distinctly whiter and, where exposed along bedding planes (and to a less degree on fracture planes), the surface is marked by weathered-out cracks, making polygonal patterns a few feet across. Both strata are weakly cemented and noncalcareous but contain giant concretions which are very calcareous, hard, and, on weathered surfaces, are stained brown with iron oxide. The 75 feet of thinner-bedded sandstones above, containing some shale and coal, are best seen at Marshall. The shales occur at frequent intervals and are often lignitic. The one workable coal seam is sometimes at the top of this division but again is overlain by 5 or 10 feet of shales and thin sands; all, however, lie below the more persistent sandstone referred to under (3) above. Aside from the coal seam, no horizon above the basal sandstones is more definite than the *Ostrea glabra* zone, which occurs 15, or 20 feet from the base of the series. The sandstone above the coal is not unlike the second massive bed above the bottom. It weathers into the same angular patterns and has the same appearance in the hand specimen. Its thickness is from 8 to 15 feet. The overlying clays, as shown in this area, are yellow and purple, and have frequent lignitic bands but no coal, at least within the limits of the area covered by the map.

#### I-K 10. CALIFORNIA AND SOUTHERN OREGON.

The Upper Cretaceous (Chico formation) of California has long been known. It was described by Diller and Stanton<sup>284b</sup> as part of the "Shasta-Chico series." (See J-K 10, Chapter XIV, p. 615.) Anderson<sup>27</sup> discussed its general relations. Stanton<sup>782a</sup> has recently stated the following regarding the fauna:

On the Pacific coast the Horsetown fauna is succeeded by the littoral Chico fauna, which is distributed from the Yukon River to Lower California, occurring on the lower Yukon, the Alaska Peninsula, Queen Charlotte and Vancouver islands, in middle and southern Oregon, in the Sacramento Valley and the Coast Ranges of California to San Diego, and on the peninsula of Lower California as far south as latitude 31° 30'. There are considerable local variations in this fauna, as would be expected in view of its great range in latitude. The assemblage of forms found on the Yukon is quite different from that occurring in the Sacramento Valley, and still another facies is found in southern California, but these are all connected by common species, so that there is no hesitation about referring both the northern and the southern facies to the Chico fauna. The fauna as a whole, like the later Horsetown fauna, is Indo-Pacific in its affinities and is strikingly different from the faunas of the Atlantic border and interior regions of North America. Whiteaves and F. M. Anderson have argued for a connection during Chico time between the Pacific and interior seas, but the evidence brought forward in support

of this view is based on types that have a world-wide distribution and on those that are only similar, not specifically identical. In my opinion direct connection has not been proved. In time range the Chico formation apparently began somewhat earlier and continued somewhat later than the Colorado fauna of the interior seas, but it did not extend to the end of the Cretaceous, and latest Cretaceous time is probably not represented by marine deposits on the Pacific coast.

The character and relations of the Chico vary in different localities from southern California northward through the Coast Range and the northern Sacramento Valley. The Chico in the San Luis quadrangle is described by Fairbanks<sup>325</sup> as follows:

The Atascadero formation, the local representative of the Chico group, consists mainly of certain soft sandstones of a grayish-yellow color. The formation derives its name from Atascadero Creek. A few poorly preserved fossils were found in it at several points along the northern slope of the Santa Lucia Range.

\* \* \* \* \*

Near the coast the Atascadero formation occurs above the San Luis (pre-Cretaceous) formation, but northeast of the Santa Lucia Range it rests on the Toro (lower Cretaceous). In the latter region the Atascadero terminates downward in a conglomerate which is in places 100 feet thick and contains large granite boulders. The striking contrast in general lithologic character between the Atascadero and Toro formations is indicative of a marked change in conditions of deposition. The hypothesis that there is a hiatus in the Cretaceous sediments is well founded. It is based, on the one hand, on the fact that the Atascadero sediments extend over the Toro across both strike and dip, indicating that the Toro had been upturned and planed off before the Atascadero began to be deposited (as may be seen at many points, particularly on the divide between Atascadero and Santa Margarita creeks), and, on the other hand, on the fact that the Atascadero in the same locality rests indiscriminately upon the Toro and San Luis formations.

Another interesting fact should be mentioned in connection with the discussion of an unconformity. The serpentine here, as in other portions of the Coast Ranges, wherever it comes in contact with the lower Cretaceous is intrusive, while it has nowhere been observed to penetrate the Atascadero formation. There were at least two epochs of igneous activity during the Cretaceous, and three if the formation of the San Luis Buttes be included; this supports the view that marked movements occurred during Cretaceous time.

The Chico is developed on the east side of the Coast Range in the mountains bordering the San Joaquin Valley, according to Arnold and Anderson.<sup>34b</sup> A quotation from their paper has been given in Chapter XIV (pp. 616-617), outlining the general sequence of the Cretaceous beds in the Coalinga district. The rocks are there separable into three divisions, of which the lowest is supposedly of Knoxville (Lower Cretaceous) age, and the middle and uppermost contain Chico (Upper Cretaceous) fossils. The Chico portion is described as follows:

The middle one of the main divisions into which the Knoxville-Chico rocks are divisible upon lithologic grounds comprises a thick series of alternating thin beds of dark shale and sandstone with the above-mentioned heavy conglomerate at its base and with the characteristic massive, concretionary sandstone beds that form the upper division overlying. Its thickness, including the conglomerate zone, measures at least 4,800 feet. \* \* \* The conglomerate is locally extremely variable and is not continuous. It may in places be traced directly into massive sandstone or even into thinly bedded sandstone and shale, as along Alcalde Canyon between 2 and 3 miles west of Alcalde. It represents throughout the district, however, an important stratigraphic horizon characterized by a coarsening of the sediments. \* \* \*

The uppermost of the three divisions of the Knoxville-Chico is predominantly concretionary sandstone in the lower part and shale in the upper part and has a thickness of at least 4,700 feet. \* \* \* Taken as a whole the upper division is strikingly distinct from other

formations in the district and seems to represent a separate stratigraphic unit, although no unconformity has been made out at its base.

The lower half of the upper division consists chiefly of massive sandstone beds, often weathering cavernous. \* \* \* The sandstone is usually drab, medium grained, and not very hard.

Above the succession of concretionary sandstone beds, and forming the upper half of the upper division of the Knoxville-Chico, comes a less prominent and less uniform succession of beds in which shale is predominant. \* \* \* This upper half of the upper division consists of two main members predominantly of shale, each approximating 1,000 feet thick, separated by a much thinner but more prominent member of concretionary sandstone, in general similar to that lower down. \* \* \* The lower of the two shale members has few exposures but is notable for the presence in it of different kinds of deposits, such as blackish, thinly bedded clay shale and yellowish and whitish calcareous and arenaceous shale and sand, and for the presence of ammonites, baculites, *Inoceramus*, and other fossils, which weather out in a fragmentary state on the surface of the clayey soil. \* \* \* The sandstone separating the two shale members varies from 200 to 300 or 400 feet in thickness and consists of yellowish-gray and brown sandstone full of large brown concretions. It is of the same type as the characteristic Chico concretionary sandstone farther down in the section. \* \* \* The uppermost member is one of particular interest owing to its individuality among the known types of Cretaceous deposits, its large content of organic material, its petroliferous nature, and its similarity to the Eocene beds. It is at least 1,200 feet thick and consists principally of shale but has a considerable admixture of sand and sandstone. For convenience it will be referred to as a whole as the purple shale member. The most characteristic beds of this zone are of purplish-brown, fairly hard, thinly bedded, both siliceous and calcareous clay shale, in which the tests of Foraminifera are very abundant. This shale bears a resemblance to some of the less siliceous shale in the upper part of the overlying Tejon (Eocene), especially to that shale as it occurs in the southern part of this district, and is not unlike some argillaceous phases of the Monterey shale (middle Miocene) of the outer Coast Ranges and the shale mapped as Santa Margarita (?) (middle Miocene) along Reef Ridge and at other points in this district. \* \* \*

Above the purple shale of the uppermost Cretaceous lie dark clay and clay shale beds aggregating several hundred feet in thickness, which appear to form an upward continuation of the shale of the Chico but which are mapped with the Tejon (Eocene). Fossils recently found near the northern edge of the Coalinga district show that the higher of these beds belong with the sandstone of the Tejon above, but there is reason to believe that 200 feet or so of beds at the base belong in the Chico. \* \* \* Whether the line of separation between the Cretaceous and Tertiary occurs at the top of the purple shale or somewhat higher, within the darker clay shale, it is noteworthy that it should occur within a zone of fine sediments and be marked by no break of evident stratigraphic importance. However, in spite of the apparent transition between the shale of the Cretaceous and that of the Eocene in the northern part of the Coalinga district, it is believed that they are separated by an unconformity. The evidence of this is the progressive disappearance of the upper members of the Knoxville-Chico southward in the district, whereas the basal Tejon is believed to represent a fairly constant horizon. \* \* \* This thinning and disappearance of the members is probably the effect of erosion upon them before the deposition of the Eocene.

For a general correlation of the Mesozoic and Cenozoic formations of the Coast Range, see Chapter XVII (p. 818).

In the Santa Cruz quadrangle the Chico is very thick. Branner<sup>97a</sup> states:

The Chico strata along the coast are made up for the most part of hard siliceous shale, sandstone, and massive, coarse conglomerate. The general dip of the beds, for a distance of 3 miles along the coast south of the mouth of Pescadero Creek, is toward the southwest and the section apparently exposes about 9,400 feet of strata. These strata dip at high angles, however, and may be repeated by folds, or to some extent by faults, thereby making the thickness appear greater than it is. This is the case 2 miles north of Pigeon Point, where massive conglomerate is faulted into contact with sandstone and shale.

The upper portion of the formation is characterized by massive, coarse conglomerate with interbedded sandstone. The conglomerate shows evidences of much crushing, faulted and crushed pebbles being plentiful in it.<sup>a</sup>

The Chico of the northern portion of the valley of California was described by Diller and Stanton.<sup>284b</sup> A recent account by Diller<sup>279a</sup> is contained in the Redding folio. He says in part that the Chico formation is composed chiefly of yellowish sandstone which is in places pebbly and which, though conglomeratic toward the base, passes upward into gray shales. It extends throughout the Sacramento Valley and is covered by later formations except around the valley borders. Northeastward it extends through Lassen Strait between the Klamath Mountains and the Sierra and possibly connects with the Chico of northern California and Oregon. The greatest thickness observed in the Redding quadrangle is about 500 feet. The formation thickens rapidly southwestward from Redding and is conformably underlain by the older beds that constitute the Horsetown and the Knoxville. It rests with marked unconformity on the older formations around the north end of the Sacramento Valley, and it is unconformably overlain by the Ione, which has generally been assigned to the Miocene.

#### I-K 17-18. ATLANTIC COASTAL PLAIN.

See contribution by W. B. Clark, Chapter XIV (pp. 608-614).

#### J 12. PLATEAU PROVINCE OF UTAH AND COLORADO.

In southwestern Utah the Upper Cretaceous comprises Colorado strata and Montana (?) strata, and the Colorado is coal bearing. The stratigraphy is stated by Richardson<sup>669</sup> in the following table and comment:

*Outline of coal-bearing and associated rocks in the southern Utah coal region.*

| System.         | Series.               | Formation.         | Character.                                                                                               | Thickness (feet). |
|-----------------|-----------------------|--------------------|----------------------------------------------------------------------------------------------------------|-------------------|
| Tertiary.....   | Eocene.....           | Wasatch.....       | Varicolored shale, limestone, sandstone, and conglomerate.                                               | 500+              |
| Cretaceous..... | Upper Cretaceous..... | Unconformity.      |                                                                                                          |                   |
|                 |                       | { Montana (?)..... | Buff sandstone and drab shale..                                                                          | 500±              |
|                 |                       | { Colorado.....    | Buff sandstone and drab shale, including workable beds of coal in the lower part.                        | 2,500±            |
| Jurassic.....   |                       | Unconformity.      |                                                                                                          |                   |
|                 |                       |                    | Varicolored shale and sandstone, with lenses of limestone and gypsum overlying massive marine limestone. | 800±              |

Throughout the plateau province \* \* \* Upper Cretaceous strata lie directly upon beds of Jurassic age. \* \* \* A thin bed of conglomerate at the base may be of Dakota age. The greater part of the Cretaceous rocks, including the coal, are assigned to the Colorado, but the upper few hundred feet contain fresh-water shells and plants of undetermined age, which may possibly belong to the Montana. The succession of Cretaceous strata in the southern Utah region is unlike that in western Colorado and northeastern Utah, so that the formation names used in the coal fields of those areas can not be applied to the rocks in the area under consideration. The coal in southern Utah is older than that in the Uinta Basin region, which includes the

<sup>a</sup> For list of fossils see the work cited.—B. W.

Book Cliffs field, the largest and most important in the State. The southern Utah coal belongs to the same group as that in the Weber River field.

The Cretaceous strata which form the escarpment of the Roan or Book Cliffs extend south of the fortieth parallel across the basin of Green River and around that of Grand River from central Utah to western-central Colorado. They comprise the Dakota sandstone, the Mancos shale, and the Mesaverde formation, and are unconformably succeeded by the Eocene. The following section is summarized from Richardson:<sup>667</sup>

Eocene.

Unconformity.

Mesaverde: Alternating buff sandstone and drab or carbonaceous shale, with beds of coal in lower part; shale prevails in the lower part, and sandstone in the upper; beds of sandstone lenticular; sections variable; thickness 1,200 to 2,200 feet, decreasing westward; fossils consist of plants and invertebrates of fresh and brackish water. Transition marked by increase of sands upward and appearance of brackish and fresh water, in place of marine conditions.

Mancos: Clay shale, black or blue gray, with local lenses of limestone and near the top thin beds of buff sandstone, contains Montana fossils in the upper part and Colorado fossils near the base; thickness about 3,000 feet.

Dakota: Quartzitic buff sandstone, commonly conglomeratic, with layers of carbonaceous shale and low-grade coal; thickness 25 to 200 feet, but formation sometimes wanting on account of irregularities of surface on which it was deposited.

Unconformity.

The following section is given by Lee<sup>530</sup> in an account of the Grand Mesa coal field:

*Generalized section of [Cretaceous] rocks in the Grand Mesa coal field, Colorado.*

| System.       | Group.    | Formation.   | Member.            | Thickness (feet). | Characteristics.                                                                                                                                                                                                                                                                                                                   |

Colored in various shades of red, yellow, green, blue, etc.                                                                                                                                                     |

## J-K 13-14. EASTERN COLORADO, KANSAS, AND NEBRASKA.

Darton <sup>238a</sup> gives the following general account of the Cretaceous of the Great Plains:

*Dakota-Lakota formations.*—In 1893 Prof. Lester Ward discovered that the so-called Dakota sandstone of the Black Hills contained not only a Dakota flora but in its lower beds extensive flora of lower Cretaceous age. As the Dakota sandstone in its type region is characterized by a distinct upper Cretaceous flora, it became necessary to restrict the term "Dakota" in the Black Hills to the upper sandstone carrying the upper Cretaceous plants. In investigating the stratigraphy of the uplift it was found that the upper sandstone is separated from the lower sandstone, which was designated the Lakota sandstones, by a persistent body of shale which has been designated the Fuson formation. In tracing these formations northward, it was found that the principal plant-bearing horizon in the northern Black Hills was in the Fuson formation, which has yielded a large and beautiful flora of lower Cretaceous plants, which Professor Ward has described. The tripartite composition of the old "Dakota" group in the Black Hills is very distinct throughout the uplift and apparently is a widespread feature in adjoining regions.

\* \* \* \* \*

*Benton group.*—The rocks of this group are the most widespread and constant in characteristics of all the sedimentary deposits of the Central Plains region, their salient feature being a thick succession of shales overlying the Dakota sandstone. They present, however, persistent subdivisions or horizons of variation. The thickness is variable, ranging from about 400 feet in the southeast to 1,600 feet in the Black Hills.

In nearly all the half million square miles under consideration the group comprises three members—a basal, dark shale series known as the Graneros shale, a medial limestone known as the Greenhorn limestone, and an upper shale series with sandy layers known as the Carlile formation. Toward its base the Graneros shale includes a horizon marked by local deposits of sandstone; the Greenhorn limestone always presents alternations of slabby limestone and shales; the Carlile formation generally has a sandstone bed at or near its top, not far below which concretions usually occur. The Greenhorn limestone is characterized by great colonies of *Inoceramus labiatus*, a species rarely found at all in other horizons; the upper portion of the Carlile contains *Prionotropis woolgari*, which appear to be restricted to that horizon and to characterize it throughout the region and even in the Bighorn Basin. Throughout east Wyoming and Black Hills region the middle part of the Graneros shales includes, not far above the local sandstone horizon a series of hard gray shales and fine-grained thin-bedded sandstones filled with fish scales, which weather light gray and from their hardness often give rise to a ridge or cliff. These have been termed the Mowrie beds and are conspicuous along both sides of the Bighorn uplift, all around the Black Hills, and along the Laramie Front Range to the Colorado line.

\* \* \* \* \*

*Niobrara formation.*—This deposit occupies a wide area in the central Great Plains region, succeeding the Carlile without suggestion of unconformity and, except in the vicinity of the Bighorn Mountains, consisting largely of carbonate of lime. Its thickness varies considerably from apparently less than 100 feet in some portions of eastern South Dakota to 700 feet in central-southeast Colorado.

At the type locality on Missouri River at the mouth of the Niobrara the formation is represented by a chalk rock having a thickness of about 200 feet. In southern Nebraska and Kansas, where it appears extensively, the amount is considerably greater, 350 feet being the estimate of the Kansas geologists. The formation usually presents purer and harder carbonate of lime deposits near its base, constituting the Fort Hays limestone in Kansas and the Timpas formation in Colorado. The characteristic fossil of this horizon is the *Inoceramus deformis*, which is a conspicuous feature in Colorado and for some distance north into Wyoming.

Along the foot of the Rocky Mountains and the Laramie Front Range the formation usually presents three limestone layers, a lower massive bed and two upper layers, separated by limy shales, the uppermost overlain by impure limestones, which weather to a bright-yellow color and always contain flat masses of limestone consisting of colonies of *Ostrea congesta*. The formation thins to the north in Colorado and Wyoming, becoming about 400 feet thick northwest of Cheyenne, and about 200 feet on the slopes of the Black Hills. The bright-yellow color of the weathered beds is a conspicuous feature. The point farthest west at which the formation was noted is southwest of Casper. It is not characterized along the slopes of the Bighorn Mountains, although doubtless it is there represented by some gray shales, not distinguishable from those of the adjoining formations, for there is no suggestion of hiatus in the sedimentary series.

*Pierre shale.*—The great shale series of the Pierre formation occupies a vast area in the central Great Plains and was probably originally of even greater extent, for it appears to have been removed by erosion in the mountain uplifts, in eastern Nebraska, and in southern and eastern Kansas. No special investigation has been made of the Pierre stratigraphy, and, although the beds seem to be uniform in composition, probably a careful study of the distribution of its numerous fossils would show widespread stages. One of these is the upper horizon of concretions with *Lucina occidentalis*, giving rise to "tepee buttes," which appears to extend from Arkansas Valley through Colorado to and all around the Black Hills. In places along the western margin of the area great variations in thickness are presented, the shales becoming thicker and local sandstone beds being included. West of Denver the formation appears to have a thickness of over 7,700 feet, and of considerably over 3,000 feet at Florence and near Boulder.

*Fox Hills formation.*—The Fox Hills formation appears to be present everywhere between the Pierre and the Laramie, merging into both formations and constituting beds of passage between them. In some districts the Fox Hills beds begin abruptly with a sudden change from the dark shales of the Pierre to sandstones or sandy shales of the Fox Hills containing some distinctive species. It is probable that this change does not take place at the same horizon throughout, and the Fox Hills fauna appears in connection with the sandy sediments.

Usually the Fox Hills deposits are less than 300 feet thick, but in the Denver region, where they comprise a thick mass of sandy clays in their lower portion, they attain a thickness of a thousand feet. The top member in this region is a persistent characteristic sandstone, 50 feet thick, which appears to be the same as the Trinidad sandstone in the Spanish Peaks district in south Colorado. The top of the Fox Hills formation is not always clearly definable and in most cases can only be placed arbitrarily at the horizon where the first deposits of evident fresh-water origin appear.

The divisions thus distinguished are commonly classified as the Dakota sandstone, the Colorado group (Benton and Niobrara formations), and the Montana group (Pierre and Fox Hills of the eastern plains). The term Dakota was proposed by King<sup>506c</sup> and given the present definition by Eldridge,<sup>303</sup> who at the same time proposed the term Montana. The strata, faunas, and distribution of the Colorado have been described in detail by Stanton.<sup>775</sup>

#### K 12. NORTHEASTERN UTAH, NORTHWESTERN COLORADO, AND SOUTHWESTERN WYOMING.

The Cretaceous strata of the eastern Uinta Range were described by Powell<sup>638</sup> under the names Henrys Fork, Sulphur Creek, Salt Wells, and Point of Rocks groups. The latest work in this region has been by Gale,<sup>353</sup> who has described the Rangely oil district, which lies in Colorado just north of the fortieth parallel. In a correlation table Gale shows that the Cretaceous of western Colorado is now

divided into five formations—Dakota, Mancos, Mesaverde, Lewis, and Laramie—and he gives <sup>353d</sup> the relations of this classification to those of Hayden, King, Powell, and White, as well as the reasons for abandoning the earlier ones.

For the Rangely field Gale gives in substance the following account <sup>353c</sup> of the several Cretaceous formations:

The Dakota sandstone presents the following descending section at the southern foot of Blue Mountain, a southern outlier of the Uinta Range:

*Section of Dakota sandstone at Willow Creek.*

|                                                                                                                                         | Feet. |
|-----------------------------------------------------------------------------------------------------------------------------------------|-------|
| 1. Sandstone, weathered brown (overlain by dark-gray and black slaty shale, supposed to represent the base of the Mancos [Benton])..... | 10    |
| 2. Shale with beds of white clay and a hard siliceous conglomerate; shale very black and slaty near its base.....                       | 110   |
| 3. Sandstone, white, cross-bedded, containing conglomerate layers.....                                                                  | 40    |
| 4. Interval, probably shale, covered by sandstone slide rock.....                                                                       | 180   |
| 5. Sandstone.....                                                                                                                       | 3     |
| 6. Shale, variegated in colors of pink and green, containing also one or more beds of dense reddish-purple limestone.....               | 95    |
| 7. Conglomerate of coarse, perfectly rounded pebbles in a scant sandy matrix; pebbles largely of chert and siliceous material.....      | 45    |
|                                                                                                                                         | 483   |

According to Stanton Nos. 4 to 7 may be older than Dakota and may correspond to the Fuson or the Lakota (both Lower Cretaceous?) or to the Morrison formation (Jurassic?). Farther west, in Utah, the Dakota shows much the same divisions as those given above, but the basal conglomerate thins out eastward and the formation is reduced to two thin sandstone beds separated by shale.

The Mancos shale, which overlies the Dakota, is homogeneous, with the exception of a few sandy layers, and is probably nearly 5,000 feet thick. It includes Benton, Niobrara, and part of the Pierre, and is characterized by Benton fossils near the base and by a Montana fauna having some Fox Hills elements near the top.

The Mesaverde succeeds the Mancos and is the youngest Cretaceous remaining in the Rangely field. It consists of massive sandstones, interbedded with sandy shales and many beds of carbonaceous shale and coal. The thickness is about 5,000 feet. Gale describes its members in detail.

North of the Rangely field, in southern Wyoming, Cretaceous strata form the Rock Springs dome in the great area of Eocene. Schultz <sup>716</sup> describes the strata there exposed as Mesaverde, Lewis, and Laramie(?) and says:

The present investigation led to the conclusion that the subdivisions previously mapped by King and Powell could not be applied to the sequence of rock in this region. The fossils collected by this party and studied by F. H. Knowlton and T. W. Stanton indicate that the several formations have the geologic time values indicated in the accompanying table, where the general character and succession of the Cretaceous and Tertiary rocks, together with their economic importance, are set forth. [Only the Cretaceous part of the table referred to is quoted here.]

*Cretaceous rocks in northern part of Rock Springs coal field, Wyoming.*

| Group.   | Formation.   | Economic designation.    | Thickness (feet). | Description.                                                                                                                                                                                                         |
|----------|--------------|--------------------------|-------------------|----------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
|          | Laramie(?).  | Black Buttes coal group. | 2,371±            | Massive basal bed of white and yellow sandstones, showing traces of conglomerate in places; forms prominent scarp. The overlying bed consists of variable sandstones, clay, and coal beds. Fossils abound in places. |
|          | Lewis shale. |                          | 750±              | Dark-gray, drab, and black shales, highly gypsiferous, with some soft shaly sandstone and large concretions. Produces region of low relief.                                                                          |
|          |              | Almond coal group.       | 900               | Soft white and brown sandstones, sandy shale, and clay with numerous beds of coal and bituminous shale.                                                                                                              |
|          |              |                          | 800               | Massive white and yellowish sandstones, with little shale and ferruginous matter. Upper third conglomeratic, with fine black and gray quartz pebbles. Sandstone forms pronounced escarpments and hogback ridges.     |
| Montana. | Mesaverde.   | Rock Springs coal group. | 2,400             | White to yellow sandstone, interbedded shale and clay with several large coal beds ranging from a few inches to 2 or 3 feet. The heaviest sandstones are grouped near the base of the formation.                     |
|          |              |                          | 860               | Drab, yellow, and brown sandstones and interbedded shale and shaly sandstone with little or no bituminous matter. Massive sandstones are grouped near top of formation, giving rise to the "Golden Wall."            |
|          |              |                          | 940               | Shaly sandstone and arenaceous shale, in places highly gypsiferous. Much of it very friable, producing low benches and badland ridges.                                                                               |
|          |              |                          | 550+              | Black and drab shales, very soft and friable.                                                                                                                                                                        |

The Cretaceous of southwestern Wyoming has been described by Veatch,<sup>839a</sup> who gives the following classification from Jurassic up to Eocene, inclusive, the upper and lower parts of his geologic column not being here quoted:

## Section in southwestern Wyoming.

| Systems and groups.                        | Formations.              | Character of rocks.                                                                                                                                                                                          | Thickness (feet).                                                                                                                                                                                                                                                                                                                                                                                                                                                                  |              |
|--------------------------------------------|--------------------------|--------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|--------------|
| Eocene.                                    | Bridger.                 | Greenish sand and clays, composed largely of volcanic ash, with occasional calcareous white bands filled with fresh-water shells. Contains a large mammalian fauna.                                          | 1,200-1,800                                                                                                                                                                                                                                                                                                                                                                                                                                                                        |              |
|                                            | Green River.             | Predominantly light-colored calcareous beds, characterized by light-colored thin-bedded shales with abundant fish and plant remains. Layers of dark bituminous shales show near Fossil at base of formation. | ° 2,000 ±                                                                                                                                                                                                                                                                                                                                                                                                                                                                          |              |

The numerous formations listed in the above table are described in detail by Veatch, who states the general relations as follows:<sup>839d</sup>

The exact base of the Cretaceous in this region is not known. The lowest fossiliferous Cretaceous beds are clearly near the base of the Upper Cretaceous, and the Dakota, as well as the Cretaceous beds which Darton has found beneath the Dakota in eastern Wyoming, if they exist in this region, are thus inferred to be represented in the upper part of the Beckwith formation. The top of the Cretaceous is likewise in doubt, involving, as it does in other parts of the Rocky Mountains, rather conflicting lines of stratigraphic and paleontologic evidence. In the present discussion the Cretaceous is made to terminate with the great dynamic revolution which interrupted the period of relative quiescence in this area, which extended without important interruption from the earliest Carboniferous to late Cretaceous time. These disturbances produced important folds and faults, involving the movement of these sediments through thousands of feet. This known portion of the Upper Cretaceous series has the enormous thickness of over 20,000 feet. Its fossils indicate that it contains the time equivalents of the Benton, Niobrara, Montana, and Laramie groups of the eastern section, but the natural lithologic subdivisions do not correspond with these faunal subdivisions and do not agree with those east of the Rocky Mountains. There is in this section an entire new member—the Bear River formation—characterized by brackish and fresh water forms, which, although attaining a great thickness, is essentially of local development.

Regarding the division line between the Cretaceous and the Eocene of southwestern Wyoming, Veatch<sup>839e</sup> makes the following statement:

In the Wasatch group as thus defined by Hayden the field work of the season of 1905 showed three divisions—(1) a basal member composed of reddish-yellow sandy clays, in many places containing pronounced conglomerate beds, which has been named the Almy formation; (2) a great thickness of light-colored rhyolitic ash beds containing intercalated lenses of white limestones with fresh-water shells and leaves, the Fowkes formation; and (3) a group of reddish-yellow sandy clays with irregular sandstone beds closely resembling (1) lithologically and separated from (1) and (2) by a pronounced period of folding and erosion. The last group has been called the Knight formation and is the horizon of the *Coryphodon* remains found in this vicinity. The Almy and Fowkes formations belong, with the Evanston, in the conformable series separated on the one hand by a pronounced period of folding and erosion from the Laramie beds, and on the other from the *Coryphodon* Wasatch beds by a period of folding and erosion of great magnitude though of much less importance than the one between the Adaville and the Evanston. The fossils from the Almy and Fowkes have, without exception, been considered Eocene, but the formations are treated with the Evanston because of their very intimate stratigraphic relation to it and the stratigraphic isolation of the Evanston, Almy, and Fowkes from the beds above and below. Whether it can ever be conclusively proved from the limited paleontologic data available that the line between the Cretaceous and Eocene should be drawn in this section between the Evanston and Almy, so that one great physical break will be thrown into the Cretaceous and the other secondary physical break into the Tertiary, is very doubtful. Stratigraphic geologists will, in the absence of very positive paleontologic data to the contrary, and none such exist at present, favor taking one physical break or the other for the line between the Cretaceous and Tertiary, preferably the earlier and greater one. The Knight formation is not in dispute and has therefore been treated under the Eocene.

The formations distinguished by Veatch in southwestern Wyoming have been identified and traced northward from the forty-second parallel to the Gros Ventre Range by Schultz.<sup>a</sup>

In the Wind River Basin, which lies northeast of the western Wyoming area just described and is separated from it by the Wind River Range, the stratigraphic

development of the Cretaceous is more like that of the Rock Springs dome and other areas farther north, though the upper beds are largely concealed by overlap of the Wind River Eocene. Woodruff<sup>948</sup> has described the part of the basin that is included within the Lander oil field and gives the following tabular description of the Cenozoic and Mesozoic formations:

*Geologic formations [Cenozoic and Mesozoic] in the Lander oil field.*

| Era.      | System.     | Series.               | Group.    | Formation.            | Character.                                                                                             | Thickness (feet).                                                       |             |

|           |             | Upper Cretaceous.     | Colorado. | Mancos shale.         | Drab sandy shale merging upward into moderately rusty very sandy shale.                                | 6,110.                                                                  |             |
|           |             |                       |           |                       | Dakota sandstone.                                                                                      | Massive ferruginous sandstone.                                          | 20 to 56.   |
|           |             | Lower Cretaceous (?). |           |                       | Shale, sandy, and sandstone in both massive and shaly beds and beds of conglomerate locally developed. | 400 to 410.                                                             |             |
|           |             | Jurassic (?).         |           |                       | Morrison formation.                                                                                    | Variegated sandy shale and conglomerate composed of water-worn pebbles. | 236 to 242. |
|           |             | Jurassic.             |           |                       | Sundance formation.                                                                                    | Olive-green fossiliferous limestone and shale.                          | 347 to 350. |
|           |             | Triassic (?).         |           |                       | Chugwater formation ("Red Beds").                                                                      | Sandy shale and massive sandstone.                                      | 1,500.      |

**K 13. NORTHERN COLORADO AND WYOMING.**

In northwestern Colorado Cretaceous strata outcrop between the pre-Cambrian of the Park Range and the Tertiary of the wide basin on the west. Just north of the fortieth parallel is the Yampa coal field, which has been examined by Fennerman and Gale.<sup>329</sup> They give the following section:

*Generalized columnar section in Yampa coal field, Colorado.*

|                                                                         |              |
|-------------------------------------------------------------------------|--------------|
| Cretaceous:                                                             | Feet.        |
| Laramie formation—sandstone and shale, with coal.....                   | 1,000        |
| Lewis shale—dark shale, calcareous layers.....                          | 1,000-2,000  |
| Mesaverde formation—sandstone, shale, and coal seams.....               | 2,500-3,500  |
| Mancos shale—dark shale, containing limestone and sandstone layers..... | 2,000-2,500± |
| Dakota formation—conglomerate and shale.....                            | 200±         |
| Jurassic-Triassic (?) "Red Beds" (Triassic to Carboniferous?).          |              |
| Archean (ancient crystalline and metamorphic rocks).                    |              |

The Dakota and Mancos present no special peculiarities. The Mesaverde, being the coal-bearing formation, was studied in detail and yielded the following generalized section:

*Generalized section of the Mesaverde formation in Yampa coal field, Colorado.*

|                                                                                                                                                   |              |
|---------------------------------------------------------------------------------------------------------------------------------------------------|--------------|
| Sandstones (occasionally massive) and shales, containing coal, especially in upper part (upper coal group).....                                   | Feet.<br>400 |
| Twentymile sandstone member.....                                                                                                                  | 75           |
| Weak sandstones and shales, with frequently a prominent ledge-making yellow sandstone about 250 feet from the top.....                            | 600          |
| Sandstones (occasionally massive), shales, and coals of the middle group.....                                                                     | 400          |
| Trout Creek sandstone member.....                                                                                                                 | 75           |
| Shales and weak sandstones, with few massive beds, containing in the lower part the upper seams of the lower group of coals.....                  | 400          |
| Massive sandstone, with subordinate shaly sandstones and shales, containing near the top the lower seams of the lower group of coals.....         | 750          |
| Slabby or shaly sandstones with some shales, frequently having greater strength at two or three horizons, on erosion giving rise to hogbacks..... | 750          |
|                                                                                                                                                   | 3,450        |

Above the coal-bearing Mesaverde lies the Lewis shale, a marine formation between 1,000 and 2,000 feet thick, which grades into the sandstones below and above by thin sandy strata. The Lewis is followed by the "Laramie," a terrane characterized by sandstones and coal beds, with shales, which occupies the stratigraphic position of the Laramie of adjacent areas but from which in this district no fossils have been obtained. A part of the "Laramie" is shown to have a thickness of 312 feet, but this is presumably but a small part of the thick terrane.

North of the Yampa field the Cretaceous outcrops range into Wyoming, on the southern boundary line of which Ball<sup>53a</sup> determined the following section:

*Section of Cretaceous rocks in the western portion of the Little Snake River coal field, Wyoming.*

| Formation.         |                      | Description.                                                                                                                                                                                                                               | Thickness (feet).   |                     |
|--------------------|----------------------|--------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|---------------------|---------------------|
|                    |                      |                                                                                                                                                                                                                                            | North end of field. | South end of field. |
| Laramie formation. |                      | Brown and gray shaly and concretionary sandstones and dark shale, with several beds of coal. In the southern end of the field the lower half is yellow, softer and more sandy and apparently contains little coal. Marine fossils in base. | 4,000               | 0-2,500             |
| Montana group.     | Lewis shale.         | Drab, slightly sandy, highly gypsiferous shale, with a few thin, soft sandstones. Not coal bearing.                                                                                                                                        | 1,600               | 2,300 (?)           |
|                    | Mesaverde formation. | Upper and lower members consist of heavy sandstone with a few interbedded shales. Intermediate member consists of shaly sandstone and shale. Upper member coal bearing.                                                                    | 2,500               | Bottom not seen.    |
|                    |                      | Dark-drab concretionary calcareous shale, with several thin, soft brown sandstones. Not coal bearing.                                                                                                                                      |                     | Bottom not seen.    |

Still farther north the following section of the Cretaceous in southern Wyoming west of Rawlins was observed by E. E. Smith<sup>752a</sup> in the Great Divide Basin coal field:

*Section of Cretaceous rocks of Great Divide Basin coal field, Wyoming.*

| Group.    | Formation.                 | Thickness (feet).   |                     | General characteristics.                                                                                                                                                                                                                                                                                                     |
|-----------|----------------------------|---------------------|---------------------|------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
|           |                            | South end of field. | North end of field. |                                                                                                                                                                                                                                                                                                                              |
| (?)       | Laramie.                   | 3,900±              | 1,050               | Alternating layers of yellowish-brown and white massive sandstones, thin brown sandstone, and drab, brown, and black shales. Sandstones are very resistant in southern portion. At north end the sandstones in the basal part are more resistant than those in the upper part and constitute prominent topographic features. |
| Montana.  | Lewis shale.               | 1,520±              | 520                 | In southern part of the area it consists of very dark drab shale with considerable gypsum and several thin layers of rusty sandstone. In the northern part of the area it consists of drab shale and soft yellowish-brown sandstone containing some thin layers of gypsum. Produces a region of low relief.                  |
|           | Mesaverde.                 | 3,600±              | 2,000±              | Near the top and at the base are two massive white sandstones which are resistant and form two prominent ridges or hogbacks. Between them is a soft brown sandstone interbedded with drab to brown shale.                                                                                                                    |
|           | (a)                        | 5,000±              | 4,000±              | Upper portion is exposed only at south end of field and consists of soft brown shaly sandstone interbedded with drab to brown shale. Lower portion consists of very dark drab calcareous shale, containing numerous thin, soft brown sandstones near the top. Produces areas of low relief.                                  |
| Colorado. | Frontier sandstone member. | 900±                | 500                 | Three massive yellowish-brown sandstones with dark shale between, containing numerous concretions. Upper sandstone is slightly conglomeratic.                                                                                                                                                                                |
|           | Mowry shale member.        | 700±                | 1,000               | Compact gray and black shales which break with conchoidal fracture and contain abundant fish scales.                                                                                                                                                                                                                         |
|           |                            | 30±                 | 20±                 | Massive yellowish-brown to pink sandstone resembling Dakota.                                                                                                                                                                                                                                                                 |
|           |                            | 100±                | 60±                 | Black shale which breaks with conchoidal fracture.                                                                                                                                                                                                                                                                           |
|           | Dakota sandstone.          | 100-150             | 100-175             | Massive yellowish-brown to pink sandstone, containing small chert pebbles near base. Locally quartzitic.                                                                                                                                                                                                                     |

<sup>a</sup> This formation is equivalent to the Niobrara and the basal shale portion of the Montana. A local name will probably be applied to it.

Regarding the formations, Smith remarks:

The coal-bearing formations show considerable change in character from the southern to the northern edge of the field. Those of the Cretaceous system thin rapidly toward the north and the outcrops of the beds of the undifferentiated Tertiary become more and more narrow, owing to the overlap of Wasatch conglomerate. The accompanying section [above] shows the thickness and general characteristics of the coal-bearing formations near the Union Pacific Railroad and in the gap between Whisky Peak and the Ferris Mountains.

East of Rawlins the Cretaceous strata extend around the Park and Medicine Bow ranges into the Laramie Plains. They surround the Fort Union (Tertiary) in the Hanna coal field of Carbon County. Veatch<sup>841</sup> has reported on the section, in which he found a marked unconformity between the "Lower Laramie" (equivalent to Laramie of Denver Basin) and the "Upper Laramie" (Lance formation). He gives the following classification:

*Generalized section of Cretaceous and Tertiary rocks of central Carbon County, Wyo.*

| System.             | Group.                      | Formation.                 | Thickness (feet).                | Characteristics.                                                                                                                                                                                                                              |                                                             |
|---------------------|-----------------------------|----------------------------|----------------------------------|-----------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|-------------------------------------------------------------|

|                     | Dakota.                     | 80-125                     | Coarse conglomeratic sandstones. |                                                                                                                                                                                                                                               |                                                             |

<sup>a</sup> It is the belief of Dr. T. W. Stanton that the Mesaverde and part of the Lewis also belong to the Pierre, as that formation is developed east of the Rocky Mountains. A local name will therefore probably be applied to this lowest division of the Montana in this region.

## K 14-15. IOWA AND MINNESOTA.

In Iowa the Cretaceous is represented by the Dakota sandstone and the Colorado group. The Dakota is exposed in the western part of the State where it was originally studied and was named from the town of Dakota, Nebr., on Missouri River. It is also penetrated in many artesian wells and has a thickness of 50 to 100 feet. The formation consists of more or less calcareous shale and sandstone, with thin bands of lignite.<sup>586</sup>

The Colorado exhibits a section of shale and chalky limestone, having near Hawarden, Iowa, a thickness of 50 feet but elsewhere ranging from a thin edge to 150 feet. The strata carry *Prionocyclus wyomingensis*, *Inoceramus labiatus*, and *Ostrea congesta*. Selenite is of common occurrence in the shales.

In Minnesota the Cretaceous is widely distributed over the western part of the State but so heavily covered by drift that but few outcrops appear. Hall<sup>394a</sup> gives a total of 500 feet of beds, white sandstone of the Dakota at the base and soft blue shale and incoherent sandstone of the Benton above.

## K 18. LONG ISLAND.

The Cretaceous strata which appear along the northern shore of Long Island have been carefully correlated with the New Jersey section by Veatch,<sup>837a</sup> who concludes that the "basal beds are the stratigraphic equivalents of the Raritan and are Upper Cretaceous. The Matawan beds are apparently well represented but their character changes going seaward" to gray sands and clays. "No greensand beds comparable to the great greensand marl beds of New Jersey have been found, their stratigraphic position being occupied by fine lignitiferous sand with occasional clay beds." Hollick<sup>460</sup> expresses another view.

## K 19. MASSACHUSETTS.

At Gay Head and elsewhere on the island of Marthas Vineyard are exposures of the Vineyard series of Shaler,<sup>728a</sup> which comprises Cretaceous strata and Miocene beds (unconformable?) upon them. Shaler says:

The Gay Head section consists of three divisions. The central part (that is, that part which faces nearly west) has a length of about 3,500 and an average height above the sea of about 80 feet. At the southern end of this section there is an exposure of about 2,000 feet in length, which trends toward the southeast. At the northern end of the principal section there is another short and incomplete section which trends nearly east and west. These three divisions constitute one great and nearly continuous sea cliff having a length of over 6,000 feet.

\* \* \* \* \*

The face of this cliff shows us a great number of thick, steeply inclined beds of sand, clay, and lignitic matter, of extremely vivid and contrasted colors. The colors range from the dazzling white of the sandy beds to the nearly pure black of the carbonaceous layers, with intermediate hues of brown, green, yellow, and red. \* \* \*

The orderly arrangement of the beds in the section is greatly masked by the continued slipping of large wedges of the deposits down the steep incline of the talus. When we apply a correction for this slipping the beds are seen to lie in a tolerably regular order, dipping usually to the northeast, with inclinations varying in general from 20° to 60° of declivity but rising in one place to 90°.

In 1890 Shaler was able to reexamine the section at Gay Head, then more clearly exposed by exceptional rains, and determined that the strata were closely folded, not monoclinical. He distinguished certain divisions of the "Vineyard series" as follows:<sup>730a</sup>

The section at Gay Head is apparently divisible into two tolerably distinct elements, viz, a lower division, the upper limits of which are not determined, which is likely to prove of Cretaceous age; and an upper part of the section, which from the fact that it contains bones of cetaceans is likely to prove of Tertiary age—the two together forming the greater part of the longitudinal section of Gay Head. Above these two more ancient portions of the escarpment lies an extended series of unfossiliferous sands, which apparently belong to a somewhat later age than the other portion of the section. To this age we may also presumably assign the extensive series of beds exhibited in the Weyquosque series. These later-formed beds are, at least in the Weyquosque cliffs, deposited unconformably upon the earlier series. A portion of these later unfossiliferous sands are involved in the contortions at Gay Head, and a portion of them lie unconformably upon the edges of the beds which were involved in the dislocation. It seems likely, therefore, that this later series will in the end be found divisible into two parts—a portion which was laid down before and a portion formed after the greater part of the disturbance had been effected.

Shaler was in doubt as to the age of the different divisions. White<sup>894</sup> identified a number of Cretaceous plants from "several localities and horizons in the Vineyard 'series.'" Dall<sup>209</sup> described Miocene faunas apparently from the same closely folded strata, and Pliocene forms from sands which lie unconformably upon them. (See Chapter XVII, p. 823.)

Supposed Cretaceous clays have been reported in well borings in Boston. W. O. Crosby<sup>184</sup> was the first to suggest that these clays were pre-Pleistocene. Later F. G. Clapp<sup>139</sup> reported these distinctive clays from several wells in Boston, and discussed in detail the boring at Ames Building, the samples of which he examined critically. The following log and notes are taken from Clapp's paper:

*Record of boring at Ames Building, Boston.*

|                                                                   | Thickness.   | Depth.       |
|-------------------------------------------------------------------|--------------|--------------|
|                                                                   | <i>Feet.</i> | <i>Feet.</i> |
| Coarse sand and gravel . . . . .                                  | 17.          | 17           |
| Sand . . . . .                                                    | 1            | 18           |
| Gravel and sand . . . . .                                         | 5            | 23           |
| Coarse gravel and white clay . . . . .                            | 3            | 26           |
| Stony sand, gravel and clay with much water (very hard) . . . . . | 16           | 42           |
| Blue clay . . . . .                                               | 18           | 60           |
| Fine sand . . . . .                                               | 5            | 65           |
| Clay, sand, and gravel, with water (till) . . . . .               | 12           | 77           |
| Hard dry nearly white clay, with boulders . . . . .               | 136          | 213          |
| Slate (Carboniferous) . . . . .                                   | 15           | 228          |

The material below 77 feet is dry and in a previous boring had been called rock and not entered by the drill. All the samples of this bed were seen by the writer and found to consist mostly of a very fine grained gray to white clay, which became plastic when wet. It varied from very soft and putty-like to nearly as hard as the underlying slate. The material when examined by Dr. W. T. Schaller, of the United States Geological Survey, was found to consist of SiO<sub>2</sub>=59.18 per cent and (Al<sub>2</sub>O<sub>3</sub>, Fe<sub>2</sub>O<sub>3</sub>, P<sub>2</sub>O<sub>5</sub>, TiO<sub>2</sub>)=27.11 per cent, thus being a very pure clay. \* \* \*

This clay is important for the reason that it is unlike the general type of clay found at Boston. All the Pleistocene clays of the vicinity are of blue-gray to brown or buff colors; this clay is light gray to nearly white. The Pleistocene clays contain numerous bowlders and pebbles composed of all kinds of rock found in New England, but in this clay only two bowlders have been discovered, and these consist of rock only found in the vicinity of Boston, and which forms the bedrock of the region. The Pleistocene clays are interstratified with glacial deposits; this clay rests on bedrock and is separated from the overlying Pleistocene clay by a bed of till. This clay is much dryer than the overlying Pleistocene clay. \* \* \*

Samples of the white clay from the Ames Building boring were compared at the office of the United States Geological Survey with samples of clay collected by Mr. Veatch from a number of borings on Long Island, New York, and found to agree very closely with them in appearance. Mr. Veatch has correlated the Long Island deposits with the Raritan formation of New Jersey. If this correlation is correct, it is possible that the Boston deposits may be of similar age. This is rendered more probable by the similarity of the material in the Boston borings to some of the clays on Marthas Vineyard.

K-L 12-13. NORTHERN WYOMING.

The Bighorn Basin, in northern Wyoming, is surrounded by Cretaceous strata which Fisher<sup>331b</sup> described under the names Morrison, Cloverly, Colorado, Pierre, and Laramie and associated formations. Recent surveys by Woodruff<sup>947a</sup> yield the following section of the southwestern portion of the Bighorn Basin :

*Section along Shoshone River near Cody, Wyo.*

| System.     | Formation.             | Thickness (feet).         | Characteristics.                                                                                                                                                      |                                                                                                                                                                           |
|-------------|------------------------|---------------------------|-----------------------------------------------------------------------------------------------------------------------------------------------------------------------|---------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| Tertiary.   | Wasatch formation.     |                           | [See p. 774.]                                                                                                                                                         |                                                                                                                                                                           |
|             | Unconformity.          |                           |                                                                                                                                                                       |                                                                                                                                                                           |
|             | Fort Union formation.  | 3,100                     | [See p. 774.]                                                                                                                                                         |                                                                                                                                                                           |
| Cretaceous. | Unconformity (?)       |                           |                                                                                                                                                                       |                                                                                                                                                                           |
|             | Laramie (?) formation. | 2,630                     | Dull green sandy shale with local brown leaf-bearing beds and gray massive sandstone.                                                                                 |                                                                                                                                                                           |
|             | Montana group.         | Undifferentiated Montana. | 760                                                                                                                                                                   | In lower part gray massive sandstone and dark-colored sandy shale in alternating layers; in upper part dark and light gray shale alternating, and numerous lignitic beds. |
|             |                        | Eagle sandstone.          | 220                                                                                                                                                                   | Gray massive sandstone, weathering tan, and gray sandy shale with dark coaly bands. Locally coal bearing.                                                                 |
|             | Colorado shale.        | 3,375                     | Black to dark-gray shale with rusty sandstone at base and gray massive sandstone at short intervals in lower half. Thin beds of coal occur a little below the middle. |                                                                                                                                                                           |
|             | Cloverly formation.    | 300                       | Gray, green, and maroon shales and gray compact sandstone.                                                                                                            |                                                                                                                                                                           |

As shown in the above table, the thickness of sandstone and shale between the top of the Colorado formation and the great unconformity at the base of the Wasatch formerly mapped by Fisher<sup>a</sup> as "Laramie and associated formations" is here tentatively subdivided into Eagle, undifferentiated Montana, Laramie (?), and Fort Union. These formations are suggested on

<sup>a</sup> Fisher, C. A., Prof. Paper U. S. Geol. Survey No. 53, 1906, p. 8.

lithologic and paleontologic evidence. \* \* \* At the beginning of the field season, in the absence of definite fossil evidence, differences in lithology alone were accepted as a basis for the subdivision into formations. A subsequent study of the fossils, both in the field and in the laboratory, by T. W. Stanton and F. H. Knowlton, has shown that the lithologic units do not coincide in all particulars with the formations as they are recognized farther north and elsewhere. Fossils collected at various localities in the fields point to the presence of the Eagle and Laramie formations, though the evidence is not conclusive, as many of the species are either new or heretofore unknown to the formations, and strictly characteristic specimens are lacking. A fresh-water fauna which contains forms suggestive of upper Montana occurs in beds between the Eagle and Laramie (?). There is abundant fossil evidence to prove the presence of the Fort Union formation. A suggestive break occurs at the base of the conglomerate beds noted in the table, which was thought in the field to be an unconformity at the base of the Fort Union, but later study of the plant collections shows that Fort Union forms occur a few feet below this horizon. As the final determinative evidence has not been obtained, the divisions shown in the table are only provisionally introduced.

For notes on the northeast side of the Bighorn Basin, see L 12-13 (p. 690).

#### K-L 13. SOUTH DAKOTA AND NORTHWESTERN NEBRASKA.

Darton <sup>232, 233, 237, 238</sup> has described the strata of South Dakota and northwestern Nebraska in several publications. In the Newcastle folio <sup>236</sup> he gives the local development of the Cretaceous as follows :

| Upper Cretaceous:                                                                                        | Feet.   |
|----------------------------------------------------------------------------------------------------------|---------|
| ◊ Laramie formation—massive soft buff sandstone with concretions and carbonaceous shales.                | 800     |
| Fox Hills formation—thin hard sandstone in sandy shale, and soft clayey sandstone below.                 | 75-150  |
| Pierre shale—dark gray shale or clay with concretions containing many fossils.....                       | 1,250   |
| Niobrara formation—gray calcareous shale, and impure chalk.....                                          | 200     |
| Carlile formation—variable gray shale.....                                                               | 700     |
| Greenhorn limestone—thin bedded, hard gray limestone, with <i>Inoceramus labiatus</i> .....              | 50      |
| Graneros formation—dark shale.....                                                                       | 1,000   |
| Dakota sandstone—gray to buff sandstone mostly very massive.....                                         | 50-100  |
| Lower Cretaceous:                                                                                        |         |
| Fuson formation—gray to red shales with thin sandstones.....                                             | 15-30   |
| Lakota sandstone—massive cross-bedded gray to buff sandstone, with local coal beds and conglomerate..... | 150-200 |
| Morrison shale—massive sandy shale and fine sandstone.....                                               | 150     |
| Unconformity.                                                                                            |         |

#### L 10. WESTERN WASHINGTON.

Cretaceous sandstones are supposed to form a large part of the Olympic Peninsula, in Washington. Arnold <sup>29a</sup> examined them on the western coast and states:

The rocks supposed to be Cretaceous in age, the correlation being based on their stratigraphic position and lithologic character, are confined to the western coast of the peninsula. They extend over most of the territory from 1½ miles south of Point of the Arches to 1 mile north of Cape Elizabeth and consist almost entirely of a coarse gray sandstone, with occasional zones of black shale and rarely a little conglomerate. The thickness of the formation is probably over 5,000 feet, although, owing to its complex structure, this is only a very rough approximation.

#### L 10-11. JOHN DAY BASIN, OREGON.

(See Chapter XIV, p. 621.)

#### L 12-13. EASTERN IDAHO, NORTHWESTERN WYOMING, AND MONTANA.

Cretaceous strata occur here and there in the Yellowstone Park and vicinity. Stanton <sup>779</sup> reported on the strata and their correlation and showed that representatives of the Colorado and Montana are present. Certain strata which were

doubtfully referred to the Dakota are now<sup>a</sup> regarded as in part referable to the Kootenai and in part probably to the Bear River.

In an unpublished manuscript F. C. Calkins describes and correlates the Colorado formation in the Philipsburg quadrangle, Montana, as follows:

Immediately above the Kootenai formation in the Philipsburg district is a very homogeneous accumulation of fissile black shale whose upper part contains thin beds of low-grade coal near Drummond. On Mount Princeton the shale is about 450 feet thick. The greater part of the shale is barren of fossils, but according to Dr. Stanton it lithologically resembles the Colorado shale of areas farther east. Immediately above the coal near Drummond a *Unio* which may be of Colorado age was found.

At the top these shales pass by a rapid gradation into beds dominantly arenaceous, attaining a thickness of more than a thousand feet. They consist mainly of greenish flaggy sandstones but comprise considerable shale and several beds of conglomerate.

In the lower part of the sandstone on Mount Princeton and about 4½ miles east of Drummond, very imperfect specimens doubtfully referred by Dr. Stanton to *Mactra* and *Callista* were collected which appear to be of Colorado age. About 1½ miles southeast of Drummond a small collection of plants from a horizon a few hundred feet above the base of the sandstones is reported upon as follows by Dr. Knowlton:<sup>b</sup>

"There are three things in this little collection—a *Marchantia* which is probably new, a conifer which is probably a *Glyptostrobus*, and a fern that is pretty close to if not identical with *Aspidium oerstedii* Heer. The latter is from Patoot, which = Senonian = Fox Hills. I can not place this material definitely, but should incline to regard it as possibly Upper Cretaceous."

In 1910 Mr. Pardee collected more satisfactory fossils from a limestone outcrop in Coberly Gulch, 10 miles north-northwest of the northeast corner of the quadrangle. The exact position of the horizon is not known; the limestone bed, however, is underlain by about 400 feet of sandstone and shale similar to those above the black shale, so that it is virtually certain that the fossils occur at least 400 feet stratigraphically above the main body of black shale.

The list of forms identified by Dr. Stanton and his comment on them follows:

6552. Specimen No. 10-P, 4. NE. ¼ NW. ¼ sec. 34 and SW. ¼ sec. 27, T. 10 N., R. 12 W., Granite County, Mont.  
*Modiola* sp.  
*Cyrena securis* White.  
*Corbula* sp.  
*Glauconia coalvillensis* Meek.  
*Admetopsis subfusiformis* Meek.

"The horizon is in the Colorado group. The same association of forms occurs in the Oyster Ridge sandstone member of the Frontier formation of southwestern Wyoming."

By way of summary it may be said that lithologic and paleontologic evidence put the correlation of the black shale and about 400 feet of the overlying beds with the Colorado beyond reasonable doubt. It is probable, however, that some beds of Montana age occur in this district.

Calvert<sup>115</sup> describes the Cretaceous of the Lewistown coal field, in central Montana, as follows:

The Lewistown coal field \* \* \* lies between longitude 109° and 110° 15' west, and the 47th parallel divides it into two nearly equal portions. It is thus located in the center of Montana, including the west-central part of Fergus County and a few square miles of north-eastern Meagher County. The greater part of the field lies in the Judith Basin, a name applied to the upper drainage area of Judith River. \* \* \* The Little Belt and Big Snowy mountains are in the southern part of the field and the Judith and South Moccasin groups lie well within its northern borders. The area as described includes about 1,500 square miles. \* \* \*

The rocks of the Lewistown coal field range in age from lower Carboniferous to Quaternary, inclusive. \* \* \* The succession of the rocks and the relation of the principal coal-bearing beds to strata above and below are shown in the following generalized section:

| Claggett formation (Upper Cretaceous): White and brown sandstone in lower part and greenish sandy shale above. |       |
| Eagle sandstone (Upper Cretaceous):                                                                            |       |
| Shale, dark bluish, containing carbonized wood fragments . . . . .                                             | 5     |
| Sandstone, soft, yellowish, cross-bedded, containing iron concretions and woody fragments..                    | 53    |
| Sandstone, soft, white, usually without bedding.....                                                           | 170   |
| Sandstone, white, with coaly layer at top.....                                                                 | 10    |
| Colorado shale (Upper Cretaceous):                                                                             |       |
| Shale, dark gray to black, with a few thin sandy members . . . . .                                             | 720   |
| Sandstone, hard, greenish, weathering brown, fine grained, ferruginous.....                                    | 3     |
| Shale, dark gray to black, with a hard bed 420 feet above base.....                                            | 675   |
| Sandstone, grayish brown, thinly bedded, containing an abundance of fish scales (supposed Mowry).....          | 47    |
| Shale, dark gray to black, alternating hard and soft layers.....                                               | 890   |
| Sandstone and shale, alternating, brownish in color throughout.....                                            | 25    |
| Kootenai formation (Lower Cretaceous):                                                                         |       |
| Shale, maroon, argillaceous.....                                                                               | 200   |
| Sandstone, grayish, coarse grained, cross-bedded.....                                                          | 8     |
| Shale, maroon, argillaceous.....                                                                               | 60    |
| Sandstone, gray, coarse grained, cross-bedded . . . . .                                                        | 25    |
| Shale, maroon, argillaceous.....                                                                               | 72    |
| Sandstone, massive, coarse grained to pebbly, weathering soft gray . . . . .                                   | 50    |
| Coal and coaly shale.....                                                                                      | 10    |
| Shale and sandstone, alternating; the shale is sandy and the sandstone thinly bedded. . . . .                  | 87    |
| Morrison formation (Jurassic?).                                                                                |       |

The above section, being compiled from measurements made in several places in the field, should not be considered as a type of any one locality.

The Colorado shale decreases in thickness northward from the Big Snowy Mountains, for a section of that formation to the south of the uplift shows that the interval between the Kootenai red shale and the Eagle sandstone is 2,400 feet, whereas the same interval 15 miles northeast of Lewistown is less than 1,600 feet.

Throughout the field the Kootenai is fairly uniform in thickness, although the individual members comprising the formation vary locally. As a formation it is readily distinguished by the bright maroon-colored shales and by the coarsely cross-bedded sandstone just above the coal.

In 1908 Stone <sup>798</sup> gave an account of the Cretaceous and Tertiary rocks surrounding the Crazy Mountains, west of longitude 115°. Further studies in 1908-9 by Stone and Calvert <sup>799</sup> led to a revision of the classification and nomenclature, which is expressed in the following table and notes abstracted from their report:

*Stratigraphy of the Upper Cretaceous and early Tertiary in the vicinity of the Crazy Mountains, Montana.*

|                                                                                                                                                                                                      |                                                                                          |
|------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|------------------------------------------------------------------------------------------|
| Fort Union formation, 4,000+ feet: Massive sandstones and intercalated shales.                                                                                                                       | } Livingston formation as originally defined for a lithologic unit (andesitic material). |
| Lebo andesitic member, 450-2,200 feet: Fort Union fossils; Torrejon mammals.                                                                                                                         |                                                                                          |
| Lance formation ("Laramie" or "Ceratops beds"), 1,000-2,400 feet: Light-gray sandstone and variegated shales. (Stanton thinks equivalent to Laramie of Denver Basin. Knowlton thinks is Fort Union.) |                                                                                          |
| Lenep sandstone, 250-460 feet: Dark-colored sandstone with intercalated shales. Few fossils. Not definitely correlated with Fox Hills sandstone.                                                     |                                                                                          |
| Bearpaw shale.                                                                                                                                                                                       |                                                                                          |
| Judith River formation.                                                                                                                                                                              |                                                                                          |
| Claggett formation.                                                                                                                                                                                  |                                                                                          |
| Eagle sandstone. Livingston flora nearly through this sandstone.                                                                                                                                     |                                                                                          |
| Colorado.                                                                                                                                                                                            |                                                                                          |
| Kootenai (Lower Cretaceous).                                                                                                                                                                         |                                                                                          |
| Jurassic.                                                                                                                                                                                            |                                                                                          |

The following notes give the substance of Stone and Calvert's remarks, though not a literal quotation.

In the upper valley of Musselshell River and north of the Crazy Mountains the basal Cretaceous rocks belong to the Kootenai formation, which rests conformably on the Morrison formation. The Kootenai is 235 feet thick, is composed of shale and sandstone, and is not coal bearing. It is overlain conformably by Colorado shale, about 1,300 feet thick, prevailingly dark colored and carrying marine invertebrates.

The four formations of the Montana group, Eagle, Claggett, Judith River, and Bearpaw, are found here. The Eagle is mainly massive sandstone, about 200 feet thick, and in some places carries coal which usually is unworkable. The Eagle is a conspicuous ledge or ridge maker. The Claggett is composed of dark shales and white to light-brown sandstones of marine and brackish-water origin, from 400 to 800 feet thick, and is overlain by the Judith River formation, which has about the same range in thickness. The Judith River is prevailingly of fresh-water origin, carries thin beds of coal, and has fossil shells, bones, and wood.

Above the fresh-water Judith River is the upper marine Cretaceous shale, 700 to 1,000 feet thick, known as the Bearpaw shale. This shale is commonly dark-colored and has fossiliferous limy nodules. The Cretaceous section is normal to the top of the Bearpaw. Resting on these marine shales and evidently of a transitional nature is about 300 feet of dark-colored fresh and brackish water shale and sandstone. The stratigraphic relation of these beds is like that of the Fox Hills sandstone, but enough fossils have not yet been obtained to make the correlation positive. These beds are more or less tuffaceous.

There is some question as to the age of the overlying Lance formation, which is 1,000 to 2,400 feet thick and composed of light-colored fresh-water sandstone and shale. The paleobotanic collections are ascribed by Knowlton to the Fort Union, but the vertebrate and invertebrate fossils point to Cretaceous age for the same beds. There is no doubt that they should be in part correlated with the "Ceratops beds," but whether the latter are Cretaceous or Tertiary is as yet unsettled.

Resting conformably on the Lance formation is another series of tuffaceous sandstones and shales. The beds are about 2,200 feet thick at the north end of the Crazy Mountains and 460 feet on Fish Creek northeast of the mountains. They are of Fort Union age and will be described in future papers as the Lebo andesitic member of the Fort Union formation.

The youngest consolidated strata in the Crazy Mountains are the massive sandstones and shales of the Fort Union formation. They are of fresh-water origin and are shown to be Tertiary both by plant and by animal remains. The thickness is unknown but exceeds 4,000 feet.

At the north end of the Crazy Mountains the Upper Cretaceous formations gradually lose their distinctive lithologic characteristics, and all from the Eagle to the massive sandstones of the Fort Union become merged into a single series of tuffaceous beds several thousand feet thick and constituting a single lithologic unit. On the west side of the Crazy Mountains, therefore, the Eagle sandstone is overlain conformably by a great series of sediments more or less andesitic in composition

and varying in age from lower Montana to Tertiary. These in turn are overlain by the Fort Union.

The Kootenai (Lower Cretaceous) and Colorado formations extend northward from the fields described and have been traced around the Big Belt Mountains, according to Fisher,<sup>332b</sup> who says (see also Chapter XIV, pp. 621-623):

The Colorado shale rests with apparent conformity upon the underlying Kootenai and is overlain conformably by the Eagle sandstone, the lowest member of the Montana group. Although conformable relations appear to exist between the Kootenai and Colorado formations in this region, the Dakota, which occupies a position between these two formations in other localities, is, as previously stated, believed not to be present. If this is true, there is a hiatus at this contact representing at least several hundred feet of beds. It is possible that Dakota time is here represented by marine sediments not easily separable from the Colorado shale.

The Upper Cretaceous section of central Montana was established by Stanton and Hatcher,<sup>785</sup> from whose report the following general facts are abstracted:

The Benton (or more properly the Colorado, as more than the Benton is included) consists of dark clay shales with intercalated bands of sandstone, especially in the upper portion, and frequent calcareous concretions. The fossils of the lower portion are *Inoceramus labiatus*, *Scaphites warreni*, and others. The upper part yields *Inoceramus umbonatus*, *I. exogyroides*, *Pholadonya papyracea*, *Scaphites ventricosus*, *Baculites asper* (?), and many other forms. The total thickness is estimated at 800 feet.

Immediately above the Colorado is the Eagle formation. At its base the Eagle consists of sandstones and shale which grade into the underlying shale, but its conspicuous member is a massive light-colored cross-bedded sandstone, more than 100 feet thick. Above this member are softer beds of sandstone together with shale and lignite. Fossils are scarce but include, of invertebrates, *Cardium speciosum*, *Thetis ?circularis*, *Mastra alta*, *Placenticerus whitfieldi?*, and others, and, of vertebrates, remains of the dinosaur *Ornithomimus grandis*. The thickness is probably 300 feet or more.

The Claggett formation is a body of dark clay shales, about 400 feet thick, which rests on the Eagle. In the upper part are yellow sandstone beds, and the passage into the Judith River is by gradual transition. The lower part of the Claggett contains *Gervillia borealis*, *Baculites ovatus*, *Baculites compressus*, and other characteristic Pierre forms. The sandstone beds contain a fauna which "has long been considered a typical 'Fox Hills' fauna." Stanton concludes that "faunas similar to that of the Fox Hills sandstone have a great vertical range and are likely to be found at any horizon within the Montana group where a littoral or shallow-water facies is developed."

The Judith River consists chiefly of fresh-water deposits together with layers laid down in brackish water, especially near the top. There are also local marine beds. Workable coals occur in the upper portion. The thickness is about 500 feet. Extended descriptions of the Judith River formation are given in the bulletin cited.

The Bearpaw shales are marine and succeed the prevailingly fresh-water Judith River. They are dark clays which include many calcareous concretions. The thickness is estimated at 750 feet. The commoner forms in the varied invertebrate fauna are listed in Stanton and Hatcher's report.

The grounds for distinguishing the Eagle, Claggett, Judith River, and Bearpaw formations as divisions of the Montana group are fully stated, their correlations are discussed, and special reports on the faunas and the flora are presented.

The distribution of the Cretaceous and early Tertiary in eastern Montana is shown as determined by the special surveys of coal fields<sup>a</sup> and reconnaissances connecting them.

Notes relating to the development of the sequence in particular fields (Lewis-town coal field, Crazy Mountains, Livingston district, and Great Falls coal field) are given elsewhere in this chapter.

For the northeast side of the Bighorn Basin, Washburne<sup>867</sup> determined the following section of the Cretaceous. (For Tertiary, see p. 775.)

*Cretaceous rocks on northeast side of Bighorn Basin.*

| Series.               | Group.   | Formation.                          | Thickness (feet). | Characteristics.                                                                                                                                                             |
|-----------------------|----------|-------------------------------------|-------------------|------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| Upper Cretaceous.     | Montana. | Laramie (?) formation. <sup>a</sup> | 150-700           | Massive sandstone with subordinate shale. Contains workable coal.                                                                                                            |
|                       |          | Bearpaw shale.                      | 150               | Dark marine shale.                                                                                                                                                           |
|                       |          | Judith River formation.             | 300-400           | Variegated clays and soft sandstone.                                                                                                                                         |
|                       |          | Claggett formation.                 | 400-500           | Massive fresh and brackish water sandstones and dark shale. Coal not workable.                                                                                               |
|                       |          | Eagle sandstone.                    | 150-225           | Massive fresh and brackish water sandstones, separated by carbonaceous shale. Contains workable coal.                                                                        |
|                       |          | Colorado shale.                     | 4, 400            | Dark shale with one or two conspicuous sandstones, not divisible in this field, though more than 1,500 feet of the lower part is known to be equivalent to the Benton shale. |
| Lower Cretaceous (?). |          | Unconformity                        |                   |                                                                                                                                                                              |
|                       |          | Cloverly.                           | 0-275             | Bright-colored clays, with massive sandstones at the top and bottom. Coal not workable.                                                                                      |

<sup>a</sup> The evidence is not sufficient to class this formation as undoubted Laramie, consequently the term is used throughout this report in a questionable sense.

In the wide basin southeast of the Bighorn Mountains near longitude 106° and latitude 43° the general section of the Cretaceous is, according to Shaw:<sup>735a</sup>

Cretaceous:

Montana—upper two-thirds principally sandstone with coal; lower third dark shale with no coal.

Colorado—mostly dark-brown shale with some brown sandstone layers, and at the top a buff to white sandstone, which may be Niobrara. Near the base is the Mowry member, a very resistant dark shale which weathers white.

Cloverly—massive, brown, resistant sandstone, which commonly forms a pronounced hogback.

Near the top there is some shale, and at the bottom a fine conglomerate.

<sup>a</sup> Bull. U. S. Geol. Survey No. 316, 1907; No. 341, 1909.

Of the formations Shaw writes as follows:

The coal-bearing rocks described above are unconformably overlain by Tertiary and Quaternary formations. The White River, a Tertiary formation of white sandy clay and conglomerate, covers a considerable area in the southeastern part of the field. It is spread over parts of all the older formations, and is even found high up in the mountains. The so-called Chalk Buttes, 3 miles southwest of Douglas, are also composed of Tertiary rocks, and the outcrop of similar rocks extends westward for 25 miles along the foot of the mountains.

L 13-14. SOUTH AND NORTH DAKOTA.

A representative section of the Cretaceous of the Great Plains northeast of the Black Hills is given by Darton.<sup>245</sup>

*Generalized section [of Cretaceous] for the Belle Fourche quadrangle, South Dakota.*

Thin sandstone near bottom.                                                                                                                                                                                                                                                         |
|                         |                   | Greenhorn limestone.                                         | Impure gray slabby limestone with shale intercalations.                                                                                                                                                                                                                                                                                                 |
|                         |                   | Graneros shale.                                              | Gray fissile shale with scattered concretions. Thin bed of sandy limestone near middle and bentonite near base. Mowry shale member, composed of hard gray shale and fine-grained sandstone, weathering light gray and containing numerous fish scales. Local bed of sandstone. Dark fissile shale with concretions and thin sandstone layers near base. |
|                         | Dakota sandstone. | Gray to brown sandstone, mostly massive below, slabby above. |                                                                                                                                                                                                                                                                                                                                                         |
|                         | Lower Cretaceous. | Fuson formation.                                             | Gray to purple sandy shale and thin sandstones.                                                                                                                                                                                                                                                                                                         |
|                         |                   | Lakota sandstone.                                            | Gray to buff sandstone, massive to flaggy, mostly hard.                                                                                                                                                                                                                                                                                                 |
| Cretaceous or Jurassic. |                   | Morrison shale.                                              | Massive sandy shale, greenish gray to maroon.                                                                                                                                                                                                                                                                                                           |

Leonard<sup>532</sup> recognizes in the Upper Cretaceous of North Dakota the Laramie, Montana (Fox Hills and Pierre), Colorado (Niobrara and Benton), and Dakota. He describes the strata in detail, but they present no special peculiarities.

In a later discussion of this area<sup>533</sup> Leonard refers the Laramie of his previous report to the Lance and Fort Union formations and says concerning the strata of the Lance formation that "they have the same stratigraphic position as the Laramie formation, with which they correspond in whole or in part."

## M 9-10. VANCOUVER ISLAND.

The Cretaceous of Vancouver Island forms three areas—the Nanaimo, Comox, and Quatsino, named from southeast to northwest. There are local differences of stratigraphy among the basins, but in general the terrane closely resembles that of Queen Charlotte Island, except that the two lower formations of that island are lacking on Vancouver. Dawson <sup>256b</sup> states:

In the northern part of Vancouver Island the Cretaceous which still remains appears to consist of outliers of a distinct and older basin and may probably be regarded as having been originally continuous with that developed in the Queen Charlotte Islands. The Cretaceous rocks of Quatsino Sound have so far afforded the best sections, and in these we appear to find the three higher members of the Cretaceous section of the Queen Charlotte Islands, as it exists in the vicinity of Skidegate Inlet. \* \* \* In comparing these with the corresponding rocks of the Queen Charlotte Islands it is probable that the thickness of the Quatsino beds is somewhat less and that the conditions met with in the lower or coal-bearing portion of the series are more distinctly littoral at Quatsino, sandstones and conglomeratic layers being relatively more important. The Cretaceous rocks which extend along the northeast shore of Vancouver Island, from Port McNeill to Beaver Harbor, may in part represent the lowest or coal-bearing portion of the Quatsino section. A few fossil plants obtained from Beaver Harbor are Middle Cretaceous and possibly referable to a horizon near that of the lowest beds at Quatsino, but are regarded by Sir William Dawson as distinctly newer than these, though possibly older than much larger collections since made at Port McNeill, which have not yet been worked up in detail, the Nanaimo and Comox Cretaceous floras. It is thus evident that we have not merely a single horizon to deal with along this part of the northeast coast. No trace of the lower subdivisions represented at Skidegate (D and E) has yet been found on Vancouver Island.

The relations of the Cretaceous rocks of the Queen Charlotte Islands and those of the northern part of Vancouver Island, as now understood, may be expressed as below, in tabular form:

|                    | Queen Charlotte Islands.                                                                                                                                         | Northern part of Vancouver Island.                                                                  |
|--------------------|------------------------------------------------------------------------------------------------------------------------------------------------------------------|-----------------------------------------------------------------------------------------------------|
| Upper Cretaceous.  | A. Upper shales and sandstones, 1,500 feet.                                                                                                                      | A. Port McNeill beds (?).<br>Upper shales.                                                          |
| Middle Cretaceous. | B. Coarse conglomerates, 200 feet.<br>C. Lower shales and sandstones, with coal, 5,000 feet.<br>D. Agglomerates, 3,500 feet.<br>E. Lower sandstones, 1,000 feet? | B. Coarse conglomerates.<br>C. Lower sandstones and shales with coal.<br>D. Wanting.<br>E. Wanting. |

In the course of the examination of the Cretaceous rocks of the northern part of Vancouver Island, it has been found that these rest unconformably on a rough and irregular denudation surface of the older rocks. \* \* \* Owing to this circumstance the higher Cretaceous beds successively overlap the older rocks, and as the areas of these beds which have escaped subsequent denudation are probably to a great extent those which have filled the deeper portions of the hollows, it follows that the actual outcropping edges of the beds rarely give a complete section of the entire thickness of the formation.

In 1873 Richardson <sup>671</sup> made a report on the Nanaimo and Comox fields, which contains numerous detailed sections of the Cretaceous strata. Dawson <sup>259</sup> summarizes the facts as follows:

The rocks accompanying the coals are sandstones, conglomerates, and shales, being largely of the character of littoral formations but also containing, particularly in the shaly members of

the series, truly marine fossils. They hold also in some layers abundance of fossil plants, and in appearance and degree of induration much resemble the older Carboniferous rocks of some parts of eastern America. Coals of a workable character have been found only in the lower part of the Cretaceous series, which is represented with closely similar characters in the Comox and Nanaimo areas. The somewhat variable character of the Cretaceous measures as a whole is, however, shown by the fact that Mr. Richardson found it necessary to adopt a different scheme of subdivisions for the two areas, notwithstanding their general correspondence. The sections at Comox and Nanaimo are as follows, in descending order:

| Comox.                        |              | Nanaimo.                                  |              |

| Productive coal measures..... | 739          |                                           |              |
|                               | 4,911        |                                           | 5,266        |

The age of the productive coal measures of Nanaimo and Comox is approximately that of the Chico group of California, in which, however, in its typical locality, coals are not found.

**M 11. CANADIAN ROCKIES, ALBERTA AND BRITISH COLUMBIA.**

George M. Dawson<sup>255b</sup> classified and described the Cretaceous of the Canadian Rockies as follows:

The sections representing the upper part of the Cretaceous rocks of the mountains are, unfortunately, very unsatisfactory, the best being that of the Northwest Branch. \* \* \* The volcanic beds are there followed by dark shales which afford a few fossils referred to the Benton group and are estimated to attain a minimum thickness of 1,400 feet. Above these are sandstones and shales, generally of pale tints and possibly several hundred or a thousand feet in thickness, which are supposed to represent the Belly River series of the plains to the eastward. A concealed area beyond these is presumed to be underlain by the Pierre shales, and still higher in the section are beds referable to the base of the Laramie, with characteristic fossils. The thickness of the Laramie at this place is indeterminate but must be considerable. \* \* \*

A provincial general representation of the Cretaceous beds of the mountains of this region, as compared with those of the plain to the east, may be given as follows, in descending:

|                    | Rocky Mountains.                                                      | Foothills and plains.                                                                          |

|                    | Dakota and upper part of Kootanie series to coal-bearing horizon..... |                                                                                                |
|                    | Lower part of Kootanie series.....                                    |                                                                                                |
|                    | 13,350                                                                | 8,290                                                                                          |

T. W. Stanton comments as follows on the foregoing section:

The lower part of the strata Dawson referred to the Kootenai in this region doubtless includes some marine Jurassic. (See Whiteaves, Description of a species of *Cardioceras* from the Crows Nest coal fields: *Ottawa Naturalist*, vol. 17, 1903, pp. 65-67.) This Jurassic ammonite is one of the fossils mentioned by McElroy as occurring in the lower beds of the Kootenai below the coal and plant-bearing horizon (Rept. Geol. Survey Canada, vol. 13, 1900, p. 91A).

McConnell's description <sup>559a</sup> supplements that given by Dawson:

The Cretaceous is essentially a clastic formation and contains beds ranging through every degree of coarseness, from fine-grained fissile shales to heavy conglomerates.

\* \* \* \* \*

The lower part of the series consists mainly of beds and bands of flaggy sandstone, alternating with dark shales. The shales are usually somewhat arenaceous and pass gradually, by the addition of more sandy material, into pure sandstones. They are also occasionally carbonaceous and in a number of places inclose coal seams, some of which are workable. The sandstone occurs characteristically in somewhat thick beds and is usually coarse grained and soft, but harder quartzitic beds are not altogether absent. It weathers to a dull red color. The bands of sandstone are little persistent and if traced along their strike for any distance are found to break up into subordinate beds, separated by thin shaly partings, or to pass altogether into shales. The upper part of the section contains some conglomerate, in addition to the shales and sandstone. This occurs in massive beds, measuring up to 150 feet in thickness, and is composed of rounded siliceous pebbles, with some shaly and calcareous grains, embedded in a hard siliceous matrix. The pebbles are usually small, seldom exceeding an inch in diameter, and the rock passes insensibly into sandstone. The section here is more arenaceous than is usually the case, and there is reason to believe that it occupies a comparatively high position in the series and that the lower part contains a greater proportion of shales. The Cascade River section, a few miles farther north, which is undoubtedly lower, shows no conglomerate, and the sandstones are also of less importance, and in nearly every case where beds of Cretaceous age overlie the Banff limestone in an undisturbed condition, showing that the base of the formation is present, they consist almost entirely of dark shales.

\* \* \* \* \*

The following fossils were collected near the base of a small Cretaceous outlier situated 3 miles north of the east end of Devil's (Minnewanka) Lake: *Oxytoma mucronata*, *Trigonia intermedia*, *Trigonoarca tumida*,<sup>a</sup> all three characteristic of the Queen Charlotte Island series, and species of *Terebratula*, *Ostrea*, *Camptonectes*, *Lima*, *Cyprina*, ammonites, and belemnites.

A small collection, obtained from the shales faulted under the Cambrian limestones at the gap of the south fork of Ghost River, includes amongst others, such Benton species as *Scaphites ventricosus* and possibly *S. warreni*, and an *Inoceramus* like *I. undabundus*.

McEvoy <sup>564</sup> gives a detailed section of 4,736 feet of Cretaceous beds in the Crows Nest Pass basin near Morrissey and notes 1,000 feet or more of shaly limestone and calcareous shales below the measured section, as well as 4,000 to 5,000 feet of soft shale and sandstone above it. He concludes that the total thickness of Cretaceous strata in the Crows Nest Pass basin is 12,000 to 13,000 feet.

#### M 12. NORTHWESTERN MONTANA.

In northwestern Montana, at the eastern base of the Rocky Mountains, Cretaceous strata form the valley floors and foothills. In a reconnaissance survey in 1901 Willis <sup>940a</sup> distinguished Dakota, Benton, and Laramie.

<sup>a</sup> "Most probably Jurassic" [Fernie shale].—T. W. Stanton. See also statement by D. B. Dowling in *Bull. Geol. Soc. America*, vol. 17, 1906, p. 298.

Laramie sandstone [<sup>a</sup>]: Sandstone, hard, gray, cross-bedded, and soft, shaly, interbedded, carrying layers of oyster shells and containing plant remains.

Benton shale: Shale, dark bluish gray, very fissile, fossiliferous, with occasional beds of sandstone, medium grained, brown, and thin limestone layers.

Dakota sandstone: Sandstone, yellow and brownish, and shale, arenaceous, with plant remains and fresh-water shells.

A recent reconnaissance <sup>b</sup> by M. R. Campbell and C. A. Fisher shows that the Colorado is exposed in a broad strip extending from the Big Belt Mountains north by west, possibly to or into Alberta. This strip is flanked on both sides by the Eagle sandstone and higher formations of the Montana group, including the Judith River.

#### M-N 11-14. PLAINS OF ALBERTA, SASKATCHEWAN, AND MANITOBA.

Dawson's classification of the Cretaceous strata of the southwestern part of the Great Plains in Canada is given on page 693 in comparison with that of the Cretaceous in the Rocky Mountains. The Athabaska and Peace River sections are described on pages 699-700.

The standard section of the Upper Cretaceous of Canada was established by Dawson <sup>254</sup> in a study of the region between the base of the Rocky Mountains and the meridian of 110° 45', near Medicine Hat, on the South Saskatchewan. Dawson's classification is as follows:

|                                                                                                                                                                                                                                          |       |
|------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|-------|
| Laramie:                                                                                                                                                                                                                                 | Feet. |
| Porcupine Hill beds: Sandstones, frequently thick bedded and generally comparatively soft, with intercalated grayish and blackish shales and shaly clays. Fresh water.....                                                               | 2,500 |
| Willow Creek beds: Soft sandstones, shales, clays, and sandy clays, generally with pronounced reddish or purplish tint. Fresh water.....                                                                                                 | 450   |
| St. Mary River beds: Sandstones, shales, and shaly clays in frequent alternations, and generally well bedded. Fresh water except near base.....                                                                                          | 2,800 |
| Cretaceous:                                                                                                                                                                                                                              |       |
| Fox Hill sandstones: In some parts of the district well defined as a massive yellowish sandstone, but inconstant, and apparently often represented by a series of brackish-water transition beds between the Laramie and the Pierre..... | 80    |
| Pierre shales: Neutral gray or brownish to nearly black shales, include a zone of pale soft sandstone in the northeastern part of district, and frequent intercalations of harder sandstones near the mountains. Marine.....             | 750   |
| Belly River series: Composed of an upper or "pale" and lower or "yellowish" portions and consisting of alternations of sandstones, sandy clays, shales, and clays.....                                                                   | 910   |
| Lower dark shales: Gray to nearly black shales, frequently with arenaceous shales.....                                                                                                                                                   | 800   |

Details of occurrence and local character of each of these formations are given in the subsequent pages of Dawson's report and he states his interpretation of the geologic history. <sup>254a</sup>

The region east of that examined by Dawson, lying between the meridians of 106° and 110° 50', was studied by McConnell, <sup>558</sup> who recognized Belly River, Pierre, and Fox Hill, overlain conformably by the Laramie, and the latter overlain unconformably by Miocene.

<sup>a</sup> "The 'Laramie' of this section is probably Judith River or older. The distinction between Laramie and Judith River was not generally recognized when these fossils were examined."—T. W. Stanton.

<sup>b</sup> Data contributed from manuscript records of the United States Geological Survey.

On the North Saskatchewan and its tributaries Tyrrell<sup>816</sup> distinguished the following beds:

| Laramie:                                                                                                                                                                                                                                                                                                                                | Feet. |
|-----------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|-------|
| Paskapoo series: Gray and brownish weathering lamellar or massive sandstones and olive sandy shales. This is an exclusively fresh-water deposit.....                                                                                                                                                                                    | 5,700 |
| Edmonton series: Soft whitish sandstones and white or gray, often arenaceous clays, with bands and nodules of clay ironstone and numerous seams of lignite. These are of brackish-water origin and correspond to the lowest portion of the St. Mary River series of Dr. Dawson's report (Geol. Survey, Rept. for 1882-84, p. 114c)..... | 700   |
| Fox Hill and Pierre: Brownish-weathering sandstones and dark-gray clay shales.....                                                                                                                                                                                                                                                      | 600   |
| Belly River series: Soft whitish sandstones and arenaceous clays, changing toward the east to light-brownish and yellowish sandstones and sandy shales; bottom not seen.                                                                                                                                                                |       |

In the foothills evidence was found of the presence of rocks of the age of the Benton shales, which immediately underlie the sandstones of the Belly River series, but our knowledge of them is as yet too imperfect to allow of our treating of them in any way, and we can therefore simply record their occurrence.

No intrusive rocks occur anywhere throughout the district, and below the top of the Laramie there is no evidence of any unconformity between the different formations, although in some cases the extreme irregularity of the bedding gives the strata very much the appearance of having been laid down unconformably one on the other.

[The Belly River series is represented by] white or light-gray clays and soft clayey sandstones, interbedded with bands and nodules of clay ironstone. These nodules are often highly calcareous, breaking with a smooth, sharp fracture. Toward the center, on a freshly broken surface, they are of a clear slate-gray color; around are darker and darker layers, till the outer one, which is very dark brown, almost black.

As has already been pointed out in the reports of Dr. Dawson and Mr. McConnell, this series, if followed toward the east, is found to lose gradually its clayey character and to consist of purer and much more massive sandstones, generally of a yellowish color.

The Fox Hill and Pierre are described by Tyrrell as consisting of—

dark or light gray, very friable clay shales, weathering down into a soft tenacious clay, interbedded with bands of coarse-grained yellow sandstone. Unlike the beds both above and below, it is of purely marine origin, having been laid down in a sea of varying though generally very considerable depth.

The thickness of the formation, wherever it could be measured, was found to be from 600 to 700 feet.

\* \* \* \* \*

It is quite impossible here to separate the Fox Hill sandstone from the Pierre shales, as they are completely interbedded from the top to the bottom of the group. In descending Battle River this is particularly noticeable, as at the top of the group yellow sandstones are met with containing *Placenticeras placenta*, teredo burrows, etc., and at the bottom a sandstone quite undistinguishable from that above is seen holding precisely the same fossils. In the southern part of the district, nodules of clay ironstone are common throughout the shale, and fossils are plentiful, both in the nodules and in thin bands of included sandstone, but to the northward, fossils become much more rare and new species begin to appear, which are not known to the south.

The fossils found in the district, so far as known at the time of the report, are listed by Tyrrell to the number of 32 species.

No workable beds of coal occur in this group within the district, though in the shales on the top of the high ridge to the north of the Neutral Hills a thin band of carbonaceous shale is seen over a considerable area, and at Egg Creek, near the North Saskatchewan, there is a thin seam of coal of fine quality.

For an account of the Edmonton and Paskapoo series, see Chapter XVI (pp. 781-782).

In the eastern portion (M-N 13-14) of the area under consideration the classification of the Cretaceous differs from that given for the western portion (M-N 11-12) in the recognition, by Tyrrell,<sup>817b</sup> of Dakota, Niobrara, and Benton. Tyrrell gives the following systematic account in a report which contains also many local details:

The Dakota sandstone formation, resting unconformably on the limestones of the Devonian, is composed of white or reddish sandstones, either cemented by a calcareous matrix or often quite incoherent, being then an even-grained white quartzose sand. It grades up into a light-green and rather hard sandstone, commonly interstratified with thin bands of shale.

Very few fossils have been found in this sandstone, and those that have been found are confined to the greenish upper beds.

Overlying the Dakota sandstones, the Benton formation occurs as a band of dark-gray, almost black shale, holding a considerable quantity of carbonaceous material. This shale is evenly bedded and breaks down readily into thin flakes, on which account it generally forms sloping banks. With the dark shales are associated thin beds of white, soft, sweet-tasting magnesian clay.

It is generally quite destitute of fossils, but in a few places undeterminable fragments of oysters and Inocerami have been collected from the shale.

\* \* \* \* \*

The Niobrara formation conformably overlies and is an upward extension of the Benton. The rock, however, instead of being a soft fissile shale, with little or no admixture of calcareous material, is a lighter-gray calcareous shale or marl, sometimes varying to a band of moderately hard limestone. This is especially the case at the top of the terrane, where a band of grayish chalky limestone is generally met with. This band is often highly charged with pyrite.

A very characteristic feature of the formation is the presence of a large number of Foraminifera, among which *Globigerina cretacea* is often very conspicuous and in great abundance.<sup>a</sup>

The terrane varies considerably in thickness. In the Manitoba Oil Co.'s bore on Vermilion River it appears to have a thickness of 130 feet. On North Pine Creek its total thickness is less than 400 feet and probably is not more than 200 feet. On Bell River it is probably less than 250 feet. In the Swan River valley, near Thunder Hill, it would seem to have a thickness of 540 feet, but it is quite possible that the upper beds represent a foraminiferous horizon in the overlying Pierre formation.

This terrane is known to extend southward through the western portion of the province of Manitoba, having been recognized in the valleys of the Assiniboine and other streams near the face of the Manitoba escarpment and in the borings from the deep wells at Morden and Deloraine. It is doubtless continuous with the Niobrara shales and limestones, originally described by Messrs. Meek and Hayden, from the banks of the Missouri River in Nebraska. Northwest of the area now described a fragment of typical Niobrara rock was collected from Carrot River, about west longitude 103°, by Mr. A. L. Russell, beyond which it has not been traced, and its exact correlation with the beds on Athabasca River is not yet known.

\* \* \* \* \*

Grading upward from the top of the Niobrara formation the Pierre shales occupy the summits of all the higher lands of the Riding, Duck, and Porcupine mountains. In the Riding Mountain and farther south this formation naturally separates itself into an upper and a lower subdivision, which the writer has elsewhere called the Millwood and the Odanah series.<sup>b</sup>

\* \* \* \* \*

Farther west the Pierre is highly fossiliferous, but in northwestern Manitoba fossils are very scarce, and of those recorded in the following list<sup>a</sup> the Radiolaria are from a bed of shale on

<sup>a</sup> For list see the work cited.—B. W.

<sup>b</sup> Tyrrell, J. B., The Cretaceous of Manitoba: Am. Jour. Sci., vol. 40, 3d ser., 1890, pp. 227-232.

Bell River, and the remainder are from ironstone nodules from the west bank of the Assiniboine Valley at Millwood, a short distance south of the present map.

The total thickness of the Pierre in northwestern Manitoba is 800 feet or more. The Millwood series, as seen in the valleys on the northern face of riding Mountain, has a thickness of between 450 and 500 feet, while about 300 feet of the overlying Odanah series is there also seen, reaching to near the summit of the mountains and being immediately overlain by the drift deposits. The top of the Odanah series is not seen.

#### O 4-5. ALASKA PENINSULA.

Atwood <sup>42b</sup> in a report on the mineral resources of southwestern Alaska discusses the Jurassic and Cretaceous of the peninsula, stating in regard to the Upper Cretaceous:

Upper Cretaceous sediments are exposed in the mountains northwest of Chignik Bay and west of Chignik Lake. They are also present in the Herendeen Bay district. They \* \* \* consist of sandstones, shales, conglomerates, a little limestone, seams of bituminous coal, and some lignite. Upper Cretaceous fossils were procured by Paige <sup>a</sup> from the coal measures in the Herendeen Bay field and by the present writer from the several other localities above mentioned in this district and in the region of Chignik Bay.

(See also Chapter XIII, p. 574.)

#### O 8. SOUTHEASTERN ALASKA.

See Chapter XIV (pp. 632-633).

#### O 10-12. NORTHERN BRITISH COLUMBIA AND ALBERTA.

The northern portion of the great Cretaceous area of the plains has been examined on Liard, Peace, and Athabaska rivers and their tributaries. McConnell <sup>560b</sup> describes the structural relations in the eastern foothills and out on the plains and concludes:

The Cretaceous section along the Liard shows two great shale and sandstone series separated by a heavy band of sandstones and conglomerates. The lower shales, from the imperfect fossil evidence at hand and also from their lithologic character, may be referred tentatively to the horizon of the Queen Charlotte Islands, or Kootanie formation, the upper shales to that of the Benton, while the intervening conglomeratic band probably represents the Dakota. The lithological succession of the Cretaceous beds here is almost identical with that which obtains in other parts of the Cordilleran belt north of the international boundary and on the Queen Charlotte Islands and shows that similar conditions of deposition prevailed at the same time over this whole area.

The Cretaceous rocks cross the Liard with a width of over a hundred miles and north of the river enter a bay in the mountains, the extent of which to the northwestward is not known; southward they are connected with the great Cretaceous basin in the plains.

South of the Liard the next section examined is that of Peace River, which was seen by Selwyn <sup>725</sup> and McConnell. <sup>562</sup> Dawson <sup>253a</sup> observed the Cretaceous rocks more fully in a parallel section on Pine River, a tributary of the Peace near longitude 121° and utilized Selwyn's notes in the following discussion:

Cretaceous beds in the vicinity of the [Rocky] Mountains appear to be composed almost exclusively of sandstones and conglomerates and with little exception maintain this character

<sup>a</sup> Paige, Sidney, The Herendeen Bay coal field: Bull. U. S. Geol. Survey No. 284, 1906, p. 103.

on the Pine River as far as the Middle Forks. \* \* \* The sandstones are generally brownish in color, contain little calcareous matter, and are often quite coarse in grain. They are usually regularly bedded, and broad surfaces are frequently ripple marked. In the coarser grits and conglomerates the constituent fragments are found to be almost entirely of cherty material like that occurring in the more resistant of the limestone beds about the summit of the pass. \* \* \* From sections exposed in the nearly bare hillsides of Pine River, the thickness of the series must be at least 2,000 feet and may be much more. \* \* \*

While there is no means of arriving at the precise age of most parts of the sandstone series of the upper Pine River, I see no reason to doubt that it forms the coarse littoral portion of the Cretaceous rocks which spread so widely to the eastward. It seems probable, as more fully detailed elsewhere, that fine shaly materials become increasingly abundant in receding from the mountains, and that the rocks eventually resolve themselves into the subdivisions described below. \* \* \*

1. Upper sandstones and shales with lignite coals (Wapiti River sandstones).
2. Upper dark shales (Smoky River shales).
3. Lower sandstones and shales with lignite and true coals (Dunvegan sandstones).
4. Lower dark shales (Fort St. John shales).

The preceding paragraphs refer particularly to the Cretaceous of the eastern foothills of the Rocky Mountains. The typical development of Cretaceous strata in the northern plains of the Athabaska and Peace River region differs from that of the foothills. It has been well described by McConnell,<sup>561a</sup> who says:

The Cretaceous section in the Peace-Athabaska country includes beds ranging in age from the Laramie to the Dakota, but the lithological succession of the various divisions differs from that which obtains on the Great Plains and also varies in different parts of the district. This feature of the formation, together with the further fact that most of the fossils collected are new to science and therefore useless for the purpose of correlating the beds here with known horizons elsewhere, makes it difficult to classify the different terranes in a satisfactory manner and also renders necessary the provisional use of some new names. The following illustration shows the succession of the various divisions of the Cretaceous on the two rivers, and also their ages, so far as the stratigraphical and paleontological evidence at hand admits:

| <i>Athabaska River section.</i> |             | <i>Peace River section.</i> |
|---------------------------------|-------------|-----------------------------|
| Laramie.                        | Laramie.    | Wapiti River sandstone.     |
| Foxhill sandstone.              | } Montana.  | { Foxhill sandstone.        |
| La Biche shales (upper part).   |             | { Smoky River shales.       |
| Unrepresented.                  |             | { Dunvegan sandstone.       |
| La Biche shales (lower part).   | } Colorado. | { Fort St. John shales.     |
| Pelican sandstone.              |             | { Peace River sandstones.   |
| Grand Rapids sandstone.         |             | { Loon River shales.        |
| Clearwater shale.               |             |                             |
| Tar sands.                      | Dakota.     | Unrepresented.              |

For an account of the stratigraphy, with notes on the faunas and correlation, McConnell's report should be consulted, but the following summary indicates the nature of the formations enumerated in the preceding table:

The Laramie is an alternation of yellowish and grayish flaggy and massive sandstones with grayish and dark clays and shales. It carries thin ironstone bands and lignite and is at least 1,000 feet thick in the plateaus south of Lesser Slave Lake. No determinable fossils were obtained in it.

The Montana comprises 50 feet of alternating sandstone and shale (Foxhill) and 700 feet of shale, the upper part of the La Biche shales. "The exact junction between the Montana and the Colorado was not definitely ascertained, owing to

the scarcity of fossils and to the fact that the La Biche shales pass downward from the Montana into the Colorado without any structural break or lithologic change of any kind."

The Smoky River shales of the Peace River section are the equivalents of the upper part of the La Biche shales of the Athabaska section. They are dark-grayish to bluish-black shales, 200 feet thick, with bands of ironstone. The fossils belong to a typical "Pierre and Foxhill fauna."

The Dunvegan is a littoral formation which is lacking in the east and thickens westward from 100 feet on Smoky River to 600 feet at Dunvegan and 2,000 feet at Table Mountain, on Peace River. It consists of sandstone and arenaceous shales and carries fresh-water, brackish-water, and marine fossils, evidence of estuarine conditions and deposition on an oscillating surface. It occupies the stratigraphic position of the Belly River series of Assiniboia and Alberta, but the Belly River does not contain any marine fossils. The fauna of the Dunvegan is said to be like that of the Bear River formation of Wyoming, inasmuch as it contains "two of the most characteristic species of the Bear River, *Corbula pyriformis* and *Corbicula durkei*," but Stanton<sup>a</sup> does not consider the likeness established by these species. The Dunvegan overlies the Colorado, whereas the Bear River underlies it.

The beds of the Peace River section which are assigned to the Colorado comprise about 1,500 feet of shale and sandstone, constituting three named formations. The Fort St. John is 700 feet thick, the Peace River is a lens which thins out eastward, and the Loon River is about 400 feet thick. The Loon River apparently rests directly on the Devonian.

In the parallel Athabaska section the corresponding formations that make up the Colorado are 930 feet in thickness. Compared with the Peace River section the divisions are stratigraphically equivalent as follows: La Biche (lower part) = Fort St. John; Pelican sandstone and shale and Grand Rapids sandstone = Peace River sandstones; Clearwater shale = Loon River shale.

McConnell says:<sup>561c</sup>

The Tar sands underlying the Clearwater are assigned to the Dakota on lithologic and stratigraphic evidence, as no fossils were found in them. They rest on Devonian limestones and occur in the same position as the sands of undoubted Dakota age, which outcrop along the eastern edge of the Cretaceous in Manitoba and south of the international boundary in Minnesota. They consist of an almost homogeneous mass of tar-cemented sands, ranging in texture from a coarse silt to a grit, and vary in thickness where fully exposed from 140 to 220 feet.

#### P 8. LEWES RIVER, YUKON PROVINCE.

Rocks of Cretaceous age, both igneous and sedimentary, are described by Dawson<sup>253</sup> as occurring along the Lewes and other valleys of the inner Coast Ranges. He says:

Besides the Triassic rocks previously referred to, the Mesozoic period is represented also by strata of Cretaceous and Laramie age. These rocks are distinctively more recent in appearance than and rest quite unconformably on all the older formations, though they have since been to some extent involved in their flexures. On the lower part of the Lewes, below the mouth of the Little Salmon, these rocks are cut across by the river for a distance of at least 35 miles. Some

<sup>a</sup> Personal statement.

fossil mollusks and plants have been obtained from this area, from which it would appear to include beds referable to the Middle or Lower Cretaceous<sup>a</sup> and to the Laramie period, and it is not improbable that the series is a consecutive one between these limits, as the total thickness represented must be very great. \* \* \* The rocks comprise, in their lower portion, coarse conglomerates, graywacke sandstones, yellowish and gray quartzose sandstones, and dark calcareous slates. The upper portion, in which Laramie plants are found, consists chiefly of rather soft sandstones, shales, and clays, generally of pale colors. Evidence of contemporaneous volcanic action is observable in both parts of the series, and the higher beds include lignite coal of good quality.

Some miles farther up the Lewes, midway between the Little and Big Salmon rivers, peculiar green graywacke sandstones and green, highly calcareous conglomerates occur, which are provisionally referred, though with some doubt, to the Cretaceous. They are at least newer than the Paleozoic rocks, being composed of fragments of those and of granites.<sup>b</sup>

Conglomerates and sandstones similar to the last are again found near the lower end of Lake Labarge, on the east side, and are associated with black calcareous slates, which recur in several places along the same side of the lake, farther up, and from which a few fossils have been obtained. These seem to show that the beds are on or near the horizon of series C, of the Queen Charlotte Islands, which is of Middle Cretaceous age, approximately equivalent to the Gault.<sup>a</sup>

On the Upper Pelly River, 43 miles below Hoole Canyon, a single low outcrop of hard dark shales, containing fossil plants of Cretaceous or Laramie age, was found, but in the absence of further exposures along the river in that vicinity nothing can be said of the extent of this area, except that it must be quite limited in width. Again, on the Stikine River, between Glenora and Telegraph Creek, there are local occurrences of conglomerates and soft sandstones which may be regarded as probably Cretaceous, though no paleontological evidence is forthcoming.<sup>b</sup>

The position of these last-noted areas, as well as that of those along the Lewes River, occurring as they do in a zone of country immediately within the line of the Coast Ranges, is analogous to that held by Cretaceous rocks on the Skeena and in other localities still further southward in British Columbia. Further investigation will probably show that the rocks of this age occur in many additional places, and occupy somewhat extensive areas in this belt of country. In the vicinity of the Lewes, particularly, it is noted that the plane of the original base of the Cretaceous, now thrown into a number of folds, is about that of the present surface of the country, and these rocks may therefore be expected to recur frequently in the form of troughs or basins, more or less strictly limited and only to be discovered in detail by thorough examination. The loose material brought down by the Big Salmon River appears to indicate the existence of a considerable development of these rocks not far up the valley of that stream.

#### P-Q 4. LOWER YUKON, ALASKA.

The large area mapped as Cretaceous on the lower Yukon includes the Nulato sandstone, and the strata probably range in age from Lower Cretaceous to upper Eocene, according to Brooks,<sup>101r</sup> who says:

Cretaceous rocks outcrop almost without break on the lower Yukon from the mouth of the Melozi River to the head of the delta and northward into the basin of the Koyukuk River. In this part of the Yukon Valley Dall made the first geologic observations in the interior of Alaska over 40 years ago. In his summary of Alaskan geology,<sup>c</sup> made many years after, he assigned some coal-bearing beds to the Kenai (Eocene) and reported that they were succeeded by marine fossil-bearing sandstone. Spurr<sup>d</sup> corroborated Dall's observations and, accepting Eocene as the age of the underlying coal-bearing beds, assigned the succeeding strata to the

<sup>a</sup> In the opinion of T. W. Stanton these strata are probably of Jurassic age.—B. W.

<sup>b</sup> In the opinion of A. H. Brooks these strata are probably of Kenai (Eocene) age.—B. W.

<sup>c</sup> Dall, W. H., and Harris, G. D., Correlation papers—Neocene: Bull. U. S. Geol. Survey No. 84, 1892, pp. 347-348.

<sup>d</sup> Eighteenth Ann. Rept. U. S. Geol. Survey, pt. 3, 1898, p. 196.

Miocene under the name Nulato sandstone. This conclusion seemed to be further supported by fossils from sandstone which were determined as Miocene. The stratigraphic position of the coal-bearing beds of the Yukon will be considered below, but it will be noted that so-called Kenai of the Yukon embraces beds as divergent in age as the Upper Cretaceous and the upper Eocene. The stratigraphic work of Collier<sup>a</sup> in 1902, followed by that of Hollick in 1903 and the studies of their collections by Stanton and Knowlton, have yielded ample proof of the Upper Cretaceous age of both the Nulato sandstone and the underlying coal-bearing beds. \* \* \* Near Nulato there seems to be exposed a conformable series, consisting of sandstones, shales, and conglomerates, which represent continuous sedimentation from the middle of the Cretaceous to the Upper Eocene.

Schrader's Koyukuk report<sup>b</sup> makes mention of Lower Cretaceous fossils in an impure limestone, associated with volcanic rocks, which outcrop near the sixty-sixth parallel, and to the south of these of an impure limestone which carried Upper Cretaceous fossils, but assigned the Nulato sandstone to the Miocene.

Collier<sup>163</sup> gives the following description and tabular arrangement of the Cretaceous and Tertiary of the region:

The Upper Cretaceous is represented near Nulato by sandstones, conglomerates, and dark-colored shales, which outcrop along the river at intervals for about 100 miles. These have in part yielded a marine invertebrate fauna of Upper Cretaceous age, as determined by Stanton. Fossil plants were found in the same general horizon and were assigned by Dr. Knowlton to the Upper Cretaceous. It is evident, therefore, that these beds include both marine and fresh-water deposits. The fresh-water beds carry coals of commercial importance. The Cretaceous beds have undergone considerable deformation but are not metamorphosed and, in fact, are only slightly indurated.

The succeeding horizon is made up chiefly of sandstone and conglomerate, with some shale. It is called the Kenai series and is of upper Eocene age. These beds usually carry abundant plant remains, which show them to be of fresh-water origin. The Kenai series has been named from its typical occurrence on Kenai Peninsula and has been identified in various other parts of Alaska. It occurs in isolated areas on the Yukon near the boundary and near Rampart and is more extensively developed near Nulato. On the upper river it unconformably overlies various horizons below the Upper Cretaceous, but near Nulato its relation to the Upper Cretaceous seems to be one of conformity. The Kenai beds are, as a rule, little disturbed, but in some localities they have suffered considerable deformation. The Kenai is the great coal-bearing horizon of Alaska. Its coals are usually characterized by the presence of fossil resin, or amber.

*Provisional tabular statement of Yukon stratigraphy.*

| Age.                  | Formation name.                                | Contact relations. | Lithologic character.                                                    |

<sup>a</sup> Bull. U. S. Geol. Survey No. 213, 1903.

<sup>b</sup> Twenty-first Ann. Rept. U. S. Geol. Survey, pt. 2, 1900, pp. 476-477.

## Q 7. UPPER YUKON, ALASKA.

In 1905 Prindle and Hess <sup>641</sup> reported the occurrence of a Cretaceous sandstone in the Rampart region. More recently Prindle <sup>640</sup> has revisited this locality and found fossils assigned to the Upper Cretaceous. The rock in which this fauna occurs is a black carbonaceous sandy argillite. Granitic rocks cut these beds, showing a later intrusion of acidic rocks than was previously known. The areas are too small to show on the map.

(See also Q 7, Chapter XIV, pp. 635-636.)

## Q 8. NORTHERN YUKON TERRITORY.

According to Camsell, <sup>128c</sup> Peel River, which flows northward from the Rocky Mountains in Yukon Territory to the Mackenzie Delta, emerges from a lower canyon, cut across folded slates of supposed Devonian age, and thence to a tributary called the Snake—

cuts a deep valley 500 to 700 feet in soft shales and sandstones of Cretaceous age. A section of the bank \* \* \* shows about 200 feet of yellow and red shales, which toward the base are interbedded with layers of sandstone, resting on massive sandstone 50 feet in thickness. \* \* \* Farther downstream the banks consist principally of sandstone, with thin beds of shale interposed between sandstone beds. In parts the sandstone contains concretions, many of which are 10 feet in diameter. Apparently the river in this portion cuts through a low anticline. \* \* \* The Snake River has a deep and narrow valley cut into soft gray argillaceous sandstones, which lie horizontally or dip at a low angle to the east. The sandstone is massive, but the beds are separated from each other by thin seams of a harder red-weathering sandstone, which contains many fossils of ammonites. \* \* \* South of Snake River is a range of hills whose highest points are 2,000 feet above the river. This range is built up of hard gray sandstone, very similar to the sandstone of the Snake River valley, only a little more indurated and approaching a quartzite.

The fossils collected in the sandstone of Snake River have been referred by Whiteaves to the Cretaceous period. The list of forms is: *Panopœa* or *Pleuromya*?, *Thracia*, *Tellina*?, *Inoceramus*, *Desmoceras*? possibly *D. affine* cf. *D. liardense* W.

## Q-R 8-10. MACKENZIE BASIN.

Dawson <sup>257d</sup> refers to Richardson's observations on the lower Mackenzie and along the Arctic coast eastward, in accordance with which Cretaceous rocks are indicated in this region. McConnell <sup>560c</sup> made a reconnaissance of the Mackenzie and Porcupine basins, and regarding the area here in question says:

The plains bordering the lower part of the Liard and the upper part of the Mackenzie rest on Devonian limestones and shales, and the Cretaceous rocks were not detected in descending the latter stream until the Dahadinni River, in latitude 64° north, was reached. They consist here of a couple of hundred feet of dark-gray shales and sandstones. They are exposed along the valley for 10 or 12 miles, and are then concealed by the boulder clay, but probably continue under the latter as far as the Tertiary basin at the mouth of Bear River, a distance of 50 miles. The Cretaceous beds here occupy a depression between two high ranges of limestone mountains and can not have a greater width than 10 or 15 miles. They have been separated from the Cretaceous beds which form the western shores of Great Bear Lake by the elevation of the Mount Clark range.

Forty miles below Bear River the Cretaceous beds reappear on the banks of the Mackenzie, and with the exception of one break of a couple of miles where they have been removed by

denudation, underlie the valley all the way to the Ramparts, a distance of 90 miles. The fossils obtained both from this area and from the one above Bear River consist of fragments of ammonites and Inocerami, too imperfect for specific determination.

A hundred and twenty miles below the Ramparts the Mackenzie enters a third Cretaceous area, and the largest one on the river. Cretaceous beds appear in the banks a short distance below old Fort Good Hope and extend down the Mackenzie to the head of its delta and westward across the Rocky Mountains and down the Porcupine to about longitude 139° west. They consist on the Mackenzie of coarse shales interstratified with some sandstones and fine-grained conglomerates; in the mountains of several thousand feet of barren sandstones and quartzites underlain by dark shales; and on the Porcupine of the same two series underlain by a great thickness of alternating shales, sandstones, and conglomerates, holding *Aucella mosquensis* var. *concentrica*. The intermediate dark shales are probably of Benton age, while the lower division, so far as the fossil evidence goes, represents the Queen Charlotte Island formation and the Dakota.

Cretaceous shales holding *Aucella* and passing upward into fine-grained conglomerates occur on the Yukon for many miles above and below the mouth of the Tatonduc and were traced by Ogilvie up the latter stream for some distance. They have been greatly disturbed and are folded up in broad bands with the underlying Paleozoic limestones.

These rocks are described in greater detail by Brooks and Kindle.<sup>103</sup>

The area of Cretaceous west of Great Bear Lake is briefly described by J. M. Bell.<sup>64</sup> The rocks are shales and sandstones which lie in nearly horizontal attitude. On Bear River the strata dip very gently downstream and consist of dark ferruginous and arenaceous shales overlain by thin-bedded and jointed sandstones. No fossils were collected and the correlation as Cretaceous depends on stratigraphic and lithologic comparison.

The paleontology of this area is discussed by F. B. Meek.<sup>585</sup>

#### R 5. NORTHERN ALASKA, ARCTIC SLOPE.

(See Chapter XIV, p. 636.)

#### R 22. WEST COAST OF GREENLAND.

The Nugsoak Peninsula and Disco Island, on the west coast of Greenland, present sections of late Lower Cretaceous and of Upper Cretaceous littoral strata. The coast of the Cretaceous sea was apparently not far from the present seacoast, the more easterly exposures of the sediments carrying plant fossils without marine remains and being coarse clastic rocks, whereas the strata farther west are marine clays. The latest account of these strata is that given by White and Schuchert,<sup>902</sup> whose conclusions are in part as follows:

The Cretaceous and Tertiary rocks in the region described lie everywhere unconformably upon a hilly basement of old crystallines, chiefly gneiss and diorite (Kærsut, Pagtorfik, Ekorfat), or upon early Cretaceous or pre-Cretaceous (?) basalts (Niakornat, Alinaitunguak, Atanikerdluk). The greatest altitude of the sedimentary terranes is at Atanikerdluk, 3,400 feet above sea level. The old basalts are highly altered and usually occur as breccias (Niakornat, Alinaitunguak).

The prevailing easterly dips of the Lower Cretaceous along the north side of Nugsoak Peninsula, in which the strata should dip westerly, since it is in that direction that the higher and younger beds appear, may be in part explained by fault compensation, as illustrated at Ujarartorsuak. A certain degree of irregularity of dip, the variable and often strong coastward dips as well as the low altitude of the Tertiary at its eastern border on the south side of

the peninsula (Atanikerdluk), are probably due to inequality in the post-Tertiary epeirogenic movements.

The sediments appear to have been derived from the east, since the light-colored sandstones and conglomerates are most abundant on that side of the sedimentary belt (Kock, Kæsut), where marine fossils appear to be wanting. At one of the eastern localities (Ujarartorsuak) fresh-water shells occur with plants. To the west dark homogeneous shales with abundant remains of marine animals predominate.

Sedimentation appears to have been continuous in some portion of this region throughout Cretaceous and early Tertiary times, since no marked unconformities or unmistakable evidence of interruption of deposition have been seen. In certain sections, however, there appears to be, either in a variable thickness of the series or a slight difference of attitude, evidence of movements or erosion prior to the imposition of the Tertiary basalt cap, though these may be only local or of minor extent. But in many well-exposed sections there is no local trace of sedimentary discontinuity between the Mesozoic and Tertiary.

The entire thickness of the clastic deposits is probably over 3,500 feet. They are divided by Heer into four series, on the basis of their vegetable contents. Of the lowest of these, the Kome series, developed on the north coast of the peninsula, a thickness of probably not over 700 feet is exposed above tide. The discovery of additional dicotyledons in the Kome series, from which hitherto only *Populus primæva* was known and which was regarded as Urganian in age by Heer, casts a serious doubt on the reference of those beds to so low a stage in the Lower Cretaceous. The flora as a whole is, however, to be compared with that of the Virginian Potomac formation, with some, perhaps the upper portion, of which the Kome series is probably synchronous.

The Atane series, hitherto not positively known on the north shore of Nugsuak Peninsula, is clearly present at Ujarartorsuak with characteristic Atane plants. Farther west, at Kook Angnertunek and Niakornat, the dark homogeneous shale series probably represents both the Atane and Patoot members of the Upper Cretaceous, since of the marine organisms found here some are identical with those occurring at Ata and Patoot, the typical localities for the two divisions of the Upper Cretaceous. The marine invertebrates from the Atane series, which Heer correlated by means of fossil plants with the Cenomanian of Europe, strongly indicate that the series is to be correlated with the Fort Pierre and Fox Hills or Montana formation of the western United States. Paleobotanically the Atane series is so closely related to the Vineyard series of Marthas Vineyard, the Amboy clays of the Raritan region of New Jersey, or the uppermost Potomac of Alabama as to furnish strong reason for the belief that the middle of Heer's groups is the Greenland contemporary of the Amboy clays. The Patoot series, which appears lithologically and stratigraphically to be inseparable from the Atane series, contains at the same time many plants common in the upper part of the Amboy clays, with others allied more closely to the higher Cretaceous floras, such as that of the Laramie. The Patoot series may perhaps be safely interpreted as constituting a paleontological as well as sedimentary transition from the Atane series to the Tertiary. The thickness of the Atane and Patoot series (Senonian) is not less than 1,300 feet and may considerably exceed this.

## CHAPTER XVI.

### EARLIER TERTIARY (EOCENE AND OLIGOCENE).

*Color*, orange and light orange, in ruling and dots, and orange brown.

*Symbol*, 5, 5a, 5b, 5b1, 5c, 5d.

*Distribution*: Throughout the Atlantic and Gulf Coastal Plain, Mississippi embayment, Central America, the West Indies, Jamaica, Colombia, and along the Pacific coast to Alaska; also in the interior western United States and Canada and in Greenland.

*Content*: Marine Eocene and Oligocene of Central America, the West Indies, and Pacific coast to Alaska (5), including the coal-bearing formations of Puget Sound (Puget group) and Alaska (Kenai formation); marine Eocene and Oligocene of the Atlantic and Gulf coast plains, the Mississippi embayment, Jamaica, and Greenland (5b and 5d); continental Eocene (Puerco, Fort Union, Wasatch, Green River, Bridger, and Uinta formations) of the Interior (5b1); continental Oligocene (White River group, including Chadron and Brule formations) of the Great Plains (5c); earliest Tertiary or latest Cretaceous of the Interior (Shoshone group, Denver and Arapahoe and equivalents in Colorado; "Upper Laramie," Lance formation, and "Ceratops beds" or "Somber beds," in Wyoming, Montana, and the Dakotas), Edmonton of Alberta, "Upper Laramie" of Canadian reports, and in Colombia the Guaduas or Cerro de Oro formation (5a).

#### *Earlier Tertiary areas.*

#### B 18. COLOMBIA.

A formation which has been assigned with doubt to the Cretaceous or Tertiary is described by Hettner<sup>437a</sup> as the Guaduas formation of the Cordillera of Bogota. This was recognized by Sievers in the Cordillera de Merida in Venezuela and there entitled the Cerro de Oro series. It consists of bright-colored, especially red, yellow, or violet clays that contain particles of brown iron ore and interbedded layers of coarse sandstone which is mostly red or dirty white and which in places becomes conglomeratic. The lower portion of this formation or the upper part of the underlying Guadalupe (Upper Cretaceous) belongs to the coal-bearing strata of Colombia. No other fossils than imperfect remains of plants have been found with the coal. Karsten was of the opinion that this formation was unconformable upon the Guadalupe and therefore considered it to be Tertiary. Hettner, however, regards the unconformity as apparent rather than real, and as he could not find any sharp boundary between the two divisions, he doubted the Tertiary age of the Guaduas formation, thinking it more likely Cretaceous.

#### B-C 19. VENEZUELA.

Sievers,<sup>741b</sup> in describing the Cordillera de Merida, places provisionally in the early Tertiary a division which he calls the Cerro de Oro terrane. He says:

In Tachira, as well as elsewhere in various places in the Cordillera, massive deposits of very varied constitution lie above the limestone of Albien age. In various places one may observe coal beds occurring between shaly calcareous and sandy formations, and in two places petroleum occurs in these deposits. It is probable that the thickness varies from place to place and that it may often be impossible to establish a particular sequence of strata, especially as the formation has undergone great tectonic disturbance. However, I had the good fortune to discover at least in one place a thickness of 800 meters in which the relations of this formation were clearly presented.

The section as measured by Sievers and given in great detail shows an alternation of thin sandstone, shale, and carbonaceous layers and is compared with the Caroni series of Wall in the Island of Trinidad. Sulphur occurs as a characteristic constituent of many of the sandstones.

Regarding the age of the formation, Sievers has no definite data, as he found no fossils. The Caroni series of Wall was placed in the Miocene on fossil evidence, and Sievers regards the Cerro de Oro terrane as probably equivalent to it. On the other hand, he is not sure that it should be separated from the Cretaceous, and in the absence of fossils its age remains undetermined.

#### C 16. NICARAGUA.

Hayes <sup>427</sup> states that the Tertiary rocks along the line of the proposed Nicaragua Canal are the oldest certainly known in that section and comprise two formations, the Brito and Machuca.

The [Brito] formation presents considerable variety in its lithological composition, but it has not yet been sufficiently studied to permit of its subdivision, even if this may be eventually possible. Much the larger mass of the formation consists of somewhat calcareous nonfossiliferous shale. When fresh this is bluish gray and weathers to a yellowish or brownish color. Distributed through the shale are numerous beds of sandstone. These are also somewhat calcareous and doubtless contain a considerable proportion of volcanic ash. The sandstone beds vary in thickness from a few inches to 2 or 3 feet and occur singly or in groups. \* \* \* These sandstones, like the shales, are blue when entirely fresh but are always weathered at the surface to some shade of yellow or brown. \* \* \* They occur most abundantly near the Pacific coast and are well exposed in the headland northwest of the Rio Grande Valley at Brito. The beds here have a general though somewhat variable dip to the southwest, hence the higher portions of the formation make the cliffs along the Pacific. This seems also to be its most variable portion. In addition to the shales, which constitute its greatest bulk to the eastward, it here contains also beds of sandstone, conglomerate, and coarse breccia on the one hand, and on the other marly beds and lenses of pure limestone. Forming a part of the headland south of Brito is a bed of limestone something over a hundred feet in thickness. Small outcrops of this bed, or one very similar, have been noted at several other localities to the eastward in the Divide Hills. Its limited extent is due in part to erosion, since the dip of the bed would carry it above the tops of most of the hills to the eastward, but it is doubtful if its original extension was very great. Several of the limestone outcrops noted are probably small lenses in the shale and not connected with the more continuous bed at Brito. A portion of this limestone has a peculiar concretionary structure, some of the concretions attaining a diameter of an inch and a half, while other portions of the bed are oolitic. Immediately west of this exposure of limestone, forming a group of islets nearly covered by high tide, is a very coarse volcanic conglomerate or breccia. The larger fragments are a foot or more in diameter and quite angular, and from this extreme they grade downward to small pebbles, some of which are well rounded. The present relations indicate that the conglomerate is the stratigraphical equivalent of the limestone, replacing it within a few yards. In some places the two rocks are seen to merge, the limestone containing numerous angular fragments of volcanic rock. At other points along the coast both north and south of Brito, similar conglomerates occur. Their bedding is extremely irregular, and they afford evidence of having been formed rapidly and near the source from which their constituents were derived. While it is possible that the source of this material may have been to the eastward, it seems much more likely that it came from volcanic vents to the southwest, from volcanoes which have been entirely removed by the waves of the Pacific. \* \* \*

The exposures of the Brito formation are so infrequent and the dips are so variable that no satisfactory measure of the thickness of the formation can be obtained. Taking the observed dips between the Pacific coast and the lake shore the thickness exposed is estimated at about 10,000 feet. This of course is not the total thickness of the formation, since the bottom is not exposed at the axis of the anticline. Also the formation has undoubtedly suffered an unknown but considerable diminution in thickness by erosion, and there are no data for determining the thickness of strata which have been removed from the highest beds now observed. \* \* \*

The greater part of the Brito formation is apparently barren of organic remains. The only locations at which fossils have been found are on or near the Pacific coast. This, however, may be due to the fact that the rock exposures are not elsewhere of such a character as to facilitate the discovery of fossils, and the latter may possibly be more generally distributed than present knowledge would indicate. The fossils are confined almost wholly to the limestones and marly beds. They consist of corals, molluscs and foraminiferal remains. The latter are especially abundant. The rather meager collections have been submitted to Dr. Dall for determination. He pronounces them Oligocene and probably identical with the foraminiferal beds described by Hill from the Caribbean coast at Panama. One of the most abundant forms is a small nummulite, *Orbitoides*, probably *forbesi*, which is characteristic of the lower Oligocene. The molluscan remains were collected on the Pacific coast about 75 miles northwest of Brito in what was supposed to be a higher portion of the same formation. Dr. Dall states that these have the upper Oligocene aspect, though there are not enough of them to be conclusive. He thus confirms the view entertained in the field that successively higher beds in the Brito formation are exposed along the coast toward the northwest.

In addition to the fossils on which is based the above conclusion concerning the age of the Brito formation, it also contains rather abundant plant remains. They are in the form of driftwood and coal, and as yet no remains sufficiently well preserved for identification have been discovered. Associated with the coarser sandstones are numerous blocks of wood, whose rounded forms suggest that they are fragments of drift which were incorporated with the sand and gravel while it was accumulating. In some cases they still contain a large proportion of their original carbon, and in others this has been more or less perfectly replaced by silica or iron pyrites. The coal occurs associated with the finer sediments, and although a careful search was made, the thickest seam observed was under half an inch. While sufficient carbonaceous matter is sometimes disseminated through the shales to give them a black color, no indications were found pointing to the existence of workable coal deposits in the region examined.

Coal in workable quantity has been reported from the region southwest of the lake, between the lake shore and the Costa Rican volcanoes. The exact locality is on the Rio Hacienda, 12 miles from its mouth. It was not visited and no samples of the coal were seen, so that the report lacks verification. There appears to be no reason, however, why conditions favorable for coal accumulation should not have prevailed in some portions of this region during the deposition of the Brito beds. \* \* \*

[The Machuca formation] appears to consist chiefly of calcareous shales with which sandstones are interbedded. The constituents of the rocks are largely igneous in their origin, but there are no coarse conglomerates or breccias such as occur in the Brito. Also no pure limestones or distinctly marly beds have been discovered, although the examination of the formation has not been sufficiently exhaustive to enable one to say that such beds do not occur. \* \* \*

No fossils have as yet been found in the Machuca formation which are sufficiently well preserved for specific determination. At Cruzita, 1 mile below Machuca, the core from the diamond-drill hole in the bed of the river contains numerous indistinct organic forms. The rock is described by Dr. Ransome as an andesitic tuff containing fragments of limestone. The organic forms are revealed by the weathering of the rock with the removal of the soluble limestone, and they are also shown in the thin section under the microscope. While they can not be identified, they strongly suggest the forms which occur so abundantly in portions of the Brito formation. The beds in which they occur are evidently derived in large part from fresh volcanic tuff, though the latter was not so abundant as to prevent the growth of organisms in the sea in which it was being deposited. In the absence of conclusive fossil evidence, therefore, the age of the Machuca formation, so far as it may be determined, rests upon other and less satisfactory evidence. It is believed to be nearly or quite contemporaneous with the Brito formation—that is, Oligocene (Tertiary). The grounds on which this conclusion is based are briefly as follows: (1) There is a general similarity in lithologic composition and appearance between the two formations. (2) Both have suffered about the same amount of deformation, elevation, and erosion since they were deposited. The value of this fact for correlation depends upon the

proximity of the areas which they occupy and the evidence that the recent geologic conditions have been similar in both. (3) Both formations bear about the same relation to a group of igneous rocks which was in part contemporary with them and in part subsequently invaded their beds. The differences in composition of these intrusive rocks are not greater than differences in igneous rocks within the same area which are known to be nearly or quite contemporaneous. (4) Finally, as pointed out above, it is possible and even probable that the two formations are nearly or quite continuous through the southern part of the upper San Juan Valley.

#### C 17. PANAMA.

Howe <sup>465</sup> states, in a report on the geology of the Canal Zone:

The central portion of the isthmus along the canal line consists of rocks of igneous origin. They are the oldest rocks of the region and have been observed at the surface in the central area, between Mamei and Empire and northeast of the city of Panama. Diamond-drill borings have indicated their presence also at other points, and it is believed that they underlie at greater or less depth the whole territory included in the Canal Zone.

To the northwest younger rocks of sedimentary origin occur, resting on the older igneous mass and gently inclined toward the Caribbean Sea, so that in passing from the interior toward Colon successively younger beds are encountered. Their well-defined stratification and the abundant fossil remains of marine organisms indicate that these rocks were formed by the deposition of gravel, sand, and mud on the sea bottom, or in tidal estuaries where the materials gradually hardened into rock. Nearly the same conditions prevail on the Pacific side, where, in addition to the older igneous and sedimentary rocks, younger igneous rocks occur.

Dikes and large crosscutting masses of a basaltic nature have invaded all of the older sedimentary rocks; they occur in greatest abundance in the central and southern parts of the Zone and are believed to represent the last phase of active volcanism in the neighborhood.

From its very characteristic occurrence in the vicinity of Obispo, this name has been given to the formation about to be described that occupies a large part of the central region and consists of andesitic breccias and associated lava flows. \* \* \*

The Obispo breccias, which are believed to constitute a large part of the formation, are of variable texture, usually being composed of angular fragments an inch or more in diameter. No evidence was found that they were laid down or sorted by the action of running water. The fragments consist of andesite of a variety of textures and show slight differences in composition. The majority of the fragments appear to consist of pyroxene andesite, although a fair percentage of hornblende andesites are present. The color of the breccia on fresh exposures is a dark blue or green. The rock near the surface has been altered to a red clay.

At a few places, notably in the vicinity of Empire, lava flows of massive andesite were found associated with the breccias. The actual relation of the flows to the breccias is not clearly shown, but it is believed that they were contemporaneous and that quiet outpourings of lava alternated with the explosive eruptions that produced the breccias. The massive rock is of essentially the same composition as that composing many of the fragments in the breccias, but in most cases is too far decomposed to admit of exact determinations. \* \* \*

Judging from the extremely unconformable relations that exist between the Obispo formation and the younger rocks, it seems clear that following the eruption of the breccias the region was thoroughly dissected by the erosive action of streams. The interval between the close of the andesitic eruptions and the beginning of the next recorded epoch was of unknown extent, and the original surfaces of the Obispo rocks were completely obliterated before the next succeeding formation—the Bohio—was deposited. \* \* \*

Probably the oldest sedimentary formation represented in the Zone is that which has its most characteristic outcrops in the vicinity of Bohio.

Near the railroad station is a cliff, from which building stone has been quarried and which rises 50 feet or so from the level of the flat on which the town is built. The rock here is of a very even texture and at first glance strongly suggests a fine-grained volcanic breccia. It

is of a peculiar brownish color, unlike that of the Obispo breccia; the fragments are apparently angular and usually less than 1 inch in diameter. One of the most striking features of this rock, shown in deep borings as well as at surface outcrops, is its alteration; it mashes under a blow of the hammer and yet has not the appearance of being greatly decomposed, except at or very near the surface. The alteration seems to have been to serpentine or some related mineral instead of kaolin, as is usually the case with the other rocks, especially those of the Obispo formation.

Across the river, at the old lock site south of Bohio and east of Pena Blanca, quite a different phase of this formation is exposed; it consists of alternating layers of sandstones and coarse conglomerates all clearly water transported and deposited. Many of the boulders are a foot or more in diameter; they are of andesites for the most part, but not a few are of a lighter-colored porphyritic rock with abundant hornblende crystals. The finer layers and the cementing material are very like the rock occurring at the Bohio quarries. Cross-bedding is common and fine material often occurs in lenses in the grits and conglomerates. The prevailing strike is N. 25° E., and the dip to the northwest at an angle of about 14°.

The identity of these conglomerates and the more even-textured breccia-like rock is not at all evident in the field, but many borings made in the vicinity show a gradual transition southward from the even-textured breccias of Bohio to the conglomeratic facies at Pena Blanca.

The boring made at kilometer 24 (hole 24-b) is of interest, since it shows carbonaceous sandstones in the middle part and fossils in the lower part of the core.

Further study of this formation to the southeast and by means of borings has shown that it is of variable character, in some places clearly sedimentary and water sorted, both fine grained and conglomeratic; in other places the appearance is more that of a volcanic breccia, possibly water-laid but not water transported. \* \* \*

In general the formation may be described as a probable fluvial deposit characterized by sudden changes and transitions, the composition of the materials being fairly uniform. It is not improbable that volcanic eruptions may have been taking place during the period in which the formation was deposited and the material forming the breccia-like portion attributed directly to such a source.

The fossils previously referred to that were found in the core taken from hole 24-b occur at elevations of from 30 to 40 feet below sea level. They include, in addition to vegetable matter, certain fossils indicating probable Eocene age. At about 2 miles to the west, at a locality known as Vamos Vamos, on the left bank of the French canal, are outcrops of a limy shale with large calcareous concretions resembling boulders in a conglomerate; both the shale and concretions contain numerous fossils which Dr. William H. Dall regards as of undoubted Eocene age. Outcrops of similar rock containing the same fossils occur about 6 miles to the northwest on the left bank of the canal in the vicinity of Gatun.

The rocks at Vamos Vamos and in the vicinity of Gatun are finer grained than those of the Bohio formation and consist of shales and fine sandstones.

The fossil evidence shows with certainty that the beds near Gatun and at Vamos Vamos and Bohio are of the same age, and it is believed that they are to be regarded strictly as part of one formation, the occurrence at Bohio representing a littoral facies, while those farther to the northwest were deposited in deeper water.

In the excavations made by the French between Bohio and Pena Blanca, and also at the base of a little hill at the west end of the village of Bohio, there are outcrops of a white calcareous sandstone or marl containing some volcanic material in the form of crystals of feldspar and fine specks of a ferromagnesian mineral. In places it is extremely rich in the remains of Foraminifera, especially *Orbitoides fortisi*, and may seem to consist altogether of the shells of these minute organisms. \* \* \*

The Foraminifera of the Pena Blanca rocks, and especially the species *Orbitoides fortisi*, are characteristic of the Lower Oligocene. From their position between two well-determined occurrences of Eocene rocks it is believed that they are clearly younger than the Bohio formation and rest upon these rocks unconformably.

Directly above a conglomerate that occurs near the railroad station at Gatun is a brownish impure calcareous clay or argillaceous sandstone, apparently containing much débris of volcanic rocks and numerous fragments of shells. Many perfect fossils are to be found, but the extremely crumbling nature of the rock makes it almost impossible to obtain good specimens. Such as were collected have been determined by Dr. Dall as of probable Oligocene age and newer than the foraminiferal beds of Pena Blanca, and the rocks are to be regarded as near the base of the succeeding Oligocene formations that occur at numerous places between Gatun and the bay, notably at the Mindi Hills and at the Monkey Hills.

The conglomerate under these sandstones contains many fossils that are the same as those of the Bohio and Vamos Vamos beds, but it is believed that the conglomerate represents the base of the Gatun formation and that the Eocene fossils present were derived from the older rocks and so do not indicate the true age of the conglomerate.

Soft sandstones of a dirty greenish-gray color, derived from igneous rocks with a calcareous and clayey cement, are the most abundant rocks of the Gatun formation. Associated with them are shales, impure marls, greensands, and, at certain horizons, fine white tuffs composed of pumice, probably of the composition of a rhyolite. \* \* \* The rocks are all well consolidated, though in a few rare cases sandy layers are found which crumble on exposure to the air. These are the beds that have been referred to frequently as "indurated clays." The term is a misleading one, since true clays make up but a small part of the formation. Induration is a term applied to the process by which sandstones or argillaceous rocks are converted into quartzites or slates by heat or mineralized solutions accompanying the intrusion of igneous rocks. None of these conditions existed in the vicinity of Gatun. The rocks are of sedimentary origin and were deposited on the sea bottom at some distance from the shore in the form of sands and clays. Their subsequent hardening into rock is the result of simple cementation by calcareous solutions contained in the sea water and through pressure. Certain beds are harder than others, since the nature of their constituents favored more complete consolidation. The beds, however, are not to be regarded as unconsolidated. They are all "rock," though in some instances soft enough to be loosened with a pick.

These beds extend northward with little change in lithologic character to the Monkey Hills in the vicinity of Colon. Fossils collected in the more northerly localities indicate that the beds in this region are still younger than those at Gatun. No sharp breaks have been observed, however, and it is believed that practically continuous sedimentation took place from the time the Gatun beds were deposited until the close of later sedimentation.

The rocks belonging to the Culebra formation have been exposed by excavation from Las Cascadas to Pedro Miguel along the line of the canal, the best exposures being in the vicinity of Culebra.

The formation consists of a series of soft shales, with sandy, conglomeratic, and calcareous layers abundant. Limestones, as at Empire, Las Cascadas, and in the railroad cut between these two places, are also indicated at several points by borings. Of these the occurrences at Empire (Camacho) are undoubtedly the most massive, the others being present apparently as lenses in the shales and sandstones. Although some thick beds of very homogeneous pure clay shales occur, most of the formation is richly carbonaceous, and at a number of places in the cut lenslike seams of lignite have been found and remains of trees and plants are abundant.

The age of the Culebra formation can not be fixed with absolute certainty. Fossils collected at a number of points between Las Cascadas and Pedro Miguel were not sufficiently characteristic to determine the age of the beds, but at the lock site at Pedro Miguel collections were made at two points less than 100 yards apart that supply more definite information. The fossils from the more northerly point, 30 feet vertically above the other horizon, are regarded by Dall as representing the Oligocene, probably a reef deposit. The material from the lower and more southerly locality is pronounced Eocene by Dall. From the prevailing southerly dip of the beds in the region the fossils from the two localities were believed in the field to belong to the same horizon. The lack of continuous outcrops, however, makes it impossible to assert positively that this is so. The only fossils collected by Hill from the Culebra formation came

from the Empire limestone. Only the foraminiferal portion seems to have been determined, and these are regarded by Bagg as probably Eocene. The fossiliferous beds near Pedro Miguel are undoubtedly at or very near the top of the formation, since the dip carries them below the surface a short distance to the south, and borings at kilometer 59, slightly to the north, show the usual Culebra formation extending to an unknown depth below. The Eocene and Oligocene ages of the beds at the two localities at Pedro Miguel seem certain. In any event there can be little doubt of the Eocene age of the Culebra formation as a whole and its probable correlation with the Bohio and Vamos Vamos beds. The occurrence of an Oligocene fauna directly above the characteristic Eocene at Pedro Miguel is comparable to the sudden change that takes place at Gatun from the Eocene of the Vamos Vamos beds to the Oligocene of the Gatun formation.

The thickness of the Culebra formation has been variously estimated at from 400 to 500 feet. A boring made at kilometer 55 of the canal (hole 31) extends 40 feet below sea level, starting at 167 feet above the sea; 207 feet of Culebra beds are here indicated, while possibly 175 feet might be added as representing the part already excavated at the cut, giving a thickness of nearly 400 feet, with the bottom not yet shown.

#### C 20. TRINIDAD.

Wall and Sawkins<sup>863b</sup> distinguished the Newer Parian group in Trinidad as Tertiary and recognized five divisions. They say:

The Newer Parian group comprises a considerable succession of limestones, calcareous sands, shales, loose ferruginous sands, conglomerates, clays, and marls, which seem sufficiently related to one another by fossiliferous contents to form one group, of which the organic remains present a certain analogy with the Miocene fauna.

For distinct classification, five divisions or series are admitted, in naming which the same principle of locality already employed, and so convenient in provisional nomenclature, will be again adopted. These divisions are—

- A. The Nariva series.
- B. The Naparima marl.
- C. The Tamana or calcareous series.
- D. The Caroni or carbonaceous series.
- E. The Moruga or arenaceous series.

The Nariva series consists of clays, with shales and extremely rare yellowish limestones, and forms the substrata to the well-known red soils. \* \* \* The strata are traversed by bands of highly ferruginous matter parallel with the stratification.

The geological importance of these beds is very subordinate; they possess, probably, but a slight thickness and seem to constitute merely the inferior portion of the following division. Their relations to the Older Parian group were not ascertained, and generally, from the absence of proper sections, but little information has been obtained respecting this series. \* \* \*

The Naparima marl includes a series of strata composed of marls, conglomerates, and calcareous sand.

The mineral matter of these marls is in a state of fine division and varies from a basis of clay, with 10 to 50 per cent of carbonate of lime, to a basis of siliceous substance, consisting of the shields of Infusoriæ, and an average content of 20 per cent carbonate of lime. The clay marl contains sometimes a much smaller proportion of Infusoriæ.

There is generally a small proportion of carbonate of magnesia, and in some cases even 30 per cent, almost sufficient to combine with the carbonate of lime to form true dolomite. \* \* \* These strata have usually a highly conchoidal fracture, especially the more argillaceous marls.

The conglomerates are formed of rounded pebbles of indurated sandstone, and varieties of jasper from the Older Parian, with cement. They do not exceed 8 or 10 feet thick and are sometimes bounded by sands containing shelly fragments and a variety of calcareous matter.

Limestones occur interstratified in the marl, in rather thin beds, and of oolitic or even subcrystalline texture. Corals are of common occurrence, especially a species of *Orbicella*. \* \* \*

The Tamana calcareous series consists of the massive limestone of Tamana, L'Ebranche, and Montserrat, which varies from white to yellow in color and from granular to crystalline in texture. These strata have experienced a very complete change of structure, the particles being entirely rearranged, which is most beautifully exemplified in the obliteration of the fossil corals, whose exterior surfaces are well preserved, but toward the interior all organized texture gradually fades into the crystalline mass.

This is the most definite stratum of the whole island, and can be traced, with only two or three interruptions, from near the western to the eastern coasts. There is only one common coral (a species of *Orbicella*) which also occurs in the limestones of the Naparima marl. The stratification being usually obliterated, the dip can be but rarely determined and is always found to be to the northwest, at an angle varying from 30° to 70°. The thickness can not be less than several hundred feet.

The beds of conglomerate are composed partly of rounded pebbles of indurated sandstone and jasperized clays from the Older Parian, and partly of quartzose detrital from the northern hills (Caribbean group). The cementing matter is ferruginous, calcareous, or siliceous. These conglomerates are generally highly consolidated.

Calcareous sand and sandstone form a marked feature in this succession of strata. The former are loose, with a certain, usually small admixture of calcareous, often shelly matter, and occasionally traversed by layers of hard calcareous sandstone. The latter consist of grains of sand, with calcareous cement, which is frequently fine organic débris or larger shelly fragments, and form hard beds of a few inches to 20 or 30 feet in thickness. Both these varieties of strata contain abundance of marine shells and have supplied the larger proportion of the animal fossils collected in the island.

The remaining strata of the series consist of sands and clays, more or less fossiliferous, but not consolidated.

The sequence of strata is exposed in the cliffs at Manzanilla. The thickness, including the crystalline limestone, may be about 2,000 feet. \* \* \*

The crystalline limestone seems to form one of the lowest members, over which are calcareous sandstones, conglomerates, and calcareous sand, above which are fossiliferous clays and sands. \* \* \*

The Caroni or carbonaceous series is exposed in a complete section in the cliffs between Manzanilla and the Oropuche. Two divisions may be introduced—the lower or noncarbonaceous and the upper or carbonaceous. The former consists of shales, generally dark gray; dark, often black fossiliferous clays; a few thin beds of sand, frequently sulphurous, and associated with a small number of pebbles from the Caribbean and Older Parian groups; and in the upper part of highly laminated but unfossiliferous hard calcareous sandstone. The superior division contains strata composed of sand, with small pebbles of the usual varieties, shelly fragments, and calcareous cementing matter. The rock of Point Noir is an illustration of this.

Of shales there are all varieties, from light-colored to dark carbonaceous. The clays are frequently carbonaceous and sulphurous.

Beds of massive yellow but pulverulent sand generally overlie the larger seams of coal, with only a few feet of shale intervening.

Subordinate layers of calcareous sandstone, usually only a few inches thick, occur in places. The seams of Tertiary coal associated with the preceding strata form an important item. They are numerous and vary from a mere carbonaceous film to over 4½ feet in thickness. \* \* \*

The lower strata of the upper division contains shells similar to those at Manzanilla, but the superior beds are characterized by large shells, which are believed to be confined to that portion of the series. A few dicotyledonous leaves occur in the nodules of calcareous sand or clay. \* \* \*

The Moruga or arenaceous series is an extensive series of strata, usually of a loose sandy nature. These are well exposed in cliffs all along the southern shore and offer some characteristics quite peculiar to themselves and others which are possessed in common with the Caroni division. Thick strata of massive sand, generally loose and pulverulent, are the most prevalent beds, and, indeed, sand may be said to be in great excess. Granular sulphur is very generally disseminated in these strata, having been observed from Canary round Point Icaque to Oropuche. Shales are also numerous, but clays of rarer occurrence.

Calcareous sandstone is extensively diffused in beds not exceeding 6 to 8 feet thick, and often only a few inches, and, being very hard, resists the destructive action of the sea, running out in parallel lines on the beach often beyond low water, and forming quite a characteristic feature of this line of coast. The cementing calcareous matter seems to have been comminuted organic detritus, but in some cases the original nature of the deposit was fossiliferous sand, the indistinct impressions of the shells remaining, but their calcareous substance being entirely removed and reprecipitated as cementing matter round the grains of sand, thus binding the whole into one compact mass. \* \* \*

Layers of carbonaceous matter occur, but by no means so commonly as in the Caroni series. The vegetable structure is usually very distinct, but occasionally obliterated. The principal seam of lignitic shale is near Point Moruga. It occupies a vertical position and is 20 feet wide, containing several layers of lignite not exceeding 10 inches but much inclined to be bunchy. These carboniferous beds are all more or less mixed with shaly matter, rendering them impure. At Erin and Irois the beds of lignite are less inclined and the ligneous texture still more apparent.

Strata which will be named porcellanite occur especially at Erin, Points Cedros and Rouge, part of Point Brea, to a small extent at Moruga, and adjacent to the large seam of coal at Punta Paloma (Caroni series). By the above term it is intended to imply strata of semi to perfectly indurated and compact structure, presenting a great variety of colors, among which brick-red is predominant. They are fissured and jointed into almost cubical masses, these joints being frequently lined with vesicular slag. An alternation of colors in thin laminae frequently prevails. Some specimens are semivitrified, forming porcelain jaspers, and the fracture is frequently conchoidal.

The peculiarities of these strata are most fully developed in the central portion, diminishing in intensity upward and downward, and finally graduating into the adjacent shales or sands. The thickness has not been noticed over 70 to 80 feet.

This structure has been induced by the heat developed in the combustion of carbonaceous matter, for not only are there remnants of the original stratum with its unconsumed carbon, but this porcellanite is identically the same with the substances produced immediately above or below seams of coal which have accidentally taken fire and burnt for a length of time. The unconsumed portions are associated with granules of sulphur. Perhaps the decomposition of pyrites (extensively disseminated in this series) generated sufficient heat to occasion the ignition of the carbonaceous matter of the seams of lignite, and the cracks or fissures might permit so much air to penetrate as would support a slow combustion. That this combustion originated within the altered portions is evident from the circumstance of the adjacent lignitic beds being unaffected, which could not have been the case had the heat been transmitted from below. \* \* \*

Natural asphalt, a well-known product of Trinidad, is extensively disseminated in this series. \* \* \*

No sections sufficiently extensive occur from which to deduce any very positive order of succession; as far as could be ascertained, there seemed to be a great repetition of sands and shales of very similar characters.

The data for estimating the thickness are very uncertain; conclusions founded on the inclined positions give at least 3,000 to 4,000 feet.

## E 17-18. JAMAICA.

Hill's classification of the rocks of Jamaica is given in Chapter XV (pp. 639-642). From his account <sup>443b</sup> we take the following description of the deposits assigned to the early Tertiary:

The Richmond beds constitute the upper subdivision of the Blue Mountain series. Their arrangement and composition, consisting of shallow marine deposits of worked-over and water-assorted terrigenous material, indicate a succession of more quiet sedimental conditions than those which marked the preceding epoch.

The rocks are mostly black bituminous laminated clays and ferruginous sandstones with occasional beds of loose conglomerate. They occur in uniform alternations of thin, regular, and evenly bedded strata, varying from an inch to a foot or more in thickness. They are dull blue-black on fresh exposure, but undergo excessive oxidation and hence are ordinarily of dark-brown ferruginous colors. In general texture, arrangement, color, and stratification they resemble the Eo-Lignitic (lower Eocene) beds of the southern United States. The clays contain many small flakes of carbonized vegetal matter, and silicified wood has been found in the gravel. The gravel is mostly derived from the antecedent beds of the lower division of the Blue Mountain series. The so-called "sandstones" are composed of cemented grains of waterworn hornblende andesite derived from the underlying igneous rocks, and the shales are the same material more finely triturated and mixed with vegetal matter. The conglomerates consist of rounded pebbles of various dimensions and in places attain a thickness of 50 feet. They are almost entirely of the same material as those of the lower subdivision. Rounded fragments of the Rudistean limestone also occur in them. \* \* \* In addition to these rocks of the conglomerate, former observers have noted, from the bluff at Port Maria, specimens of gneiss and crystalline slates, "rocks of which no trace either in situ or otherwise have hitherto been found in Jamaica; also a fine-grained granite to which nothing analogous has been noted on the island. \* \* \* In this unique collection are many instances of rocks which have totally disappeared from the surface of Jamaica but which must have existed during former epochs, either in the formations of this country or in adjacent lands that have been destroyed." <sup>a</sup>

At the same locality, as also noted in the Jamaican reports,<sup>a</sup> the ordinary sandstone is rapidly transformed in its seaward extension into a promiscuous assemblage of large pebbles 6 or 8 inches in diameter. This fact indicates that some of this material came from the area to the north, now occupied by the sea. In this same bed of conglomerate were found the Eocene corals described by Duncan, and a few species of mollusks. \* \* \*

The Richmond formation outcrops in many places a short distance back of the sea along the north coasts of the parishes of St. Ann and Trelawney. It is well exposed beneath the Cambridge beds south of Cambridge, along the highway on the west side of Great River, as seen by the writer. It also occurs on the south side of the Blue Mountain Ridge in St. Andrews and St. Thomas. According to Sawkins, in the latter parish at Blue Mountain Valley it consists of "alternate bands of red clay, yellow sandstone, and light-gray shales, 1,000 to 1,200 feet in thickness."

In general, this formation underlies nearly all the later rocks, and, in our opinion, prior to the Montpelier subsidence it occupied an area as large or larger than that of the island of to-day.

From data presented in the paleontological chapter of this work the age of these beds is undoubtedly old Eocene, although it is impossible to draw an exact line between these beds and those of the lower division which we have termed Cretaceous, and they are no doubt stratigraphically continuous.

The uniform alternations of the Richmond beds indicate that they were rapidly deposited over a considerable shallow area of deposition; since much of this area was the present locus

---

<sup>a</sup>Jamaican Reports, p. 130. (Entitled "Reports on the geology of Jamaica, or Part II of the West Indian Survey," by James G. Sawkins, with contributions by others.)

of the island, it is difficult to infer the situation of the near-by land from which the material was derived; some of it may have come from the old nucleus of Blue Mountain Ridge, but in our opinion this was not of sufficient size to afford all the material. These facts, together with the presence of foreign material, are at least strongly suggestive of the occurrence of land areas during this epoch, concerning the locality of which present knowledge is wholly wanting.

The Cambridge formation is named after the typical locality of its occurrence at Cambridge, between Ipswich and Montpelier, in the parish of St. James, in the northwestern portion of the island, near the junction of the boundaries of St. James, Hanover, and Westmoreland.

In places the Richmond beds grade up into irregular alternations of impure clay, marls, and yellow limestones, which, in general, occupy a transitional position between the obviously land-derived beds of the Blue Mountain series and the ocean-derived limestones of the Oceanic series. Argillaceous calcareous marls appear in the upper part of the Richmond beds, become successively more and more frequent, and finally dominate. These are accompanied by thin beds of impure blue limestone of a segregational character, oxidizing yellow on weathering and alternating with the marls which gradually increase in thickness and relative proportion until they preponderate. Finally these yellow limestones become more purely calcareous in ascending series as the sediments become clearer and freer from land-derived material, until they finally pass into the purer White limestones.

As he was not able to correlate certain divisions of the Cambridge formation precisely with one another, Hill distinguished them under the names of Catadupa and Chapelton beds. After describing these different occurrences, he continues:<sup>443c</sup>

There are several paleontologic and stratigraphic features of the Cambridge beds which are peculiar and will require more extensive field work for final explanation. We have reason to believe that the beds are not connected but occur in broken patches, which, at least in their lower portion, like the Cretaceous beds, represent sporadic colonies of lime-making organisms, which found temporary foothold at intervals during a period of turbulent deposition generally unfavorable to a large development of marginal life. These deductions are based upon the fact that in no two localities are the sequence of sediments or association of species identical, while in others the beds do not appear between the Richmond and the Montpelier. Furthermore, the fossiliferous horizons of the Lower Cambridge are so like some of the Cretaceous that the one has been frequently mistaken for the other. The mixture of Cretaceous Rudistes and Eocene corals and Mollusca at Catadupa, as seen by us, and of Orbitoides and Rudistes in Portland, as noted by Barrett, indicates a transgression of Cretaceous life into the Eocene and further denotes the anomalous nature of this formation.

These beds, while showing sedimentary relations to the Richmond, undoubtedly represent a transitional step in the deepening which later produced the Montpelier formation. In some places it seems perfectly conformable beneath the latter, while again, as shown by Brown and seen in several places by us, they are unconformable. These apparently irreconcilable conditions can probably be explained upon the hypothesis that the island was undergoing subsidence during the Cambridge epoch, although parts of it were then dry land, which was still further covered by the Montpelier beds during the succeeding epoch. As shown in another chapter, the age of these beds, although containing a remarkable mixture of Cretaceous and Tertiary fossils, is undoubtedly Eocene, and with the Richmond beds they constitute the Eocene system in Jamaica.

Of the White limestones, Hill distinguished two series, the Oceanic and Coast series. He says:<sup>443d</sup>

The transitional Cambridge beds grade up into rocks of organic oceanic origin. These are the White limestone formation of the official Jamaican reports. They have no genetic relationship with the rocks of the Blue Mountain series and differ from them in every physical and chemical aspect.

The interpretation of the white limestones has been one of the greatest problems of Jamaican geology. There have been so many diverse opinions concerning their age and sequence that it is almost impossible to obtain from current literature any approximation of their true relations and significance. The difficulties can be readily seen by any one who reads the conflicting and apparently involved conclusions in the Jamaican reports. The fragmentary descriptions of their local occurrence are frequently well written, but through lack of correlation and erroneous deduction they fail to clear up the sequence and age of the beds. \* \* \*

The truth is, the white limestones of the Jamaican sequence represent several distinct formations and ages, from Vicksburg to recent inclusive, but that the greater portion of it, as I shall show, is of old Oligocene age. There are even some white limestones in the Cretaceous in Clarendon which are almost lithologically indistinguishable from those of the Tertiary. In recent years English geologists have observed the discrepancies of previous interpretations of the white limestone and suggested, from specimens of the material sent them, that at least an upper and lower division might be distinguished. Our investigations will show that not two but several subdivisions can be made, and that the rocks hitherto classified under this general head really belong to several distinct formations of two great series, the Oceanic and the Coastal, the former constituting most of the rocks of this character and occupying large areas of the interior upland, while the latter are confined to a narrow belt along the coast.

The older white limestone formations, constituting the greater mass of these rocks, are found in the upland area of the island and are all of Tertiary age. More exactly speaking, they are of the Vicksburg stage, which is placed in the Eocene by some writers and in the Oligocene by others. The later white limestone formations—including the Coast limestone of the Jamaican reports, which we shall describe as the Falmouth formation, and the Hospital Point limestone of Montego Bay—are of Pliocene, Pleistocene, and recent age.

There has also been much vagueness concerning the origin of these rocks, accompanied by an opinion on the part of many that they are of coral-reef origin. \* \* \*

Not the least important result of our researches will be a demonstration that the larger thicknesses of these limestones are neither of molluscan, coralline, or reef-rock origin, but are foraminiferal oceanic deposits and other offshore calcareous oceanic muds composed of organic detritus laid down at depths below that at which reef rocks were formed and in periods of geologic time prior to the appearance of the modern reef-building species in the sequence. \* \* \*

The upland white limestones or Oceanic series, as we shall call the Tertiary formations under discussion to distinguish them from the later deposits of the Coastal series, consist of white limestones of varying texture and hardness, and probably aggregate 2,000 feet in thickness. These present a perplexing series of surface and interstitial changes under the influences of solution and oxidation, as explained in their detailed descriptions, which render their study a difficult task. They consist of deeper-water organic deposits and are free from coral-reef rock, littoral shell agglomerates (such as coquina, cantera, and caleche), beach wash, eolian débris, or other elastic formations which characterize the rocks of the Coastal series. They contain few macroscopic fossils by which their age can be independently determined, but this is fixed by their microscopic fossils and their position between including fossiliferous horizons—the underlying Cambridge beds and the overlying Bowden gravels and marls.

In general, the Oceanic series occupies most of the plateau region, which practically includes all the island under 3,000 feet in altitude outside of the Blue Mountain district, except its immediate coastal borders. In the mountainous region of eastern Jamaica these rocks occur as a high piedmontal peripheral border around that end of the island. In the western half of the island the beds of the Oceanic series completely cover the old Blue Mountain series and occupy the higher summits of that portion of the island.

Owing to the elevation of the plateau region which took place after the deposition of these beds, and the subsequent contraction of its oceanic borders by erosion and subsidence, the coastward extension of the rocks is truncated and partially embedded near the littoral by the still later formations of the Coastal series, which are deposited unconformably against them.

The detailed subclassification of the Oceanic series comprises not only the Catadupa and Chapelton beds of the Cambridge formation, but also the Montpelier, Moneague, and Cobre formations. Of the Montpelier Hill <sup>443e</sup> says, quoting Charles B. Brown:

It consists of thin beds of white limestone, interbedded with a soft white chalky marl, the limestone beds invariably containing nodules of flint. The limestones are chiefly soft but seldom compact or crystalline; they form thin beds, which vary from a few inches to 4 feet in thickness and are much disturbed, so as to dip in almost every direction over small areas. The marl beds, being interstratified with these, of course show the same disturbance and dips and are similar to them in thickness. The flints and chert contained in the limestone beds lie usually in flattened nodular masses in lines of stratification and are rarely in beds themselves. They are not connected continuously but are in long, hollow flat masses, and have all the appearances of having been deposited around or in the substance of some organic form which was embedded in the limestone. These flints are chiefly of brownish-pink, brown, and gray colors. At Knockalva and other places in the vicinity the limestone contains small veins of silica, and also has become so thoroughly impregnated with that substance as to be completely changed into a siliceous limestone.<sup>a</sup>

Microscopic examinations show that the calcareous beds consist of organic oceanic material and are composed of the shells of Foraminifera, occasional sponge spicules, and fine crystals and amorphous particles of carbonate of lime, like those usually found in all chalky oceanic deposits. No terrigenous material whatever has been found in any specimens examined. The Montpelier beds are singularly free from molluscan or other visible fossils, except a large species of *Orbitoides* in its lower beds. *Nummulinæ* have also been found. \* \* \*

The thickness of the Montpelier formation is difficult to determine, owing to lack of continuous exposures. Our observations have led to the conclusion that they do not exceed 1,000 feet. Everywhere these beds show great disturbance, but not to the degree of the Blue Mountain series, usually consisting of more open folds.

The Montpelier beds are the deepest sediments preserved in the geological structure of Jamaica and represent the culmination of the great subsidence initiated in the Cambridge epoch. Judging from the rapid transition between the littoral Cambridge formations and the chinks of the Montpelier formation, this subsidence must have been rapid in geologic time.

The age of the Montpelier beds most probably corresponds to that of the late Eocene (old classification) now called the early Oligocene, agreeing approximately with the position of the Vicksburg stage of our American Tertiary. This inference is based upon the position of the beds above the undoubted lower Eocene of the Cambridge formation and below the undoubted late Oligocene of the Bowden formation, together with the occurrence of *Orbitoides mantelli*.

In regard to the Moneague formation Hill <sup>443f</sup> states:

The Montpelier beds grade up into more massive limestones, white in color, firmer in texture, often semicrystalline, sometimes containing casts of fossil mollusks and solitary corals, and occurring in well-defined bands of stratification from 1 to 5 feet in thickness. More massive texture and regular bedding especially distinguish this formation from the other white limestones of the island, such as the chalky rocks of the underlying Montpelier and the irregular lumpy texture of the overlying Cobre formations. These rocks contain many cavernous molds of Mollusca and single corals, indicating that a considerable amount of shell débris may have accompanied their original deposition. The fossils obtained near Ewarton, Retreat, and Cinnamon Hill, in a firm limestone matrix, were mostly poorly preserved molds of corals and mollusks, which the paleontologists could not determine. \* \* \*

---

<sup>a</sup> The description above given refers to Brown's lower division of the white limestone (our Montpelier beds); the upper beds (our Brownstown beds) are more compact and massive and contain fewer interstratified marls.

From their usual association with and occurrence above the Montpelier beds, there is little doubt that they were continuously deposited with the latter and possibly may represent shallowing but nevertheless deep-water beds after the culmination of the Montpelier subsidence. Our knowledge of the upper contact of these beds is very deficient. In Clarendon and St. Elizabeth they clearly occur below the Cobre and Porus (Bowden) formations.

The name Cobre formation is applied to a local occurrence of white limestone exposed in the canyon of the Cobre. Hill says that from the Bog Walk section it is evident that the Cobre formation lies stratigraphically above the supposed Moneague beds at Ewarton and below the May Pen formation. Its relations with the Bowden beds are not established. It apparently occupies an intermediate position between the Moneague and the Bowden.

For description of the later Tertiary formations, see Chapter XVII (pp. 799–801).

#### E-F 15-16. CHIAPAS, GUATEMALA, TABASCO, AND YUCATAN.

The peninsula of Yucatan is mapped in accordance with an interpretation of the map given by Sapper,<sup>694c</sup> who characterizes the Tertiary of the States of Tabasco and Chiapas as follows:

The major part of the Tertiary terranes consists of marls and shales with sandstones and conglomerates as well as limestones which are, however, of minor importance.

The fossils which Sapper cites from these formations are Pecten, Ostrea, Nummulites, Elypeaster, and different Glossophora (?), lamellibranchs, and corals.

Sapper regards these fossils as representing the upper Miocene or some of them as coming from a lower horizon. Dall thinks it probable that they represent the Oligocene. Sapper further cites certain remains of plants and Foraminifera which were determined by Schwager to be of Tertiary age.

Heilprin<sup>433a</sup> describes in the following terms the limestone of the Sierra de Yucatan, a range of hills which runs in a northwest-southeast line from Ticul in the direction of Peto:

The rock formation of the Sierra de Yucatan differs in many particulars from that of the basal plain. The surface rock, forming the crest and the slopes on either side—presumably an anticlinal structure—is a fairly compact red or reddish limestone, which seems to rest at nearly all places, as we had occasion to observe in the Caves of Calcehtok and Loltun, on a semicrystalline white or gray marble or on an exceedingly fine grained cream limestone, somewhat resembling in texture true lithographic stone. A brecciated limestone, containing fragments of the last-mentioned rock, occurs at intervals along the base of the hills, and we also found it among the rocks used in the construction of the buildings (now ruins) of Labna. I am not absolutely certain as to the age or even as to the general nature of the red rock. The brecciated masses are almost undoubtedly of marine origin, and they give evidence of the encroaches of the sea after the underlying rock had not only been formed but been converted into its present semicrystalline condition. In other words, the present range of hills probably by that time already existed. It is, however, less clear that the red or reddish rock which extends away from the base of the hills but forms their slopes is of marine origin. Its universality would seem to indicate that it was of this nature, but at many places where I examined it, on and off the crests of the hills, it bore suspicious marks of being a disintegration product, which had subsequently undergone cementation. The only fossil that I found in it, on any surface exposure, was a *Helix* (probably identical with a species now living in the same region), which was obtained from near the summit of the pass between Ticul and Santa Elena, at an

absolute elevation of perhaps 300 feet. It occurred in a thoroughly hard rock, but this circumstance is in itself no proof of actual antiquity, since in a purely calcareous region such as this one rock cementation is a rapid process, as we had occasion to observe in the terrestrial (fossiliferous) limestone now forming near a quarry about 2 miles south of Ticul. In the red rock which in the cave of Calcehtok overlies the gray limestone I found the impression of a single gastropod, which I should unhesitatingly refer to a terrestrial form and to a genus of Pupidæ close to *Macroceramus*, if indeed it is not *Macroceramus* itself. I could find no vestiges of marine mollusks, but yet they may well occur in other parts of the rock and it would, perhaps, not be safe to conclude that the entire red rock is of terrestrial origin, or that it represents a single type of formation.

No doubt attaches to the heavily bedded gray and white limestones and marbles which are so well exhibited in some of the deeper caves, such as that of Calcehtok, for example. The mouth of this cave, according to a rough approximation, is some 200 feet above the sea. At a depth of some 50 feet the red limestone appears in a solid mass, and beneath it we reach the crystalline limestones, which are disposed in layers of 10 to 15 feet thickness. Fossils are not abundant in this rock, and Col. Glenn, who had explored this cave on a previous occasion, was of the opinion that no fossils were to be found in it. After considerable search, however, we discovered a few in an indifferent state of preservation, and still later some whose characters were sufficiently defined to permit us to determine their relationship. Among these are a *Pecten*, with little doubt *Pecten nucleus*, the cast of a large *Marginella*, apparently the living *Marginella labiata*, a *Potamides* or *Cerithidea*, the impression of the apex of a large *Oliva* (of the type of *Oliva literata*), and a single impression of *Venus cancellata*. While the above forms are barely sufficient to determine the exact age of the formation in which they occur, whether Pliocene or Miocene, I am inclined to believe that it is rather the former, the mountain rock—semicrystalline or highly compact and but scantily fossiliferous—being a compressional alteration of the much less compact and highly fossiliferous rock of the basal plains. But whether Pliocene or Miocene, I think it can be all but positively assumed that it is not older than Miocene, although it has been asserted that it represented the Oligocene or Vicksburgian period.<sup>a</sup>

#### F 17-18. CUBA.

T. W. Vaughan has contributed to this work the following notes on the early Tertiary of Cuba:

The only rocks that we positively know to be of Eocene age in the island occur in the Province of Santiago, not far from the city of Santiago, where they are associated with manganese ores. This information is furnished by William H. Dall, who determined some fossils collected by Clarence King. Associated with the manganese ores in this province are foraminiferal limestones and foraminiferal marls, which appear to be of Eocene age and are tentatively referred to that epoch. It is probable that the limestones occurring along the northern foot of the Sierra Maestra from Los Negros to Cabo Cruz are also Eocene. Eocene limestones are reported from the Province of Santa Clara, particularly near Cienfuegos, from the Province of Matanzas, near the city of Matanzas, and from the vicinity of Havana. The data on which the age of these rocks has been determined for these three provinces seem doubtful, the doubt for the vicinity of Havana being so strong that the formations in that area are referred to the late Oligocene.

North of the city of Pinar del Rio and along the Rio Santa Fe, just south of the village of San Jose, sandstones underlie the upper Oligocene limestones. No paleontologic data by which the age of this formation could be determined were procured, but it may be of Eocene age.

A yellowish marl composed of the remains of *Radiolaria* has been described by several authors as occurring in Baracoa. This material underlies the upper Oligocene and is probably of early Oligocene age.

Limestones and marls of late Oligocene age constitute by far the most widespread geologic formation in Cuba. They extend uninterruptedly from the Province of Pinar del Rio to the

<sup>a</sup> Agassiz, Alexander, Three cruises of the *Blake*, vol. 1, p. 69.

Province of Santiago. The most westerly locality at which rocks of this age were observed was in the Province of Pinar del Rio, some 4 miles north of the city of that name, on the road to Viñales. Lithologically the material is either soft limestone or calcareous marl. There is a quarry in yellowish upper Oligocene limestone at the town of Consolacion del Sur, from which a fair collection of fossils was obtained through the kindness of the alcalde of that town. Limestones and marls, with a few beds of calcareous sands, occur over large areas in the vicinity of Havana, extending from the city toward the west, south, and east.

Limestones and marls of the same age, with conglomerates, occupy extensive areas around Matanzas and east of that city. The gorge of Yumuri River is cut through rocks of this age and exposes an excellent section. At this place the river runs nearly east and west through a narrow canyon 500 to 600 feet wide. From its bottom the vertical distance to the top of the highest level through which it is cut is some 450 feet. The gorge itself is about 200 feet in depth. The rocks dip at an angle of about 27° SE., the thickness here exposed being estimated at 600 to 700 feet. The whole section, except the lowest 100 feet, at the west end of the gorge, is composed of limestone, more or less impure, with a few beds of sandstones and conglomerates near the top of the section. Characteristic upper Oligocene fossils are abundant. The writer did not collect any upper Oligocene fossils in the Province of Santa Clara but has reason to believe that limestones of this age are extensively developed in its northern and southern portions.

Upper Oligocene yellowish calcareous marl or limestone are found in the vicinity of Nuevitas; also at Baracoa, where they immediately underlie the Pleistocene coastal soborruco. There is a very great development of marls and limestones, containing large numbers of reef corals, in and around the city of Santiago. The terraces in this city, excepting the lowest soborruco, have been cut into upper Oligocene formations. Upper Oligocene limestones have also an extensive development in the vicinity of Manzanillo.

#### G-H 14, H-I 15. TEXAS, LOUISIANA, AND ARKANSAS.

The following discussion of the early Tertiary of Texas, Louisiana, and Arkansas has been compiled by T. W. Vaughan from the literature, from unpublished manuscript or notes of Alexander Deussen, C. H. Gordon, and A. F. Crider, and from the results of his own researches.

Space will not permit detailed descriptions or geologic sections, and for further information the reader should consult the publications listed in the bibliography (pp. 840-865) under Nos. 297, 299, 370, 401, 406, 407, 408, 430, 485, 486, 487, 488, 633, 832, 833, 838. Additional references are given on page 731, and many of these publications contain still other citations.

#### GENERAL SECTION.

The same division of the Eocene into Midway, Wilcox, Claiborne, and Jackson can be made in the Coastal Plain area west of Mississippi River as east of that stream (see p. 731); for the Oligocene, however, a different classification is necessary, as the Vicksburg is not so far west as Red River, and the Apalachicola group is not known in the western area, the sediments stratigraphically equivalent to the Apalachicola being of estuarine or littoral character, similar to those across southern Mississippi. In the table opposite page 724 the section for Arkansas and Louisiana is modified from the one published by A. C. Veatch<sup>838a</sup> and that for Texas east of Guadalupe River has been furnished by Alexander Deussen.

#### EOCENE.

*Midway group.*—The Midway group is extensively developed from Arkansas southwestward across Texas to the Rio Grande. Usually the group has not been subdivided, and the name is therefore applied in a formational sense. However, future studies may lead to subdivision and the adoption of several proposed names for local manifestations. There is a general unconformity by erosion between the Midway and the underlying Cretaceous, but it is usually con-

cealed or inconspicuous because of the similarity of the Eocene and Cretaceous sediments. In northeastern Arkansas the Midway overlaps the Cretaceous, and rests upon a Paleozoic floor.

Stephenson and Crider, in an unpublished manuscript, state:

"In Pulaski County, Ark., the strata of the Midway formation, where most completely developed, are separable, according to Harris,<sup>a</sup> in ascending order into (a) white, compact sand (2 feet); (b) ledge of calcareous sandstone (2½ feet); (c) the 'Turritella limestone' (8 feet); (d) the 'Ostrea [Gryphæa] limestone' (3 feet); (e) the 'Enclimatoceras limestone' (1½ feet). In general, the 'Turritella limestone' in Arkansas consists of layers of hard light-gray to blue limestone interbedded with layers of sand, and this division is the one most often seen in outcrops. The formation is easily separable both lithologically and paleontologically from the underlying Paleozoic rocks and the overlying younger formations."

According to Harris and to Stephenson and Crider, the northernmost Midway outcrop is near Newark, in Independence County, Ark., whence it has been traced southward, more or less continuously, along the edge of the Paleozoic rocks to a point near Rockport on Onoshata River, Hot Springs County. North of the locality near Newark it has not been recognized on the surface or in well borings. In southern Missouri the group may be represented by the Porters Creek clay. From Olyphant, Jackson County, to Russell, White County, the Midway outcrops in numerous places along the St. Louis, Iron Mountain & Southern Railway and on the terrace-like elevation which extends almost unbroken from Russell to Olyphant. It occurs in Pulaski and Lonoke counties. The best exposures in Arkansas are between Little Rock and Malvern. It outcrops in Little Rock near the point where the Hot Springs wagon road crosses the St. Louis, Iron Mountain & Southern Railway and may be traced almost continuously from this place westward to Malvern. Outcrops of the Midway are not known in Arkansas southwest of Hot Springs County.

In Louisiana two outcrops of the Midway are known, one on the road from Marthaville to Many, at Rocky Spring Church, in Sabine Parish, and the other at King's salt works, in southwestern Bienville Parish. These outcrops have been brought to the surface by anticlinal folding. The material in both localities is calcareous.<sup>408a</sup> Harris<sup>407e</sup> says regarding a third probable outcrop:

"Farther to the south in the Sabine uplift territory—for example, along the Texas & Pacific Railway for over a mile in the vicinity of Marthaville—*Ostrea thirsæ*,<sup>b</sup> a very characteristic fossil of the basal Wilcox formation, occurs in great abundance. As the strata in that vicinity dip to the south, though but slightly, it is evident that Midway beds must occur at the surface over a considerable area to the north. Their geographic distribution has not yet been worked out."

In Texas the basal contact of the Midway has been positively identified at only two localities—on Brazos River 1½ miles above the Falls-Milam county line<sup>403a</sup> and on Frio River.<sup>832e</sup> At the former locality no erosion unconformity can be seen, notwithstanding the great faunal change; at the latter locality there is evidence of such an unconformity. Deussen, in an unpublished manuscript, says that northeast of Brazos River "at the base of this formation are usually found bluish micaceous clays or clayey sands with occasional light-yellowish fossiliferous limestone layers of marine origin. These are succeeded by sandy ledges, resting on which are generally found black selenitic clays. The outcrop constitutes the Eastern Marginal Prairies and occupies a narrow belt extending approximately north and south in Van Zandt, Kaufman, Henderson, Navarro, Freestone, Limestone, Falls, Robertson, and Bastrop counties. Much of the exposure is obscured by materials of later age. This formation in northeast Texas averages about 260 feet in thickness. The dip varies between 1° and 5° SE."

Southwest of Bastrop County the Midway has not yet been definitely traced in Texas, but evidence obtained by Vaughan along Frio River and the Rio Grande indicates that it extends into Mexico. On Frio River,<sup>832e</sup> 5 miles due north of the southern boundary of Uvalde County,

More or less contemporaneous.

<sup>a</sup> The Jackson, Claiborne, and Wilcox, which are fossiliferous and distinct in central Louisiana, grade toward the north into lignitiferous beds containing no distinct fossils. In northern Louisiana and southern Arkansas the fossiliferous Jackson limits this lignitiferous complex above. Still farther north, however, the Jackson also grows lignitiferous and merges with the rest. The Midway, likewise, in the upper embayment region shows a decidedly lignitiferous tendency and may in places merge with the lignitiferous time equivalents of the other Eocene beds.

no limestone was found, but there is a yellowish or bluish sandstone, usually rather soft, containing Midway fossils. The Midway also occurs along the Rio Grande, near the Webb-Maverick county line, above the mouth of San Ambrosia Creek.<sup>832c</sup> The material consists of dark-brownish or yellow clays and soft sandstones. The thickness was not determined.

According to Dumble<sup>298</sup> the main divisions of the Texas Eocene extend into Mexico.

*Wilcox formation.*—The following statement regarding this formation in Arkansas and Louisiana is modified from that of A. C. Veatch.<sup>838d</sup>

Overlying the limestones and calcareous clays of the Midway formation is the Wilcox formation, a series of dark, finely laminated sands and clays containing much vegetable matter, either scattered through the mass or accumulated in lignite beds, and a few layers containing marine shells. It commonly differs from the underlying Midway in the presence of lignitic material and fossil leaves and when containing marine fossils is readily distinguished from both the Midway and the overlying Claiborne. Toward the coast, where it is overlain by the very calcareous, argillaceous, fossiliferous St. Maurice formation of the Claiborne group, its upper limit can be fixed with exactness, but farther inland, where estuarine and swamp conditions persisted until Jackson time, no separation is possible except on a purely paleontologic basis. On the whole, the formation is predominantly sandy. Veatch closes his description as follows:

“The Sabine [Wilcox] formation and its equivalent beds in the undifferentiated Eocene underlie the whole of Louisiana, except the limited areas occupied by the outcrops of the Cretaceous and Midway domes, and all of Arkansas south and east of the Cretaceous and Midway outcrops. Its thickness, as shown by carefully constructed sections in which local irregularities are reduced to their proper minor importance, ranges from 300 feet in northern Bossier Parish to from 800 to 900 feet near Nachitoches and on Sabine River.”

From an unpublished manuscript by Deussen the following description of the Wilcox formation in eastern Texas is taken:

“In eastern Texas the Wilcox formation comprises a series of beds of palustrine and littoral origin, carrying deposits of lignite and glauconitic, fossiliferous, nonlignitiferous beds of marine origin. This formation consists chiefly of a great mass of lenticular beds of sand, concretion and leaf bearing sandstones and clays, sandy clays, and lignites, all of palustrine origin. Cross-bedded sands and sandstones also occur. In places the sand is indurated into a hard sandstone that is locally useful for building purposes. Thick lenses of lignite of good grade, irregularly distributed, give to the formation great economic value. Plant remains indicative of the shallow-water origin of these beds occur at a number of places. The lignitic and palustrine deposits apparently grade seaward into glauconitic and fossiliferous marls of marine origin. The great thickness of these shallow-water sediments—500 to 600 feet—is indicative of subsidence contemporaneous with deposition. It is otherwise impossible to account for this thickness. Along Sabine River close to the southern margin of the outcrop of the formation glauconitic beds of marine origin occur, which carry characteristic Wilcox fossils.

“The rocks of this formation outcrop over a wide belt of country, occurring in large portions of Robertson, Limestone, Leon, Freestone, Navarro, Anderson, Henderson, Van Zandt, Smith, Gregg, Harrison, Rusk, Shelby, Panola, and Sabine counties, occupying a position to the east and south of the Midway exposures. Where they are not covered by deposits of later age they almost invariably give rise to sandy soils easily eroded. The sandy outcrop constitutes a portion of the east Texas timber belt.

“In northeastern Texas, in the counties of Cass, Marion, Harrison, Panola, Gregg, Smith, and Upshur, the Wilcox formation is generally seen to underlie a red sandstone which carries casts of *Venericardia planicosta* and appears to be an altered greensand. This red sandstone is provisionally referred to the Mount Selman formation of the Claiborne group.

“The uppermost beds of the Wilcox formation in this portion of the State consist of a series of laminated or thinly stratified white and red sands and sandy clays, in many places merging into one another. They do not carry any lignite, so far as we are aware, nor have they yielded thus far any organic remains. These deposits are so distinctive in this portion of

the State that they have sometimes been described as a separate formation, to which the name Queen City has been applied by Kennedy.<sup>a</sup>

"The lower beds of the Wilcox in northeastern Texas, which are seen to underlie the beds above described, are similar in all respects to the deposits occurring on the Brazos."

West of the Colorado River the Wilcox or its representatives have not been definitely traced, but the studies of Penrose, Vaughan, and Dumble have proved that it is extensively developed along the Rio Grande. Vaughan<sup>832b</sup> has shown that on the Rio Grande 3½ miles above the mouth of San Ambrosia Creek, Maverick County, sandstones and thinly bedded lignitic sands carrying Midway fossils underlie coarser sands outcropping in the vicinity of the Chupadero ranch and extending thence northeastward through Carrizo Springs and Batesville. These sands are the Carrizo sands of Owen<sup>625</sup> and are probably the lower portion of the Wilcox. They are at least 150 feet thick. They are overlain by about 300 feet of fine-grained micaceous sandstones, which are succeeded by alternating beds of clay, shales, and sandstones, at least 400 feet thick, and these in turn by clays, sandstones, and lignite beds 190 feet thick.<sup>832d</sup> Dumble<sup>297b</sup> reports: "About 35 feet above the San Pedro seam [Santo Tomas] there is a band of shell breccia which contains a great number of fossils. Among there were *Ostrea divaricata* Lea, *Anomia ephippoides* Gabb, *Corbula texana* Gabb, and many others." These fossils belong to the Claiborne group and occur between the two coal seams in this mine, or the last division of the section described above belongs to the Claiborne. The Wilcox along the Rio Grande is probably at least 850 feet thick.

*Claiborne group.*—In central Louisiana the Claiborne group is divisible into a lower fossiliferous formation, the St. Maurice, and an upper formation, the Cockfield, which contains no marine fossils. The St. Maurice formation is much more calcareous, glauconitic, and clayey than the underlying Wilcox formation and where typically developed contains no lignitic nor lignitiferous matter, though to the north it changes to lignitiferous sands and clays and merges into the undifferentiated Eocene.

The thickness of the St. Maurice formation is 250 to 300 feet in the region about Monroe, but increases to over 500 feet at Winfield. On Sabine River the thickness, calculated from dip observations, is 550 feet.<sup>836</sup> In a well recently put down near Robinsons Ferry, Tex., at a depth of 1,250 feet fossils were obtained that W. H. Dall regards as Claiborne, indicating that the thickness is as much as 700 feet.

Harris<sup>407c</sup> says: "The Claiborne group borders the Sabine uplift. It is represented only by patches in Gregg, Marion, and Cass counties, Tex, and Caddo and Bossier parishes, La., where it has been for the most part carried away by long-continued erosion. It spreads out extensively in Rusk and Nacogdoches counties, Tex., and Bienville and Winn parishes, La., where the dip is slight, but it narrows down in Sabine Parish, where a steep dip carries it beneath the later Tertiary deposits."

The northwestern area of the St. Maurice formation referred to in the following note of Harris<sup>407d</sup> probably represents the Mount Selman formation of Texas.

"In the Caddo field, as already defined, marine Claiborne fossils have been found in but one locality, by the roadside about one-fourth of a mile east or east-southeast of the railway station at Vivian. Here, as at Roberta, Bolinger, and Plaindealing, in Bossier Parish, and in Ouachita County, Ark., the fossils are in the form of casts in very ferruginous indurated layers. From their appearance, which is very different from that of the fossil species so abundant and characteristic of the Claiborne from Bienville Parish to Nacogdoches County on the south, it is inferred that either these northern forms existed under considerably different conditions from their southern relatives or they represent a somewhat older type of life. It is possible that the Sabine uplift was more or less manifest in early Eocene or perhaps even late Cretaceous time. Desoto Parish, La., as well as Shelby, Panola, and Harrison counties, Tex., may have constituted an island in Claiborne time. The ferruginous, more or less brackish waters to the north of the island would naturally contain a very different fauna from that flourishing in the pure sea water to the south."

<sup>a</sup> Kennedy, William, Proc. Acad. Nat. Sci. Philadelphia, 1895, pp. 135, 136.

The Cockfield formation comprises lignitiferous sands and clays which occur in central Louisiana between the St. Maurice and Jackson formations and is extremely similar in lithologic character to the Wilcox formation, with which it was at first confused. It contains no marine mollusks and is characterized by thin, impure lignite beds and clays which in many places contain plant remains in an excellent state of preservation. It is identical in appearance with the lignitiferous complex to the north (undifferentiated Eocene), of which it forms a part, and can be definitely differentiated only when fixed between fossiliferous Claiborne and Jackson strata or by paleontologic data. (Modified from A. C. Veatch.)

Of the Claiborne group in eastern Texas Deussen has the following to say in an unpublished manuscript:

"In eastern Texas the Claiborne group comprises three formations—the Mount Selman, Cook Mountain, and Yegua—which are lithologically and genetically distinct.

"The Mount Selman formation consists chiefly of dark-green and brown sands and sandstones, with thin seams and concretions of limonite. The fossils are not plentiful and usually occur in the form of casts. This formation has been given the name Mount Selman from its typical exposure at that place in Cherokee County.<sup>a</sup> These highly ferruginous sands with casts of fossils and beds of iron ore of economic value occupy extensive areas in Anderson, Henderson, Cherokee, Rusk, Gregg, Harrison, Marion, Morris, and Cass counties.

"The formation overlying the Mount Selman has been named Cook Mountain, from Cook Mountain,<sup>b</sup> Houston County. At the base of this formation occur beds of greensand, greensand marl, and iron ore, all highly fossiliferous and of marine origin; in the medial portion lignites, lignitic clays, and sands of palustrine origin are found; at the top occurs another series of fossiliferous greensands, greensand marls, and iron ores of marine origin. The thickness along Brazos River is at least 400 feet. The outcrop appears in Robertson, Brazos, Leon, Houston, Anderson, Cherokee, Nacogdoches, San Augustine, and Sabine counties.

The lignitiferous unit stratigraphically and conformably overlying the Cook Mountain formation, was recognized by Dumble<sup>c</sup> in 1892 as a separate formation, and he applied to it the name Yegua. It consists of clays, sands, and lignites of palustrine and marine origin. The clays are characterized by the presence of fragments and concretions of selenite. The thickness of the formation varies from 375 to 750 feet. The outcrop appears in Sabine, San Augustine, Angelina, Trinity, Houston, Madison, Grimes, and Brazos counties.

"On the Brazos beds belonging to the Yegua formation are exposed between the mouth of the Little Brazos and a point southwest of Wellborn, in Brazos County. The beds as exposed in this section consist entirely of palustrine and lignitiferous deposits, barren of marine fossils. On Sabine River beds belonging to this formation are exposed from a point 3 miles below Columbus to a point a short distance below Robertson's Ferry, in Sabine County. The beds here are typical palustrine deposits."

The details of the Claiborne group have not as yet been studied between Guadalupe River and Rio Grande. Dumble's work along the latter stream has shown that representatives of the marine Claiborne outcrop from Santo Tomas, 30 miles above Lando, to the vicinity of Roma. The material consists of lignite beds near the base, soft sandstone, and clays, which are more or less calcareous,<sup>297a</sup> and greensands. The thickness of the marine Claiborne in this region is not known.

*Jackson formation.*—The Jackson formation in Louisiana immediately overlies the Cockfield and represents a return to marine conditions, being composed of calcareous gray fossiliferous sands and clays, which in places contain large calcareous concretions. It extends farther up the Mississippi embayment than any other formation bearing marine fossils except the Midway. Its most northern outcrop is in Crowleys Ridge, near Forrest City, St. Francis County, Ark. To the south of this locality the formation underlies an extensive area southward from

Pine Bluff in Jefferson County to the Louisiana line.<sup>401b, 406a</sup> It is concealed in northern Louisiana over a large area by the swamp deposits of Ouachita River, but again comes to the surface in southern Caldwell Parish and thence occupies a belt of territory that crosses Red River at Montgomery and Sabine River just below Robinson's Ferry, Sabine County.

According to A. C. Veatch<sup>838e</sup> the Eocene beds, which in central Louisiana, Mississippi, and Alabama are fossiliferous, all become lignitiferous in the upper portion of the embayment. The marine fossils of the Wilcox, St. Maurice, and Jackson epochs each extend farther northward than those of the preceding epochs, but in each case the beds bearing marine fossils grade into lignitiferous clays and sands containing no distinctive marine fossils.

Veatch says: "The first name given to this lignitiferous group, which can not be separated except on structural grounds, was the Lagrange. This included all the Eocene beds in Tennessee above the Midway and was afterward quite logically extended by its author, Prof. J. M. Safford, State geologist of Tennessee, to include the lignitiferous sands and clays of Crowleys Ridge,<sup>a</sup> which are of lower Jackson age and are the stratigraphic equivalents of the beds in the upper Chickasaw Bluffs. This formation grows more sandy to the north, where at Memphis essentially continuous sand beds 800 feet thick have been penetrated."<sup>b</sup>

The following is taken from an unpublished manuscript by Deussen:

"The Jackson formation in eastern Texas lies stratigraphically and conformably above the Yegua and beneath the Catahoula. It consists of a series of calcareous, fossiliferous clays of marine origin with large limestone concretions. It outcrops in the region between Trinity and Sabine rivers, in Sabine, San Augustine, and Angelina counties. Along the Sabine the formation is estimated to be 250 feet thick. It thins rapidly westward and disappears completely between Trinity and Brazos rivers. The formation is characterized by such fossils as *Umbrella planulata* Conrad, *Levifusus branneri* Harris, and *Trochocyatus lunulitiformis* var. *montgomeriensis* Vaughan.

"On Sabine River 1 mile below Robertson's Ferry, in Sabine County, highly fossiliferous calcareous clays and marls carrying large limestone concretions outcrop and carry characteristic Jackson fossils. The following species occur here: *Mitra millingtoni* Conrad, *Hipponyx americanus* Conrad, *Calyptræa trochiformis* Lamarck, *Ostrea trigonalis* Conrad, *Arca* (*Scapharca*) *rhombooidella* Lea, *Crassatellites flexurus* Conrad, *Cardium* (*Protocardia*) *nicolletti* Conrad, *Dione securiformis* Conrad, *Corbula wailesiana* Harris.

"The Jackson formation extends from Angelina River in Texas eastward across Louisiana into Mississippi. In Texas the time equivalents of the formation have been traced as far west as the Brazos. The equivalents in the region of the Brazos, however, are not lithologically similar to the Jackson formation and therefore do not belong to the Jackson but are here a part of the lithologic unit next to be described, namely, the Catahoula sandstone."

The Jackson has not been recognized in southwestern Texas, although more thorough investigation may discover it in that region.

#### OLIGOCENE.

*Vicksburg limestone.*—This formation is known west of Mississippi River only in a small area in northern Catahoula Parish, La. The material is yellow calcareous clay and yellow limestone, which contains typical fossils.<sup>830</sup>

In Louisiana and eastern Texas the Oligocene deposits are divided into two formations—a lower one, the Catahoula sandstone, which in east-central Texas also comprises the uppermost Eocene and which consists of semiquartzitic sandstones and sands with some clay and carries a few plant remains, and an upper one, the Fleming clay, which consists of calcareous clays with nodules of lime and occasional crystals of gypsum.

<sup>a</sup> Report of John Lundie on waterworks system of Memphis, Tenn., 1896, p. 16.

<sup>b</sup> Safford, J. M., Bull. State Board of Health, vol. 5, pt. 7, Feb. 20, 1890, pp. 98-106; Ann. Rept. Geol. Survey Arkansas for 1889, vol. 2, 1891, pp. 28-29.

*Catahoula sandstone*.—This formation is thus described by Veatch:<sup>838f</sup>

“Overlying the fossiliferous Vicksburg clays and limestones is a series of sandstones and greenish clays which are generally [very] different, lithologically, from any of the older beds of the Tertiary series in Louisiana and Arkansas. The sandstones which are the characteristic feature of this formation range in thickness from a few inches to 50 or 60 feet, and thicknesses of as much as 140 feet have been reported.<sup>a</sup> These sand beds are often cemented by silica into very hard quartzites, but such occurrences are essentially local, and the quartzitic beds pass laterally in very short distances into soft sandstones or even unconsolidated sands. These sandstones and quartzitic layers have resisted erosion more than the underlying clays and unconsolidated sands of the Eocene and so have formed a line of rocky hills, the Kisatchie Wold, extending across Louisiana, into Texas on the one hand and into Mississippi on the other.

“These beds contain no indications of marine life, but land plants are abundant and fresh-water shells have been found in several places. The change from the conditions existing in the Vicksburg is very marked and indicates an elevation during which the region where the oceanic conditions were favorable for the growth of marine life was considerably south of the present outcrop of the formation.

“These beds were observed at Grand Gulf, on Mississippi River, in Claiborne County, Miss., by Wailes, the first State geologist of Mississippi, who referred to them as the Grand Gulf sandstones.<sup>b</sup> Later Hilgard<sup>c</sup> used the name ‘Grand Gulf group’ to include the beds exposed in southern Mississippi between the Vicksburg and the relatively recent coastal clays (Port Hudson), and the name has been used with varying shades of meaning by different authors since that time.<sup>d</sup>

“In view of this confusion and in order to furnish a name not likely to be misunderstood, the name Catahoula formation is used in this paper as a synonym for the ‘typical Grand Gulf’ or the ‘Grand Gulf proper.’ This new name is from Catahoula Parish, La., which is directly across the Mississippi Valley from Grand Gulf and where there are many outcrops which are lithologically and stratigraphically counterparts of the beds of the old type locality. From this place the beds have been traced eastward through Mississippi into Alabama, where they apparently grade into a series of fossiliferous sands and calcareous clays known as the ‘Chattahoochee group.’ To the west they extend in a very pronounced line across Louisiana into eastern Texas.<sup>e</sup> The thickness of this formation, as shown by comparative cross sections based on wells at Alexandria and Boyce and on dip observations on Sabine River,<sup>f</sup> is about 1,100 feet.”

The Catahoula sandstone in eastern Texas is thus described by Deussen in an unpublished manuscript:

“The Catahoula sandstone lies stratigraphically and conformably above the Jackson formation in eastern Texas and above the Yegua in central and southwestern Texas. It lies stratigraphically and conformably beneath the Fleming clay. It consists of a series of gray and blue sandstones, interbedded with brown, gray, and green clays, gray sands, and a few deposits of lignite. The sandstones in places carry marine fossils; in other places they carry casts of palm leaves, reeds, and great quantities of silicified and opalized wood. A characteristic feature is the occurrence locally of very hard blue quartzites, which, owing to their superior hardness, resist weathering better than the adjacent materials and appear topographically in the form of hills. These quartzites pass laterally in very short distances into soft sandstones and unconsolidated sands.

<sup>e</sup> Dumble, E. T., Science, new ser., vol. 16, 1902, pp. 670-671.

<sup>f</sup> Rept. Geol. Survey Louisiana, 1902, pp. 120, 132-135, Pl. XXXVII.

"The formation ranges in thickness from 500 to 800 feet. The outcrop appears as a belt extending across the area in an east-west direction, about 15 miles in width, and including portions of Sabine, Newton, San Augustine, Jasper, Angelina, Tyler, Trinity, Polk, Walker, San Jacinto, Montgomery, Grimes, and Brazos counties."

Deussen states that great confusion has existed regarding the age and correlation of this unit and, after reviewing the literature relating to it, continues:

"As here interpreted, the Catahoula sandstone is a lithologic and stratigraphic unit which transgresses several biologic zones. Stated differently, it is conceived to be of different ages and to have been laid down at different periods in the different regions of its occurrence. In southwest Texas it is of Claiborne age, and this kind of deposition seems to have begun in this area as early as Claiborne time. In central Texas, in the region of the Brazos, it is largely of Jackson age. In eastern Texas it is largely of Vicksburg age. According to Matson, the vertical transgression continues across Louisiana into Mississippi where the formation is of post-Vicksburg age. This kind of deposition, begun in southwest Texas in Claiborne time, gradually shifted eastward, and prevailed in Mississippi as late as middle Oligocene time. If this interpretation is correct it precludes the possibility of an unconformity between deposits of Eocene and Oligocene age in the Coastal Plain; no evidence of such unconformity has been found. It also explains the apparent absence of the Vicksburg limestone in eastern Texas. Upper Eocene deposits are not absent in eastern Texas and there is no hiatus in the sedimentary series there. The assumption by Hilgard, Hopkins, and Loughridge that the 'Grand Gulf group' of Hilgard was stratigraphically continuous across Mississippi, Louisiana, and Texas is thus demonstrated to have been correct, if this interpretation is valid, but they were in error in regard to the age of the materials in Texas. On the other hand, Dumble's determination of the age of his 'Fayette beds' (the Catahoula here recognized) is demonstrated to have been correct for southwest Texas, but if the view here maintained has force he is in error in assuming that the formation in east Texas is of the same age as in southwest Texas."

*Fleming clay.*—Veatch<sup>838g</sup> says: "The Fleming clay, which was so named by Kennedy in 1892<sup>a</sup> from Fleming siding on the Missouri, Kansas & Texas Railway near the line between Tyler and Polk counties, Tex., consists of green or bluish-green calcareous clays, differing from the underlying Catahoula beds in the presence of numerous small white calcareous nodules and the absence of the characteristic Catahoula sandstone layers. Near its base it often contains a bed of bright-red clay which forms a convenient line of parting.

"Although these deposits represent less truly littoral sediments than the Catahoula beds, extended search has failed to reveal any marine remains except near Burkville, Newton County, Tex., where a brackish-water Oligocene fauna<sup>b</sup> has been found in a local development of limestone 3 to 4 inches thick. William Kennedy<sup>c</sup> reports a number of lower Claiborne (Eocene) species from this locality, but the collection made by the writer in 1902, which was by far the largest made at this point, showed none of the species listed by Kennedy. Dr. T. Wayland Vaughan later visited the outcrop and states that the fragmentary material which he was able to obtain was regarded by both himself and Dr. W. H. Dall as having a decidedly Oligocene aspect."

This formation in Louisiana outcrops in a belt of country extending from Alexandria, on Red River, westward to Burr's Ferry, on Sabine River, south of the outcrop of the Catahoula sandstone. Deussen says:

"This formation consists of grayish sandy clays with small nodules of lime, thin beds of sandstone, and bluish and greenish-gray sand with nodules of lime. The occurrence of the nodules of lime is a characteristic feature. The formation is from 200 to 500 feet in thickness. The outcrop appears as a belt of country varying in width from 2 to 7 miles, lying south of the Catahoula outcrop and extending east and west across Newton, Jasper, Tyler, Polk, San Jacinto, Walker, and Grimes counties.

<sup>a</sup> Kennedy, William, Third Ann. Rept. Geol. Survey Texas, 1892, pp. 62-63.

<sup>b</sup> Veatch, A. C., Rept. Geol. Survey Louisiana, 1902, p. 136; Maury, C. J., Bull. Am. Paleontology No. 15, vol. 3 1902, p. 80.

<sup>c</sup> Bull. U. S. Geol. Survey No. 212, 1903, p. 53.

"Much the same interpretation must be given to this formation as has been given to the Catahoula, for it appears that these clays, like the Catahoula sandstone, transgress several biologic zones."

Oligocene strata have not been recognized in southwestern Texas but may be present there.

G 17, H 16-17, I 15-17, J 16. SOUTH ATLANTIC AND EASTERN GULF COASTAL PLAIN AND NORTH END OF MISSISSIPPI EMBAYMENT.

The following discussion (pp. 731-745) has been compiled by T. W. Vaughan from the literature and from the unpublished results of G. C. Matson and E. W. Berry in western Florida, southern Alabama, and Mississippi, of E. W. Berry in western Tennessee and Kentucky, and of his own researches.

As the space allotted to this subject is limited, it is not possible to present detailed descriptions of the several formations or to give geologic sections of specific localities or lists of the important fossils. Further information will be found in the publications listed in the bibliography (pp. 840-865) under Nos. 141, 178, 179, 212, 214, 369, 403, 404, 405, 438, 557, 580, 583, 693, 737, 744, 751, 831, 835, 843. Many of these publications contain still other citations.

A series of reports on the Atlantic and Gulf Coastal Plain of the United States is in preparation in cooperation between the United States Geological Survey and the respective State surveys. These reports will present as complete discussions of the different geologic formations, the geologic structure, etc., as present information will permit.

GENERAL CLASSIFICATION.

For the Eocene formations a classification into four groups has been adopted in the Gulf and South Atlantic Coastal Plain region. The type sections of the three lower groups occur in Alabama along Alabama and Tombigbee rivers, and that of the highest is in Mississippi. These groups are the Midway, Wilcox, Claiborne, and Jackson. The marine Oligocene is divided into two groups—a lower, the Vicksburg, and an upper, the Apalachicola. The former takes its name from Vicksburg, Miss., the latter from Apalachicola River, Florida. The non-marine Oligocene of southern Alabama, Mississippi, Louisiana, and Texas has received no group name. The Catahoula sandstone and the Fleming clay of Louisiana and Texas, which are mostly of upper Oligocene age, are described on pages 729-730.

Each stratigraphic group will be described in ascending order, its distribution and variations being indicated.

EOCENE.

*Midway group.*<sup>403</sup>—This group takes its name from Midway Landing, on Alabama River, in Alabama, where it is divided into three formations.<sup>749</sup> The lowest, the Clayton limestone, rests unconformably on the Upper Cretaceous. It is an impure limestone 25 feet thick in western Alabama along Tombigbee River, but it increases in thickness to the east and along Chattahoochee River includes fully 200 feet of alternating calcareous sands and limestone. The Clayton limestone is overlain by the Sucarnochee clay, which on Tombigbee River is a series of black or dark-brown clays at least 100 feet thick. At Black Bluff, on Tombigbee River, these clays contain a few fossils but except in the lowermost strata are almost devoid of lime. Toward the east, however, they become more calcareous, and in Wilcox County, east of Alabama River, they form the basis of some fine black prairie lands. This formation has not been traced east of Wilcox County. The Naheola formation, which conformably overlies the Sucarnochee clay along Tombigbee and Alabama rivers, is composed of 150 feet or more of gray sandy glauconitic clays, containing many marine fossils. It does not extend so far eastward as Chattahoochee River.

The Midway group has been identified along Chattahoochee River between Alabama and Georgia, in the vicinity of Fort Gaines, whence it extends as a narrow belt, only a few miles wide, in a northeast direction to Montezuma, on Flint River, and a short distance beyond into Houston County.<sup>a</sup> As the group in Georgia has not been subdivided into formations, it is termed the Midway formation in this State. It is separated from the Upper Cretaceous by small erosion unconformities, but at no place has there been found good evidence of any profound physical break between the two. According to Veatch, "the formation is mainly a marine deposit consisting of sands, clays, and marl or limestone. The sand is varicolored, generally loose or friable, and contains lenticular layers of white clay. A characteristic of the lower part of the formation is a rather wide distribution of limonite in thin crusts in the sand and sandy clay and in the form of hollow concretions having black, polished botryoidal interiors. The limestone is fossiliferous and in general highly arenaceous, but in a few places it is sufficiently pure for use in the manufacture of lime. Friable marls, made up of glauconitic quartz sand, clay, and shells occur, and also laminated black clay and fuller's earth. The limestone is conspicuous at several localities and is the phase of greatest stratigraphic importance because it is abundantly fossiliferous, but sand and clay probably make up the greater part of the deposit. The thickness of the Midway on Chattahoochee River was estimated as 218 feet by Langdon.<sup>b</sup> The thickness to the northeast is probably greater, and although it can not be accurately estimated, it is probably as much as 400 feet."

There are no known exposures of the Midway formation east of Houston County in Georgia, nor are there any in South Carolina east of Santee River. Sloan<sup>744a</sup> has described an occurrence in the vicinity of Georgetown, at Perkins Bluff on Black River, of 16 feet of buhr rock, silicified black shale, and compact red sands, immediately and unconformably overlying the Peedee (Cretaceous). Species of Midway fossils were obtained from the material at this locality. This is Sloan's Black Mingo formation, and he has also referred to it other outcrops along Black and Sampit rivers.

West of Alabama the Clayton limestone, the lowest formation of the Midway group, extends into Mississippi, where it is represented by a series of hard crystalline limestones and calcareous sandy marls. The limestone of this formation was referred by Hilgard to the Ripley (Cretaceous), but later investigation by Harris and others has, on paleontologic evidence, placed it in the Midway. The limestone has a maximum thickness of 20 feet near the town of Ripley. It is overlain by 20 to 30 feet of reddish to yellow sandy marl containing lime carbonate and is slightly fossiliferous. The reddish color is due to a large amount of iron oxide. The Clayton outcrop forms a narrow strip of territory from 2 to 6 miles wide, lying just west of the Ripley (uppermost Cretaceous) area. The line of the New Orleans, Mobile & Chicago Railroad approximately follows the outcrop from Middleton, Tenn., to Houston, Miss., where the outcrop turns in a southeasterly direction west of Starksville and Macon and passes into Alabama southeast of Scooba.<sup>c</sup>

In Mississippi the calcareous sandy marls of the upper Clayton are overlain by 75 to 100 feet of gray nonfossiliferous clay, which forms the well-known "Flatwoods" area, extending from Tennessee into Alabama. To this clay Crider applied the name Porters Creek clay, originally used by Safford in Tennessee. It corresponds approximately to the Sucarnochee and Naheola formations of the Alabama section.

The Midway group is represented in Tennessee by the Porters Creek formation as described by Glenn.<sup>369</sup> Harris presents in his monograph on the Midway, already cited, definite evidence that the Porters Creek clay of Safford included Midway. According to Glenn, the Porters Creek formation rests unconformably on the Ripley (Cretaceous). He says:<sup>369b</sup>

---

<sup>a</sup> The Tertiary descriptions for Georgia are based on a manuscript furnished by Otto Veatch, who has since published a report by himself and L. W. Stephenson.<sup>843</sup> The paleontologic determinations and correlations were made by T. W. Vaughan.

<sup>b</sup> Smith, E. A., Johnson, L. C., and Langdon, D. W., Report on the geology of the Coastal Plain of Alabama: Geol. Survey Alabama, 1894, p. 369.

<sup>c</sup> Descriptions of the Tertiary formations of Mississippi are modified from A. F. Crider's "Geology and mineral resources of Mississippi" (Bull. U. S. Geol. Survey No. 283, 1906) and A. F. Crider and L. C. Johnson's "Summary of the underground water resources of Mississippi" (Water-Supply Paper U. S. Geol. Survey No. 159, 1906).

"The formation is composed mainly of a fine-grained clay that is very dark gray or in places almost black when wet, but which becomes a light gray on drying. It is familiarly known in the region as soapstone. Interbedded with this clay are sometimes found, especially in the lower part of the formation, beds of fine micaceous silty sands, which are usually indurated to soft sandstones. The lower part of the formation also contains interbedded with the gray clay and micaceous sand beds of greensand that may contain enough calcareous matter to cement certain layers into pure limestone. The calcareous matter has doubtless been derived from marine shells, the hollow impressions of which are abundant in some of the more calcareous beds. Such beds have been found near the base of the Porters Creek formation at intervals from a point just east of Middleton, Tenn., nearly to Paducah, Ky."

The thickness of the formation is about 175 feet, and Glenn states that it "outcrops immediately west of Ripley in a belt about 8 miles wide in southern Tennessee, but averages only about 4 miles in width across the State. In Kentucky it widens out again, reaching 10 or 12 miles in northern Calloway County. The outcrop narrows much as it curves westward beyond Paducah and is concealed by the alluvial deposits of Ohio River before crossing the Illinois. In Illinois it is known to outcrop only along the bank of the Ohio, at Caledonia Landing, and for some distance to the north toward Grand Chain. The exposures are for the most part poor, however, and its identification is made partly by a few indistinct fossil casts but mainly by the presence of greensand, which is absent from the Ripley below and the Lagrange above but which is found in the lower part of the Porters Creek. Farther west, across southern Illinois, its outcrop is obscured by either the Lafayette gravels and the loess or by the alluvial deposits of the Cache and Mississippi River bottoms."

Shepard<sup>737a</sup> states that the Porters Creek formation "has been identified in Missouri wells at but one point. It was reached in the Morehouse well at a depth of 248 feet, where it consisted of 197 feet of bluish gumbo."

*Wilcox group.*<sup>404, 405</sup>—This group takes its name from Wilcox County, Ala., where unusually good exposures of it are recorded. In that State it forms the most massive of the Eocene groups, having a thickness of probably not less than 900 feet. It also presents a great variety in lithologic character and in fossil contents. In general terms the Wilcox strata are cross-bedded sands, thin-bedded or laminated sands, laminated clays, and clayey sands, with beds of lignite and lignitic matter. With these are found, interbedded at several horizons, strata containing marine and estuarine fossils. The fossil-bearing beds form the basis for the separation of this group into four formations, which Smith<sup>749a</sup> describes as follows:

"The lowest formation of the Wilcox group, the Nanafalia, overlies the Naheola formation of the Midway and maintains a tolerably uniform thickness of about 200 feet entirely across the State. These beds are mostly sandy but contain great numbers of the shells of a small oyster, *Gryphæa thirsæ*. Near Alabama River and for a short distance to the east a gray siliceous clay with a tendency to indurate into a tolerably firm rock resembling very closely some of the strata of the Tallahatta buhrstone of the Claiborne group, \* \* \* is a characteristic feature of the whole section. At the base of the oyster-shell beds there are, at certain localities, other fossiliferous beds containing a great variety of forms.

"At the bottom of the Nanafalia formation there is a bed of lignite, 5 to 7 feet thick, which may be traced across the country from Tombigbee River into Pike County, where it is well exposed near Glenwood station, not far from Troy.

"The Tuscahoma formation, which overlies the Nanafalia, is about 140 feet thick and consists mainly of gray and yellow cross-bedded sands and sandy clays, generally poor in fossils except at one horizon, which is typically exposed at the locality from which the name is taken and at Gregg's and Bell's landings on Alabama River.

"Above the Tuscahoma is the Bashi formation, which averages perhaps 80 feet in thickness. It is composed of the sands and sandy clays common in the Tertiary. It is distinguished by a characteristic bed of highly fossiliferous greensand with associated beds of lignite immediately below it. By these features the Bashi may be easily identified across the width of the State. The best exposure of the fossiliferous greensands of this formation is at Woods Bluff, on Tombigbee River.

"The Hatchetigbee formation, the uppermost formation of the Wilcox group, is composed of beds of brown, purple, and gray laminated sandy clays and cross-bedded sands abounding in characteristic fossils. It is about 175 feet thick in the vicinity of Tombigbee River, but it thins to the east, though otherwise maintaining its distinctive character. These beds have been named Hatchetigbee from a bluff on Tombigbee River."

The Wilcox group extends eastward into Georgia, where it has not been subdivided into formations and has a small areal distribution. It is best exposed in the bluff of Chattahoochee River at Fort Gaines and probably continues northeastward to Flint River, but it is not easily differentiated from the Midway, except at Fort Gaines. At Fort Gaines the Wilcox and Midway are separated by a distinct erosion unconformity represented by old potholes in the limestone of the Midway filled by black sandy clay of the overlying formation. Evidence of this erosion unconformity has not been observed farther east, but this may be due to the imperfection of the natural exposures of the strata. The contact with the overlying Claiborne, where observed, is generally an undulating line of small pebbles or a stratum of coarse sand, and there is no physical evidence of any considerable time interval between the deposition of the two. According to Veatch—

"Along Chattahoochee River the formation is made up of a sandy glauconitic calcareous shell marl, in places indurated, overlain by dark laminated, often lignitic sandy clays, some beds of which are consolidated into mudstone. To the east, in Randolph County, appears glauconitic clay like fuller's earth, but near Flint River the formation is chiefly sand, in which there are massive beds of white clay.

"The thickness lying between the Claiborne and Midway at Fort Gaines is about 75 feet. The maximum thickness at any place over the area of outcrop is probably not more than 150 feet. This is not in agreement with the thickness on the Chattahoochee, estimated by Langdon<sup>a</sup> at 402 feet, but in view of the recent determination of strata of Claiborne age<sup>b</sup> in the upper part of the bluff at Fort Gaines, it is not improbable that a portion of Langdon's 'Lignitic' belongs to the Claiborne formation."

No outcrops definitely known to represent the Wilcox group occur between Flint River in Georgia and Santee River in South Carolina. In the latter State, on Dr. W. S. Boyd's plantation (the old Gourdin plantation), Sloan collected from a silicified rock fossils characteristic of the Nanafalia formation of the Wilcox group. For the formation containing these fossils Sloan has proposed the name Williamsburg. It has probably been identified at Manning.

West of Alabama, in Mississippi, the Wilcox group has not been subdivided into formations and is known as the Wilcox formation. In this State it is of a more or less sandy character throughout. Crider and Johnson<sup>179a</sup> say:

"The coarse-grained, unconsolidated sand beds are often interbedded with seams of lignite and white and chocolate-colored clays. The clays of the upper division, as at Grenada, are very dark and may properly be called shale. In the eastern half of the area loosely bedded sands predominate. The western portion, which is a series of irregularly cross-bedded sands and sandy clays, is separated from the eastern by a more or less regular line of white and chocolate-colored clays, which are used for making stoneware.

"The thickness of the group is estimated from the width of the outcrop to be 750 to 800 feet.

"The Wilcox covers the largest territory of any formation in northern Mississippi. It occupies the entire area lying between the Porters Creek outcrop and the bluffs on the eastern rim of the Yazoo Delta as far south as Grenada. The west edge south of Grenada is a line extending southeast 6 miles east of Winona, west of Philadelphia, and southwest of Meridian."

In Tennessee, Kentucky, and southern Illinois the deposits of Wilcox age are included in the Lagrange formation of Safford, redescribed by Glenn. Harris<sup>404</sup> has given a résumé of the evidence on which the determinations of the Wilcox age of the strata are based. It seems

<sup>a</sup> Smith, E. A., Johnson, L. C., and Langdon, D. W., Report on the geology of the Coastal Plain of Alabama: Geol. Survey Alabama, 1894, p. 369.

<sup>b</sup> Determined by T. W. Vaughan.

probable that the Lagrange includes more than the Wilcox, probably beds of Claiborne age, and perhaps some as late as Jackson, as the formation includes all the beds between the Porters Creek clay below and the Lafayette above. The following description of the Lagrange formation is adapted from Glenn:<sup>309</sup>

The formation consists of interbedded sands, clays, and lignitic material. Much the larger part is sand, which is mostly fine grained, though here and there throughout the formation beds of medium or coarse sand or even gravel may be found. Such coarser beds do not seem to be continuous over any large area.

The sands exposed to view are usually strongly cross-bedded and were deposited under brackish water in a sea characterized by strong and ever varying currents. The clays of the Lagrange vary from pure, fine-grained plastic material to sandy, silty clays that are in places dark from organic matter or black from lignite. The clays of the lower part of the formation are characteristically fine grained, pure, plastic, and either very light colored or white. Chemically they are highly siliceous. The plastic siliceous clays occur as lenses embedded in the sands and outcrop in a belt along the eastern part of the Lagrange area in both Tennessee and Kentucky. Many of the beds contain great numbers of beautifully preserved leaf impressions, and numerous collections of these remains have been made. It is entirely possible or even probable that the upper part should be separated from the middle and lower parts and after very detailed work criteria may be forthcoming for this discrimination. At present it is impracticable and all the beds are lumped together, though certain facts render it probable that the upper clay is considerably younger than the plant-bearing clays in the lower part of the formation at Grand Junction, Tenn., and elsewhere. Lignitic material is found throughout the formation but is more abundant in the upper part. Glenn gives the maximum known thickness as 963 feet.

The eastern edge of the Lagrange formation extends from the southwestern part of Hardeman County, Tenn., north-northeastward through Chester, Madison, Henderson, Carroll, and Henry counties, Tenn., and southwestern Calloway, northeastern Graves, middle McCracken, and northern Ballard counties, Ky. It then passes westward into Pulaski County, Ill., not far south of Caledonia Landing. It is not possible to follow it westward across Pulaski and Alexander counties because it is concealed beneath later deposits.

Shepard<sup>737</sup> reports the Lagrange formation from wells in Caruthersville and Morehouse, Mo.

*Claiborne group.*—This group, which overlies the Wilcox, is easily divisible in Alabama into three formations, the lowest being the Tallahatta buhrstone, the middle the Lisbon formation, and the upper the Gosport sand. Smith<sup>749b</sup> describes the Tallahatta as follows:

“The Tallahatta buhrstone, in the western part of the State, is predominantly composed of aluminous sandstone or siliceous claystones. They vary slightly in composition but are always poor in fossils except the microscopic siliceous shells of marine diatoms and Radiolaria. To the east the percentage of clay decreases, the rocks becoming more calcareous and fossils more abundant, and in place of the silicified shell casts of the Tombigbee and Alabama drainage basins are extensive beds of shells, mostly oyster shells. The thickness of the buhrstone varies from 400 feet in the western part of the State to 200 feet in the eastern part. In the western part of Alabama and still more in Mississippi, beds of fossiliferous greensand are abundant in both the Tallahatta and in the Lisbon strata of the Claiborne. The decay of the greensands has in many places given rise to the accumulation of deposits of brown iron ore. The Tallahatta buhrstone as here defined is the equivalent of the Siliceous Claiborne of Hilgard.”

The Lisbon formation lies between the Tallahatta buhrstone and the Gosport sand and consists of about 115 feet of calcareous clayey sands and sandy clays, generally fossiliferous. It is thus described by Smith.<sup>749c</sup>

“The lower half of these beds contains a great number and variety of well-preserved shells; in the upper half the shells of *Ostrea sellæformis* and several species of *Pecten* greatly preponderate over other forms. The most characteristic exposures in Alabama of these beds, which are the equivalents of Hilgard's Calcareous Claiborne, are at the Claiborne and Lisbon bluffs on the Alabama River.”

The Gosport sand, according to Smith,<sup>740c</sup> "so far as yet known, does not appear in any other of the Gulf States but embraces the strata of the Claiborne group lying between the top of the Lisbon and the base of the St. Stephens. The beds are in general highly glauconitic sands about 30 feet in thickness at the Claiborne and Gosport bluffs and include the fossiliferous greensands which have made the name Claiborne famous and which have furnished the greater part of the Claiborne fossils described and figured by Conrad and Lea. While this division, as above mentioned, is not known in Mississippi, Louisiana, or Texas, yet its importance in Alabama, from the historical point of view and because of the great number and variety and beautiful state of preservation of its fossils, is such as to compel mention and a distinct name. This member of the Claiborne group has been observed at a number of localities in Monroe, Clarke, Choctaw, and Washington counties. The name is from Gosport, a landing on the Alabama River a few miles below the Claiborne Bluff."

In Georgia,<sup>843</sup> although in a general way the correlatives of the formations of the Claiborne group in Alabama may be recognized, the extension of the formational nomenclature used in that State is inappropriate, for the group is not naturally divisible into the same units. The divisions recognized are the Barnwell sand and the McBean formation, with the Congaree clay member at its base.

The McBean formation rests unconformably upon strata of Lower Cretaceous age east of Ocmulgee River, and tongues of the formation extend to the crystalline rocks of the Piedmont area. Between Flint and Chattahoochee rivers the McBean rests upon the Wilcox formation, with evidence of an erosion unconformity along Chattahoochee River in the vicinity of Fort Gaines. In eastern Georgia the formation is overlain by the Barnwell sand, the relations between the two formations being somewhat obscure. Along the northern margin of the areal occurrence of the Barnwell sand there is evidence of an unconformity of slight time importance, but farther south the sand seems to rest upon the McBean formation with conformable relations. It seems probable that near the close of McBean time there was an uplift which brought the northern margin of the area of Claiborne deposition above sea level, permitting erosion to take place along the margin of the emerged area, while deposition continued in the area which remained under water. The formation consists mainly of clays, in places having the character of fuller's earth, shell marls, sandy limestones, or calcareous glauconitic sands. The maximum exposed thickness of the formation occurs at Shell Bluff, on Savannah River, where 115 feet of strata were measured. Outcrops of the formation occur in an extremely irregular belt that extends entirely across the State and ranges from a few miles to 25 miles or more in width. East of Flint River exposures are known in Columbia, Richmond, Burke, McDuffie, Jefferson, Glascock, Washington, Baldwin, Wilkinson, Jones, Twiggs, Bibb, and Houston counties. There are also exposures on Flint River in eastern Sumter county and along Chattahoochee River from Fort Gaines southward.

The Congaree clay member in eastern Georgia rests directly upon the Lower Cretaceous, the contact being marked by conspicuous erosion unconformities. It is conformably overlain by the clays and marls of the McBean formation or by the Barnwell sand, either passing into the latter by gradation or in some exposures being separated from the former by unconformities. Lithologically the Congaree clay member consists of fuller's earth in which are small lenses and pockets of sand; in some places it contains large amounts of disseminated lignitic matter and thin beds of lignite. The thickness of this member is at least 100 feet. There are numerous outcrops of the Congaree clay member from Grovetown southwestward along the "fall line" to Bibb and Twiggs counties. It is confined to the northern part of the area of the outcrop of the McBean formation, but no sharp lines separating the member either from the marls of the McBean formation or from the overlying Barnwell sand can be drawn. Clays and fuller's earth of the same general character as the Congaree clay member also occur in the vicinity of Chattahoochee River near the northern margin of the area of outcrop of the McBean formation.

The Barnwell sand directly overlies the McBean formation and is in contact with both the marls and the Congaree clay member. Along the northern margin of the Barnwell sand area

there is evidence of a local unconformity with the underlying McBean formation, but farther south the relations are conformable. The Barnwell sand is overlain by the Jackson formation, but as the exact contact between the two has nowhere been observed the nature of the contact is not known. In Burke and Screven counties the formation is overlain by the Vicksburg formation and in places questionably by the Chattahoochee and Alum Bluff formations. In the eastern part of the State the Altamaha (Lafayette?) formation probably originally covered a large part of it. The Barnwell sand consists largely of unconsolidated red and varicolored sands with some thin layers of sandstone, quartzite, silicified limestone or flint, and siliceous limonite. The sands, especially where weathered, are somewhat similar in appearance to the red residual sands of the Vicksburg formation. The maximum measured thickness of the Barnwell sand is 105 feet. East of Ocmulgee River the Barnwell sand is practically coincident in distribution with the Claiborne group as a whole. The formation overlies both the marls and the clays of the McBean formation and extends to the "fall line." It is probable that red sands between Flint and Chattahoochee rivers belong to this formation, but as yet no positive statement can be made.

In South Carolina the Claiborne group attains an extensive development, and Sloan<sup>744d</sup> has applied a number of names to its local phases, some of which are of considerable importance. The names he proposed are Congaree, Warley Hill, Cawcaw, Santee, Barnwell, and Mount Hope. Near Savannah River the succession of material is similar to that in Georgia. At the base are silicified clays, fuller's earth, the Congaree shales of Sloan; these are overlain by glauconitic sandy marls, locally with silicified shells and buhr rock, and calcareous beds, the Cawcaw shales and marls of Sloan, which are equivalent to his Warley Hill marl, Santee marl, and Mount Hope marl of the Santee area and which are succeeded by calcareous beds containing in their lower portion large numbers of *Ostrea georgiana*, these beds in turn being overlain by red sands, the typical Barnwell buhr sand of Sloan.

In the region of Santee River the geologic section is decidedly different in some respects from that of Savannah River. The Congaree shales of Sloan can be identified, overlain by glauconitic, more or less calcareous sands (the Warley Hill of Sloan), which is overlain by a soft limestone (the Santee marl of Sloan), and this is succeeded by Sloan's Mount Hope, a limestone largely composed of Bryozoa, among which are mollusks of Claiborne age.

In Mississippi the Claiborne is divisible on lithologic grounds into three distinct formations. The lower of these is the Tallahatta buhrstone, which is overlain by the Lisbon formation, and at the top is the Cockfield formation.

According to Crider and Johnson,<sup>179b</sup> the Tallahatta buhrstone, "called 'siliceous Claiborne' by Hilgard, consists chiefly of glauconitic coarse-grained micaceous sandstone that is almost quartzite. The estimated thickness is 350 feet. The formation outcrops in a belt of territory between the Wilcox and Lisbon beds and varies in width from 10 miles in northeastern Clarke County to 30 miles in Leake and Winston counties. The eastern line of outcrop is traceable from the Alabama line 4 miles south of Hurricane Creek post office to Eastville; thence it swings southwest nearly to Sterling, south of Meridian; thence it bends northwest past Battlefield, Philadelphia, Plattsburg, Hinze, and French Camp, 6 miles east of Winona, and west of Grenada. No trace of the Tallahatta has been found north of Yalobusha River.

\* \* \* \* \*

"Above the Tallahatta is a series of beds which Hilgard called 'calcareous Claiborne' and which will be termed the Lisbon formation. The series is about 150 feet thick and is composed of calcareous sands and laminated and lignitic clays. The character of the surface is little affected by the Lisbon, which is almost everywhere overlain by the Lafayette. In Alabama the area underlain by this formation is limited in extent, but in Mississippi it widens out and occupies the territory from southeastern Clarke to southern Carroll County, varying from 5 to 25 miles in width."

Hilgard<sup>438d</sup> has described "beds intervening between the Claiborne and Jackson groups." These beds are exposed where the Quitman and Winchester road crosses Coonup Creek, on the

banks of Chickasawhay River due west of the locality just mentioned, and at other places in the same vicinity. They also outcrop at Garlandville, Jasper County, and extensive beds of earthy lignite underlie the marine fossiliferous Jackson at Jackson, Miss. At the latter place, "in the penitentiary well after passing through 32 feet of surface material and fossiliferous strata of the Jackson age, lignitic clays were penetrated for 418 feet, after which a bed of shells 20 feet thick, extremely rich in greensand, was passed through into water-bearing sand." The lignitic sands and clays intervening between the marine fossiliferous Jackson and the marine Claiborne occupy precisely the stratigraphic position of the Cockfield formation of Louisiana, and the use of that name is extended so as to apply to them.

*Jackson group.*—This group, which is called a formation where not subdivided, has its typical outcrop in the vicinity of Jackson, Miss., from which place it takes its name.

In Mississippi, according to Crider and Johnson,<sup>179c</sup> "the essential materials of the Jackson group are gray calcareous and lignitic clays and sands. The outcrop occupies a belt of country 10 to 30 miles wide, extending southeast and northwest across the State from Yazoo to the Alabama line north of Waynesboro. The area is known as the 'central prairie.' \* \* \*

"The Jackson has usually been described as 'marls' and clays, but recent investigations along the line of contact with the Vicksburg have shown that there are between 50 and 75 feet of yellow, gray, or white siliceous sand at the top of the Jackson. Whether from a paleontologic standpoint this should be considered Jackson or Vicksburg we are unable to say, since no fossils have been found in the sands. They are regularly stratified, showing that they were deposited in a quiet sea with little or no current. In places near the surface the sands are slightly cemented with iron oxide, causing some layers to resist erosion more than others."

For Alabama Smith<sup>749d</sup> says: "Above the Claiborne, and constituting the uppermost member of the Eocene in Alabama, is the St. Stephens limestone, equivalent in part to the Vicksburg limestone and in part to the Jackson limestone of Mississippi. In Alabama these two formations blend so completely that it has been impossible to draw clearly the line of demarcation between them, and the St. Stephens is therefore intended to include the Alabama representatives of both. Immediately overlying the Claiborne fossiliferous sands, at many points in Clarke, Choctaw, and Washington counties, is an argillaceous limestone closely resembling the Selma chalk and like it giving rise to rich black limy soils. The fossils of this bed show that it is probably of Jackson age, but the great mass of the St. Stephens formation, between 200 and 300 feet thick, consists of a limestone of a considerable degree of purity in which the ever present fossil is a nummulitic shell, *Orbitoides mantelli*. Other shells also abound, but this is characteristic."

More detailed paleontologic investigation in Alabama will probably differentiate the Jackson and Vicksburg. This opinion is borne out by some incomplete and unpublished studies of Vaughan.

Veatch states that "in Georgia the area underlain by the Jackson formation, so far as known, is very small. The largest area is in Houston, Twiggs, and Pulaski counties. There is an isolated occurrence at Rich Hill, Crawford County, one on Oconee River in Johnson County, and probably one on Chattahoochee River near Alaga, Ala.

"The formation is the uppermost Eocene exposed in Georgia and lies directly beneath the Vicksburgian Oligocene. No evidence of a time interval between the deposition of the two has been observed, and there seems to have been no interruption in the sedimentation, although there are lithologic differences. While the formation is known to overlie the Claiborne, contacts between the two formations have not been discovered. The Jackson at Rich Hill, Crawford County, rests upon lower Cretaceous strata.

"The Jackson consists mainly of white or cream-colored massive-bedded limestone, overlain by calcareous, glauconitic, or sandy laminated clay. The limestone is highly fossiliferous, and in places the rock is made up almost entirely of a friable mass of Bryozoa and shells.

"The thickness of the formation can not be determined with much accuracy, as the line of contact between it and the Claiborne or underlying formation has not been definitely located.

The formation has a low southward dip and the width of the outcrop is only a few miles, so that the total thickness probably does not exceed 150 or 200 feet."

On the South Carolina side of Savannah River, at Johnson's Landing, are exposures of silicified limestone which is replete with Bryozoa and contains a few specimens of *Pecten perplanus*. This rock may belong to the Jackson, but in this region the exposures are poor and fossils are rare and not well preserved, rendering it difficult to discriminate between Jackson, Vicksburg, and Chattahoochee.

The thick beds of soft limestone exposed along Ashley and Cooper rivers in the vicinity of Charleston, called by Sloan <sup>746</sup> the Ashley-Cooper marl, are referable to the Jackson group. The marl is green-drab or gray-green and slightly plastic when wet, but is lighter in color and more pulverulent when dry. The marl along Cooper River usually contains less than 2 per cent of calcium phosphate; that along Ashley River may contain as high as 15 per cent. The formation exceeds 100 feet in thickness.

#### OLIGOCENE.

*Vicksburg group*.—This group takes its name from the city of Vicksburg, Miss., in the vicinity of which are excellent exposures, especially along the bluffs of Mississippi River. The outcrops of the group extend from Louisiana to Savannah River, except where they are intersected by stream valleys. In Mississippi it consists of a semicrystalline limestone in beds varying from 1 foot to 3 feet in thickness, alternating with beds of sandy fossiliferous marl of about the same thickness. Usually the beds of limestone near the surface are more or less affected by weathering and have therefore become soft and locally yellow, but below the zone of weathering there is in many places hard blue rock. The beautiful, well-preserved fossils of the Vicksburg are found mostly in the beds of marl. The thickness of the formation is between 65 and 75 feet in Mississippi. This formation marks the end of the marine conditions of the Tertiary in western Mississippi. Its outcrop occupies a narrow band just south of the Jackson area and extends across the State from the type outcrop at Vicksburg through Warren, Hinds, Rankin, Smith, Jasper, and Wayne counties into Alabama.

In eastern Mississippi near Hiwannee, on Chickasawhay River, the base of the Vicksburg, immediately overlying the Jackson, bears fossils of an older facies than those at Vicksburg and constitutes the Red Bluff group of Hilgard, which is composed of calcareous clays and some limestone beds.

The Vicksburg continues across southern Alabama, where it has not been differentiated from the Jackson (uppermost Eocene), the two being included in the St. Stephens limestone. It seems, however, that by more detailed studies the Vicksburg and Jackson can be discriminated. The Vicksburg part of the St. Stephens limestone consists of a limestone of a considerable degree of purity, in which the nummulitoid fossil *Orbitoides* is persistently present. The rock is largely a foraminiferal limestone. Other fossils are present, but this one is characteristic. In some places this limestone is hard and capable of polish, but usually it is soft and easily cut with a saw. Its thickness is between 200 and 300 feet. It outcrops across Clarke, Choctaw, and Washington counties and extends eastward into Georgia and southward and southeastward into Florida.

In Georgia the Vicksburg, according to Veatch, "consists mainly of white, massive-bedded limestone interbedded with sand and clay. The limestones are extensively silicified and in many places do not appear at all at the surface but are concealed by red coarse-grained argillaceous sand and are represented by residual flint. The limestone is generally soft but in a few places is exceptionally hard and crystalline and very fossiliferous, *Orbitoides*, Bryozoa, pectens, and their fragments forming nearly the whole of the rock.

"The thickness of the Vicksburg in the western part of the State, to judge from well records, is hardly more than 300 feet, and there is no evidence that it is likely to exceed this at the east.

"The Vicksburg formation in Georgia underlies a large area lying mainly west of Flint River. East of Oconee River the formation is usually concealed by later formations and in Screven and Burke counties only small areas are known."

In Florida the Vicksburg group is tentatively subdivided into three formations—the Marianna, “Peninsular,” and Ocala limestones. The Marianna limestone occurs in Florida mostly west of Apalachicola River; the “Peninsular” limestone constitutes that portion of the Vicksburg group underlying the Ocala limestone in Peninsular Florida and is largely contemporaneous with the Marianna limestone. Matson and Clapp<sup>580a</sup> give the following description:

“The Marianna limestone is thought to be the stratigraphic equivalent of the upper part of the bluff at Vicksburg, Miss., and some of the wells in west Florida enter beds of sand and clay which probably represent older horizons, but the stratigraphic relation of the formation to these older beds can not be determined. In west Florida, where this formation is recognized, it is unconformably overlain by beds belonging to the Apalachicola group or by post-Pliocene formations.

“The Marianna and ‘Peninsular’ formations consist of soft, porous white or light-gray limestone, sometimes resembling marl, especially when partly decomposed. Some bands of darker-colored dense limestone are reported at various localities where these formations have been penetrated by drilling, and nodules and layers of chert are common throughout them, but chert beds are especially prominent in certain horizons. The chert beds are usually darker in color than the limestone and range in thickness from a fraction of an inch to 12 or 15 feet. In some localities as many as six or seven successive beds of chert have been encountered in a single well. In general the heavier layers are more persistent, and it is usually the chert which forms a nearly water-tight cap to the artesian-water beds in these formations. Certain horizons are abundantly fossiliferous, containing innumerable specimens of *Orbitoides* and shells of mollusks, such as *Pecten poulsoni*, etc. At several localities the rock is so soft that it can be cut into blocks with a saw, and upon exposure to the weather these blocks harden rapidly, making a very fair quality of building stone. Beds of sand, sometimes 10 feet or more in thickness, are reported in some of the wells which penetrate this formation. In general, these sands appear to be most numerous in the northwestern part of the State.

“The thickness of the ‘Peninsular’ limestone and the Marianna limestone appears to be exceedingly variable. The thickness given by Foerste, from his investigations of the Vicksburgian limestones in southwestern Georgia and the adjacent part of Florida, is 220 feet, and probably this may be regarded as the approximate measure of the thickness of the Marianna. On the basis of well borings Dr. Dall estimates the thickness to be over 350 feet at Gainesville, 212 feet at Lake Worth, and 1,068 feet at St. Augustine. From recent examinations of well borings by Drs. Vaughan and Bassler, limestone of Vicksburg age is known to have a thickness of over 225 feet at Quincy, 250 feet at Alachua, and 325 feet at Bartow. Apparently there is a marked thickening of these limestones from the exposures of Georgia and Alabama southward. Of all the estimates given above the one at Gainesville is probably the most reliable, because the well is cased to the bottom.”

Rocks belonging to the Vicksburg group occur in deep wells on Key Vaca and Key West. The Ocala is described by Matson and Clapp<sup>580b</sup> as follows:

“The Ocala limestone lies stratigraphically between the ‘Peninsular’ and the beds here designated Apalachicola group. Lithologically it bears a strong resemblance to the underlying ‘Peninsular’ limestone, with which it also has a close faunal relation. These facts have led to the conclusion that the two formations are conformable, and it has also been suspected that the Ocala limestone represented a local phase of the ‘Peninsular.’ While the two formations are probably conformable, the extensive distribution of nummulites of the Ocala limestone shows that it represents a widespread change in conditions and is not to be classed as a mere local phase of the underlying beds.

“The Ocala limestone, as already noted by Johnson, is sometimes wanting, so that the overlying formations rest directly upon the ‘Peninsular.’ This relation was noted at several localities which will be mentioned in discussing the younger formations. At present it is sufficient to note its absence and to suggest that since the Ocala limestone does not appear to be a local phase of the ‘Peninsular,’ there is probably a stratigraphic break between the rocks belonging to the Vicksburg and Apalachicola groups in the central part of the peninsula.

“The Ocala limestone consists of a soft, porous light-gray to white limestone which bears a strong lithologic resemblance to the underlying ‘Peninsular’ limestone, but is distinguished from it by the included fossils. When slightly weathered the rock becomes light yellow and owing to its granular appearance is often regarded as sandstone. The removal of the calcareous material by the leaching action of underground water leaves a pale-yellow, more or less incoherent sand, containing a small percentage of calcium carbonate. When fresh the Ocala limestone is so soft that it is easily broken, but exposed surfaces often become hardened by the deposition of calcium carbonate from the waters which emerge along the outcrop. For this reason the rock frequently appears to be hard and firm. Its porosity and ready solubility permit the formation of numerous underground channels which are sometimes seen at the outcrop and are inferred from the presence of numerous sink holes. The rock contains an abundance of organic remains which are commonly preserved as casts. Nodules and large masses of chert are also common and in some localities a large part of the rock has been silicified.” \* \* \*

“The greatest thickness noted during the recent field investigation was in a sink hole near Ocala, where the formation is exposed to a depth of about 40 feet without reaching its base.”

*Apalachicola group.*—The following descriptions are adapted or copied from Matson and Clapp.<sup>580c</sup> In Florida “the Apalachicola group includes a number of beds differing widely in lithological character, though they are recognized by their fossils as integral parts of a single group. While limestones and marls predominate, the group also includes beds of nearly pure sand and clay. The entire period of deposition appears to have been characterized by the accumulation of more or less terrigenous materials, and hence the limestones are usually rendered somewhat impure by an admixture of clay and sand. At certain times the conditions appear to have been especially favorable for the development of organic life, and some horizons, such as the Chipola marl member of the Alum Bluff formation and the ‘silex bed’ of the Tampa formation, contain very large faunas.

“Owing to the lithologic variations and widely separated exposures, the exact correlation of the formations of this group is dependent upon their organic remains. While the paleontological studies, especially those made by Dall, have shed much light upon the stratigraphic relations of the different beds, there are still many points which can not as yet be fully decided. For this reason it seems best to retain the names of various beds and to indicate as far as possible their known relationships. The Apalachicola group is separated into four formations—the Chattahoochee, the Hawthorne, the Tampa, and the Alum Bluff. There is, however, some reason for believing that the first three are, in part at least, synchronous, though exact equivalence is difficult to determine where outcrops are widely scattered and faunal variations are slight. The Alum Bluff formation is clearly younger than the Chattahoochee formation, upon which it rests.”

The Hawthorne formation, “according to Dr. E. H. Sellards, is a light-colored soft, porous limestone. The original building-stone quarry which is located near the station of Grove Park, about 3 miles west of Hawthorne, is now abandoned and is badly overgrown, so that the thickness of this limestone can not well be determined. At the old phosphate mine, which is at least a mile southwest of the stone quarry, the rock is a phosphatic conglomerate. At many localities the limestones of the Hawthorne formation are silicified, forming boulders and beds of chert. This is a very common condition in the rock-phosphate region, where these limestones rest directly on those belonging to the Vicksburg group.

“Beneath the phosphatic limestones of the Hawthorne formation are beds of sand, sandstone, or gravel, which are underlain by several feet of clay. The sand beds at some localities contain iron oxide which forms a coating on the grains of silica. The clays are greenish and locally sufficiently calcareous to be called a marl. The thickness of the Hawthorne formation varies greatly, the maximum amounting to approximately 95 feet. The three members of this formation with their maximum observed thicknesses, according to Dall, consist of greenish clay 70 feet, ferruginous yellow sandstone 4 feet, and phosphate rock 20 feet. The maximum thickness of the Hawthorne formation, as given by the same author, is 125 feet. However,

over a large part of the peninsula, where the sole representative of the Hawthorne formation is the phosphatic or siliceous rock, the thickness is but a few feet.

\* \* \* \* \*

“The Chattahoochee formation consists of light-colored limestones and marls, containing some thin beds of chert, clay, and sand. The colors vary from creamy white to light gray or green on recently exposed surfaces to light yellow, brown, or more rarely pink on weathered outcrops. Lithologically there is a gradation from nearly pure limestone to sands and clays, but in general the argillaceous and siliceous limestones predominate, forming impure limestones or marls. The formation is in part composed of semicrystalline limestone, but soft, loosely coherent rock resembling an impure chalk is more common. While chert beds occur at various horizons, they are much thinner and less persistent than those of the underlying group. At times organic life appears to have been abundant and hence some layers are very fossiliferous, though the fossils are usually preserved in the form of imperfect casts and molds which have been left by the solution of the shells.

“Vaughan’s observations along the Apalachicola River show that the Chattahoochee attains a considerable thickness near the type locality.

“Well borings from Quincy indicate that the thickness of the Chattahoochee formation at that locality is slightly greater than 100 feet, but here, as elsewhere, it is difficult to determine the exact thickness of formations from well samples. The maximum thickness of the formation is probably double the figure given above and it may be even as great as 250 feet.”

The Tampa formation, named from the city of Tampa, has as its upper member “a well-stratified greenish clay containing some calcareous nodules and thin beds of limestone near the base. Scattered throughout the clay are many silicified corals, some of them having a diameter of 2 or 3 feet. The clay is very plastic and hence is valuable for the manufacture of brick. Beneath this clay is the light-gray to yellow limestone which was formerly called the ‘Tampa limestone.’ The ‘silex bed’ represents a silicified zone in this limestone and is therefore a zone of replacement. This is well shown by some of the fossils, which have been only partially silicified, and by the presence of more or less unaltered carbonate of lime in the original rock. Small nodules of chert occur at other horizons in the limestone, and outcrops of the rock are often denser and harder than exposures in quarries. Locally the limestone is hard enough to make a durable building stone. Fossils are abundant in some parts of the limestone, but they are largely represented by casts and molds, which have been left by the solution of the original shells. The ‘silex bed’ contains numerous fossils which have been wholly or partly replaced by chalcedony. Resting upon the ‘silex’ at some localities is a siliceous residual material which was formerly thought to be infusorial earth but is now known to be weathered material derived from the underlying rock. In such cases the action of the percolating water has removed the matrix, leaving many beautifully preserved pseudomorphs and casts of shells. These fossils are commonly composed of chalcedony which frequently exhibits the characteristic markings of the original shells.

“Beneath the limestone beds is a greenish clay which commonly contains a considerable admixture of sand. This clay is very plastic and resembles the clay which overlies the limestone. Judging from well records, the deposit is homogeneous, but there is a possibility that the sand contained in the well samples may be derived from thin sand partings in the clay bed.

“The information concerning the thickness of the Tampa formation is meager, but it is sufficient to fix the maximum thickness at more than 130 feet. The clay bed at the top of the formation has a known thickness of 15 feet. The limestone between the ‘silex bed’ and the upper clay is about 40 feet thick. The thickness of the ‘silex bed’ varies considerably, ranging from about 4 feet to more than 10 feet. Beneath the ‘silex bed’ is a limestone which has a known thickness of 6 feet. The clay bed at the base of the formation has been penetrated by two wells within 200 feet of each other, and the thickness varied from 41 feet to 64 feet.

\* \* \* \* \*

“The Alum Bluff formation consists of marl, sand, and clay, which are sometimes fairly distinct but more often interbedded. Limestones also occur in the formation, but they are not extensively developed and usually contain enough earthy material mixed with the carbonate

of lime to form marls. Shell marls with a calcareous or sandy matrix are common and they often occur interbedded with nearly pure sand. In general the beds belonging to this formation are light gray, but occasionally shades of green or yellow prevail. \* \* \*

“The typical Alum Bluff formation consists of coarse light-greenish gray to white argillaceous sands, often showing cross-bedding and usually containing more or less interbedded clay and fuller’s earth. One of the most characteristic features of the sands is the presence of innumerable flakes of white mica—the ‘isinglass’ of the well diggers. The change from the shell marls of the Chipola marl member is by a transition zone which contains some of the same species of shells which characterize the marls. This zone also contains nodules of calcium carbonate which often inclose fossils. The upper part of the sand is usually free from shells but occasionally contains impressions of leaves and fragments of plants. Locally the Alum Bluff formation contains some clay, and near Chattahoochee it consists of greenish sticky marl.

“The fuller’s earth has the appearance of a dense, hard fine-grained siliceous clay. It is thinly laminated and commonly light gray to greenish in color. Sand partings sometimes occur, but they are comparatively rare, the material usually being homogeneous. Beds of sand and clay are commonly associated with the fuller’s earth, the sections consisting of interbedded sand and clay.

“The aggregate thickness of the Alum Bluff formation is at least 135 feet, but the maximum thickness of a single section is scarcely one-half that amount. It is doubtful if the total thickness is represented in any single section. The thickness of the sands of the Alum Bluff formation at the type locality is about 20 to 25 feet, but farther north, at Rock Bluff, Dall reports a maximum of 63 feet. The fuller’s earth commonly occurs in beds of 2 to 10 feet in thickness associated with several feet of clay and sand or sandstone. In some places two or more beds occur in the same section, separated by beds of sand and clay. The maximum observed thickness of fuller’s earth in a single section is about 15 feet, and the aggregate thickness of the associated clays and sand which appear to belong to the same horizon is not less than 20 feet.”

Three members of the Alum Bluff formation have been recognized—the Chipola marl member, the Oak Grove sand member, and the Shoal River marl member.

“The Chipola marl member, named from Chipola River, forms the basal portion of the Alum Bluff formation and rests conformably upon either the Chattahoochee or the Hawthorne formation. At the type locality of the Alum Bluff formation it constitutes the basal division of that formation, but farther north it thins and permits the sandy beds of the Alum Bluff to lap over on the Chattahoochee formation.

“When fresh this member consists of a light-gray to yellow marl, containing many shells and shell fragments. The matrix is composed of calcareous clay containing a small percentage of fine sand. When weathered the marl becomes dark yellow or reddish yellow from the presence of hydrated iron oxide. The character of the deposit indicates comparatively quiet water, with conditions especially favorable for the development of organic life. In some localities this horizon is represented by a very sandy marl.”

This member is not known to have a thickness of more than 15 feet and the average is probably only a few feet. The limestone belonging to it is so imperfectly known that a satisfactory estimate of its thickness is difficult to make. The maximum exposure which has been reported is about 10 feet.

The Oak Grove sand member, named from Oak Grove, on Yellow River, has been correlated on paleontologic grounds by Dall with the typical sands of the Alum Bluff formation. This member consists of fine-grained light-gray to greenish sands containing many excellently preserved shells. As it is not fully exposed at the type locality, where a thickness of only 2 feet is visible, it may attain a greater thickness. The fauna of the Oak Grove sand member is closely related to that of the Chipola marl member, but it contains large species of both *Cardium* and *Lyropecten*, which appear to foreshadow the large species of those genera occurring in the Miocene marls.

“The Shoal River marl member, which has recently been recognized by Vaughan, lies stratigraphically about 30 feet above the Oak Grove sand member. It thus forms the upper part of the Alum Bluff formation. In the section at Shell Bluff, on Shoal River, the lower sand

represents the Oak Grove sand member and the upper fossiliferous marl horizon is the Shoal River marl member. Lithologically this member consists of interbedded greenish sands, clays, and marls. The color is usually greenish, oxidizing yellow, occasionally whitish or purplish, and the material varies in texture from fine clay to sand." This member is about 50 feet thick.

In Georgia, according to Veatch, "the area over which the Chattahoochee formation appears as a surface formation is small, being confined mainly to small exposures along streams and in lime sinks.

"Erosion unconformities with the underlying Vicksburg have been noted in the vicinity of Bainbridge by Pumpelly and Vaughan. The Alum Bluff formation everywhere overlies the Chattahoochee and there appears to have been a continuous deposition from the beginning of the Chattahoochee to the end of the Alum Bluff.

"The formation is, on the whole, calcareous and the rock varies from a compact pure crystalline limestone to earthy and argillaceous limestone and calcareous sand and sandstone. The strata are in places phosphatic, and the limestone at the base has been extensively silicified and contains a rich coral fauna.

"The formation has a total thickness of about 100 feet in the gorge northwest of Faceville, Decatur County. No very reliable data are at hand for estimating the thickness east and northeast of this point, where it is under cover of later formations. The thickness is not great, however, and is not likely to be in excess of 250 feet.

"The Alum Bluff formation underlies a very large area in Georgia, extending northeastward, from Decatur County to Savannah River in Screven and Effingham counties, the eastern limit of outcrop being 50 or 60 miles from the coast. This formation overlies the Chattahoochee formation conformably. The line of division between the two is, in places, indefinite, as there is no apparent abrupt lithologic or faunal change from one to the other. In the Savannah and Altamaha river exposures small unconformities between the Alum Bluff and the Miocene were observed. This formation presents several different lithologic phases—sand and sandy laminated clay, fuller's earth, phosphatic sand, quartzite, silicified clay, and local limestone or calcareous layers and nodules. Greenish or drab argillaceous sand and fine-grained sandy laminated clay form the greatest portion of the strata. The maximum thickness of the Alum Bluff in southwestern Georgia is estimated at 150 feet. The natural exposures on Savannah River do not exceed 25 or 30 feet. It is not probable that at any place the thickness exceeds 250 or 300 feet, even where it is under cover of the later formations."

Sediments of upper Oligocene age extend westward from western Florida to Mississippi River. The Apalachicola group, or marine upper Oligocene, has been identified by means of fossils in Alabama at Roberts and probably at Wallace. In wells at Mobile fossils characteristic of the Alum Bluff formation were encountered between depths of 1,250 and 1,550 feet; below these is limestone, correlated with the Chattahoochee formation. The marine upper Oligocene is not known west of Mobile, the sediments becoming estuarine in character as the axis of the Mississippi embayment is approached. The unpublished results of the recent field work of Matson and the parallel paleobotanic studies of Berry have shown that the leaf-bearing clays and sandstones near Chicoria, Wayne County, 5 miles south of Florence, Rankin County, and Raglan, near McCallum, Perry County, Miss., are of upper Oligocene age.<sup>a</sup> The exposure at Raglan (the Hattiesburg clays of L. C. Johnson) appears to represent the top of the Alum Bluff of Florida, while the one near Florence is stratigraphically lower and perhaps belongs in the upper part of the Vicksburg group. The exposure of interbedded sandstone, semiquartzitic sandstone, and clay at Grand Gulf, Miss., is, according to the available evidence, to be referred to the upper part of the lower Oligocene and is the Mississippi representative of the Catahoula formation of Louisiana at the type locality. These estuarine or fresh-water deposits of clay and sandstone represent the basal portion of the Grand Gulf group of Hilgard,<sup>438e</sup> which according to his definition included the sandstone and clays lying between the Vicksburg below and the Lafayette above, but which is now known to be a series of geologic formations, including

<sup>a</sup> Paleontologic determinations furnished by E. W. Berry.

those of lower and upper Oligocene, Miocene, and Pliocene age, with perhaps some Pleistocene. The portions of the "group" later than the upper Oligocene will be referred to in Chapter XVII (pp. 806-813). The detailed tracing of the boundaries between the successive formations is now in progress by G. C. Matson.

I 17-18, J 18, K 18-19. NORTH CAROLINA TO MASSACHUSETTS, INCLUSIVE.

The subjoined discussion of the Tertiary deposits of the northern Atlantic Coastal Plain has been prepared by William B. Clark and is based on a briefer statement<sup>144</sup> covering this region.

The Tertiary deposits of the Atlantic Coastal Plain overlie the Cretaceous formations unconformably. They have been as a whole even less changed than the Cretaceous, although they present much the same complexity, owing to the variation in the angle and direction of tilting during the successive movements of the sea floor in Tertiary time. The sediments in general form a succession of thin sheets which are inclined seaward so that successively later formations are found toward the east. At no point do we find a continuous sequence of these formations, a condition which must be regarded as marginal and due to the transgression and retrogression of the sea along the coastal border, as continuous sedimentation must have been going on over a considerable part of the continental shelf.

The Tertiary formations have variously transgressed the underlying deposits and at many points actually reach beyond them and rest directly on the crystalline rocks of the Piedmont Plateau. Similarly later formations of the Tertiary have in many places transgressed the earlier, and the latest formation provisionally referred to the Pliocene has been found over wide areas resting on earlier Tertiary, Cretaceous, and crystalline rocks alike.

The northern Atlantic Coastal Plain contains deposits that are referred to the Eocene, Miocene, and Pliocene epochs. The Eocene formations are best developed in Maryland and Virginia, although Eocene deposits of moderate areal extent are also known in New Jersey and North Carolina. The Miocene formations are most extensively developed in the drainage basin of the Chesapeake Bay in Virginia and Maryland, but strata of that age also cover large areas in North Carolina and New Jersey. The marine Pliocene deposits are limited so far as known to North Carolina, although the Lafayette formation, of somewhat doubtful Pleistocene or Pliocene age, covers extensive areas in North Carolina, Virginia, and Maryland. North of these States only small remnants of the Lafayette have been found.

*Long Island and southern New England.*—The Tertiary deposits of Long Island and southern New England are confined so far as known at the present time to a few localities on Long Island and the islands off the Massachusetts coast. The scarcity of the exposures and characteristic fossils has led to much doubt as to the age of the beds, although they have been generally regarded as Miocene. The deposits have been studied chiefly by Shaler,<sup>728, 729, 730</sup> Veatch,<sup>837</sup> Fuller, and Crosby.

On Long Island small eroded remnants of supposed Miocene strata have been found overlying the Cretaceous, and certain sandy beds penetrated in deep well borings in the vicinity of the city of Brooklyn have been thought to belong to the same horizon and have been tentatively referred to the Beacon Hill formation of New Jersey.

The residual sandy strata overlying the Cretaceous deposits at Gay Head, Marthas Vineyard, and containing a meager fauna of supposed Miocene age have also been referred to the Miocene and may represent the same horizon. Similar deposits are also reported from Block Island.

*New Jersey.*—The Tertiary deposits of New Jersey comprise representatives of both the Eocene and the Miocene. Some of the Miocene deposits are evidently unfossiliferous, so that their position in the sequence of Miocene strata can not be clearly determined. Among those who have studied and described these deposits may be mentioned Cook,<sup>169</sup> Whitfield,<sup>928</sup> Clark,<sup>142, 145, 146, 152</sup> and Salisbury.<sup>691</sup>

The following scheme of classification has been proposed for the New Jersey formations:

|              |                                                                  |
|--------------|------------------------------------------------------------------|
| Miocene..... | } Cohanse sand and Beacon Hill formation.<br>Kirkwood formation. |
| Eocene.....  |                                                                  |

The Shark River, which is limited to a small area in eastern New Jersey, consists of green-sand marls and apparently overlies the Manasquan formation of the Upper Cretaceous conformably. The deposits are about 12 feet in thickness. The fossils are marine invertebrates of lower Eocene age.

The Kirkwood formation consists of sands and clays which unconformably overlie the older deposits of Eocene and Cretaceous age. It has a thickness of about 100 feet and contains in places a considerable fauna of marine invertebrates similar to the Calvert fauna of Maryland and Virginia.

The Cohanse consists chiefly of buff sands, although sandy clays and coarse white sands are also found. It has a thickness of about 100 feet. No diagnostic fossils have been found.

The Beacon Hill formation consists of gravel and sand and probably represents the shoreward phase of the Cohanse sand in the northern part of the New Jersey Coastal Plain. It has a maximum thickness of about 40 feet. No fossils have been found.

The deep well borings near the coast have penetrated several hundred feet of characteristic Miocene sediments in which fossils that apparently represent the Calvert, Choptank, and St. Marys faunas of Maryland and Virginia are found. It is apparent that the Kirkwood formation represents the Calvert formation, but whether the Cohanse sand and the Beacon Hill formation should be regarded as Choptank, which they resemble lithologically, is impossible of determination in the absence of characteristic fossils. It has been suggested that the Cohanse and Beacon Hill may perhaps overlie all the Miocene formations of the Chesapeake region.

*Maryland and Delaware.*—An extensive series of Tertiary deposits is found in Maryland and Delaware, including representatives of the Eocene, of the Miocene, and probably of the Pliocene. All the deposits, except the Pliocene, are highly fossiliferous and have been investigated by many students of geology and paleontology. Among those who have studied the region may be mentioned Say,<sup>704</sup> Conrad,<sup>168</sup> Harris,<sup>400</sup> McGee,<sup>565a, 566</sup> Clark,<sup>149, 150</sup> Martin,<sup>149</sup> Shattuck,<sup>733, 734</sup> and Miller.<sup>595, 597</sup>

The following scheme of classification has been adopted for the Maryland and Delaware Tertiary formations:

|                   |                                      |
|-------------------|--------------------------------------|
| Pliocene (?)..... | Lafayette formation.                 |
| Miocene.....      | Chesapeake group:                    |
|                   | St. Marys formation.                 |
|                   | Choptank formation.                  |
|                   | Calvert formation:                   |
|                   | Plum Point marl member.              |
|                   | Fairhaven diatomaceous earth member. |
| Eocene.....       | Pamunkey group:                      |
|                   | Nanjemoy formation:                  |
|                   | Woodstock greensand marl member.     |
|                   | Potapaco clay member.                |
|                   | Aquia formation:                     |
|                   | Paspotansa greensand marl member.    |
|                   | Piscataway indurated marl member.    |

The Aquia formation consists chiefly of greensands and greensand marls, in places highly calcareous and here and there argillaceous. These beds overlie the earlier deposits unconformably. The total thickness of the formation is about 100 feet. The Aquia formation has been divided into the Piscataway and Paspotansa members. The deposits contain a rich fauna of lower Eocene age. The formation is transgressed by the Calvert formation toward the north and disappears near the Maryland-Delaware line.

The Nanjemoy formation consists of greensands, in many places highly argillaceous but less commonly calcareous than the Aquia formation, which it overlies conformably. The

maximum thickness of the Nanjemoy formation is 125 feet. It has been divided into the Potapaco and Woodstock members. It contains an extensive fauna of middle Eocene age. It is not known to occur on the eastern shore of Chesapeake Bay.

The Calvert formation, which overlies the Eocene formations unconformably, consists of sands, clays, marls, and diatomaceous earth. These deposits have a thickness of about 200 feet. The formation has been divided into the Fairhaven diatomaceous earth member and the Plum Point marl member. It contains an extensive marine fauna.

The Choptank formation consists of sands, clays, and marls and has a total thickness of 125 feet. An extensive marine fauna characterizes these deposits.

The St. Marys formation consists of clays, sands, and sandy clays, the last typically greenish blue and bearing large quantities of fossils. The formation has a thickness of 150 feet. It carries a distinctive marine fauna.

The Lafayette formation consists of clays, loams, sands, and gravels which are in many places highly ferruginous. The thickness is variable but in few places exceeds 50 feet. No characteristic fossils have been found in these deposits and there is much doubt as to whether they are of late Pliocene or early Pleistocene age. The formation covers a wide area on the southern peninsula of Maryland and is represented to the north, on the western shore of Chesapeake Bay, by many small outliers. It overlies the Miocene and earlier formations unconformably.

*Virginia.*—The Tertiary deposits of Virginia comprise strata of Eocene, of Miocene, and probably of Pliocene age. The Eocene and Miocene formations are highly fossiliferous. The geology and paleontology of the region have been studied by many investigators, among them Rogers,<sup>676</sup> Conrad,<sup>168</sup> Clark,<sup>149,150</sup> Miller,<sup>595,597</sup> Berry,<sup>75</sup> and Gardner.

The following scheme of classification has been adopted for the Tertiary deposits of Virginia:

|                   |                                                            |
|-------------------|------------------------------------------------------------|
| Pliocene (?)..... | Lafayette formation.                                       |
| Miocene.....      | Chesapeake group:                                          |
|                   | Yorktown formation.                                        |
|                   | St. Marys formation.                                       |
|                   | Choptank formation, probably present but does not outcrop. |
|                   | Calvert formation.                                         |
| Eocene.....       | Pamunkey group:                                            |
|                   | Nanjemoy formation:                                        |
|                   | Woodstock greensand marl member.                           |
|                   | Potapaco clay member.                                      |
|                   | Aquia formation:                                           |
|                   | Paspotansa greensand marl member.                          |
|                   | Piscataway indurated marl member.                          |

The Aquia and Nanjemoy formations of Virginia are similar in their lithologic and faunal characters to the same formations in Maryland, the deposits being less highly calcareous in central and southern Virginia than in the valley of the Potomac.

The Calvert formation in Virginia is similar in character to the same formation in Maryland. It disappears at the outcrop in south-central Virginia, owing to the transgression of the St. Marys formation.

The St. Marys formation overlaps the Choptank formation near the Maryland-Virginia line and in Virginia directly overlies the Calvert formation unconformably.

The Yorktown formation consists of sands, sandy clays, and marls. In many places the marls are highly calcareous and fragmental in character. The deposits have a thickness of 150 feet and contain an extensive fauna of marine animal remains. The formation overlies the St. Marys formation unconformably.

The Lafayette formation in Virginia is similar in character to the same formation in Maryland, the strata being found along the western margin of the Coastal Plain in outliers of various extent.

*North Carolina.*—The Tertiary deposits of North Carolina comprise representatives of the Eocene, Miocene, and Pliocene. The extent and character of the deposits have not been known until within recent years. Among those who have studied the region may be mentioned Dall,<sup>212a</sup>

Clark,<sup>140</sup> Miller,<sup>586</sup> and Gardner. To Miller we are indebted for the detailed stratigraphy and to Gardner for an exact knowledge of the molluscan faunas.

The scheme of classification adopted for the North Carolina Tertiary deposits is as follows:

|                   |                                                                                        |
|-------------------|----------------------------------------------------------------------------------------|
| Pliocene (?)..... | Lafayette formation.                                                                   |
| Pliocene.....     | Waccamaw formation.                                                                    |
| Miocene.....      | Chesapeake group:                                                                      |
|                   | Yorktown formation north of Hatteras axis; Duplin formation<br>south of Hatteras axis. |
|                   | St. Marys sand (north of Hatteras axis).                                               |
| Eocene.....       | { Castle Hayne limestone } south of Hatteras axis.<br>{ Trent marl ..... }             |

The Trent, which overlies the Cretaceous deposits unconformably, consists of calcareous marls and clays, the former locally indurated, forming a compact limestone. The deposits have a thickness of about 50 feet. The fauna consists chiefly of marine invertebrates. The formation covers a small area in the valley of Trent River.

The Castle Hayne consists chiefly of calcareous marls and sandy clays. It has a thickness of about 50 feet and contains a fauna of late Eocene age. It apparently overlies the Trent unconformably.

The St. Marys and Yorktown formations in North Carolina are in general similar in character to the same deposits in Virginia. They are both confined to the area north of the Hatteras axis.

The Duplin formation consists of sands, clays, and marls and represents the Yorktown formation south of the Hatteras axis. It has a thickness of 100 feet and contains an extensive marine fauna similar to the Yorktown but of a warmer-water facies.

The Waccamaw formation consists of sands, clays, and marls. It is confined to a narrow belt along the eastern margin of the State where it rests unconformably on older formations. It has a thickness of about 50 feet. Its fauna is marine in character and consists of characteristic Pliocene forms.

The Lafayette formation consists of sands, loams, and gravels and is confined chiefly to outliers west of the main body of Coastal Plain sediments, where it forms the series of "sand hills."

*General remarks.*—The Tertiary deposits of this region overlie the Cretaceous strata unconformably, but owing to the differential movements already described the later transgress the earlier formations in certain areas, so that the Cretaceous deposits are in some localities overlain by Eocene and in others by Miocene or later formations. The dip of the Eocene formations rarely exceeds 15 feet in the mile toward the east and is in many places less; the dip of the Miocene formations is 10 to 12 feet in the mile, and that of the Pliocene formations is even less.

The correlation of the Tertiary formations within the region and with other areas is shown in the following tables.

*Eocene formations in northern part of Atlantic Coastal Plain.*

| New Jersey.  | Maryland and Virginia. | North Carolina. | Alabama.               |
|--------------|------------------------|-----------------|------------------------|
|              |                        | Castle Hayne.   | Jackson and Claiborne. |
|              |                        | Trent.          |                        |
|              | Nanjemoy.              |                 | Wilcox.                |
|              | Aquia.                 |                 |                        |
| Shark River. |                        |                 | Midway.                |

*Miocene and Pliocene formations in northern part of Atlantic Coastal Plain.*

|              | Long Island and southern New England.         | New Jersey.               | Maryland and Delaware. | Virginia.  | North Carolina.      |

| Pliocene (?) |                                               |                           | Lafayette.             | Lafayette. | Lafayette.           |
| Pliocene.    |                                               |                           |                        |            | Waccamaw.            |
| Miocene.     |                                               |                           |                        | Yorktown.  | Yorktown and Duplin. |
|              |                                               |                           | St. Marys.             | St. Marys. | St. Marys.           |
|              | Deposits of Long Island and Marthas Vineyard. | Cohansey and Beacon Hill. | Choptank.              | (?)        |                      |
| Kirkwood.    |                                               | Calvert.                  | Calvert.               |            |                      |

The Eocene deposits are found in three distinct and separate regions, so that the relations of the strata in these areas to one another can not be satisfactorily determined.

The Shark River marl of New Jersey apparently overlies the Manasquan formation of the Upper Cretaceous conformably. The two formations constitute a continuous series of relatively deep water deposits, no evidence of erosional or other unconformity being found. These stratigraphic features, together with a somewhat undiagnostic Eocene fauna, have led to the reference of the beds to an earlier horizon than that of the Aquia formation of Maryland, which overlies the Cretaceous strata with a marked unconformity. The Shark River marl has been referred to the Midway horizon of the Gulf.

The Aquia and Nanjemoy formations contain a distinctively Wilcox fauna, the Aquia being clearly lower Wilcox and the Nanjemoy probably upper Wilcox, although a few Claiborne forms appear in the upper beds of the Nanjemoy and it may in part belong to that horizon.

The Trent and Castle Hayne formations occupy a small area south of the Hatteras axis in North Carolina. The faunas have not yet been fully studied, but the forms found are of late Eocene age, which would suggest their reference to the Jackson, although they may also represent a part of the Claiborne as well. The bryozoans in the Castle Hayne have led Bassler to refer this formation to the Vicksburg.

The Chesapeake group and equivalent Miocene deposits from the New England coast to the Hatteras axis in North Carolina belong to a single geologic province, the strata and the fossils presenting a marked similarity throughout, though showing indications of increasingly colder waters toward the north. The Duplin formation south of the Hatteras axis is a part of the southern province and contains a fauna characteristic of much warmer water than that of the Yorktown, the synchronous formation to the north.

The Waccamaw formation is limited to the belt near the coastal border of North and South Carolina and contains a subtropical fauna.

The Lafayette formation has been traced along the western margin of the Coastal Plain, occurring as outliers on the adjacent Piedmont Plateau, from Pennsylvania, where the last remnants are found, to North Carolina. Berry<sup>80</sup> has shown that the deposits at Lafayette, Miss., the locality from which the name is derived, are of Eocene age, so that the term Lafayette is really a misnomer. Much question still exists as to whether the Lafayette of the Atlantic Coastal Plain is late Pliocene or early Pleistocene.

## I-J 11. GREAT BASIN, NEVADA AND CALIFORNIA.

The Esmeralda formation <sup>814</sup> occurs in southwestern Nevada along the base of the Sierra Nevada in the ranges developed by later Tertiary movements. It is tentatively assigned to the Oligocene and described as a lake deposit. Its general character appears to place it among the continental deposits of mixed character. The southern portion of the Great Basin, lying in southeastern California near the Nevada line, comprises Death Valley and the adjoining ranges, which are composed largely of Tertiary strata. Spurr <sup>772a</sup> says:

In the eastern part of the [Grapevine] range, where the road crosses from the Amargosa Valley into Furnace Creek, there is found a great amount of conglomerate, forming high hills. These conglomerates are very coarse and contain rounded pebbles and boulders of all sizes, made up of reddish and white quartzite and black and gray limestones bearing the badly preserved Paleozoic fossils above mentioned. The conglomerate is as hard and firm as the rocks from which it is derived. It is water-laid and well stratified and evidently a shore formation. The whole thickness exposed is estimated at 4,000 feet. It is sharply folded, together with the limestones from which it is derived, but it abuts abruptly against these limestones on the west.

The irregularity of the contact between conglomerate and limestone denotes a great erosion interval, yet no unconformity of attitude is apparent.

This conglomerate seems to fringe the north edge of the bold Paleozoic scarp of the Grapevine Mountains across the greater portion of the range. It is found at various points. A little west of Pyramid Peak conglomerate occurs, interbedded with and running laterally into a hard limestone, which has all the appearance of being calcareous tufa. A specimen examined microscopically bears out this idea and shows that the rock is probably a chemical precipitate. It is like a rock found in crossing the Panamint Range from Death Valley to Windy Gap, and also like one from the Esmeralda formation, between the Candelaria Mountains and the Pilot Range.

Besides these rocks there occur, as parts of the same series, semiconsolidated gravels, with clays partially hardened to slaty shales, limy clays partially consolidated to argillaceous secondary limestones, and sands partially hardened to cherty and limy sandstones, all interbedded. All these, including the conglomerate and the limestone tufa, have a general light-yellow, often greenish color, characteristic of the series.

This sedimentary series makes up the greater portion of the Funeral Range. Along Furnace Creek valley and on both sides of it the mountains consist chiefly of yellow-green strata capped by basalt. The lava seems to occur interbedded with the sedimentaries, as well as overlying them. The series is here consolidated into a hard clay rock, with occasional thin sandstone, and the general yellow-green color is changed in places to reddish, yellowish, and pinkish. The rocks are often gypsiferous and contain abundant grass remains, which are, however, indeterminable. From the yellow-green Tertiary series in the hills just east of the mouth of Furnace Creek there has been taken much borax, which occurs as borate of lime in beds in the strata. \* \* \*

On the eastern side of Death Valley, southward from Furnace Creek, the upturned yellow-green Tertiaries, with some few intercalated sheets of lava, constitute the mountains. Beneath some of these sheets the clays are baked to a red, natural brick. The lavas seem to occur chiefly at the top of the yellow-green series, or at a still higher horizon, for the great mass of beds exposed in the lower portion of Furnace Creek contains no lava sheets; yet in these beds occur occasionally lava boulders and pebbles, so that we conclude that the period was one of continual volcanic activity. From fragments of lava picked up at the base of the mountains and

from observations at a distance the lower lavas seem to be not so basic as the upper ones, which are chiefly olivine basalt. A single specimen of biotite andesite was all that was collected to represent these more siliceous volcanics.

Near the summit of the pass, just east of Furnace Creek, there come in above the yellow-green Tertiary series softer dark-brown honeycombed conglomerates, recalling the similar rocks of Meadow Valley Canyon. Thin sheets of basalt are interbedded with the conglomerates, but the great sheets lie on top. Patches of this same upper conglomerate series were elsewhere observed, and at one place its contact with the underlying yellow-green series appeared slightly discordant. The conglomerate contains pebbles and boulders which are chiefly of lava and must have been derived from the sheets of basalt which were periodically poured out during the deposition of the beds.

A rough estimate of the thickness of this whole series of slightly consolidated beds and volcanics puts it at not less than 4,000 feet and the nature of the sediments shows that they must have been deposited in standing water. The presence on some of the beds of gypsum, borax, and calcareous tufa shows that at some periods the waters in which the sediments were deposited were evaporated. They were, therefore, those of an inclosed lake, which was probably of great dimensions. It is likely that a large portion of the beds were deposited in fresh water at a period different from that in which the chemical precipitates were laid down.

The borax in these beds is probably contemporaneous with the borax deposits in similar folded Tertiaries at Daggett and elsewhere in the Mohave Desert. Between these two localities, moreover, the strata, so far as known, appear to be roughly continuous. The strata of Mohave Desert are exposed on a grand scale at Cajon Pass, where they contain beds of black lignite.

Northward from Furnace Creek, at Silver Peak, are found beds of the Esmeralda formation, which are entirely similar in nearly every respect to those at Furnace Creek. Moreover, the fossils found in the Esmeralda beds indicate a nearly similar age to that indicated by fossils found in the Tertiary strata of the Mohave Desert, just west of Cajon Pass.

The upper part of the Furnace Creek beds is identical in appearance with certain semi-indurated and slightly folded conglomerates and sandstones found in Meadow Valley Canyon, which have been referred to the Pliocene.

#### J 10. SACRAMENTO VALLEY AND COAST RANGES, CALIFORNIA.

The general relations of the Eocene of the Pacific coast to the underlying strata are thus stated by Arnold:<sup>31</sup>

A widespread unconformity exists between the Eocene and the Cretaceous on the Pacific coast of North America. Throughout Washington, Oregon, and certain parts of California this unconformity is angular, while over considerable areas in California and at one locality in Oregon the unconformity may only be recognized by a more or less marked hiatus in the faunas.

It is a noteworthy fact that wherever the line between the marine Eocene formations (Martinez, Arago, Tejon, etc.) and the Cretaceous beds is marked by an angular unconformity, the underlying beds are either of lower Cretaceous (Knoxville) or middle Cretaceous (Horseshoe) age, and that wherever the Eocene rests on the Chico, or upper Cretaceous, with the one exception at San Diego, the unconformity is not angular and, as far as the stratigraphic evidence goes, the two formations represent an apparent uninterrupted period of sedimentation.

The apparent conformability of the Eocene on the Cretaceous, together with the superficial similarity of their faunas, led Gabb and Whitney, of the early California Survey, to class the Martinez and Tejon formations with the Cretaceous. White, Stanton, and Merriam have,

however, shown the Eocene age of the Martinez and Tejon. Of the relationships existing between these two and the Chico, or upper Cretaceous, Dr. Merriam has the following to say:<sup>a</sup>

"The Martinez group, comprising in the typical locality between 1,000 and 2,000 feet of sandstones, shales, and glauconitic sands, forms the lower part of a presumably conformable series, the upper portion of which is formed by the Tejon. It contains a known fauna of over sixty species, of which the greater portion is peculiar to itself. A number of its species range up into the Tejon and a very few long-lived forms are known to occur also in the Chico. Since the Martinez and Chico are faunally only distantly related it is probable that an unconformity exists between them."

Another fact showing the relations existing between the Eocene and the Cretaceous is the occurrence in the Eocene beds in the Roseburg region, Oregon, of oysters so similar in appearance to the characteristic Cretaceous fossil, *Gryphæa*, that without their accompanying Eocene fauna these oysters would certainly be mistaken for Cretaceous forms.

\* \* \* \* \*

Rocks of marine origin and Eocene age are found at many localities throughout Washington and Oregon west of the Cascade Range and over considerable areas of the Coast Ranges in central and southern California. Although Eocene rocks probably once fringed the greater part of the western base of the Sierra Nevada, they are now all removed by erosion or covered by later formations except at one locality near Merced Falls. For the most part the Eocene rocks of the Pacific coast are either sandstone or shale. Conglomerate is found at the base of the formation throughout southeastern Oregon, north of San Diego, and at a few localities along the northeastern flanks of the Coast Range; and at Port Crescent, Wash., Eocene fossils are associated with tuff, but these occurrences are exceptional. Also, diatomaceous shales occur at the top of the Eocene series in the vicinity of Coalinga, Cal., where they are believed to be the source of important deposits of petroleum. Coal and other indications of shallow and brackish water conditions are found over much of Washington and Oregon and California, usually overlying marine Eocene beds. The maximum thickness of the Eocene sediments varies from 8,500 feet east of the Cascades,<sup>b</sup> 10,000 to 12,000 feet in western Oregon,<sup>c</sup> to 9,000 ± feet in southern California.<sup>d</sup>

The Tejon is the prevailing marine Eocene formation of California. Notes on its general relations and the extent of its occurrence have already been quoted from Arnold. Stanton<sup>777</sup> discussed the stratigraphic and faunal relations with the Chico and concluded that the Tejon and Chico are distinct. Gabb<sup>351</sup> had described the Tejon as Cretaceous, whereas Cooper<sup>170</sup> and White<sup>889</sup> had regarded it as a transition from Cretaceous to Eocene.

Arnold<sup>33</sup> has recently published the following classification and description of the rocks in the Santa Maria district:

The Santa Ynez Range is mostly composed of a thick terrane of marine sediments equivalent to a part or all of the Tejon formation and the Vaqueros formation. The former is Eocene and the latter lower Miocene in age. This terrane comprises a continuous succession of marine sediments of detrital origin, seeming to present no point at which an angular unconformity exists, although the line at the base of the coarse conglomerate containing the Vaqueros fossils doubtless marks a long time interval.

\* \* \* \* \*

The lower portion of the terrane is made up of a thick series of greenish-gray coarse and fine sandstones, many of them concretionary in character, interbedded with dark, fine-grained thin-bedded shales in lesser amount. Toward the middle of the terrane the shale increases in amount, alternating with thin beds of sandstone. Much of the shale has a characteristic olive-gray color. \* \* \* The shales and sandstones give place above the middle of the terrane to deposits of shallow-water character—coarse sandstone and a great quantity of coarse, in many places greenish or reddish gravelly conglomerate. This conglomerate contains abundant Vaqueros [Miocene] fossils and probably represents the base of that formation

and a period of shallow-water conditions with which the Vaqueros began. The conglomerate gives place in turn to more shale and sandstone, which continue to the summit of the terrane. At the top there is a conformable gradation into the Monterey (middle Miocene) beds, the summit of the Vaqueros being marked by a calcareous zone in many places—as, for instance, southwest of Lompoc, where the two formations are divided by a very prominent exposure of hard limestone.

In the hills west of Tulare Lake lies the Coalinga oil district, studied by Arnold and Anderson,<sup>34c</sup> who tentatively assigned to the Tejon formation a series of beds described as follows:

The formation mapped as the Tejon in the Coalinga district is made up entirely of sedimentary strata that dip toward the great valley in the monocline along the eastern flank of the mountains and are exposed on the surface in a narrow discontinuous belt between the Cretaceous beds which underlie them and those of the Miocene which overlie them. The beds so mapped have a thickness of 1,600 to 1,850 feet and are divisible into two main members of approximately equal thickness—a lower one consisting of sandstone in the southern part of the district and of dark clay shale and sand in the northern part, which is certainly of Eocene age, with the possible exception of a small thickness at the base, and an upper one of light-colored organic shale which affords few species of fossils and no conclusive evidence as to its age. This upper member may represent either Eocene or Oligocene time, but the facts that there seems to be a gradation from the beds of the lower member into those of the upper and that the two invariably occur together in this region favor its assignment to the Eocene. It is made up of thin beds of whitish and purplish siliceous, argillaceous, and locally calcareous shale, which is easily recognizable and which lends individuality to the formation. The shale is very similar, especially in some places, as north of Coalinga, to the siliceous shale of the formation along Reef Ridge that is described later as the Santa Margarita (?) formation, and the two must not be confused: It is also somewhat similar to the purple shale of the upper Chico. Where the Tejon formation is thick, shale and clay form a greater proportion of the whole than the sandstone, but a great local variation in the thickness of this member is noteworthy because due to the great unconformity between it and the overlying Miocene beds. A large portion of the formation had been worn away before the Vaqueros (lower Miocene) sandstone was deposited on its upturned surface. It is possible that an unconformity occurs within the beds mapped as Tejon at the base of the upper shale, but no discrepancy in dip between the beds of the two divisions has been found, and the succession of beds is seemingly continuous.

As already pointed out, an unconformity exists between the Chico (Upper Cretaceous) and Tejon (Eocene) beds, in spite of the facts that no sharp line of demarcation is to be drawn between the Tejon and the underlying Chico in the northernmost part of the district and that there appears to be a gradation from the beds of the former into those of the latter, as if they had been formed during a continuous period of sedimentation. In the southern portion of the district the Tejon overlies unconformably beds that belong to an earlier portion of the Cretaceous, either lower Chico or Knoxville, thus proving that a period of land conditions and orogenic disturbances preceded the Tejon.

Tejon group was the name applied by J. D. Whitney to the fossiliferous strata in the vicinity of Fort Tejon, Kern County, and Martinez, Contra Costa County, which were included by Gabb under his division B, or Upper Cretaceous.<sup>a</sup> As the result of later studies the fossils of this formation are now considered to be of Eocene age. Strata of the same age occur extensively in the region of Carquinez Straits, east of Mount Diablo, and have been found at a number of different points along the western border of the San Joaquin Valley, notably at New Idria and in the region discussed in the present paper.

For a general correlation table of the Tertiary formations of the California Coast Range see Chapter XVII (p. 818).

## J 12. PLATEAU PROVINCE OF UTAH.

In southwestern Utah the Cretaceous is overlain by Eocene (Wasatch) strata. Richardson<sup>669a</sup> says:

The Cretaceous rocks are unconformably overlain by Eocene strata, which, as already stated, outcrop in the Pink Cliffs and underlie the Markagunt and Paunsagunt plateaus. The unconformity, marked by a basal conglomerate containing pebbles of the underlying rocks, is emphasized by the absence of the upper members of the Cretaceous system, which are well developed in other parts of the plateau province. The Eocene rocks consist of a variable succession of shale, limestone, sandstone, and conglomerate that are characteristically varicolored. Shades of red and white predominate and are beautifully developed in the Pink Cliffs. Fossils are extremely rare in these rocks and only a few fragments of *Vivipara* and *Unio* have been obtained in this area, but the characteristic peculiarities of stratigraphy and coloring of the rocks leave little room for doubt that, except possibly a few feet of basal beds containing conglomerate of doubtful significance, they belong to the Wasatch formation of the Eocene series, which is so largely developed in the High Plateaus of Utah and from which characteristic fossils have been obtained in a number of places.

## J 12-13. SAN JUAN BASIN, COLORADO AND NEW MEXICO.

The Tertiary of the San Juan Basin of New Mexico and Colorado comprises possibly the Animas formation and certainly the Puerco and Torrejon formations (Eocene). The Animas formation is thus described by Cross:<sup>186a</sup>

In the article already cited on the post-Laramie deposits of Colorado, the writer referred to a series of strata occurring on the Animas River below Durango, which had been visited by Mr. T. W. Stanton and found to be very similar to the Denver beds. In the summer of 1894 the writer was able to hurriedly examine this series of beds as exposed on the railroad below Durango and found them to resemble the typical Denver beds in a very high degree. These strata occur above the Laramie and below the Puerco and, as far as the present meager observations show, are conformable with both of them where now preserved. The beds are some 700 feet or more in thickness and are composed of yellowish-brown clays, tuffs, sandstones, and conglomerates, in which andesitic material greatly predominates, and present a variety rivaling that in the Denver beds.

A few fossil plants occur, but those found thus far are poorly preserved, and the only identifiable species collected is *Magnolia tenuinervis* Lx., a common Denver bed species originally described from Table Mountain. No invertebrate fossils have been found as yet, but it seems probable that a number of vertebrate species, described by Cope as from the Laramie of the Animas River section, came out of the strata which so closely resemble the Denver formation.

In an article discussing the relations of the Puerco and Laramie deposits Prof. Cope refers to the succession of beds on the Animas River, saying: "According to the observations of Mr. David Baldwin the Laramie beds succeed [the Puerco] downward, conformably it is thought by Mr. Baldwin; and have a thickness of 2,000 feet at Animas City, N. Mex. [Colorado?]. A few fossils sent from time to time by Mr. Baldwin identify the Laramie. This is especially done by the teeth of the dinosaurian genus *Dysganus* Cope, which is restricted to the Laramie formation elsewhere, also by the presence of the genera *Laelaps* and *Diclonius*, which in like manner do not extend upward into the Puerco beds."

According to the statement of Prof. Cope, made personally to the writer and quoted with his permission, these fossils were collected incidentally to the investigation of the Puerco fauna and for the purpose of identifying the underlying formation. He believes it most probable that they came from what are here called the Animas beds, which extend for several hundred feet below the Puerco. Prof. Cope now regards the *Dysganus* and *Diclonius* as closely allied to the horned dinosaurs (*Ceratopsidæ* Marsh, *Agathaumidæ* Cope), which, as will be shown, form the most characteristic element of the vertebrate fauna known in the Arapahoe and Denver beds.

The Animas beds, as this post-Laramie formation may be called, are to be regarded as a most direct equivalent of the Denver beds, identical in peculiar lithologic character, lying between typical Laramie and Puerco, and containing fossils which, so far as known, indicate a similar fauna and flora.

The Tertiary of the northwestern part of the San Juan Basin is outlined in a recent map accompanying a report on the coals of the region, in which M. K. Shaler<sup>727</sup> thus states the relations of the Tertiary and Cretaceous:

The Animas beds outcrop only in a narrow belt along the north border of the field, thinning rapidly both east and west from Animas River. If present at all in the central part of the area, they are hidden by the Puerco marl, which north of Pueblo Alto apparently overlaps the Cretaceous rocks. Unconsolidated white sand, unquestionably of Puerco age, here lies in contact with an irregular surface of Laramie coal, immediately overlying the basal sandstone member of that formation. At this place the outcropping Laramie is only about 200 feet thick.

The upper and lower limits of the Puerco marl are difficult to determine in the area of flat-lying beds near Rio Chaco. There is nearly everywhere a marked gradation between these rocks and the Laramie, although the main body of the Puerco is easily distinguished by the presence in it of fossil mammal remains and silicified wood.

The available notes on the stratigraphy of the Puerco and Torrejon have been well summarized by James Hervey Smith:<sup>761</sup>

The Puerco formation is located in northwestern New Mexico at the headwaters of Puerco River, from which the formation takes its name, and where it "reaches a thickness of outcrop of about 850 feet."<sup>a</sup> The rocks of this formation consist of "sandstones and gray and green marls."<sup>a</sup> The formation is thus characterized by Wortman:<sup>b</sup> "The thickness of the beds is roughly estimated at 800 to 1,000 feet, and as far as can be observed they lie conformably upon the Laramie."

The fossils occur at two horizons which are separated by barren strata 700 to 800 feet thick (not 30 feet as erroneously quoted by Dall in the Eighteenth Ann. Rept. U. S. Geol. Survey, pt. 2, p. 347). "The lower fossil-bearing strata occur in two layers, the lowermost of which lies within 10 or 15 feet of the base of the formation. This is succeeded after an interval of about 30 feet by a second stratum in which fossils are found. \* \* \* Both of these strata are red clay, and at no place did we find them more than a few feet in thickness."<sup>c</sup>

This horizon "is especially and sharply distinguished by the occurrence of the remains of *Polymastodon*, which appear to be entirely absent from the upper horizon."<sup>c</sup> The upper horizon is richer in fossils than the lower. "The genera *Chirox* and *Pantolambda* appear to belong exclusively to the upper beds."<sup>c</sup>

Wortman believes that the upper fossiliferous horizon contains several layers, and that their vertical range is somewhat greater than that of the lower horizon. Matthew states that the "Upper and Lower Puerco beds do not contain a single species in common, and only three or four genera pass through. The two faunas are entirely distinct. Dr. Wortman proposes to call the upper beds the Torrejon formation, retaining the name Puerco for the lower beds."<sup>d</sup> Scott correlates the Puerco with the Cernaysien of Europe.<sup>e</sup>

Osborn<sup>623a</sup> briefly describes the Puerco, 500 feet (*Polymastodon* zone), as basal Eocene, characterized by small archaic mammals; and the Torrejon, 300 feet (*Pantolambda* zone), as the equivalent of a part of the Fort Union formation of Montana, also still characterized by descendants of Mesozoic types.

<sup>c</sup> Wortman, quoted by Osborn, op. cit., p. 2.

<sup>d</sup> Science, new ser., vol. 6, 1897, p. 852.

<sup>e</sup> Scott, W. B., Science, new ser., vol. 2, 1895, p. 499.

The coal field between Gallina and Raton Spring, N. Mex., in the San Juan coal region, is described by Gardner<sup>358a</sup> as follows:

In the vicinity of Gallina and to the south beyond Lajara the variegated shales of the Wasatch rest horizontally against the foot of the Sierra Nacimiento, covering the highly inclined strata of the Cretaceous and lower sedimentary rocks. The Wasatch bears many fragments of vertebrates, and collections were sufficient to permit its positive identification.

In the southern portion of the area, along the mountain foot northeast of Cuba and along the headwaters of Rio Puerco, the Wasatch is underlain by a mass of variegated bituminous shale, with two beds of massive sandstone. The sandstones form prominent escarpments, the upper immediately west and the lower about 10 miles southwest of Cuba. The entire thickness of these beds is about 800 feet. They are highly inclined along the mountains, and northeast of Cuba they are overturned and dip toward the mountains at about 70°. The high dips of the massive sandstones are in marked contrast to the unconformable horizontal shale of the overlying Wasatch. The prominent sandstone escarpments swing westward from Cuba, the lower being traced across the area beyond the limits of the present mapping. The upper escarpment could not be traced with certainty. The prominent escarpment of the Wasatch to the north follows in a general way parallel to these escarpments. Near a small pond, about 7 miles N. 76° E. of Ensino Spring, vertebrate fossils were collected from 25 feet of dark and gray argillaceous sand and shale immediately overlying the basal escarpment sandstone. A careful study of these fossils has been made by J. W. Gidley, of the United States National Museum, and the specimens have been compared with original material in the American Museum of Natural History, New York. This comparison definitely places them in the Torrejon formation.<sup>a</sup> The Laramie reappears from beneath the lower escarpment, striking almost at right angles with it, thus bringing out a marked unconformity between the two. It does not follow from the fossils that the lower escarpment is of Torrejon age. It is probable that there is an unconformity between the Puerco and the Torrejon. This accounts for the Torrejon fossils immediately above the basal escarpment sandstone, which is in all probability the lowest member of the Puerco. It is certainly at the base of an 800-foot mass below the Wasatch, exposed along the headwaters of Rio Puerco, as originally described by Cope.<sup>b</sup> Along Rio Puerco the base of the Wasatch is 750 feet above the top of the basal Puerco sandstone. At the point where the Torrejon fossils were collected the base of the Wasatch, as determined by both stratigraphic relationship and fossil evidence, is only 135 feet above the top of the same sandstone. Hence the 800 feet of the original Puerco is represented by only the basal sandstone, from 30 to 50 feet thick, unconformably overlying the Laramie. This sandstone is unconformably overlain by 110 feet of Torrejon, above which, also unconformably, lies the Wasatch.

### J 13. GREAT PLAINS OF COLORADO.

In the plains southeast of Denver the Oligocene and possibly part of the Eocene are represented by the Monument Creek formation. Darton<sup>240</sup> describes it as—

an extensive deposit of conglomerates, sand, sandstone, gravel, and clay, known as the Monument Creek formation. It lies on the Laramie formation to the east and the Arapahoe formation to the west, and at Palmer Lake it abuts against the granite at the foot of the mountain. There are two members, a lower one of sands and clays and an upper one of conglomerate and sandstone. The latter caps numerous buttes and plateaus in the high region west and north of Calhan and north of Monument.

Fossil bones of Titanotherium have been discovered by the writer<sup>c</sup> and Mr. C. A. Fisher in the upper member of the region north of Calhan and southwest of Elizabeth, which indicate

<sup>a</sup> Torrejon is a name proposed by J. L. Wortman (Bull. Am. Mus. Nat. Hist., vol. 9, 1897, pp. 260-261) for a fossil zone at the top of the original Puerco of Cope.

<sup>b</sup> Cope, E. D., Rept. Chief Eng., 1875, pt. 2, p. 1008.

<sup>c</sup> Darton, N. H., Age of the Monument Creek formation: Am. Jour. Sci., 4th ser., vol. 20, 1905, pp. 178-180.

that this portion of the formation is of Oligocene age. The lower member may be Oligocene, or perhaps Wasatch or Bridger, in age.

In southern Colorado just east of the mountains is the Huerfano basin, described by Hills<sup>448, 449</sup> and studied by Osborn.<sup>622</sup> The latter summarizes Hills's conclusions and his own:

In this third paper (1891) Prof. Hills positively identified the "upper beds" as equivalent to the Bridger group, and restricted the term Huerfano to these beds, applying the terms Cuchara to the middle division and Poison Canyon to the lower division. These divisions, correlated with the measurements previously assigned them, would then occur as follows:

|                            |   |                        |                                      |         |
|----------------------------|---|------------------------|--------------------------------------|---------|
| Huerfano series (Eocene).. | { | Huerfano beds.....     | Bridger group.....                   | 3,300   |
|                            |   | Cuchara beds.....      | } Lower Eocene (Green River, Wasatch | } 300   |
|                            |   | Poison Canyon beds...} | and Puerco).....                     | } 3,500 |

While these studies were in progress a large collection of fragmentary bones was made by Mr. Milligan, of Gardner, which is now preserved in the museum of the Colorado Scientific Society and which Prof. Hills kindly enabled the writer to carefully examine.

The essential features of Prof. Hills's conclusions may be summarized as follows:

1. The identification of the total Huerfano series of 3,300 feet with the Bridger or middle Eocene, and the provisional identification of the Cuchara and Poison Canyon series with the lower Eocene, in the absence of fossils, upon stratigraphical evidence.

2. The post-Laramie formation of a great anticlinal axis, as the eastern border of the Huerfano Lake to the east and southeast of the Wet Mountain Range and Spanish Peaks, and the subsequent removal of this axis by erosion.

3. The eruption of the laccolithic Silver Mountain and Spanish Peaks subsequent to the deposition of upper lake deposits of Bridger age.

4. The drainage of the Huerfano Lake to the north through the Wet Mountain Valley.

It should be stated here that these opinions were expressed at a time when several geologists had identified Laramie deposits east of the Rockies as Tertiary, owing partly to Prof. Marsh's identification of a Laramie dinosaur with *Bison alticornis*.

For the sake of clearness of contrast it may be well to summarize at this point the geological conclusions formed by the writer and Dr. Wortman during their brief reconnaissance of this region:

1. That west of the Huerfano Canyon the variegated marls, clays, soft shales, and sands aggregate only 800 to 1,000 feet in thickness, and are nearly horizontal in position. They may be positively divided into Upper beds, equivalent to the Bridger, and Lower beds, equivalent to the Wind River, or Upper Wasatch. These constitute the only true Huerfano Lake deposits.

2. That the Cuchara and Poison Canyon beds are unconformable with the Huerfano beds and older than the Eocene, probably marine Cretaceous, as partly determined by the presence of a species of *Baculites* in the yellow sandstone of the typical Poison Canyon section.

3. That the present canyon of the Huerfano River cuts through the base of the main anticlinal axis of post-Laramie origin, which formed the eastern boundary of the lake. This axis extended to the south so as to include the base of Silver Mountain toward the Cuchara divide; but it lies from 3 to 7 miles west of the anticlinal axis described by Prof. Hills.

4. That the Huerfano Lake deposition did not extend as far to the east or south as the Spanish Peaks, and that the variegated beds observed there are of older origin. This would materially effect the geological age of the prominent neighboring laccoliths.

The geological features of these conclusions can hardly be dignified by the term "a theory of the Huerfano Lake," for they were formed during a hasty reconnaissance of this basin, while Prof. Hills's theory certainly deserves the deliberate consideration of a prolonged survey. In fact, this basin, with its volcanic disturbances and eruptions, presents in compact form a fascinating problem in the geology of Tertiary times.

Hills<sup>451b</sup> describes the Poison Canyon, Cuchara, and Huerfano formations as they occur in the Spanish Peaks quadrangle. The two older formations (Poison Canyon and Cuchara) are placed doubtfully in the Eocene, the Poison Canyon being regarded as possibly equivalent to the Arapahoe of the Denver basin. Osborn's determination (1897) of the Eocene (Bridger and Wind River) age of the Huerfano formation is sustained by later studies of the fauna by Wortman and Matthew.<sup>623a</sup>

#### J 13. EAST-CENTRAL COLORADO.

The Florissant lake beds, discovered by Hayden and described by Peale and Scudder,<sup>719</sup> occupy an area too small to be shown on the map, about latitude 39°, longitude 105° 20', in the pre-Cambrian mass of the Colorado Front Range. The beds consist of volcanic ash, from showers and washed volcanic detritus, more than 50 feet thick. The deposit is noted for the rich harvest of fossil insects it has yielded. For descriptions of these fossils Scudder<sup>720, 721, 722, 723</sup> and Cockerell<sup>161, 162</sup> should be consulted.

#### J-K 12-13. UINTA VALLEY, ROAN OR BOOK PLATEAU, AND GRAND MESA.

South of the Uinta Range in Utah lies the Uinta Valley, which Emmons<sup>320</sup> examined cursorily in course of his work for the Fortieth Parallel Survey. The strata extend into northwestern Colorado and were there studied by White,<sup>888</sup> who distinguished the Wasatch, Green River, Bridger, and Uinta groups, applying the term Uinta to the rocks described by Powell as the Browns Park group. The Wasatch, Green River, and Bridger are described as conformable, and the Uinta as resting unconformably upon the Bridger and older formations around the east end of the Uinta Range. According to the recent work of Gale<sup>355</sup> in this area, the Browns Park formation is of later age than the true Uinta of King. It underlies the Bishop conglomerate (Bishop Mountain of Powell), which is the same as the Wyoming conglomerate of the Fortieth Parallel Survey. In Gale's preliminary report<sup>354</sup> the Tertiary formations are described as follows:

[The "Browns Park" formation] consists of loose or slightly consolidated sandy material with local harder sandstone beds and some beds of gravel. Contains much calcareous material in the form of cement or filling between the quartz sand grains. Its color is everywhere chalky or limy white. The thickness is not determined.

[The Green River formation is] composed of shale, sandstone, and beds of oolitic rock. The shaly beds predominate and are very compact and firmly bedded. They are generally exposed in escarpments and high bluffs, in which the weathered beds have a very characteristic chalky-white aspect. The shales are, however, of various shades of gray, drab, and light brown and are in many places hard and thin bedded. In some districts the lower part contains much massive white sandstone. Measured sections exceed 2,400 feet; upper limit not reached.

[The Wasatch formation is] composed chiefly of clay or soft clay shale; commonly variegated, but various shades of red and drab predominate. It also contains beds of pebbles or conglomerate of very perfectly rounded siliceous material, such as jasper, colored vein quartz, chert, or flint. Sandstones in places very massive and hard. From 4,000 feet in thickness on the eastern side of the Uinta Basin to about 2,500 feet near the Utah line.

[The Fort Union or earlier beds are] not readily distinguished from the Wasatch in the Uinta Basin, but are apparently more clearly differentiated in the Yampa field. As developed in the latter region they consist of massive white or light-colored sandstones and shales

containing valuable coal beds sharply defined at the base by a conglomerate or conglomeratic sandstone, without doubt marking an unconformity of considerable magnitude. Thickness estimated as about 800 feet on Lay Creek north of Lay.

Osborn<sup>623g</sup> describes the later Eocene deposits of the Uinta Basin as comprising the Uintatherium zone (800 feet), provisionally equivalent to the upper part of the Bridger; the Eobasileus zone (350 feet), equivalent to the upper zone of the Washakie Basin; and the Diplacodon zone (600 feet), which is the true Uinta of King and properly the Uinta formation. This last he regards as "approaching if not equivalent to the lowermost White River Oligocene—that is, lower Titanotherium zone or Chadron formation."

Eocene strata extend southward from the Uinta Valley and White River in Utah and Colorado and, rising, form the Roan or Book Plateau. Their southern margin has been traced by Taff and Richardson in connection with surveys of the underlying (Cretaceous) coal measures. Lee<sup>530a</sup> states the section as follows:

The Grand Mesa coal field is located on the southern rim of the Uinta coal basin, which lies partly in northwestern Colorado and partly in Utah. It derives its name from Grand Mesa, a high table-land between Grand and Gunnison rivers. The coal beds underlie the mesa and outcrop along the south and west sides. They extend westward into the Book Cliffs field, north of Grand Junction,<sup>a</sup> and eastward into the Anthracite-Crested Butte region,<sup>b</sup> long known for its anthracite coal, and thence northward along the Grand Hogback, recently described by Gale.<sup>c</sup>

*Generalized section of rocks in the Grand Mesa coal field, Colorado.*

[Only the Tertiary part of the section is here given.]

| Formation.                   | Thickness (feet). | Characteristics.                                                                                                                                                                                                                                                                                                                                                                                 |
|------------------------------|-------------------|--------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| Green River.                 | 200-1,800         | White friable sandstone and clay shale, capped by basalt.                                                                                                                                                                                                                                                                                                                                        |
| Ruby (probably Wasatch).     | 500-2,000         | Conglomeratic sandstone and shale, varicolored. In the eastern part of the field the rocks are mainly red and conglomeratic beds are numerous. The basal conglomerate consists principally of quartz and chert pebbles and the higher ones of various crystalline, metamorphic, and extrusive rocks. In the western part of the field lighter colors prevail and the rocks are finer in texture. |
| Unconformity                 |                   |                                                                                                                                                                                                                                                                                                                                                                                                  |
| Ohio Creek.<br>Unconformity. | 100               | White friable conglomeratic sandstone, containing pebbles of quartz, jasper, and igneous rock.                                                                                                                                                                                                                                                                                                   |

J-K 13, L 13-14. GREAT PLAINS OF COLORADO, WYOMING, MONTANA, NORTH AND SOUTH DAKOTA.

In the northern and central parts of the Great Plains area there are several nonmarine formations lying near the boundary between the Cretaceous and Tertiary, concerning the exact age and correlation of which there has been much controversy. They are the Denver and Arapahoe formations of the Denver Basin and the Lance and Fort Union formations of the Dakotas, Wyoming, and Montana. The earlier history of the discussion concerning them, in which the more general Laramie question is involved, was summed up by Clark <sup>141</sup> in 1891. The Arapahoe and Denver formations were first recognized as distinct from the Laramie by Cross and Eldridge <sup>322</sup> in the course of their detailed study of the Denver Basin. The following statement concerning their age is quoted from Cross: <sup>322a</sup>

Until the discoveries which are described in preceding chapters were made the strata of the Arapahoe and Denver formations had been uniformly assigned by geologists to the Laramie, under the accepted definition of the latter as the uppermost division of the conformable Cretaceous series; and not only had they been assigned to the Laramie, but no characteristics of any kind had been mentioned, or apparently observed, by which these upper beds might be even locally distinguished from the lower, coal-bearing horizon. This correlation was based on the presence of the true Laramie below the beds in question, on the failure to notice their peculiar and distinguishing characteristics, and on the assumptions regarding the unity of the fossil flora, whose species were, however, collected from widely separated horizons in the Golden section.

In the earliest descriptions of these formations by Mr. Eldridge and the writer they were assigned to the Tertiary. The reason for this assignment was the discovery that between the Laramie and Arapahoe epochs there had occurred an orographic disturbance whose magnitude was measured, for this locality, by the presence in the Arapahoe strata of pebbles of highly indurated clastic rocks, sandstones, conglomerates, etc., clearly belonging to various geological horizons as far down as the Trias, representing erosion of 14,000 feet of strata, according to the section of the formations in question in the Denver region. The lithological character of the Denver beds showed that the interval of unknown duration between the Arapahoe and Denver epochs had witnessed the occurrence of volcanic eruptions on a gigantic scale, and also subsequent local erosion.

Up to the time when these formations were thus identified, great orographic movements in the Rocky Mountains had been commonly supposed to mark the ending of Mesozoic time, and to be in great measure the cause of the wonderful changes that took place at this period, especially in vertebrate life, as shown by the remains in the earliest known Eocene deposits. The beginning of Tertiary time was also known to be widely characterized by great volcanic outbreaks, recorded in the sediments of the Green River, Florissant, and other Eocene basins. Hence it seemed natural to place the Arapahoe and Denver beds in the Tertiary, as, perhaps, the earliest lake deposits of Cenozoic time. Examination of the paleontologic evidence available at the time showed either that it did not controvert the assignment or, as in the case of the fossil plants, was entirely untrustworthy because the floras of the distinct horizons involved could not then be compared.

The recent discoveries of fossil vertebrate remains are said by paleontologists to show that the life of the epochs under discussion was much more nearly allied to Mesozoic than to Cenozoic types, and in deference to this opinion the post-Laramie formations are classed in this report with the Cretaceous. But such a course raises at once the question as to the nature and position of the boundary between Mesozoic and Cenozoic time in the Rocky Mountains and broadens very materially the treatment which must be given to the problem.

Cross <sup>192</sup> recently contributed a paper to the discussion of the age of the Laramie formation in which he proposed to distinguish those strata which unconformably succeed the latest conformable Cretaceous as the Shoshone group. After describing in much detail the various local formations which may be referred to the Shoshone group, he says: <sup>192a</sup>

In the preceding discussion I have avoided the question as to the age of the Shoshone beds, whether Cretaceous or Eocene. I desire now to urge their reference to the Eocene. The Denver beds were originally referred by me to the Eocene, but the great weight attached to the Mesozoic affinities of the vertebrate fauna by paleontologists led to a tentative acquiescence in the assignment of the Arapahoe and Denver formations to the Cretaceous, in the Denver monograph. In that volume I reviewed various aspects of the question and can add but little to what was there said. The main point seems to be that the Laramie and Shoshone beds belong to a transition series between the Cretaceous and Eocene and that whatever break occurs between any two formations is possibly bridged over by deposits of some other locality. The Laramie is related to the Judith River and other brackish-water formations of the Montana Cretaceous, the Shoshone to the great succession of Tertiary local deposits. The retreat of marine waters and the decided uplift of a large continental area marked the appropriate boundary between Cretaceous and Eocene from the stratigraphic side.

The name Lance formation has recently been adopted by the United States Geological Survey for the dinosaur-bearing strata variously known as the "Ceratops beds," "Lance Creek beds," "Hell Creek beds," and "Somber beds," which have by some geologists been assigned to the Cretaceous and referred to or correlated with the Laramie and by others included in the Fort Union and assigned to the Eocene. The typical area is in Converse County, Wyo., where the formation has yielded an abundant and varied vertebrate fauna, including Triceratops and several other genera of dinosaurs and a number of small primitive mammals. Recent areal work in connection with the examination of coal lands by the United States Geological Survey has shown that the Lance formation is widely distributed in Wyoming, Montana, North Dakota, and South Dakota. It is mapped together with the Denver, Arapahoe, etc., as "Earliest Tertiary or latest Cretaceous" (5a).

The Fort Union formation was named by Meek and Hayden, <sup>586a</sup> who stated that it consists of "beds of clay and sand, with round ferruginous concretions, and numerous beds, seams, and local deposits of lignite" and "occupies the whole country around Fort Union [at the mouth of Yellowstone River], extending north into the British possessions to unknown distances; also southward to Fort Clark." The formation as developed in this original area is now generally regarded as Eocene, and it is so mapped with the other formations of the "Continental Eocene" (5b1), but the underlying strata which Knowlton (see pp. 763-764) called the lower member of the Fort Union are excluded from it and assigned to the Lance formation.

The argument for placing the Lance formation in the Cretaceous has been presented by Stanton, <sup>783</sup> who does not share with Cross the view that there is a widespread unconformity of great significance between the Laramie and the Shoshone, although he, like all other geologists, clearly recognizes that there are very pronounced local unconformities. Stanton's argument is based on the actual stratigraphic sequences and upon the relations of the vertebrate and invertebrate

faunas. He does not consider that the floras furnish sufficient evidence for correlation with the Tertiary, and he concludes:

In the interior region of North America the formations between the uppermost marine Cretaceous and the Wasatch together constitute a real transition from the Cretaceous to the Tertiary.

Notwithstanding the fact that there are several local unconformities at various horizons and perhaps some of more general distribution, there is no conclusive evidence that any one of these represents a very long period of erosion not represented by sediments elsewhere in the region.

The Fort Union formation, properly restricted, is of early Eocene age, the determination resting chiefly on its stratigraphic position and its primitive mammalian fauna, which is related to the earliest Eocene fauna of Europe. The very modern character of the flora tends to confirm this correlation.

The "Ceratops beds" are of Cretaceous age, as decided by stratigraphic relations, by the pronounced Mesozoic character of the vertebrate fauna with absence of all Tertiary types, and by the close relations of its invertebrate fauna with the Cretaceous. The relation of the flora with Eocene floras is believed to be less important than this faunal and stratigraphic evidence. Taken in their whole areal extent they probably include equivalents of the Laramie, Arapahoe, and Denver formations of the Denver Basin.

Knowlton,<sup>508</sup> presenting the evidence from the point of view of the paleobotanist, also discusses the stratigraphy and regarding his conclusion states:

The present paper deals with the extensive series of fresh-water deposits of the Northwest (that is, broadly, the region east of the Rocky Mountains and between Wyoming and the valley of the Mackenzie River), comprising what is here considered as the Fort Union formation. It is shown that the Fort Union embraces more than has been commonly assigned to it. Conformably below the beds by some geologists considered as the true Fort Union occur dark-colored sandstones, clays, and shales, which have often been incorrectly referred to the Laramie, or its equivalent, but which are stratigraphically and paleontologically distinct from the Laramie, and the contention is here made that these beds, which include the "Hell Creek beds" and so-called "somber beds" of Montana, the "Ceratops beds" or "Lance Creek beds" of Wyoming, and their stratigraphic and paleontologic equivalents elsewhere, are to be regarded as constituting the lower member of the Fort Union formation and are Eocene in age.

Knowlton<sup>508a</sup> sums up his argument as follows:

1. The Fort Union formation is a fresh-water Tertiary formation of wide areal extent, mainly east of the Rocky Mountains, ranging from Wyoming and western South Dakota over western North Dakota, eastern and central Montana, the central Canadian provinces, and reaching the valley of the Mackenzie River.

2. It is shown that the Fort Union formation may be separated into two members on lithologic grounds. The present paper deals only or largely with the stratigraphy and paleontology of the lower member, which includes the "Hell Creek beds" and so-called "somber beds" of Montana and the "Ceratops beds" of Wyoming.

3. The areal distribution of the lower member is traced in Montana, North and South Dakota, and Wyoming, and its probable extension in other areas is indicated. Complete lists of the fossil plants are given by localities for each of the areas.

4. It is shown that the lower member rests, in some cases unconformably, in others in apparent conformity, on the Fox Hills or Pierre, and the conclusion is reached that an erosional interval is indicated during which the Laramie, if ever present, and other Cretaceous and early Tertiary sediments were removed.

5. It is shown that the beds under consideration, being above an unconformity, can no longer be considered as a part of the "conformable Cretaceous series" and hence are not Laramie.

6. It is shown that the two members of the Fort Union, although usually distinct lithologically, can not be separated structurally, sedimentation having been uninterrupted, except locally.

7. The paleontological elements of the lower member are considered at length, beginning with the plants. It is shown that of the 84 species, 61 are common to the upper member and only 11 species to the Laramie of Colorado, while 15 species are common to other American Eocene and nine species to the Miocene. The Eocene age of the Fort Union is fixed by tying its flora to that of various Old World beds of known Eocene position.

8. The invertebrate evidence is shown to be in substantial accord with that of the plants, there being only four of the 49 species common to the Colorado Laramie. All, with a single possible exception, are fresh-water forms.

9. It is shown that the vertebrates afford no positive evidence of Cretaceous age. That the dinosaurs exhibit Cretaceous affinities is not denied, since, being without known descendants, it is possible to compare them only with their progenitors. It has been proved beyond question that they survived the profound orogenic movement and attendant physical break at the top of the Laramie in the Denver Basin of Colorado, and lived on in Arapahoe and Denver time, and it is shown that in the areas considered in this paper they passed over a similar erosional interval and are found in association with the Fort Union flora, which is of Eocene age.

10. The mammals of the lower Fort Union show very little relationship with Jurassic or Cretaceous forms but find their closest affinities with those of the Puerco and Torrejon, which are of acknowledged Eocene age.

11. The chelonians are shown to be of little value in their bearing on the age of the lower Fort Union, especially when compared with the Judith River forms, which are evidently in confusion.

12. It is held that the line between Cretaceous and Tertiary should be drawn at the top of the true Laramie.

13. The final conclusion is reached that the beds here considered ("Hell Creek beds," "somber beds," "Ceratops beds," "Laramie" of many writers) are stratigraphically, structurally, and paleontologically inseparable from the Fort Union, and are Eocene in age.

#### K 10. ROGUE RIVER VALLEY, OREGON.

Diller<sup>281</sup> says:

Coal occurs at numerous localities in the Rogue River valley of southwestern Oregon, between the Cascade Mountains on the east and the Klamath Mountains, locally called the Siskiyou Mountains, on the west.

\* \* \* \* \*

The Cascade Range, east of the coal belt, is made up mainly of Tertiary lavas; the Klamath Mountains, on the west, are composed of granular igneous rocks and a smaller proportion of pre-Cretaceous sediments.

The soft rocks in which the Rogue River valley has been cut are sandstones, shales, and conglomerates. They dip generally eastward, extending beneath the lava fields of the Cascade Range. The older sediments along the western border of the valley, by Bear Creek from the Toll House to Ashland, Phoenix, and Jacksonville, are Cretaceous in age and do not contain coal. The coal-bearing rocks lie east of Bear Creek as far north as Medford, but beyond that point they overlap the Cretaceous rocks and occupy the whole northern portion of the Rogue River valley.

## K 12. NORTHEASTERN UTAH AND SOUTHWESTERN WYOMING.

The southwest corner of Wyoming and the immediately adjacent part of Utah were mapped by Veatch,<sup>839a</sup> who subdivided the Tertiary (all Eocene) as follows:

| Eocene:                                   | Feet.       |
|-------------------------------------------|-------------|
| Bridger formation.....                    | 1,200-1,800 |
| Green River formation.....                | 2,000±      |
| Wasatch group:                            |             |
| Knight formation.....                     | 500-1,500±  |
| Unconformity.                             |             |
| Fowkes formation.....                     | 0-2,500+    |
| Almy formation.....                       | 2,100-2,200 |
| Evanston formation ("Upper Laramie")..... | 0-1,600+    |
| Unconformity.                             |             |
| Cretaceous.                               |             |

Veatch's table, from the Jurassic to the Tertiary, inclusive, and his comments regarding the division line between the Cretaceous and the Tertiary are quoted in Chapter XV (pp. 676-677). For detailed descriptions of the formations see the work cited.

The sequence of Wasatch strata thus described by Veatch is correlated by Osborn with the Wasatch near Black Buttes in the Washakie Basin; with the Wasatch of the San Juan Basin, New Mexico (1,500 feet); with the Wasatch of the Bighorn Basin, Wyoming (2,391 feet, Loomis); and with the lower portion of the Huerfano formation of Colorado.

The Bridger and Washakie basins lie in southern Wyoming on either side of the Rock Springs dome. The Eocene on the western margin of the Bridger Basin has been studied stratigraphically by Veatch,<sup>839f</sup> and the lower Eocene on the flanks of the Rock Springs dome by Schultz.<sup>716a</sup> Schultz defines the area and gives the following section of Tertiary rocks:

The field here considered lies along the eastern margin of the great Green River Basin and includes in part, on the east, the Great Divide Basin. It lies on the north flank of the Rock Springs dome, which is completely surrounded by Tertiary beds.

| Unconformity          |                        |                   |                                                                                                                                                                                                                                                                                             |
| Wasatch. <sup>a</sup> |                        | 400-825           | Variiegated clays, shales, and sandstones, the sandstones in places being slightly conglomeratic.                                                                                                                                                                                           |
| Unconformity.         | Black Rock coal group. | 1,200-2,650±      | Alternating layers of white, yellow, and brown sandstones, gray, drab, and carbonaceous shales, with coal beds and conglomerate containing granite and quartzite pebbles. Numerous bands of white concretionary sandstone weathering in irregular shapes. Basal sandstone is conglomeratic. |

<sup>a</sup> Abundant collections of plants have been obtained from the lower third of this formation and determined by F. H. Knowlton, who studied the collections, as undoubtedly Fort Union.

Osborn<sup>623f</sup> gives a columnar section of the Bridger formation, 1,875 feet, as developed in the Bridger Basin, based on detailed stratigraphic and paleontologic work by Matthews and Granger. Five divisions are distinguished according to faunas. The Bridger is assigned to middle Eocene time and correlated with the upper part of the Huerfano formation, the lower part of the later Eocene (Uintatherium zone) of the Washakie Basin, Wyoming, and the lower part, or Uintatherium zone, of the later Eocene of the Uinta Basin of northern Utah; also with the Clarno formation of the John Day Basin, Oregon.

#### K 12. WIND RIVER BASIN, WYOMING.

E. G. Woodruff has contributed the following data on the Tertiary of the Wind River Basin:

The highest Tertiary beds recognized in the Wind River Basin are called by Osborn and others the Wind River formation (Eocene). They consist of alternate beds of gray, drab, and pink very sandy shale and a few sandstone members near the base. In several areas about the edge of the basin a conglomerate member is the base of the formation. The Wind River is notably unconformable above the Fort Union formation, and probably was deposited subsequently to the formation of the Wind River Basin. The material composing it is believed to have been derived from the surrounding mountains. The thickness of the formation is undetermined. The Fort Union formation (Eocene) peeps out from beneath the Wind River cover in a few places around the edge of the Wind River Basin. It is believed that all of the Fort Union is not represented in any of these exposures. The formation where seen consists of a series of sandy shales and both shaly and massive sandstones which are generally pale rusty colored but are locally gray. The underlying formation is the Mesaverde (Upper Cretaceous).

Osborn,<sup>623d</sup> who bases a section of the Wind River formation on work done by Hayden and Loomis, assigns 1,200 to 1,400 feet to the formation, with red beds at the base. The strata comprise the Lambdotherium and Bathypopsis zones (lower to middle Eocene) and fall into two divisions which correspond to the upper part of the Wasatch of the Bighorn Basin and the lower part of the Huerfano formation of Colorado. (See J 13, pp. 758-759.)

#### K 13. WYOMING AND COLORADO.

The eastern border of the Washakie Basin has been mapped by Ball,<sup>53</sup> who determined the following section of the Tertiary on the southern line of Wyoming:

The coal field drained by Little Snake River extends from the Sierra Madre westward to and partly into the Red Desert, and from the summit of the Elkhead Mountains of Colorado northward to the divide between the Pacific and Great Divide Basin drainages, a few miles south of the Union Pacific Railroad.

The area discussed in this paper is located near the middle of the southern boundary of Wyoming.

The stratigraphic relations of the coal-bearing and associated formations, with their general character and approximate thicknesses, are shown in the following table [only the Tertiary part of the table is quoted]:

*Generalized section of coal-bearing rocks in western portion of the Little Snake River coal field, Wyoming.*

| System.   | Formation.                                | Economic designation. | Description.                                                                                                                                                                                                       | Thickness (feet).   |                     |

|           |                                           |                       |                                                                                                                                                                                                                    | North end of field. | South end of field. |
| Tertiary. | Upper part of Wasatch and later Tertiary. |                       | Variegated clay passing upward into brown and gray shales, sands, and sandstones. Not coal bearing.                                                                                                                | Top not seen.       |                     |
|           | Wasatch.                                  | Upper coal group.     | Shale and soft sandstone, with many beds of impure coal.<br>Conglomerate.                                                                                                                                          | 8,500               | 0 to 4,000          |
|           | (?) <sup>a</sup>                          |                       | Gray and brown sandstones and gray and drab shales, with many coal beds.<br>White to dark clay shale. No coal.<br>Heavy sandstone with interbedded shale and numerous beds of good coal; conglomerate at the base. |                     |                     |

<sup>a</sup> The three lower members of the upper coal group have the stratigraphic position of the "Upper Laramie" of A. C. Veatch (Coal fields of east-central Carbon County, Wyo.: Bull. U. S. Geol. Survey No. 316, 1907, pp. 244-260).

Osborn correlates the upper part of the section in the Washakie Basin as later Eocene, Uintatherium and Eobasileus zones. The strata are largely volcanic ash. The lower zone (250 feet) is widely distributed. The upper zone (250 feet or more) is restricted to Haystack Butte and the surrounding badlands.

E. E. Smith <sup>752</sup> gives the following section of the Tertiary in southern Wyoming, on the eastern margin of the large area mapped as Eocene. (See Chapter XV, p. 680, for the Cretaceous section.)

The Great Divide Basin coal field is situated along and north of the Union Pacific Railroad in south-central Wyoming and embraces portions of the northeast end of Sweetwater County, the northwest end of Carbon County, and the southeast corner of Fremont County.

The coal-bearing rocks of the area here described are of Upper Cretaceous and Tertiary ages. They consist of the Colorado, Montana, Laramie, undifferentiated Tertiary, and Wasatch formations. Of these, only the last four contain workable coal beds. Thin beds of coal occur in the basal portion of the Colorado, but at no place within the area treated do they reach minable thickness. The coal-bearing formations show considerable change in character from the southern to the northern edge of the field. Those of the Cretaceous system thin rapidly toward the north and the outcrops of the beds of the undifferentiated Tertiary become more and more narrow, owing to the overlap of Wasatch conglomerate. The accompanying section shows the thickness and general characteristics of the coal-bearing formations near the Union Pacific Railroad and in the gap between Whisky Peak and the Ferris Mountains.

*Section of the Tertiary rocks of the Great Divide Basin coal field, Wyoming.*

| System.     | Group.                                  | Formation.            | Thickness (feet).   |                     | General characteristics.                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                          |

|             |                                         |                       | South end of field. | North end of field. |                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                   |
| Tertiary.   |                                         | Wasatch.              | 900±                | 1,800±              | In the southern part of the area it is composed of massive white and yellowish-brown soft sandstones alternating with layers of drab to black carbonaceous shale. The sandstone members harden locally and weather into forms resembling large concretions. The basal portion is also concretionary and contains small granite pebbles. In the northern part of the field it consists entirely of white conglomerate containing decomposed granite boulders up to 6 feet in diameter in the upper portion, and of coarse-grained white sandstone containing scattered boulders of granite and sedimentary rocks in lower portion. |
|             |                                         | Unconformity          |                     |                     |                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                   |
|             | Undifferentiated Tertiary. <sup>a</sup> | (?)                   | 7,980±              | 2,000               | Alternating layers of soft yellowish-brown and white sandstones and drab, brown, and black shales. The middle portion consists of soft shale and sandstone and is not exposed in this area. Massive white sandstone at the base is conglomeratic and contains pebbles of Paleozoic rocks. At the north end of the field only the lower part of the formation is exposed. The proportion of shale is much greater than at the south end. The basal portion contains conglomeratic layers with Cretaceous pebbles up to 8 inches in diameter.                                                                                       |
|             |                                         | (?)                   | 800±                | 1,800               | Alternating layers of soft drab, brown, and black shales and thin strata of dark, rusty-brown resistant sandstone. Sandstone is increasingly conglomeratic toward the top. Shales in northern portion erode into badland forms.                                                                                                                                                                                                                                                                                                                                                                                                   |
|             |                                         | Unconformity          |                     |                     |                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                   |
| Cretaceous. | (?)                                     | Laramie. <sup>b</sup> | 3,900±              | 1,050               | Alternating layers of yellowish-brown and white massive sandstones, thin brown sandstone, and drab, brown, and black shales. Sandstones are very resistant in southern portion. At north end the sandstones in the basal part are more resistant than those in the upper part, and constitute prominent topographic features.                                                                                                                                                                                                                                                                                                     |

<sup>a</sup> The fossil evidence from this group is conflicting and the age of the group can not be decided until further paleontologic work is done.

<sup>b</sup> Marine Cretaceous (upper Montana) species were obtained about 500 feet above the base of this formation in sec. 1, T. 21 N., R. 89 W., and at the base in sec. 26, T. 26 N., R. 90 W. They may probably be found at various places in the lower portion, and therefore no definite formation line can be drawn on paleontologic evidence. The base of the sandstones has been used in mapping the formation because it is the only line which is marked lithologically.

Between the Washakie Basin on the west and the Laramie Basin on the east lies the Hanna Basin of Carbon County, Wyo., which comprises the "Lower Laramie" and "Upper Laramie" of Veatch.<sup>841a</sup>

Veatch's generalized section of the Cretaceous and Tertiary strata is quoted on page 676. His "Lower Laramie" is now recognized as Laramie and as of Cretaceous age. His "Upper Laramie" is regarded by Knowlton as equivalent to the Lance formation ("Ceratops beds"), which Knowlton believes is of Eocene age and equivalent to the lower part of the Fort Union formation, but which Stanton

and others believe is of Cretaceous age and older than the Fort Union, representing in fact the upper part of the Laramie.

Tertiary strata occur in the Laramie Basin and in the valleys of the adjacent slopes on the east and northeast. They have been mapped by Darton,<sup>247</sup> who assigns the deposits on Little Medicine Bow Creek, at the north end of the basin, to the Chadron formation, the lower formation of the White River group (Oligocene). The age of the other occurrences has not been determined.

The elevated basin of Middle Park, Colorado, contains strata which are correlated by Cross with the Denver formation. They were first described by Marvine,<sup>577</sup> who distinguished a "doleritic breccia" and a "lignitic formation," the latter 5,500 feet thick. Cross<sup>185</sup> reviewed Marvine's observations in detail in the field and reported on the stratigraphy and correlation of the formations. The strata are unconformable to the marine Cretaceous, and their correlation with the Denver formation is determined on their stratigraphic condition, lithologic similarity, and closely related floras. Cross<sup>186</sup> says:

The "doleritic breccia" of Marvine is a series of dark tuffs, conglomerates, and breccia beds, made up of a large series of andesitic fragments, of types identical with those in the Denver formation. These beds are coarser in texture and are more variable than the Denver strata but resemble them very much in many details. The sharp line drawn by Marvine between the "breccia" and his "Lignitic" series does not appear justifiable. While Marvine does not refer to volcanic materials in the upper series, there is in fact a gradation between the lower, dark, almost purely andesitic strata and the lighter-colored beds above, in which granitic débris usually predominates, although micaceous and hornblende andesites are abundant for more than 2,000 feet upward in the series, as far as the writer's observations go.

Plant remains are the only fossils as yet known from the Middle Park strata. These were found by the Hayden Survey party in the "Lignitic" series only, but they occur also in the dark tuff layers of the lower beds. A number of the species described by Lesquereux as from Middle Park are now known to have come from the Eocene lake bed at Florissant, Colo. The entire known fossil flora of the Middle Park series has been studied by Mr. Knowlton. \* \* \* Twenty-five satisfactory species are known from these strata, and by far the strongest alliance is with the flora of the Denver formations.

Along the Grand River near Hot Sulphur Springs the stratigraphic relations of the Middle Park beds are clearly shown. They here rest upon the upturned and eroded section of the Mesozoic series, from the Jura to the Fox Hills, and overlap the former to the granite.

According to Shaw,<sup>735</sup> the following Tertiary formations occur in the Glenrock coal field in east-central Wyoming:

- Red and light-gray conglomerate and sandstone.
- White clay, more or less calcareous and commonly sandy (White River formation).
- Fort Union (?) formation (shales, sandstones, and coal).

#### K 13-14. GREAT PLAINS OF SOUTH DAKOTA, WYOMING, COLORADO, AND NEBRASKA.

Eocene strata are lacking in part of the northern Great Plains, the lower Oligocene being the lowest Tertiary. In considerable areas it rests on the eroded marine Cretaceous, though there are outlying remnants on later formations, and it constitutes the White River group of Hayden, which includes the Chadron and Brule formations of Darton. Darton<sup>238b</sup> says:

Early in the study of Great Plains geology the Tertiary formations were divided into the White River group below and the Loup Fork above. This distinction is a clearly recognizable

one, although, as now well known, there were confused under the name of Loup Fork a number of separate formations ranging in age from Miocene to early Pleistocene.

The White River group has been studied mainly in the Big Badlands, lying southeast of the Black Hills, where three principal subdivisions were defined, the lower one as the Titanotherium beds, the middle as the Oreodon beds, and the upper as a series consisting of the Protoceras sandstone and some overlying clays. This classification is distinctly set forth by Dr. Wortman.<sup>a</sup> In the Oreodon clays there is often a marked sandstone horizon known as the Metamynodon beds.

In mapping the geology of western Nebraska, in 1897, I had need to subdivide the formations in the valley of Platte River and Pine Ridge, where I found that the White River group consisted of the usual basal series, the Titanotherium beds, which I designated the Chadron formation, and the usual overlying series of flesh-colored sandy clays, the Oreodon beds, to which the name Brule clays was applied.

\* \* \* \* \*

The Chadron formation [consists mainly of] sandy clays and greenish-gray sandstones, mostly of soft texture, in which characteristic Titanotherium remains are of frequent occurrence. The upper limit to the formation is placed arbitrarily just below some pink clays lying below a thin bed of limestone, which is believed to be at the same horizon as one in the Big Badlands, where it immediately overlies the last of the beds of Chadron character. The thickness of the formation appears to be about 200 feet at most; but, as it lies on a very uneven surface, the amount varies greatly. The sandstones, which occur at various horizons, appear to lie in narrow belts, doubtless indicating channels of deposition. The lineal character of some of these channels is very distinctly exposed in the western portion of Goshen Hole.

The Brule clay consists mainly of a hard sandy clay of pale-pink color and massive structure, having near the base a thin layer of limestone. Locally some portions are sandy and contain beds of sandstone. \* \* \* In the northern face of Scotts Bluff, \* \* \* from the base of the overlying Gering beds to the surface of the river, there is a vertical interval of 500 feet continuous outcrop. The formation also has a small additional thickness below the level of the river. \* \* \* The badlands topography is a characteristic feature of most exposures of the Brule clay. \* \* \* The basal portion of the formation generally includes a thin bed of limestone, and at various horizons there are occasional irregular lens-shaped masses of sandstone. \* \* \* [The limestone] is a very thin bed of compact cream-colored rock lying on a series of pinkish and greenish clays which are regarded as the base of the formation.

Beds of volcanic ash occur in the Brule clay, some of them of wide extent and apparently at constant horizons. One bed conspicuous in many outcrops lies at 60 to 70 feet below the top of the formation in the district south and southeast of Gering. It is about 150 feet below the top at Scotts Bluff, a position which it holds for some distance to the west. Another higher bed often occurs. Fossil bones of various mammals and turtles characteristic of the Oreodon fauna of the Oligocene occur in the Brule clay.

Osborn<sup>623b</sup> assigns the Chadron formation to the lower Oligocene and gives its homotaxis and synonymy. The lower part of the Brule Osborn places in the middle Oligocene and the upper part in the upper Oligocene; the former comprising the Oreodon zone and "Metamynodon sandstones," the latter containing the Lep-tauchenia zone and "Protoceras sandstones." He also gives the homotaxis and synonymy of the lower and upper parts of the Brule.<sup>6231</sup>

<sup>a</sup> Wortman, J. L., On the divisions of the White River or lower Miocene of Dakota: Bull. Am. Mus. Nat. Hist. vol. 5, 1893, pp. 95-105.

## K-L 10. COAST RANGE OF OREGON.

According to Diller,<sup>273</sup> Eocene rocks form the mass of the Coast Range from a point near the Columbia to Coquille River. Three groups of strata are distinguished—(1) the oldest, composed in general of igneous sediments closely related to lavas of earlier or contemporaneous eruption; (2) shales, containing here and there much material of igneous origin; and (3) sandstones, forming the uppermost group. Diller describes many local occurrences and cites Dall's determinations of fossils from specific places.

These Eocene terranes constitute the Arago group (named from exposures near Cape Arago), which is divided into the "Pulaski" and Coaledo formations.<sup>275</sup>

The "Pulaski" formation comprises all the Eocene strata below the coal-bearing Coaledo formation in the Coos Bay and Port Orford quadrangles. It consists chiefly of soft yellowish sandstone interstratified with thin beds of shale but includes also small bodies of limestone composed largely of remains of algæ and Foraminifera. During the "Pulaski" epoch and particularly toward its close there were volcanic eruptions which resulted in basalt flows and tuff beds.

The Coaledo formation consists of sandstones and shales with coal beds. The strata were deposited chiefly in brackish waters and thus contrast with the marine "Pulaski." Sandstones predominate in the lower part of the Coaledo, whereas in the upper portion light-colored shales are characteristic.

The Arago group, composed of the "Pulaski" and Coaledo formations, comprises about 10,000 feet of strata. The uppermost portion as measured near Cape Arago consists of foraminiferal and other shales (2,200 feet) and sandstones (850 feet). The sandstones are distinguished by Dall<sup>211a</sup> as the Tunnel Point beds.

Regarding the correlation of the Arago group Dall<sup>211b</sup> states:

These beds are composed of sandstones and shales and extend northward from Cape Arago to Cape Gregory and thence eastward to Miners Flat, on the south shore of the entrance to Coos Bay, Oregon. They have an average dip of 70° NE. and a thickness of over 3,000 feet. They contain *Cardita planicosta*, *Ampullina* sp., and other middle Eocene forms which suggest their correlation with the Claibornian of the Gulf column. They are apparently newer than the blackish rocks of the region about the junction of Little River and the North Umpqua, which also contain *Cardita planicosta* but which have also a large proportion of distinct species. They appear to be older than the brackish-water deposits which inclose the Coos Bay lignites, though the latter have occasional intercalary marine layers which contain species of fossil shells apparently identical with members of the Arago fauna. The brackish-water species comprise forms belonging to *Corbicula*, *Cyrena*, and *Melania* or *Cerithiopsis*, forcibly recalling those which occur in the lignite beds of the Puget group, some of which prove to be identical.

The Umpqua beds above alluded to contain a notable number of "*Loxonema*" *turrita* Gabb, which is stated by him to be common in the Tejon, and have been referred by Diller<sup>a</sup> to the Tejon group. While this disposition of them may be confirmed by a study of their fauna and is probable, the Arago beds, which were not at first discriminated from those of the Umpqua, now appear, from the differences in their fauna, to require separation as a distinct series of beds.

<sup>a</sup> Bull. Geol. Soc. America, vol. 4, 1893, p. 219.

See Harris <sup>a</sup> on the correlation of the Tejon. There seems to be a strong probability that part of the beds heretofore referred to the Tejon represent the basal Eocene, but at present we are without sufficient evidence to speak positively.

Diller describes the Arago group in the Coos Bay <sup>275</sup> and Port Orford <sup>277</sup> folios and the Umpqua in the Roseburg folio.<sup>274</sup> The following quotation is from the Coos Bay folio:

The rocks of the Eocene period in this region have been called the Arago formation, but in this quadrangle they are grouped into two formations—the Pulaski and the Coaledo. These formations occupy almost the whole of the Coos Bay region. They are composed generally of sandstones and shales, which are especially well exposed near the mouth of Coos Bay and at Cape Arago, where they contain *Cardita planicosta* and numerous other characteristic Eocene fossils. Heavy-bedded sandstones prevail in the eastern part of the area, toward the Coast Range, where the Eocene rocks have a wide distribution, and shales become abundantly interstratified with the sandstones in the western part, near the coast. In the eastern part of the quadrangle the sandstones are penetrated and separated by dark, heavy intrusions of igneous rock, basalt, and the overlying sandstone near by generally contains much sediment derived from it.

The strata among which the coal beds are found contain at a number of places the fossils which characterize the Arago formation, and it is therefore evident that the coal-bearing strata are of the same age as that formation and form part of it.

#### L 10. JOHN DAY BASIN, OREGON.

Merriam distinguished as probably Eocene the Clarno formation, a deposit of "tuffs, ashes, and lavas," which overlies the Chico (Upper Cretaceous) and is overlain by the John Day formation (Oligocene) at Clarno Ferry, on John Day River, Oregon. He says: <sup>590a</sup>

At numerous localities along the western side of the John Day Basin there are exposed, either below the lowest John Day beds or above the Chico Cretaceous, several hundred feet of strata which certainly do not belong to either of these horizons. To these beds the name Clarno formation has been applied by the writer.

Typical exposures of the Clarno are to be seen at Clarno's Ferry, on the John Day east of Antelope, near the town of Fossil, on Cherry Creek, and near Burnt Ranch.

The Clarno formation is made up almost entirely of erupted materials. Part of the section consists of rhyolite and andesite flows, but the most characteristic portion comprises sedimentary beds grading from ashy shale to coarse tuff. The ash and tuff beds frequently contain plant remains in abundance and were evidently, at least in part, deposited in water. The strata seem in some places to have accumulated very rapidly. At one locality where large specimens of *Equisetum* have been found in shaly beds, the stems are standing erect and cutting across the stratification planes. This could occur only where deposition or shifting of the ashy mud was taking place very rapidly. The wide extent of the plant beds, which seem to be present at nearly all of the well-known occurrences of the formation, indicates the existence of lacustrine conditions, intermittently at least, over this region during the Clarno epoch.

The thickness of the Clarno formation is not less than 400 feet. It will probably be found to exceed that limit. The strata are usually gray to buff but sometimes show brilliant coloration in shades of red, green, and blue.

The relations of the Clarno to the Cretaceous may be seen just east of the town of Mitchell, where a considerable thickness of andesite and tuff is resting upon the Chico. Again, on the wagon road between Allen's ranch and Mitchell, the Clarno appears to rest upon the western side of the Knoxville anticline.

<sup>a</sup> Science, vol. 22, Aug. 18, 1893, p. 97.

Where the Clarno has been found in contact with the John Day there is no apparent angular unconformity of the strata. The difference in induration and weathering is, however, very noticeable. The sedimentary parts of the Clarno show a much greater degree of induration than the John Day beds immediately above and tend at all localities to form steep bluffs ornamented frequently with balanced rocks or grotesque figures. The soft beds of the Lower John Day normally weather into rounded, mud-covered domes or more gently sloping banks.

On the river above Clarno's Ferry this formation dips about  $15^{\circ}$  to  $25^{\circ}$  to the north and beneath the Lower John Day. Fine exposures continue along Pine Creek east of the ferry. North of the town of Fossil the Clarno is again seen typically developed and dipping under the John Day. Along Currant Creek it is well exposed and is close to or in contact with the Columbia lava.

At most of the localities mentioned the Clarno shows a considerable thickness of lava beds toward the top. These flows are not, however, the uppermost part of the section. The base of the formation is formed by andesite flows in several places, but it was not determined whether the whole section is present at these points.

At most of the Clarno localities where careful collecting has been done, plant remains are found to be fairly abundant. Repeated attempts have been made to obtain vertebrate or invertebrate fossils also, but, so far as the writer is aware, none have ever been discovered. The plants are, perhaps, most common in a bed of tuff and ash, 100 or more feet in thickness, belonging to the middle or the lower part of the formation.

Knowlton <sup>590b</sup> reported on the fossil plants as follows:

In attempting to work out the bearing of the plants above enumerated on the question of the age of the beds, it should not be overlooked that any conclusions drawn might be quite different from what they would be were the whole flora of each of the localities to be considered. For example, Dr. Merriam's collection from Bridge Creek embraces only 14 previously named species, whereas the complete known flora of this locality includes over 40 species. And further, it is impossible at the present time, without having worked out the affinities of the Tertiary floras of California and elsewhere, to give with any degree of completeness the outside relationships of the flora of the John Day region. The following conclusions, however, are not likely to be greatly modified by subsequent work.

The oldest horizon represented by these collections seems to be that near the crossing of Cherry Creek. The species, though few in number, seem to have their greatest affinities with forms from the lower Tertiary, and it is probable that this horizon should be referred to the lower or middle Eocene. There are a few species in common with Bridge Creek, but in general its flora has a slightly older facies.

The Bridge Creek, as already suggested, has an ample flora which is represented by a wealth of individuals. A large proportion of its species are endemic, but on considering the obvious relations of these, as well as the forms known from other localities, an upper Eocene age is indicated.

Several other of the localities seem to be of the same age as the Bridge Creek beds, namely,  $1\frac{1}{2}$  miles east of Clarno's Ferry, 3 miles above Clarno's Ferry, and one-half mile northeast of Fossil. Not more than three previously named species are known from either of these localities, and not rarely the identification of some of these is more or less doubtful, but as nearly as can be made out they should be of the same age as Bridge Creek.

It will be noticed that the determination of the plant remains, both as regards the flora as a whole and with respect to its subdivisions, agrees with the statement relating to stratigraphic succession. The Bridge Creek beds, with the few specimens from the shales  $1\frac{1}{2}$  miles east of Clarno's Ferry, are considered upper Eocene, while those from Cherry Creek are held to be an earlier facies.

## L 10. CASCADE RANGE AND YAKIMA VALLEY, WASHINGTON.

The Eocene of the upper Yakima Valley comprises sediments and igneous rocks which in order from older to younger are the Swauk formation, Naches formation, Kachess rhyolite, Teanaway basalt, gabbro, Roslyn formation, and Manastash formation. The following descriptions are condensed or quoted from those of George Otis Smith: <sup>756, 758a</sup>

The Swauk formation consists of conglomerate, sandstone, and shale, which vary greatly in character from place to place. At the base there is usually a conglomerate or arkose derived directly from the older rocks and composed largely or exclusively of their material. Arkose sandstones and carbonaceous shale make up the greater part of the formation. The thickness is 3,500 to 5,000 feet but varies with inequalities of the underlying surface, which are considerable. The shales contain abundant and well-preserved fossil leaves, which are regarded by Knowlton as of Eocene age.

The Roslyn formation occurs in a small basin in the upper Yakima, where its extent and structure have been well determined in the development of the coal mine opened upon its principal coal bed. The greater part of the formation consists of massive sandstones, with which fine-grained clay shales are interbedded. The thickness is approximately 3,500 feet. The included flora is quite distinct from that of the Swauk formation and has Miocene affinities, but, though evidently younger than the Swauk, it is considered to belong in the Eocene.

The Manastash formation is the latest Eocene sedimentary deposit known in the Yakima Valley. It rests directly upon the pre-Mesozoic schists, with a well-developed basal conglomerate, and consists of about 200 feet of sandstone and shale. But two small areas are known, and they might readily be confused with other similar sandstones, which, however, do not have the flora that the Manastash contains. It has been described by Knowlton, who states that none of the species occur in the Roslyn or Swauk formations. They are correlated with species found in the Florissant beds of Colorado and at Corral Hollow, California.

The Naches formation is composed of interbedded sandstone and basalt, the sedimentary rock predominating in the lower and the volcanic in the upper portion. \* \* \* No occurrences of the Naches formation are known outside of the Snoqualmie quadrangle.

Since the Naches and Swauk formations are not found in juxtaposition, there is lack of direct stratigraphic evidence regarding their relative ages. It is noteworthy, however, that they have similar relations to both the older and later rocks, a fact which suggests that they may be nearly contemporaneous. The evidence afforded by fossil plants confirms this view.

## L 12. BIGHORN BASIN, WYOMING.

For the southwest side of the Bighorn Basin Woodruff <sup>947</sup> determined the following section of the Tertiary:

*Section of coal-bearing and associated rocks exposed along Shoshone River near Cody, Wyo.*

| System.     | Formation.             | Thickness (feet).                        | Characteristics.                                                                                                                                              |
|-------------|------------------------|------------------------------------------|---------------------------------------------------------------------------------------------------------------------------------------------------------------|
| Tertiary.   | Wasatch formation.     |                                          | Various colored shales interbedded with sandstone and conglomerate.                                                                                           |
|             | — Unconformity —       |                                          |                                                                                                                                                               |
|             | Fort Union formation.  | 3,100                                    | Gray to drab sandy shale and tan-colored massive sandstone. In the lower part of the formation conglomerates occur at intervals through 1,000 feet of strata. |
|             | — Unconformity (?) —   |                                          |                                                                                                                                                               |
| Cretaceous. | Laramie (?) formation. | [See p. 684 for the Cretaceous section.] |                                                                                                                                                               |

For the east side of the Bighorn Basin Washburne<sup>867</sup> gives the following section:

*Stratigraphic column on the east side of the Bighorn Basin, Wyoming.* \*

| System.            | Formation.            | Thickness (feet).                | Characteristics.                                                                                                    |
|--------------------|-----------------------|----------------------------------|---------------------------------------------------------------------------------------------------------------------|
| Tertiary (Eocene). | Wasatch formation.    | 500                              | Bright-colored clays, with a few thin lenses of sandstone. Contains workable coal in the central part of the basin. |
|                    | Unconformity          |                                  |                                                                                                                     |
|                    | Fort Union formation. | 1,000-2,000                      | Dark-colored shale and massive sandstone. Contains workable coal.                                                   |
|                    | Unconformity (?)      |                                  |                                                                                                                     |
| Cretaceous.        |                       | [For the Cretaceous see p. 690.] |                                                                                                                     |

Loomis<sup>546</sup> has discussed the conditions of deposition in the Bighorn Basin and has shown that the strata are mainly fluvial, using the term to cover all kinds of flood-plain deposits, in contrast to lacustrine. Osborn<sup>623c</sup> says:

Geologically the section is 2,391 feet thick, divided into lower, middle, and upper levels, all showing flood-plain rather than eolian characteristics, but indicating different rates of deposition and consequent longer or shorter exposure of the deposits to the sun and air. Only the middle or red beds are decidedly fossiliferous, and they seem to have been exposed longest to the air, leaving the bones of terrestrial animals on the flats; they contain the typical Wasatch, *Coryphodon* and *Eohippus* fauna. Occasionally truly aquatic animals, such as crocodiles, fishes, and turtles, becoming stranded or inclosed in lagoons far from the river, mixed their remains with those of the land animals. Loomis's approximate analysis of the natural habitat of the total vertebrate fauna is: Aerial, 3 per cent; terrestrial and arboreal, 77 per cent; amphibious, 12 per cent; aquatic, 10 per cent.

The section compiled by Osborn<sup>623b</sup> from Loomis gives the *Lambdotherium* zone as the highest fossiliferous horizon of the Bighorn Basin, with 730 feet of unfossiliferous clays above it. *Lambdotherium* occurs at the base of the Wind River section and thus serves to correlate the two.

#### L 12. WESTERN MONTANA.

The areas in southwestern Montana on the headwaters of the Missouri, which are distinguished by the "Later Tertiary" color on the map, include possibly Eocene and certainly Oligocene deposits. Douglass<sup>288</sup> describes the Sage Creek beds (Eocene?), White River (Oligocene), and Fort Logan beds (upper Oligocene, John Day?).

The Eocene (?) "occurs on Sage Creek about 7 miles northeast of Lima, Beaverhead County." The fossils found are considered to represent *Heptodon*?, *Hyrachynus priscus* Douglass, and *Metamynodon*?

The deposits of White River age are shown to be lacustrine, in contrast to those of the Great Plains, and "appear in the main to represent the *Titanotherium* and *Oreodon* beds of South Dakota."

The Fort Logan beds of Douglass are the lower Deep River beds of Scott.<sup>717</sup> They occur on Smith River, formerly known as Deep Creek, southwest of the Little

Belt Mountains. Scott quotes from the first description by Grinnell and Dana (1875):

The Tertiary beds found here consist for the most part of homogeneous cream-colored clays, so hard as to be with difficulty cut with a knife. The beds are horizontal. \* \* \* Some bluffs were noticed where the Miocene beds attain a thickness of about 200 feet and these were capped by 50 feet of the Pliocene clays, both beds containing characteristic fossils.

Scott infers an unconformity between the two, there being suggestions of erosion in the surface of the lower and "the fossil contents of the two series of strata" being "very strikingly different."

Calkins, in an unpublished manuscript, states that the age relations of the Tertiary rocks in the Philipsburg quadrangle are very imperfectly known.

If the Eocene is represented at all, it is probably by a very thick accumulation of cemented gravels observed at the east end of the Anaconda Range and by some of the andesitic and rhyolitic tuffs associated with them. These rocks are considerably tilted but show far less deformation and metamorphism than the pre-Tertiary rocks of the region. No fossils have yet been found in them.

See also L 12, Chapter XVII (pp. 831-832).

#### L 12. BULL MOUNTAIN COAL FIELD, MONTANA.

According to Woolsey,<sup>950</sup> the Fort Union formation in the Bull Mountain coal field (latitude 45° 30', longitude 108°) is 1,400+ feet thick and consists chiefly of gray to buff sandstone, alternating with gray shale. The sandstone, though extremely variable, is commonly massive and evenly distributed throughout the section. Coal beds occur at intervals of about 100 feet or less and are most numerous in the upper part. The base of the formation is strongly marked by contrast with a band of olive-green clay shale, which belongs to the next lower formation.

Richards<sup>665</sup> and Lupton<sup>553</sup> have reported later on the central and eastern parts of the field respectively.

#### L 12. RED LODGE COAL FIELD, MONTANA.

Woodruff<sup>946</sup> describes the Fort Union formation in the Red Lodge coal field as 8,500 feet thick and as consisting of sandstone and shale, with carbonaceous shale and coal at several horizons. Workable coal beds are confined to a zone above the middle of the section. The formation is therefore divided into:

|                               | Feet. |
|-------------------------------|-------|
| Upper barren member.....      | 1,975 |
| Middle productive member..... | 825   |
| Lower barren member.....      | 5,700 |
|                               | 8,500 |

The lowest member is composed mostly of yellowish sandstone and shale. Beginning 1,650 feet above the bottom of the formation is a group of beds 1,000 feet thick, composed of varicolored sandy shale with a few beds of soft yellowish sandstone, numerous beds of carbonaceous shale, and in the upper part a few coal beds, one of which contains 18 to 24 inches of coal. Above this group carbonaceous shale and coal beds occur at diminishing intervals as the productive member is approached. \* \* \*

In the middle productive member \* \* \* the sandstone and shale resemble the sandstone and shale of the lower member and do not seem to indicate any essential difference in

conditions of deposition, but the carbonaceous shale and workable coal beds intercalated with the other rocks serve to distinguish the member. As indicated above, the coal beds of the middle member do not begin abruptly but are presaged in the lower member by thin beds of coal. At the upper limit of the middle member, however, there is a sharp transition from the productive measures to the barren beds above. \* \* \*

The upper barren member \* \* \* is composed, like the lower member, of sandstone and shale, with a very little carbonaceous material. Shale predominates in the lower portion and sandstone in the upper portion.

#### L 13. PLAINS EAST OF THE BIGHORN MOUNTAINS, WYOMING.

The Tertiary strata of northern Wyoming were described by Darton<sup>239</sup> under the names De Smet formation and Kingsbury conglomerate and were assigned to the Cretaceous system. Later investigations show that the "De Smet" formation and the Kingsbury conglomerate comprise the Fort Union formation (Eocene). Details of the coal-bearing section of the strata in the Sheridan coal field are given by Taff,<sup>809</sup> and in the Buffalo coal field by Gale and Wegemann.<sup>357</sup> The name "De Smet" has been abandoned by the Survey in favor of Fort Union, and the Kingsbury conglomerate is now treated as a member of the Fort Union, as it also is of Fort Union age.

#### L 13. MILES CITY COAL FIELD, MONTANA.

The Fort Union formation in the Miles City coal field is described by Collier and Smith<sup>167</sup> as follows:

The rocks consist of comparatively fine material, mainly clay shale and sandstone, including lignite and thin beds of impure limestone. They are all fresh-water deposits and contain an extensive fossil flora of about 400 species of plants which resemble those of modern times, and a fauna including fishes, fresh-water mollusks, and reptiles.

The total thickness of Fort Union rocks exposed in the Miles City field is about 900 feet, which may be increased by data obtained from drill holes at Miles City to a total of 1,400 feet. From a comparison of the section at Miles City with that exposed about 70 miles to the northeast near Glendive, it is inferred that the base of the Fort Union formation is not very deeply buried, and it is probable that some of the drill holes at Miles City have penetrated to underlying Cretaceous rocks.

The Fort Union rocks exposed are rapidly separated into two members by a marked difference in lithologic character. The lower member, about 500 feet thick, consists mainly of alternating beds of clay shale and sandstone, having a general dark-gray or somber hue. In detail the individual layers of this part of the formation, especially the sandstones, show numerous irregularities of deposition. Thin layers of ferruginous limestone occur at short intervals throughout the section, and concretion-like masses of the same material, more or less lenticular in form, are included in the shales and sandstones. The thicker sandstone beds are usually characterized by more or less irregular cross-bedding. Coal is found at numerous horizons, but the beds are extremely variable in thickness and horizontal extent.

#### L 13. SENTINEL BUTTE COAL FIELD, NORTH DAKOTA AND MONTANA.

The Fort Union formation in the Sentinel Butte field (latitude 47°, longitude 104°) resembles the beds as developed in the Miles City field. It is described by Leonard and Smith<sup>534</sup> as follows:

The Fort Union formation has a thickness \* \* \* as measured on its outcrop of 900 feet. If to this be added 820 feet of lignite-bearing rocks, which are probably to be referred to

the Fort Union, penetrated by the Medora well below the lowest lignite outcropping in the field, the total thickness is 1,720 feet.

Overlying the heavy sandstone which forms the summit of Sentinel Butte and constitutes the topmost member of the Fort Union formation, there are about 40 feet of calcareous clay and limestone, as shown in the Sentinel Butte section. These beds are merely the remains of a formation which doubtless at one time covered a large area in this region. Strata which have yielded Oligocene vertebrates and which occupy a similar horizon immediately over the massive sandstones at the top of the Fort Union occur in Chalk Butte, 70 miles farther southeast. Other similar buttes in northwestern South Dakota and southeastern Montana have likewise been referred to the Oligocene.

On the basis of mammalian remains, Osborn<sup>623</sup> correlates a portion of the Fort Union with the Torrejon formation of New Mexico. In the San Juan Basin of northwestern New Mexico the Torrejon is conformably underlain by the Puerco, which carries a basal Eocene fauna.

#### L-M 10. OLYMPIC PENINSULA AND PUGET SOUND REGION, WASHINGTON.

Arnold<sup>29b</sup> describes Eocene deposits on the north coast of the Olympic Peninsula as follows:

The oldest formation of definitely known age on the Olympic Peninsula is a 1,200-foot series of black basalt and greenish basalt tuffs and tuffaceous sands found in the vicinity of Port Crescent and here designated the Crescent formation. It comprises the region immediately west of Crescent Bay and a prominent ridge extending eastward from the latter to Freshwater Bay. *Venericardia planicosta* Lamarck, *Turritella wasana* Conrad, and other characteristic fossils found in the tuff indicate the Eocene age of the series and its general contemporaneity with the Tejon of California.

The basalt occurs in two thick sheets, an upper and a lower, each of which may represent several surface flows. Between the two basalt sheets and intimately associated with the top of the lower is a series of roughly bedded fossiliferous tuffs. \* \* \* In the region of Crescent Bay the lower basalt has an exposed thickness of 200 feet, while the tuffs and upper basalt sheet each show approximately the same. The Freshwater Bay section gives basalt and coarse massive basalt tuff 600 feet, thin-bedded green tuff 355 feet, and black vesicular basalt 200 feet. The base of the Crescent formation is not exposed, so that the subjacent rocks are unknown. The overlying sediments consist of coarse conglomerates separated from the basalt by an erosion interval. Faults define the contact between the Crescent formation and the Clallam formation (Oligocene-Miocene) adjacent.

These basalts and tuffs are the only rocks of igneous origin found along the whole length of the northern shore of the peninsula. Taking into consideration the volcanic activity which prevailed during the Eocene in the Cascade Range, only a comparatively short distance away, this single and rather limited occurrence of eruptives seems rather remarkable. The paucity of igneous rocks, however, may possibly be accounted for, at least along the northern coastal border of the Olympics, by the fact that formations younger than the basalt are the only ones exposed, and it is possible that some of these newer rocks are underlain by the Eocene basalt series.

The Puget group comprises many thousand feet of estuarine and marsh deposits, which are extensively coal bearing. Willis<sup>939</sup> says:

The coal-bearing rocks of the Puget Sound basin have been designated the Puget formation. They are prevailing sandstones of variable composition, texture, and color, thinly interbedded, and frequently cross stratified. Their composition varies from that of a typical arkose, consisting of slightly washed granitic minerals, to siliceous clay. Beds of conglomerates or concentrated

quartz sands have not been observed. Carbonaceous materials are generally present as fragments of plants, as vegetal ooze in greater or less proportion to the other constituents, and as distinct coal beds. Carbonate of iron is frequently an integral constituent of the rocks.

In color they are, when fresh, generally bluish gray, shading to brownish black. They weather to buff tints, which are usually dull. The coarser and more massive varieties form beds 20 to 100 feet thick, in which bedding planes are not distinguishable. The finer deposits are thinly laminated and carry abundant leaf impressions, which occasionally interlap with one another so as to form a mass of leaf fragments. \* \* \*

In many of the sandstones silvery-white mica has developed as a secondary mineral, but they exhibit no other indication of metamorphism. The coals, on the contrary, being chemically more sensitive, have undergone metamorphism to a greater or less extent through loss of combined water and concentration of fixed carbon. \* \* \*

The stratigraphic relations of the Puget series are not determinable within the area under discussion, since the strata nowhere come in contact with older sedimentary rocks. Sixty miles northward, on the Skagit River, is a contact between similar coal-bearing strata and older metamorphic schists, described in an earlier report as possibly a surface of deposition or of faulting. Examination of this locality in 1895 led to the discovery of small pebbles of the schist forming a basal conglomerate in the sandstone beds next the contact, which was therefore a surface of deposition during a transgression by the sea. Fossils found in limestone under the schists are stems of crinoids of Carboniferous or Triassic age, whereas the coal-bearing sandstones of this locality are assigned by Knowlton to the Eocene on the evidence of numerous leaf impressions.

The age of the Puget formation has been in doubt because of the obscurity of stratigraphic relations, the general absence of marine fauna, and the indeterminate character of the flora. \* \* \*

A preliminary examination of the fossil plants enabled Knowlton to report that the lower beds of the series are Eocene, whereas the upper beds may be of Miocene age. The floras from horizons several thousand feet apart in stratigraphic range are so distinct as to afford means of correlating separate strata of the Puget formation. \* \* \*

The measured sections of the Puget group exhibit total thicknesses of 5,800 feet on Green River, 5,500 feet on South Prairie Creek, and 5,480 feet in Carbon River Canyon. None of these measures is complete. In each instance the lowest stratum is of the Puget group outcropping on an anticline, and the highest is the limit of exposure where the rocks pass under later formations. These sections overlap, and there are also higher beds exposed on South Prairie Creek above the limit of the measured sections. These considerations justify the inference that the thickness of the Puget group may probably be 9,000 feet or more.

C. A. White,<sup>890</sup> who gave the name Puget to the strata described by Willis, quotes Newberry on the resemblance of the flora to that of the "Laramie" and comments on the molluscan faunas of the two as follows:

The fauna to which one instinctively turns for the purpose of zoological comparison with this Puget estuary fauna is that of the Laramie group. Such a comparison is especially suggested by the known floral relations of the two groups of strata, their presumable contemporaneity of origin, and the nonmarine character of the molluscan faunas of both. Upon making a comparison, however, important zoological differences appear. It is true, there are two species of *Corbicula* in the Puget fauna that are so closely like Laramie forms as to suggest specific identity upon casual examination, but the differences between the two faunas are strikingly shown by the family and generic characters of the other members of the Puget fauna as compared with the Laramie fauna.

For example, a species of *Teredo* has been found in the Puget group, but no member of the *Teredinidæ* has yet been found in the Laramie. Two species of the Puget fauna are referred to the *Tellinidæ*, but no member of that family has yet been found in the Laramie. But the generic form which gives an especially unique character to the Puget fauna is that of *Batissa*.

This genus has not hitherto been known to occur in North America in either a fossil or living condition, nor has it been found nearer to this continent than certain of the Pacific islands. Still the hinge characters observable on these Puget estuary specimens leave no room for reasonable doubt that they are strictly congeneric with true *Batissa*. Indeed, a species of that genus which is now living upon the Fiji Islands is closely related to this fossil form.

Knowlton (in manuscript) has described 365 species of plants from the Puget group. The lower strata are Eocene and the upper are possibly Miocene. The general character and distribution of the flora are stated by Knowlton<sup>507</sup> as follows:

The flora of the Puget formation is an exceedingly rich one. Over 100 species have already been named and described, and from the material in hand it seems safe to assume that the number will reach 250 [365]. Inasmuch as a very large proportion, perhaps more than nine-tenths, of the plants are new to science, it becomes extremely difficult to settle their affinities and determine satisfactorily their bearing on the question of age. It is only by a study of their general facies that results along either line can be obtained.

While the Puget flora as a whole may be considered relatively uniform, there are well-marked differences between the plants found in the lower beds, as represented at Carbonado, Wilkeson, and South Prairie Creek, and those found in the upper beds at the highest point in the Carbon River canyon, the Clay mine on Green River, Snoqualmie Pass, and at Steels Crossing near Black River Junction. Certain few genera are found throughout the series, but thus far no species has been noted as common throughout. On the other hand, both lower and higher beds are characterized by a considerable number of genera. Thus *Quercus*, *Juglans*, *Rhamnus*, *Populus*, and *Laurus* are found from base to summit. The following genera have thus far been found in the lower beds but not at all in the upper: *Cladophlébis*, *Lastrea*, *Dryopteris*, *Anemia*, *Calamopsis*, *Sabal*, *Siphonites*, *Ficus*, *Eucalyptus*, and *Aralia*; and the following have been detected in the upper but not in the lower: *Rhus*, *Castanea*, *Betula*, and *Platanus*.

The lower beds, on account of the abundance of ferns, gigantic palms, figs, and a number of genera now found in the West Indies and tropical South America, may be supposed to have enjoyed a much warmer, possibly a subtropical temperature, while the presence of sumacs, chestnuts, birches, and sycamores in the upper beds would seem to indicate an approach to the conditions prevailing at the present day.

A number of species of plants have been found to be common to the west and east sides of the Cascades. This number is not large, but they are important and easily recognized forms, and there is indication that the number will be increased when the material in hand has been more thoroughly studied. This would indicate that approximately similar conditions of climate and topography prevailed throughout this general area during the Puget epoch. The Cascade Range as it now exists did not then intervene.

The Puget group is well described by George Otis Smith,<sup>754</sup> who brings together the data quoted above, with additional details.

#### M 10. SOUTHERN BRITISH COLUMBIA.

At the junction of Similkameen and Tulameen rivers, British Columbia, is a basin containing strata assigned by Camsell<sup>129a</sup> to the Oligocene:

These sedimentary rocks alone in the northern part of the district cover an area of nearly 50 square miles, the basin being 14 miles long with a variable width of from 3 to 5½ miles. They consist of thick beds of sandstone, with clay, shales, and several seams of lignite. The base of the series appears to be a very coarse grained sandstone containing many large rounded white feldspars in a matrix of calcareous material. This rests on the eastern side of the basin, on the Copper Mountain series of rocks [monzonite], while on nearly all other boundaries the sediments dip under the more recent volcanic rocks, which lie as sheets on them. In parts

also these volcanics have thrust themselves through the sediments and now appear as islands in the older rocks. The strata do not now lie horizontally but have been tilted at low angles, making an irregular series of folds. Some faults also occur.

Many drill holes have been bored in this Tertiary basin in search of lignite seams, and with some good results. Most of them, however, were put down at or near the edge of the river, and only one near the western edge of the basin. \* \* \* These have disclosed the thickest lignite seams to be in the vicinity of the town of Princeton, where a bed over 18 feet in thickness was struck at a depth of 49 feet below the surface. The hole in which this seam was found was sunk near the bridge over the Similkameen River to a depth of 280 feet. In this hole lignite seams aggregating 35 feet 7 inches were crossed in the first 90 feet, while the rest was in shales and sandstones.

Several drill records are given, the strata having been penetrated in one hole to a depth of 1,000 feet. In regard to the character of the lignite, Camsell states:

Though these beds are of the same age as the Coldwater group of the Nicola country, in which coal also occurs, there is a difference in the quality of the fuel contained in each. The Nicola coal is a true bituminous, whereas this is a lignite. The former, also, is considerably higher in fixed carbon and lower in water, while the fuel rate is 1.447, as against 1.108 of the Princeton coal.

Some of the beds of the Princeton coal basin are only in a primary stage of formation, and they still show the brown, woody fiber of the slightly altered vegetable remains. Much retinite also occurs in them. Some also have been completely destroyed by combustion, and it is to the combustion of an underlying bed of lignite that Dr. Dawson attributed the metamorphism and color of the rocks at the Vermilion Bluffs.

#### M-N 11-12. GREAT PLAINS, ALBERTA.

The Eocene of the Great Plains in Alberta is the Paskapoo series of the Canadian Survey, the so-called "Upper Laramie," which is areally continuous with the Fort Union and is approximately its equivalent. Beneath the Paskapoo lies the Edmonton, which is classed as Cretaceous by Stanton on the evidence of brackish-water faunas and dinosaurian remains, whereas by Knowlton it is placed in the Tertiary on account of the flora which it contains. The Canadian Survey regards the Edmonton as Cretaceous. Both these formations are mapped as earliest Tertiary or latest Cretaceous (5a).

Tyrrell's original descriptions<sup>816a</sup> of the Edmonton and Paskapoo are in part as follows:

The Edmonton series is perhaps, on the whole, the most characteristic series of the entire region, for though its thickness, wherever determinable, was never found to exceed 700 feet, the horizontal position of the strata causes it to underlie a very large extent of country.

It consists generally of whitish or light-gray clay and soft clayey sandstone, weathering very rapidly with more or less rounded outlines. In some places, as on Red Deer River and in the Hand Hills, it is seamed with a great number of beds of ironstone, which, with thin beds of lignite and lignitic shale, give a definite banded character to all the escarpments. It also contains a great number of nodules of compact ironstone, which are often perched on little pinnacles cut out of the soft sandstone. In the northern portion, especially along the North Saskatchewan, the banded appearance is seldom seen, though, with the exception of a smaller quantity of ironstone, the rock has very much the same character as farther south.

This is essentially the coal-bearing horizon within the district, all the coal found east of the foothills, except probably the seams on the upper North Saskatchewan and at Egg Creek,

being of this age. The top of the formation is marked by an extensive coal deposit, seen first in the Wintering Hills as a thin bed of carbonaceous shale, but on being traced northward is found to thicken very greatly, till on the North Saskatchewan, near Goose Encampment, it has a thickness of 25 feet. The bottom of the series lies conformably on the Pierre shales, without any sharp line of demarcation between the two. In fact, the shales gradually lose their massive character and change almost insensibly into thin beds, which are of decidedly brackish-water origin. In the Pierre remains of land plants and animals are very rare, while here traces of land plants become fairly plentiful, and on Red Deer River dinosaurian bones are met with in great abundance, showing, with the presence of estuarine shells, the partly land-locked character of the area within which the beds were deposited.

\* \* \* \* \*

Under the Paskapoo series we group all the Laramie rocks lying above those of the Edmonton series; thus it will include Dr. Dawson's Porcupine Hills and Willow Creek series and all but the lowest 700 to 900 feet of his St. Mary River series. On the plains no place was seen where its total thickness could be measured, but at the outer edge of the foothills, on Little Red Deer River, a thickness of 5,700 feet at least was determined, the bottom of the formation not being seen, and it is probable that a considerable thickness had been denuded from the top.

The beds consist of more or less hard light-gray or yellowish, brownish-weathering sandstone, usually thick bedded but often showing false bedding; also of light bluish-gray and olive sandy shales, often interstratified with bands of hard lamellar ferruginous sandstone, and sometimes with bands of concretionary blue limestone, which burns into an excellent lime. The sandstones consist of very irregular though slightly rounded grains of quartz, feldspar, and mica, cemented together in a calcareo-argillaceous matrix.

The whole series, as shown by its invertebrate fauna, is of fresh-water origin.

#### N 4. CHICHAGOF COVE, ALASKA PENINSULA.

Palache<sup>628</sup> distinguished marine sediments containing abundant fossil remains which show them to be of lower Eocene age. He described the terrane as the Stepovak series and divided it into lower and upper beds. The lower beds comprise coarse breccias or agglomerates and fine tuffs composed wholly of igneous material. The coarse agglomerates contain angular fragments, a foot or less in diameter, of white or greenish porphyry, and rarely granite. They are cemented by comminuted material which consists essentially of interwoven hornblende needles. Although macroscopically the rocks are varied in appearance, microscopically they are very similar. They are pyroclastic, but some exhibit a little evidence of water sorting and others may be called flow breccias. They contain pecten-like fossil shells which are too imperfect for determination. The upper beds consist of soft shales, sandstones, and grits, with some thin beds of limestone and here and there a chert band.

After describing local sections and the folded structure of the Stepovak series, Palache continues:

Concerning the fossils collected from this formation Dr. Dall says: "The fossils from the Stepovak beds are Eocene, probably of about Claiborne age (middle Eocene), and are the only typical Eocene yet discovered in Alaska."

(See quotations in regard to the age of the Kenai under O-P 5, Kenai Peninsula, pp. 785-787, and O 4-5, Alaska Peninsula, pp. 783-784.)

## N 4, O 4-5. ALASKA PENINSULA.

The general geology of the Alaska Peninsula was thus stated by Stanton and Martin:<sup>786</sup>

The Alaska Peninsula contains a coarse crystalline core of granite or of similar rocks, flanked on the eastern side by Mesozoic sediments and on the western side by late Tertiary or post-Tertiary beds. The Mesozoic beds are overlain in places by early Tertiary formations. Both the Mesozoic and the Tertiary beds are cut by andesite and basalt. The intrusion and volcanic outflow has continued from late Jurassic time until the present, the region containing several active volcanoes.

The structure of the region is varied. The west shore of Cook Inlet has its general position outlined by a number of great overthrusts, by which the Triassic rocks have been brought in contact with the Upper Jurassic. The Alaska Peninsula is a region of open folding, with the folds crosscut by an irregular series of faults.

At Herendeen Bay Atwood,<sup>42a</sup> in 1908, distinguished the following section:

*Geologic sequence in western part of Alaska Peninsula.*

| Age.                 | Geographic distribution.                                                        | Lithologic character.                                                                                 | Thickness (feet). | Remarks.                                                                                                             |
|----------------------|---------------------------------------------------------------------------------|-------------------------------------------------------------------------------------------------------|-------------------|----------------------------------------------------------------------------------------------------------------------|

Atwood's comment follows:

Eocene, Miocene, and post-Miocene formations are exposed in this portion of the peninsula. The Eocene strata include at least 5,000 feet of sandstone, shales, conglomerates, and seams of lignite and form the central portion of the Aleutian Range in the Balboa-Herendeen Bay district. They extend westward at least as far as Pavlof Bay and eastward to the Chignik Bay region. Several collections of fossil shells and plants have been procured from these beds. The shells are those of marine invertebrates and have been determined by W. H. Dall to be of upper Eocene age. Mr. Dall reports that some of the material from these strata may be upper Eocene or Oligocene. The plants, as determined by F. H. Knowlton, are all of Kenai age. They were procured from beds that are interstratified with those from which the shells were

obtained. Kenai plants from Alaska have been determined by Mr. Knowlton to be of upper Eocene age and the harmony between the age determinations of the plants and animals is exceedingly satisfactory. The nature of the Eocene deposits indicates that the area of sedimentation was several times just below sea level, probably near to shore, and at other times above sea level, receiving wash from higher lands, or overgrown by dense growths of vegetation.

#### O 5. KODIAK ISLAND AND KATMAI BAY.

Dall<sup>210</sup> refers as follows to Katmai Bay and Kodiak Island:

Katmai Bay, some miles westward from Amalik Harbor, is the site of a village and trading station. The portage across the mountains of the peninsula ends here. On this portage both coal and petroleum have been found, the exact locality not being stated. The latter is a dark lubricating oil, which is said to float on the surface of certain ponds or lakes. No information could be obtained about the coal, but it almost certainly belongs to the age of the Kenai beds.

\* \* \* \* \*

Tertiary beds occur in various places on the islands of the Kodiak group, both of Kenai age and of the later Unga beds containing Miocene marine fossils.

On the island of Kodiak marine Miocene strata are found, and among the specimens brought back by Wossnessenski were clay ironstones containing plant remains referable to the Kenai group. These stones were used by the native women for reddening the inner surface of dressed skins, and the only indication of locality for them is that they came from the northern part of the island. About the middle of the island, surrounding Ugak Bay, at the old settlement of Orlovsk and on the northern shore of Miliuda Bay next southward, and on the opposite side of the island, part of the shores of Uganuk Bay and of Uganuk Island in the bay, sandstones with lignite in thin seams, overlain in places by marine sandstones like those of Unga, are reported on the authority of Kharitonoff and other Russians familiar with the island.

#### O 8. SOUTHEASTERN ALASKA.

During the season of 1907 Atwood visited the two localities in southeastern Alaska where Eocene strata had been reported,<sup>953a</sup> and he has furnished the following information. On the shores of Hamilton Bay, Kupreanof Island, there is a small area of sandstones, shales, conglomerates, and lignite, which lithologically resemble the Kenai formation of other portions of Alaska. The localization of these strata to a somewhat restricted basin is also suggestive of the Kenai. They rest unconformably upon much-deformed beds of Triassic age and older and are overlain unconformably by glacial drift and recent alluvium. The flora obtained from a stratum not more than 15 feet in thickness contains, according to F. H. Knowlton, Upper Cretaceous cycads, possibly redeposited from older strata, and many typical Kenai plants.

At Killisnoo Inlet, an irregular reentrant on the west shore of Admiralty Island, sandstones, shales, conglomerates, and lignites outcrop on the shores. These strata have the same character as those near Hamilton Bay and are of similar small extent. They rest unconformably upon strata that are considered to be of Paleozoic age, and on their truncated edges there is some glacial drift. No record of animal life was found in this locality, but the plant remains contain Upper Cretaceous and Kenai (Eocene) forms.

At these two localities in southeastern Alaska the stratigraphic and floral studies seem to indicate a period of continuous deposition from late Cretaceous time into Eocene time. Such conditions prevailed in other portions of Alaska.

## O 10. FINLAY AND OMENICA RIVERS, BRITISH COLUMBIA.

McConnell,<sup>562c</sup> in his report on Finlay and Omenica rivers, British Columbia, says:

Beds consisting of conglomerates, interbedded in places with shales and sandstones, occupy the bottom of the valley of the Finlay from the Ingenica River north to the Tochieca and continue northward along the valley of the latter stream. Similar beds appear again on the Finlay a few miles farther west in a parallel longitudinal valley, which it enters and follows for some distance. They are also found on the Omenica from the Black Canyon up to its junction with the Tchutetzeca.

The pebbles of the conglomerate are usually small but in places are several inches in diameter. They consist mainly of slate, quartz, and limestone. Oxide of iron is occasionally present in the matrix in sufficient quantities to give a reddish coloration to exposures. The shales are dark in color, are evenly bedded, and are interstratified in places with small lignite seams. The sandstones are usually somewhat argillaceous and occasionally consist largely of mica derived from the disintegration of the underlying schists.

The Tertiary conglomerates and associated rocks \* \* \* are distributed in narrow strips along the deep valleys of the district and were nowhere found on the highlands. They were probably deposited in lakes during a Tertiary depression and evidence the pre-Tertiary age of the present main river channels. The conglomerates are occasionally horizontal or nearly so, but in most cases they are tilted at angles ranging from 10° to 40°, showing that they have been affected to some extent by the later mountain-making movements.

Some leaves and other plant remains, obtained from the shales interbedded with the conglomerates, were examined by Sir J. William Dawson, who lists eight species and concludes:

"All the above fossils, so far as determinable, appear to indicate the Upper Laramie period. Of the collections in my possession, the plants seem most nearly to resemble those of the Lignite series on the Mackenzie River, which are referable to the Upper Laramie. There is nothing among the plants to indicate any other horizon."

Knowlton regards these deposits as of Fort Union age.

## O-P 5. KENAI PENINSULA.

Kenai Peninsula lies between Cook Inlet and the ocean and is the type locality of the Kenai formation. The strata have been recently studied by Moffit and Stone,<sup>602</sup> who state:

The upper member of the list of bedded sedimentary rocks [of Kenai Peninsula] is a succession of sandstones and shales, with interbedded coal seams, which overlies the lower Jurassic unconformably and forms the whole northern coast line of Kachemak Bay and the eastern coast line of Cook Inlet as far north as Cape Kasilof. Isolated masses of these rocks also occur at various points on the south shore of the bay. These beds, while slightly folded and sometimes faulted, are not always thoroughly consolidated. They were described by Dall and furnish the type exposures of the Kenai beds. \* \* \* This formation, consisting of partly consolidated sandstones and shales, is of economic importance because of the lignitic coal seams interstratified with its various members. As previously pointed out, it rests unconformably on the Seldovia lower Jurassic rocks.

Fossils from the Kenai beds of Port Graham and Ninilchik were described by Heer as early as 1869. The former locality was afterward visited by Dall,<sup>a</sup> who collected fossils there, as well as from other localities on the north side of Kachemak Bay. The Kenai beds probably underlie the whole of the Kenai Plateau, but their northward dip carries them below sea level

<sup>a</sup> Dall, W. H., Report on coal and lignite of Alaska: Seventeenth Ann. Rept. U. S. Geol. Survey, pt. 1, 1896, pp. 787, 842.

a few miles south of Kasilof River, and they do not appear again. These coal measures were thought by Heer to be of Miocene age, but Dr. Dall referred them to the Oligocene and gave a list of plant and animal remains collected at Port Graham, among which are both Coniferæ and broad-leaved trees, the total number of species amounting to 44. He says: "The deposit appears to have formed at the bottom of a lake."

Dr. F. H. Knowlton in the same report <sup>a</sup> gives a list of plant remains from the Kenai formation collected by Dr. Dall in 1895, as well as those previously known from the same region, and states that they are believed to be of Eocene or Oligocene age.

Later, in speaking of the typical Eocene strata of Chichagof Cove, Dr. Dall <sup>b</sup> says:

"The only representative of the Eocene epoch known in Alaska previous to the Harriman Expedition was the Kenai series (formation), which had been referred by Heer to the Miocene and by others to the Eocene but which has of recent years been recognized as Oligocene by the present writer and others."

In the same publication <sup>c</sup> Dr. Knowlton, after describing a collection of fossil plants from Kukak Bay, makes this statement concerning their age:

"It is hardly necessary at this time to go into a history of the plant-bearing horizons of Alaska. \* \* \* It is sufficient to state that the named species above enumerated are typical of the so-called Arctic Miocene, which is now regarded as of the age of the upper Eocene. The species described in this paper as new are in various ways allied to forms characterizing this horizon, and I do not hesitate to refer this collection to the upper Eocene."

The determination of marine Oligocene invertebrates and upper Eocene floras from nearly related strata may seem to suggest that there was a sequence of deposits which included the two terranes, but Atwood's results of 1908 appear to indicate that the Kenai plants are associated with marine Eocene fauna. (See pp. 783-784.) Moffit and Stone continue:

The Kenai formation as exposed in Kachemak Bay is composed of soft light-gray sandstones and clay shales, with numerous interspersed coal seams. Four partial sections of the formation aggregate 1,763 feet of strata. \* \* \* [They contain] seams ranging in thickness from a few inches to 7 feet. \* \* \* The sandstones are medium grained, soft, light gray, sometimes iron stained, and occur in beds from a few inches to 30 feet thick. Cross-bedding was noted at one horizon. Some portions of the heavier beds of sandstone are hard and weather out in nodular blocks. In these blocks the best-preserved fossil plants are sometimes found. In one locality lenses of grit occur in a sandstone mass. The pebbles in the grit are smaller than one-half inch in diameter and are mostly quartz. Dall <sup>d</sup> reports conglomerates in the Kenai series on Kachemak Bay, but the author found none in the portion he visited. Sandstone at places grades into sandy shale.

The shales of the Kenai formation on Kachemak Bay are all light-colored clay or mud rocks, grading on one side into arenaceous shale and on the other into clay. The shales are soft and crumbly on the outcrop and when wet become plastic. Beds of clay that have been baked by the burning of coal seams are red and hard. Small blocks of gray hard limestone were found at one locality and suggest that calcareous sediments in small amount may be contained in the formation. Limestone was not seen in place.

The abundant coal seams in the Kenai rocks of this field are all lignite. They vary in thickness from mere streaks to beds several feet thick. Eldridge <sup>e</sup> counted 36 seams along the

<sup>e</sup> Eldridge, G. H., A reconnaissance in the Susitna basin, Alaska: Twentieth Ann. Rept. U. S. Geol. Survey, pt. 7, 1900, p. 21.

beach at Tyonek, varying in thickness from a foot to 15 feet, and Kirsopp<sup>a</sup> figures 73 seams on the north shore of Kachemak Bay. Much of the Kachemak Bay lignite, especially that in the lower beds, is hard and glossy, clean to handle, and tends to break cubically. The higher beds, however, are dull and lighter and show more woody fiber.

The thickness of the formation exposed in Kachemak Bay has not been determined, and it is almost impossible of determination because there are stretches over which the beds can not be traced. Anchor Point is near the base of the formation, but it is not known how far the coal-bearing rocks extend beyond the head of the bay, except that coal has been found 15 miles up Sheep Creek. Kirsopp<sup>b</sup> published a section from Anchor Point to the head of the bay, including 2,683 feet of coal-bearing measures. This section contains at least 126 feet of lignite in seams over 2 feet thick. Estimated roughly, there probably are about 1,500 feet of strata between Bluff Point and the base of Coal Point. From Coal Point to McNeil Creek the dip is strong and 3,000 feet may be a low estimate. From McNeil Creek to the top of the bluff at Falls Creek at least 1,000 feet are exposed. Hundreds of feet of strata probably overlie the section measured at Falls Creek and outcrop in the bluff north of the head of the bay. The writer is inclined to think that 10,000 feet may not be a high estimate for the thickness of the Kenai formation in the Kachemak Bay field.

### P 3. NUNIVAK ISLAND AND YUKON DELTA.

Dall<sup>210a</sup> reported an occurrence of sandstones, probably Kenai, at Etolin Harbor, Nunivak Island, but G. M. Dawson<sup>260</sup> describes the rocks as "cellular olivine diabase" and the island as composed of nearly horizontal basaltic flows.

Cape Vancouver is a prominent point rising from the flats of the Yukon Delta and composed of sandstone and sandy shales, capped by basalt flows in the higher hills. Dawson says:

The north shore of the cape, which alone was examined, forms scarped bluffs or cliffs, rising from the edge of the sea, and presenting fine exposures of sandstones and sandy shales, well bedded and dipping southward, at low and undulating angles. At the extremity of the cape these beds appeared to be horizontal, and on the south side, though imperfectly seen from a distance, they seem to lie at higher and more irregular inclinations.

The sandstones, where examined, are gray, bluish and brownish in color, rather soft, and sometimes nodular. They contain a few very thin and dirty seams of coal or lignite, of which the thickest seen was only a few inches. There are also in the sandstones numerous carbonaceous fragments and occasional fossil leaves, of which a couple were collected.

Sir William Dawson found these plants to represent *Juglans acuminata* and assigned them to the Miocene. The horizon is now placed in the upper Eocene by Knowlton.

### P 5. COOK INLET NEAR TYONEK.

The exposures of the Eocene on the west shore of Cook Inlet, about 3 miles south of the village of Tyonek, and the beltlike continuation of the strata to the northwest at least as far north as Beluga River have been called Kenai and consist of sandstones, shales, conglomerates, and some lignite. None of the material, so far as known, is of marine origin. The deposits are such as to suggest estuarine origin or sediments laid down on the land adjoining bodies of water. In the section exposed along the shore of Cook Inlet, more than 2,000 feet of sediments are shown. The beds are but slightly deformed. The base of the formation is not exposed, the eroded surface of the upturned beds being mantled by glacial drift.

<sup>a</sup> Kirsopp, J., jr., Coal fields of Cook Inlet, Alaska: Trans. Inst. Min. Eng., London, 1901.

<sup>b</sup> Idem, p. 3.

Plant remains which have been obtained from this locality have all been determined by Knowlton to belong to the Kenai, or to be of upper Eocene age. The exposures along the beach near Tyonek were described by Spurr <sup>771</sup> in 1900. The Yentna and Hayes River beds of Spurr, which occur north of Tyonek on the lower Susitna and in Skwentna Valley, are now also regarded as of Kenai (Eocene) age.

#### P 6. MATANUSKA VALLEY.

Matanuska River enters Cook Inlet at its northeastern embayment. It comprises a large area of coal-bearing strata classed as Kenai (Eocene) and described by Paige and Knopf <sup>627</sup> as follows:

The Kenai of the Matanuska basin comprises a series of sandstones, shales, arkoses, numerous coal seams, and a large volume of conglomerate. The rocks are well indurated and, as first noted by Mendenhall, resemble the Paleozoic coal measures of the Appalachian region. The sandstones are gray, hard, and tough and are characterized by the presence of silvery shreds of white mica. At some localities, as in the leaf-bearing strata in the Kings Creek coal measures, the sandstones contain shale fragments. The shales show no unusual features; they are dark bluish, fissile, and interstratified with the sandstones in very regular beds. The arkoses were noted only on the ridge north of Tsadaka Creek, abutting against the quartz diorite mass. They are composed of feldspar, quartz, and chlorite and locally contain granite pebbles. Certain strata are fine examples of regenerated granites.

Conglomerate is found at Castle Mountain, between Kings and Chickaloon creeks, and at Conglomerate Mountain, between Tsadaka and Eska creeks. At both places the deposit is at least 1,000 feet thick. Thin sandstone beds, not exceeding a few feet in thickness, are intercalated with the conglomerate and pinch out along the dip. The pebbles of the conglomerate are well worn and possess a well-defined shingling. Their diameter averages 4 inches and ranges up to 8 inches. Greenstone porphyries form the principal material of the conglomerate, with some quartz porphyry and very rarely some granite and vein quartz. The matrix of the pebbles is a grit.

\* \* \* \* \*

Heavy beds of conglomerate dipping to the north can be seen on the east side of Chickaloon Creek. They are part of a great series of sandstones, shales, and conglomerates, probably not less than 3,000 feet thick, which are overlain by basaltic porphyries at an elevation of about 4,700 feet.

The coal of the Kenai of the Matanuska basin is bituminous except where modified by igneous rocks. The seams vary in thickness up to a maximum of 17 feet.

The age of these strata has been determined by Knowlton as Kenai (upper Eocene). Fresh-water gastropods have also been found in them.

#### P 6-7. CONTROLLER BAY TO CAPE YAKATAGA.

On the southern coast of Alaska, in latitude 60°, Tertiary sediments which resemble the Kenai in character but may be younger have been examined on Controller Bay and are known to extend east to Cape Yakataga. They have been classified in several formations and described in detail by Martin, <sup>573a</sup> who says:

The Tertiary sediments \* \* \* consist of monotonous repetitions of shales and sandstones, with an included mass of coal-bearing arkose and one or more massive conglomerates. The total thickness, as shown in the following table, is many thousand feet. The structure of the region in which these rocks outcrop is complex, exposures at critical points are often wanting,

and neither the lithologic character of the beds nor the fossils which they contain are sufficiently distinctive to make it possible to recognize with certainty the complete stratigraphic succession.

The presence of two easily recognized horizons, the arkose and the conglomerate, give distinctive character to two parts of the stratigraphic column. The arkose, with its associated coal, is restricted in areal distribution to the region north of Bering Lake, and the conglomerate to the region south of the lake. Between these regions are areas of no outcrops, and none of the beds of either region can be recognized with certainty in the other.

*Section north of Bering Lake.*

| h. Sandstone.....                                                                         | 1,000 |
| i. Soft shale.....                                                                        | 500+  |

The succession in each of these sections may be assumed as reasonably correct, although there is a possibility that the thicknesses are too great because of there having been repetition of the less characteristic beds by faulting. The correlation of the beds of one section with those of the other rests at present upon evidence which is incomplete and unsatisfactory and must be regarded as suggestive rather than conclusive. It is probable that one of two correlations is true: The shale and sandstone of the Stillwater formation, (*d*) may overlie the conglomerates (*e*) of the Katalla formation with a concealed interval of unknown extent between them, or *a* and *b* may be identical with *h* and *i*. In the former case the conglomerates underlie the coal field; in the latter case the coal underlies all, or nearly all, of the entire region under discussion. The stratigraphic and structural field evidence proves nothing either way but suggests, as the most probable relation, that the entire section north of Bering Lake overlies the section south of the lake.

The Tertiary rocks contain fossils at many localities, but they are usually poorly preserved or not characteristic. They consist chiefly of leaves and of marine Mollusca, but include also a few echinoids, Crustacea, fish, and fresh or brackish water Mollusca.

\*            \*            \*            \*            \*            \*            \*            \*

The paleontologic evidence may be summarized as follows:<sup>a</sup>

1. The marine Mollusca from the sandstone of the Tokun formation are either so poorly preserved as not to admit of specific identification or belong to undescribed species.<sup>b</sup> They are almost certainly Miocene, but can not be definitely correlated with any known Miocene faunas of other regions.

2. The plants from the coal-bearing rocks include poorly preserved individuals which suggest species of the Kenai formation of Cook Inlet, generally considered to belong in the upper Eocene or Oligocene. The best-preserved specimens, however, represent species which are not known in the Kenai and which are suggestive of later Tertiary age. There is no positive evidence that the exact equivalent of the Kenai occurs in this region.

<sup>a</sup> Data furnished by W. H. Dall and Ralph Arnold on the Mollusca, by F. H. Knowlton on the plants, and by W. B. Clark on the echinoids.

<sup>b</sup> This statement applies to all the faunas of this region.

## P 6-7. MOUNT WRANGELL DISTRICT.

Moffit and Knopf<sup>600a</sup> thus refer to the local occurrence in the Mount Wrangell district of deposits which are provisionally assigned to the Tertiary.

A formation consisting of soft, thin-bedded shales and sandstones, associated with large amounts of well-rounded conglomerate composed mainly of diorite cobbles, occurs in the region of Coal Creek, north of White River, near the international boundary. The area in which these rocks are exposed is small, but there is some probability that they underlie the volcanic cappings of the mesas which form prominent features of this part of the White River region.

The strata lie nearly horizontal and rest upon older rocks which stand on edge. In places they are ligniferous, and petrified wood of exogenous character is common as float in gulches cutting the formation.

The resemblance of these rocks to those of similar patches scattered throughout the Yukon basin<sup>a</sup> leaves little doubt as to their Tertiary and probably Kenai age. Rocks of identical character occur near the head of Chitistone River and, like those of the White River region, are covered by a heavy series of volcanic flows.

## P-Q 5-6. FOOTHILLS OF THE ALASKA RANGE.

The Bonnifield and Kantishna placer districts lie on the northern slopes of the Alaska Range. In course of prospecting for gold, lignites have been located and the field is thus described by Prindle:<sup>639</sup>

Deposits containing lignite coal have a wide distribution in the northern foothills of the Alaska Range, but the only section to be considered here is that extending east from Cantwell River to Wood River, a distance of about 50 miles, and northward to the flats. The low spaces within this area between the east-west ridges of old metamorphic rocks are occupied by these deposits. They are for the most part but slightly consolidated and have been so deeply incised by the drainage systems that in places nearly complete sections are exposed. That the present areas are only a part of masses formerly much larger in extent is shown by small isolated patches of these deposits that lie slantingly on the upper slopes of ridges and by well-worn pebbles derived from them that lie scattered on the tops of the highest ridges, 1,500 to 2,000 feet above the occurrences of the valleys. These deposits have been folded, the flexures being for the most part broadly open, with dips of 30° to 35°, but locally closer, with resultant vertical dips attended in places by consolidation of the gravel beds to conglomerate; in addition, here and there parts of the deposits have been faulted.

The material comprises alternating beds of sands, clays, coal, and gravels that are divisible into three parts—an underlying white deposit composed of angular and some well-worn, sub-angular, fine quartz gravels, with a large admixture of kaolinic material where the bedrock is feldspathic; an intermediate member of yellowish cross-bedded sands and fine well-worn gravels, dark plastic clays, and coal beds; and an upper member composed almost entirely of gravels. The feldspathic schists produce by weathering a large amount of white clay, and the quartz veins which in places in these rocks are very numerous furnish abundant quartz material, and these characteristics of the old bedrock have gone over into the basal members of the sediments. The transition from the decomposed products of the schists that still retain their structural position to the same materials in the overlying deposits is in some places strikingly exhibited. The thickness of these underlying deposits was not determined, but one section was observed in which 100 feet of them was exposed. The sands and clays of the intermediate member are naturally less conspicuous than the underlying beds but have in many places become indurated by the burning of the coal beds and baked to a conspicuous red color. The

---

<sup>a</sup> Collier, A. J., Coal resources of the Yukon, Alaska: Bull. U. S. Geol. Survey No. 218, 1903, p. 19.

overlying gravels at the localities where their relations to the underlying deposits were observed, whether in horizontal or tilted strata, were found to be structurally conformable. They are characterized by a yellow color. They include both fine and coarse material, are well worn and well rounded, and the predominant constituents are white quartz and chert of various colors, principally black. There is a considerable proportion of metamorphic rocks and many pebbles of compact chert conglomerate. In the upper part of the gravels, in strong contrast with their medium to fine grained material, are locally many boulders of granitic rocks and diabase and a few well-rounded boulders of dense chert and quartzite conglomerates. The greatest observed thickness of these deposits was approximately 3,500 feet. The upper gravels constitute about half of the entire deposit.

Fossil leaves are observable nearly everywhere in the beds associated with the coal, but except where these beds have been baked by the burning of the coal the fossils are poorly preserved. The age of the coal-bearing member has been determined as Kenai. The age of the gravels has not been determined, nor is it definitely known that they are chronologically conformable with the underlying deposits, but they have been folded at every point where folding was observed, along with the underlying deposits. Where valleys have been extensively developed in these deposits bench gravels have in many places been laid down on the truncated edges of the older deposits, and where these older beds are horizontal the bench gravels are in apparent conformity with them, obscuring the relationship. It is probable that deposits of various ages since the Kenai, formed under varied conditions of sedimentation, occur in this area and that the coarse material in the uppermost part of the gravels owes its origin to glaciation.

Parts of the gravel members of these deposits are auriferous and have supplied the gold for the Bonfield region. There is a marked resemblance between these coal-bearing deposits, with their thick beds of overlying gravels, and the Kenai beds of the Seventymile Creek area near Eagle, with their coal-bearing deposits and thick beds of conglomerate formed largely of the same kinds of material.

#### Q 3. SEWARD PENINSULA.

Moffit,<sup>598</sup> in his report on the Fairhaven gold placers, states that "In the north-eastern part of Seward Peninsula lignitic coal has been mined in a small basin on Kugruk River. The associated strata are sandy and shaly and include thin limestones. Though folded and jointed, they are less metamorphosed than the neighboring schists. No fossils have been found and the age is indeterminate," but the rocks are presumably late Cretaceous or early Tertiary. The area is too small to be shown on the map of North America.

#### Q 3-4. NORTON SOUND.

Mendenhall<sup>587</sup> mentions the occurrence of coal-bearing strata supposed to be of Tertiary age outcropping on Tubutulik and Koyuk rivers.

#### Q 4-5. KOBUK RIVER.

Strata belonging to the early Tertiary were found by Mendenhall<sup>588</sup> on Kobuk (Kowak) River and also farther east on Dall River, in separate local basins. They comprise conglomerates, of quartz pebbles with some pebbles of the neighboring crystalline rocks, soft sandstones, shales, and lignite beds. On the basis of four recognized species of plants Knowlton referred the strata to the "Arctic Miocene" (upper Eocene).

## Q 5-6. YUKON VALLEY.

Spurr <sup>770</sup> distinguished an occurrence of Tertiary strata which he described as the Twelvemile beds and provisionally referred to the Miocene or Pliocene. These are now regarded as of Kenai (Eocene) age, according to Brooks (personal communication). Spurr says:

Twelvemile Creek is one of the branches of Mission Creek. Near the point of junction of these two streams are exposed in numerous outcrops slightly consolidated and coarse-bedded gravels and sands which carry seams of light-brown sandy lignite. Fragments of wood, considerably altered, having a diameter of as much as 2½ inches, are found, but no fossil leaves or shells. Occasional pieces of black, shiny lignite, such as is found in the Kenai series and less abundantly in the Mission Creek series, occur, but in such a manner as to lead to the suspicion that they are fragments derived from these older rocks. The beds are slightly folded, having a dip of about 20°. Near the mouth of Twelvemile Creek the dip is southward, though about a mile above Twelvemile Creek, on Mission Creek, the dip is to the north, though the strike remains nearly the same; thus a shallow syncline is indicated.

The rocks of the Mission Creek series, which underlie these beds, are sharply folded, and although no actual contact was seen, it is probable that an unconformity exists. Below Mission Creek the rocks of the Kenai series are well indurated, forming compact conglomerates and sandstones, and they are apparently conformable with the rocks of the underlying Mission Creek series, with which they are infolded. It appears, therefore, that the Twelvemile beds can not be correlated with the Kenai series, and yet they are older than the horizontal Pleistocene silts and gravels which are exposed all along the course of the Yukon. They may be provisionally referred to the Miocene or Pliocene. From their nature they seem to be fresh-water lake deposits.

## Q 7. UPPER YUKON.

A belt of coal-bearing, probably fluvial deposits crosses the international boundary in the Yukon Valley. The occurrences on the Alaskan side of the line are described by Brooks and Kindle: <sup>103a</sup>

The Kenai formation has usually been described as occurring in local basins, either of lacustrine or fluvial origin. That described here appears, in part at least, to be of fluvial origin. The distribution \* \* \* indicates that a belt of the Kenai rocks runs parallel to the Yukon from Eagle to Birch Creek. While this zone has not been traced continuously, it is sufficiently well known to justify the opinion that it was originally deposited as one continuous belt. \* \* \* The conglomerate of the Kenai on Woodchopper Creek and Seventymile has been found to be auriferous, which lends weight to the assumption that the deposits are of fluvial origin.

## R 5-6. ARCTIC COASTAL PLAIN.

In traversing the Colville region Schrader <sup>708a</sup> distinguished the Eocene and Pliocene strata as the Colville series, which he describes as follows:

The Colville series is named from the large river along which it occurs and is excellently exposed. It is a series of Tertiary terranes which underlies the flat tundra country, or Arctic Coastal Plain, that succeeds the more southerly rolling plain formed by the Upper Cretaceous or Nanushuk series, which it apparently unconformably overlies, being itself in turn unconformably overlain by the Gubik sands. \* \* \*

The series consists principally of heavy-bedded silts, soft sandstone, limestone, shale, and lignite. It is best exposed along the Colville in the region of the mouth of the Anaktuvuk, where it forms steep-faced bluffs about 200 feet in height, extending for a number of miles both up and down the river.

The Colville series has been but little disturbed. The beds lie nearly horizontal. \* \* \* Observations made along Colville River indicate that the series has a thickness of 500 or 600 feet.

On account of difference in degree of consolidation of the beds, together with their fossil and lignite contents, the series has been separated by the writer into two parts, upper Colville and lower Colville. It is possible that an unconformity may exist between the lower and upper parts of the series, but if present it must be very slight.

The lower Colville (Oligocene) constitutes the main portion or lower three-fourths of the section exposed at the mouth of the Anaktuvuk. It is about 150 feet thick, while the upper Colville at this same locality is about 40 to 50 feet thick. The lower Colville contains the more indurated class of rocks and consists mainly of partially consolidated silts in beds 6 to 8 feet in thickness. They are usually light slate-colored or ash-colored, constitute about one-half of the lower Colville section, and are generally much less consolidated toward the top than near the base. The harder rocks, which increase in volume toward the base of the section, include impure dull-gray medium to fine grained sandstone with detrital lignitic plant remains; slate-colored and brownish calcareous shale, with disseminated undeterminable vegetable detritus; lignitic coal in layers 1 to 5 feet in thickness; dark slate-colored or brownish chert, containing cavities incrustated with chalcedonic silica; rusty brown, very ferruginous sandstone or impure ironstone, and some iron-stained siliceous conglomerate, which also contains lignitic vegetable remains. There are also a few layers of hardened silts, forming a rock of very fine texture, resembling soft, smooth hone stone.

The lower Colville is tentatively classed as Oligocene, on account of the presence in it of lignite beds and vegetable remains, and from its resemblance to the Kenai beds occurring elsewhere in Alaska, and also on the ground of its relation to the supposed Pliocene silts which it immediately underlies.

The Kenai is now generally referred to the Eocene. For Schrader's description of the upper Colville (Pliocene) see Chapter XVII (p. 838).

#### R 26-27. NORTHEAST COAST OF GREENLAND.

Nathorst,<sup>609</sup> in a report on the geology of northeastern Greenland states:

The Tertiary is found in two different facies. On Hochstetters Vorland they occupy a large territory and are composed of fine-grained yellowish sandstone with impressions of marine shells. These are found, according to Copeland, in great quantities, but the collections that were here brought together had to be left behind to a great extent on Kuhn Island. The specimens that were brought home were some unidentifiable casts of *Cytherea*, *Venus*, and *Lucina*, to which Th. Fuchs later added *Astarte* and *Pecten*, after he had again been over the collections. This locality deserves to be explored again, but unfortunately the ice rarely breaks up and, remaining solid for years, makes the shore seldom accessible from a vessel.

The rest of the Tertiary is found in connection with the basalts and is covered by them. Whether it is also underlain by them is not made clear from the text, but judging from the map it would seem to be the case. They sometimes contain layers of coal, and on Sabine Island are found fossil plants, namely *Taxodium distichum miocenum* Hr., *Populus arctica* Hr., *Diospyros brachysepala* Al. Br., and *Celastrus* sp., described by Heer. These specimens indicate the flora to be contemporaneous with the common Arctic Tertiary flora that Heer considers to be of Miocene age [upper Eocene (?), Knowlton].

## CHAPTER XVII.

### LATER TERTIARY (MIOCENE AND PLIOCENE).

*Colors*, yellow, light yellow, lemon-yellow.

*Symbols*, 4, 3, 2.

*Distribution*: Later Tertiary, where the Miocene and Pliocene are recognized but can not be separated or individually identified in the present state of knowledge. The Miocene is separately indicated on the Pacific coast and on the Atlantic and Gulf coasts, so far as surveys permit. Elsewhere on the map it is comprised with Pliocene under the term "Later Tertiary" (4). The Pliocene is distinguished on the Atlantic and Gulf coasts, so far as surveys permit, in California, and in northern Nevada. Elsewhere on the map it is classed with the Quaternary (1), as in the valley deposits of the Great Basin; or with the Miocene under the heading "Later Tertiary" (4). The Lafayette formation of the Atlantic and Gulf slopes, including the Altamaha of Georgia, is shown only where it completely conceals the underlying formations.

*Content*: Pacific coast marine deposits; Alaskan Arctic Coastal Plain deposits; fluvial and lacustrine beds of the Interior; western Gulf coast marine formations; and late marine Tertiary of Mexico, Central America, and South America. Monterey shale and equivalents of the Pacific coast; beds of Carrizo Creek, California; and marine Miocene of the Atlantic and Gulf slopes. Does not include so-called "Arctic Miocene" nor "Old Miocene," both of which are included in "Marine Eocene." Marine Pliocene of the Coast Ranges of California; Humboldt formation (nonmarine) of Nevada; and marine Pliocene and Lafayette of the Atlantic and Gulf slopes east of the Mississippi, including the Altamaha of Georgia; also Yucatan.

#### *Later Tertiary areas.*

#### B-C 18. COLOMBIA.

Karsten <sup>473</sup> describes certain strata of Cretaceous age as occurring in the Cordillera of Colombia (see Chapter XIV, pp. 581-582) and states that they are covered unconformably by a micaceous white or yellow sandstone, of more or less coarse grain, succeeded by quartzose (?) and variegated marls and by clay shales, which include beds of lignite that alternate with the shales in thin layers and in beds up to 3 meters in thickness. The latter group, which is distinguished by paucity of fossils, is not very thick in the higher regions, but it becomes thicker and more important in the lower regions and in the valleys of Magdalena, Cauca, and Patia it constitutes the surface to the exclusion of almost everything else.

According to the region it is sometimes represented chiefly by conglomerates, or again by sands and clays; the latter, which are for the most part variegated in color and micaceous, often contain pebbles and pass into puddingstones. The conglomerates are formed of pebbles, of the size of a fist or smaller, of a siliceous schist or of a quartzite which belongs to the rocks which contain Foraminifera and which are united by siliceous cement. In some districts of Magdalena this complex overlies the reddish-brown sandy marls which have been described above and which contain flakes of mica; the latter should be studied in order to ascertain whether it belongs to the Cretaceous or itself constitutes the lowest member of the Tertiary series. The latter hypothesis appears to me most probable because the Tertiary conglomerates rest directly upon this dense marl; the Cretaceous marls do not contain any mica. They are firmer and more distinctly stratified and in their upper portion inclose thin layers of limestone.

Karsten mentions the occurrence of petroleum in these strata, and continues:

Limestones are rare in this Tertiary series. On the Upper Magdalena I have never observed any fossils. At Popayan I found a thin bed of argillaceous shale and limestone resting upon porphyry and containing shells of Tertiary mollusks (gastropods, *Cardium*, and *Rostellaria guadichaudi* D'Orb.) very like those of the present. \* \* \*

With regard to the gigantic bones of extinct mammals, I may say that I saw them in Colombia constantly in a red sandy marl which lies upon the Tertiary. In Ecuador one finds them not only in the lower places but also upon the plateau and on the slopes of trachytic volcanic cones, where they lie in part in a volcanic tuff that is to the general view very like this marl. These remains are very widely distributed in the country.

Karsten gives numerous localities at which he observed the remains of fossil bones.

## E 14-15, F 14 AND 16, G 12 AND 14, AND H-I 11. MEXICO.

Several localities at which the Miocene or Pliocene have been identified in Mexico are mentioned by Aguilera,<sup>90</sup> and are here referred to under the index headings enumerated above. A general account of the Tertiary of Mexico is given by Felix and Lenk.<sup>327</sup> The local occurrences are the same as those given by Aguilera, but it is profitable to refer to their lucid and connected description.

## E 14. OAXACA.

The Pliocene of Paso Real, at Tuxtepec, in Oaxaca,<sup>91</sup> includes conglomerates of old crystalline rocks which overlie sands and white sandstones and contain *Pecten (Euvola) bowdmensis* Dall, *Lævicardium sublineatum* Conrad, *Calliostoma* cf. *linuum* Dall, *Anguinella virginica* Conrad, *Xenophora* cf. *conchyliophora* Born, *Natica canrena* L., *Natica (Polynices) perspectiva* Rogers, *Strombus pugilis* L., *Sconsia sublævigata* Guppy, *Pyrula papyratia* Say, *Melongena (Solenistra) mengeana* Dall, *Marginella wilcoxiana* Dall, *Marginella cinerarea* Dall, *Oliva* cf. *litterata* Lamarck, *Pleuritoma (Drillia) alesidota* Dall, *Conus* cf. *verrucosus* Bruguière.

## E 15. CHIAPAS.

In Chiapas,<sup>90</sup> in the vicinity of Simojovel, the Miocene is composed of dark argillaceous shales, blue clays, brown sandstones, and interbedded limestone of a white color, which assumes a reddish tint and which extends to the north in the plateau of central Chiapas. The following fossils have been found: *Pecten*, *Ostrea*, *Turritella*, *Conus planiceps* Heilprin, *Clypeaster* cf. *meridamensis* Michelin, etc.

In the vicinity of Coatzacoalcos, upon the river of the same name, there are white and brown sandstones which contain *Amusium papyraceum* Gabb, *Anomia simplex* D'Orbigny, and *Lævicardium sublineatum* Conrad, of the Pliocene.

In the vicinity of Tenejapa, Chiapas, occur marine Pliocene rocks consisting of micaceous sandstones and argillaceous shales, together with andesitic tuffs, conglomerates, and marls which contain *Ostrea*. This terrane occurs also in the valley of the Rio Chiapas beyond the boundaries of the State of Chiapas. It is found in the hills of Tabasco, near Macuspana, with *Natica canrena*; on the frontier between Tabasco and Vera Cruz, near Tenosique; and in the peninsula of Yucatan with *Ostrea virginica*, *Pecten gibbus*, *Pyrula papyracea*, etc.

## F 14. VERA CRUZ AND HIDALGO.

In the States of Vera Cruz and Hidalgo<sup>90</sup> lacustrine deposits of Miocene age occur in the vicinity of Zacualtipan and at Tehuichila. They consist of argillaceous shales with beds of lignite and contain *Hippotherium (Hipparion peninsulatum* Cope), *H. rectidens* Cope, and *Protohippus castilloi* Cope.

The marine Pliocene is recognized by its fossils at Santa Maria Tatetla, at Papantla, and at Tuxpan, in Vera Cruz.

## F 16. PENINSULA OF YUCATAN.

The northern portion of Yucatan is occupied by Pliocene and possibly in places by post-Pliocene limestone, which forms a broad plain that rises gradually south-

ward to the hills of the Sierra de Yucatan. Heilprin <sup>433</sup> describes the plain and says:

The rock formation over the greater part of the plains is that of a gray or white shell limestone, highly indurated or subcrystalline in local areas, but rarely to the extent of obliterating its fossiliferous character. Secondary depositions of calcite, in the form of veins, crystals, and nodular masses, are abundant. Where less compact the rock may be said to be a mass of loosely united shells, a condition that is best shown in the superficial layers. Good sections of the rock are seen only in the walls of the aguadas and cenotes and in a number of railway cuts which traverse it both in a north-south and east-west line; the rock surface is, however, visible over a very large part of its extent, being but scantily covered with soil and supporting only an indifferent vegetation. Its decomposition has liberated large quantities of red earth, similar to that which is found in our own northern region (*terra rossa*) and on coral islands (for example, the Bermudas, Bahamas), and which is seemingly a residual product representing impurities of one form or another which were introduced into the limestone at the time of its formation. \* \* \*

The paleontological evidence of the fossils contained in the limestone is to the effect that the latter belongs to two periods of geological time, the Pliocene and the post-Pliocene, but stratigraphically it is not easy to draw a line of demarcation between the two formations. It, indeed, appears as though the post-Pliocene, except in the coastal area, were present only in patches, having been removed through atmospheric decay and denudation. It is in most places easily distinguished by the large numbers of *Venus cancellata* which fill the rock, making a true *Venus cancellata* bed, such as I observed capping the Pliocene beds on the Caloosahatchie, Florida, just below Fort Thompson. The beds occupy similar positions and hold equivalent relations to the construction of the land and may, therefore, be considered as counterparts of an identical formation.

For lists of living and extinct species, see the work cited. Heilprin continues:

The exact position in the Pliocene series which these Yucatan rocks hold can not, perhaps, be stated, but they with little doubt correspond at least in part with the series occurring in Florida which I have designated the "Floridian." It is true that the number of extinct species of the mollusks is seemingly less in the Yucatan rock than in that of Florida, but it should be said that in addition to the forms above enumerated, there are a considerable number, occurring mainly in the condition of unrecognizable casts, which may largely represent extinct species.

Dall and Vaughan agree with Heilprin on the Pliocene age of the fossils cited by him. Sapper <sup>694b</sup> says:

The Tertiary beds are in general but slightly inclined. In the vicinity of Istapa, of San Antonio, Tenejapa, and Tumbala there are horizontal beds. They are more modern than the andesitic eruptions, for they include the andesites in the conglomerates and the horizontal strata even rest directly upon the andesite.

In the peninsula of Yucatan the Tertiary terranes predominate and it would seem that from south to north there is a sequence of more recent beds until one reaches the post-Pliocene (Quaternary) deposits of the northern coast.

The southern region of Yucatan is composed of calcareous formations which in many places abound in cherts. Between the beds of limestone there are also some beds of marl and others of alabaster, and in the marls there may be found in the Cerro de Ixconconcal, near Icaiche, certain fossils which may serve to determine the relative age of the deposits.

These fossils are apparently not cited, but the beds are supposed to be those which are mapped by Sapper as limestones with marl and alabaster and are regarded by Dall as Oligocene. All the other formations distinguished by Sapper, comprising the white and red limestones, as well as his Pliocene, are here placed in the Pliocene.

## F-G 12. LOWER CALIFORNIA.

At Santa Rosalia and Boleo, Lower California,<sup>9d</sup> there are deposits of upper Miocene age which probably correspond to the beds of Carrizo Creek, California, and which are characterized by *Pecten (Plagioctenium) cedroscensis* Gabb, *Pecten (Pecten) carrizoensis* Arnold, *P. (P.) keepi* Arnold, *Semele* aff. *pulchra* Sowerby, and *Malea* aff. *ringens* Swainson.

For a general statement of the geology of Lower California and sources of information, see Chapter XV (pp. 644-647).

## G 14. TAMAULIPAS.

In the valley of the Rio Bravo, near Matamoros, Tamaulipas, the marine terrane of the late Tertiary is well represented, and according to Aguilera<sup>9d</sup> it is possible to recognize several of Dumble's subdivisions of the later Tertiary of Texas, namely, Oakville, Lapara, and Lagarto.

## H-I 11. TIA JUANA, LOWER CALIFORNIA.

At Tia Juana, Lower California,<sup>9d</sup> there occurs a formation equivalent to the Purisima formation of California, which belongs at the base of the Pliocene. In the island of Cedros this formation is present but not mapped and is characterized by *Pecten (Nodipecten) veatchi* Gabb, *Pecten lecontei* Arnold, and *Pecten (Plagioctenium) cedroscensis* Gabb.

## E 18. JAMAICA.

The classification of the geologic formations of Jamaica is given in Chapter XV (p. 640), and the older formations are discussed in Chapters XV and XVI (pp. 639-642, 717-721).

According to Hill<sup>443</sup> the later Tertiary is separated from the early by a hiatus corresponding to the middle Oligocene. The formations representing the late Oligocene or Miocene and the Pliocene are classified as the Bowden, May Pen, Kingston, and Manchioneal formations, in ascending order.

Under the heading "Bowden and allied formations" (the Yellow limestone of some previous authors), Hill<sup>443g</sup> says:

This series includes a class of formations which represent the products of events more recent in the history of the Jamaican sequence than those hitherto enumerated. Its members occur around the coastal perimeter of the island, principally along the margins of the sea at altitudes nowhere exceeding 250 feet, and deposited unconformably against the sides of an older mainland. Here and there on the south coast they fill previously formed erosion plains. They were all made during epochs subsequent to an epoch of elevation whereby the white limestones of the Oceanic series and all preceding formations had been elevated into land, had undergone tremendous denudation, and had again suffered partial marginal subsidence.

They are of four types of formations, to wit, beds of impure marine limestone, gravel, and marl; alluvium of the Kingston type; elevated coral reefs as illustrated in the Barbican and Hopewell formations; and littoral deposits of calcareous mud, with embedded fossils of contemporaneous origin with the elevated reef formation. The four types in their general lithologic characters are analogous to the marine, littoral, alluvial, and coral-reef formations now being made around the margins of Jamaica.

The Bowden and allied formations of later Tertiary age constitute the older beds of the Coastal series and are all marginal to the main upland mass of the island. They apparently

represent a series of fringing formations extending around the older plateau region. These in turn are bordered by still later and lower-lying formations.

Along the south coast of the east end of the island, between Morant Bay and Port Morant, there is an extensive occurrence of gravel beds less than 50 feet in thickness, containing rolled specimens of nearly every species of volcanic rock found in the island, which grades upward into an impure stratified brown and buff colored marl, the latter having a thickness of 200 feet as measured in the bluff upon which Capt. Baker's house at Port Morant stands. The loose gravels at the base of this section have a very recent appearance, a deception which is further aided by the fact that they occur at beach level and contain perfectly preserved fossils resembling modern shells. The fossils heretofore reported from Bowden are found in the gravel bed and, less abundantly, in a few feet of the lower part of the overlying marls, at the foot of the hill, at the beginning of the road leading up the hill to Capt. Baker's, and in such abundance that as many as 400 species of mollusks have been determined by Dr. Dall from two barrels of material collected by Messrs. J. B. Henderson, jr., and C. T. Simpson, and the writer. A few specimens occur higher up the hill, while near the summit there is a body of firm crystalline secondary limestone containing molds of the characteristic fauna. The physical characters of this formation can be traced from Bowden to Morant Bay and beyond nearly to Yallahs Island, but there it loses its identity. On the road from Bath to Bowden its position above the Cambridge beds is fairly well revealed.

The stratigraphy of the formation has not hitherto been presented correctly, although in the Jamaican reports under the name of the "Yellow limestone" it was partially confused with the entirely different beds herein described as the Cambridge formation, and the gravel beds were mapped with the Pleistocene and Recent formations. Hence its identity as a formation did not appear in these reports.

It is only on the south coast of the east end of the island that the Bowden beds have the characters mentioned. It is evident that the formation with modified lithologic features occurs elsewhere on the island, for the Bowden fossils have been found on the opposite side by us and reported from round the district of Vere, near the coast of Clarendon, by other writers, in formations of quite a modified lithologic nature. Probably the Buff Bay, May Pen, and Porus formations, next to be described, are allied and synchronous deposits.

For details of the several related formations named, see the report cited.

The Manchioneal formation is of marine origin and is composed of alternating layers of loose yellow marl and lumpy white limestone with well-defined bedding planes, and locally of alternating evenly bedded marl and impure limestones. Hill describes exposures that exhibit from 100 to 200 feet of deposits of this character. Fossils are not numerous and the occurrences appear to be of small area. Hill<sup>443b</sup> says:

From the low position of the Manchioneal formation adjacent to the coast and unconformably against the older and more disturbed white limestones, it is evident that it was a marginal fringing deposit. Its stratigraphic position above the Bowden formation and below the undoubted elevated reef rock, as well as the paleontologic evidence of its pteropods and Brachiopoda, indicates the Pliocene age of this formation. The contained corals, here poorly developed but occurring in increased proportions in the succeeding beds, mark the first definite appearance of the marine reef-building species in the Jamaican sequence.

The Kingston formation is described as consisting mainly if not entirely of material derived from adjacent uplands of the mountains and plateau. It varies in composition, being mostly detritus of the Blue Mountain series to the east of the Rio Cobre and largely white limestone débris to the west of that stream. It has been

successively accumulated through several geologic epochs and may ultimately be classified into several distinct terranes. Hill <sup>4431</sup> says:

For the present, however, we shall recognize but two principal stages—an older one, to which the name of Kingston will be applied, and a newer one, which will be called the Montego.

The Kingston formation is the oldest of the formations of old gravel and other alluvium occurring upon the plains of the Liguanea type. This is the formation upon which the city of Kingston and suburbs are built, including the strip of land known as the Palisades, and the plain extending back of Kingston to the foot of the mountains. \* \* \* The material consists of boulders, gravel, and pebble of varying sizes, usually very angular, and representing every known material of the Blue Mountain series. These are embedded in a matrix of dull red arenaceous clay, producing a chocolate soil and derived from the Minho beds so conspicuously exposed in situ in the mountains north of Kingston.

The thickness of this formation is unknown, but over 200 feet are exposed in the thalweg of Hope River, and probably fully this thickness is concealed. It is even likely that it may be nearly a thousand feet in places. \* \* \*

As a whole, it represents excessive deposition, first as estuarine or littoral material during an epoch when the coasts were submerged, and later talus deposits of subsequent epochs, when the land was rapidly rising and stream erosion was very active, as discussed more fully in another part of this paper. The alluvial deposits in the bottom of the larger interior basins are also closely synchronous with the Kingston formation, and it is probable that these basins are products of the same great erosion epoch which preceded the Kingston deposition.

Fossils are generally missing from the Kingston formation; speculation concerning its age must be founded entirely upon stratigraphical relations. In our opinion it is clearly older than the elevated reefs of the Barbican and Hopewell formations, of presumable Pleistocene age, and younger than the Bowden formation, being nearly allied by position to the age of the Manchioneal, which we consider Pliocene.

The present beds of both the Hope and the Cobre rivers deeply indent the Kingston formation, cutting far below the surface of the plain. The alluvium of these stream valleys and their general level constitute distinct deposits which are later described under the head of the Montego formation.

In his further description Hill gives many details regarding the elevated reefs and miscellaneous coastal formations contemporaneous with them.

#### E 19. SANTO DOMINGO AND PORTO RICO.

Gabb <sup>252b</sup> placed the Tertiary of northern Santo Domingo in the Miocene and probably that of Porto Rico as of the same age. Regarding Santo Domingo Gabb says:

All of that part of the island which lies north of the Cibao Mountains, except a part of the peninsula of Samana, is made up of Tertiary rocks, usually bordered by a narrow strip of more modern age. They also form one or two insignificant deposits on the south side about San Cristobal and the Nizao, and are said further to cover a part or all of the valley of the lakes running to Port au Prince in Haiti. The work of the geological survey not having extended to the latter region I shall confine my observations to the others.

The district covered by this formation in the north, including its extension into Haiti, toward Cape Haitien on the west, and into Samana and south of the bay east, is little less than 150 miles long, although, cutting off these prolongations, it forms a compact area of about 100 miles long by 30 miles wide, or say, in round numbers, about 3,000 square miles. It abuts against and even overlaps the lower foothills of the central chain, underlies the whole valley of the Yaqui and Yuna, makes up the entire northern or Monte Cristi Range, and sends others

along both sides of Samana Bay. In the south it forms a little group of hills extending from near the Jaina River across the Nigua and thins out in a few isolated patches toward the Nizao. Its total thickness in the vicinity of the Nigua River is about 400 feet, and it is made up of a succession of brown earthy and sandy beds, occasionally calcareous, superposed on a thin stratum of conglomerate. The top of the series is a rather compact calcareous deposit containing corals. The fossils, except the corals, are usually badly preserved and very meager in species; a small oyster, two species of *Pecten*, and some echinoderms being the only recognizable forms. Besides these, a few internal casts of gastropod shells have been discovered. The corals are so embedded in their matrix that they can only be collected satisfactorily when they are weathered out, and this same process of weathering is only too apt to destroy the delicate structure of their surfaces. They are, however, nearly all of the massive forms and are so thoroughly fossilized as to be well adapted for polishing.

But while the formation is so small in area and so unsatisfactory in general characters on the Santo Domingo side, it becomes, in the Cibao, the most interesting on the island. Cut through by all the tributaries of the Yaqui the sections are numerous and excellent for study. Its local modifications are well illustrated by sections innumerable, into and across the Monte Cristi Range on one side and into the southern hills on the other. In short, it would be difficult to find a region where the facilities furnished to the geologist are greater, or where the results could be more certainly arrived at. Add to this that a larger part of the formation is highly fossiliferous, and that the fossils, whether shells or corals, are almost always preserved entire and hard; as beautiful as the famous fossils of the Paris basin, or as the less known though equally beautiful specimens from Jackson, Miss.

The entire thickness of the formation in the Cibao is probably over 1,500 and under 2,000 feet. It is made up of coarse sandstones at the base, sometimes bearing beds of conglomerate, which are, however, rather local in extent. These beds are best developed between the Bao and the Yaqui, where, being uptilted, their thickness is best seen, and are about 600 feet thick. They gradually merge into gray shales, which form a transition to the heavy blue-shale beds underlying the town of Santiago and called by the English paleontologists the Nivaje shale. The upper part of this member is always of a light yellowish brown or buff color and sometimes, especially at its upper part, contains beds of sandstone. The whole of this shale member may be safely estimated at about 800 feet of average thickness. The remainder of the formation, say 400 feet more in all, varies locally. It caps the greater part of the Monte Cristi Range, and while north of Moca it forms high bluffs of a nearly white earthy rock, in which it is doubtful whether the argillaceous or the calcareous ingredients preponderate, it forms north of Esperanza sheets of a compact limestone, which, less pure, forms the cap on the isolated table mountain of Monte Cristi. Near Cevico it appears as an impure lime rock containing corals and Foraminifera, and similar beds occur also on Samana and south of Savana la Mar; while the caves of San Lorenzo, in the same beds, are in a hard, coarse-grained calcareous sandstone. Nor do the variations cease here. Near the mouths of the ancient Miocene rivers running from the then much smaller islands now constituting the Cibao Mountains, and among which the Mao was probably the largest, the gravel débris of these streams was deposited, occasionally alternating with a bed of coarse sandstone, synchronously with the formation of the coral reefs and beds of fine white mud which now glistens in the sun on the top of the Monte Cristi Range. We have thus an ideal section as follows:

|                                                                                                                                                                                                                                                                                                                        | Feet. |
|------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|-------|
| White calcareous marl, north of Moca; white or light-brown limestone ("Tufaceous limestone" of Heneken); light-brown calc sandstone, San Lorenzo Bay; gravels of Mao and Savaneta; limestones of Samana, San le Mar, Cevico, and the north face of the Samba Hills; oyster beds of Samba Hills, south of Guayubin..... | 400   |
| Brownish or yellowish shale of Guayubin; conglomerate of Angostura of the Yaqui; sandstone strata near Santiago; dark-blue shale of Santiago; gray shale with beds of sandstone of Rio Verde and in the hills north of Moca.....                                                                                       | 800   |
| Coarse gray sandstone with some conglomerate; seen best in the hills south and southeast of Santiago, also in a few places in the north range.....                                                                                                                                                                     | 600   |

These three members are so intimately united that their separation is purely arbitrary. Beds of sandstone are found in the shale, and beds of shale extend far down into the lower member. Very few if any fossils have been found in the sandstone, though the gravels of Angostura yield shells abundantly, in connection with fragments of fossilized wood. The same species of fossils occur in all parts of the series, and I have collected from a bed of sandstone at the very summit of the Mao gravel a series of shells identical with those embedded in the rocks of the "nonfossiliferous sandstone" plain east of Guayubin, and which are found abundantly in the blue shale of the Gurabo, Amina, or Verde.

Fossils are not regularly distributed either vertically or laterally, but seem to occur in colonies. The blue-shale bluff under the city of Santiago, 60 feet high from the level of the river, does not show a single streak where they are ever abundant enough to repay the trouble of hunting, although isolated shells occur throughout. At Puñal, but a few miles off, near the Rio Verde, shells and corals abound. The same irregularity exists throughout, and although there is but little change in the species of the Mollusca in their vertical range, there is a marked difference between the eastern and western ends of the basin. Shells that are absent or scarce on the Verde are common on the Gurabo and westward, and vice versa. The corals found in the shale are almost always of the cup forms, while the massive corals are almost exclusively confined to the upper beds and are particularly abundant on the north flanks of the Samba Hills. In all the shale beds and to the extreme top of the series Foraminifera occur and in some places are found in great numbers. They are not very numerous in species, probably not exceeding half a dozen. The Orbitoides ranges throughout all the strata and is not only found wherever any other fossil occurs but is often, especially in the higher beds, the only recognizable organic remains. It has more than once proved of great value to me in distinguishing these limestones from the overlying post-Pliocene calcareous beds.

With one or two small exceptions all these rocks are entirely unaltered. On the southern limit, in contact or nearly so with the underlying Cretaceous in the vicinity of the Bao River and on the Yaqui, the coarse sandstones are slightly modified, though still retaining their stratification and mechanical structure unchanged. On the Yaqui at Tabera this rock is highly uptilted and slightly contorted, as will be seen by reference to the description of the locality. Also in the northern range a similar slight metamorphism occurs southeast of Puerto Plata.

Gabb then discusses the geologic age of the West Indian Tertiary rocks and gives the age of many fossils, including 217 supposed extinct species and 97 known to be living. He concludes, "We are therefore at or near the top of the Miocene."

#### F 17-18. CUBA.

T. W. Vaughan has contributed to this work the following notes on the later Tertiary of Cuba:

An extremely interesting fact in the Cuban stratigraphy is that, so far as we at present know, there is absolutely no true Miocene on the island. The Miocene as described by De Castro, Salterain, and others is now referred to the upper Oligocene. From the evidence now before us, it seems most probable that during Miocene time none of the now existing portions of the Island of Cuba were submerged beneath the ocean.

The data regarding the presence of Pliocene strata are unsatisfactory. The only data on which we could base a conclusion are derived from the notes and collections of William Palmer. In the western part of Havana, on the Calle Infanta, opposite Castillo de la Punta, Palmer collected fossils from a quarry in soft white limestone. The bottom of the quarry is about at sea level. According to Palmer the same formation extends to approximately 60 feet above sea level. The fossils obtained from this locality may be Pliocene, though it is probable that they are Pleistocene. The limestone which is being quarried between Almandares River and Camp Columbia, on the north side of the road, may be of Pliocene age.

Surrounding the greater portion of Cuba, but especially along the northern coast and bordering the southern coast of Oriente from Cape Maisi to Cape Cruz, is a low coastal shelf nowhere exceeding a maximum elevation of 30 or 40 feet. There is beneath this shelf in places a lower terrace some 5 or 6 feet above the water's edge. Both of these terraces are composed of elevated coral-reef rock. The material is a limestone presenting an extremely rough upper surface and replete with the remains of numerous species of corals which are all, so far as examined, at present living in the surrounding Antillean seas. These reefs have been formed and elevated within very late geologic time.

A coating of surface gravel exists over the plain in the Province of Pinar del Rio on the south side of the Sierra de los Organos. The material has been derived from the rocks constituting the mountains and has been distributed through the agencies of streams and floods. It is probably of Pleistocene age.

#### G-H 14, H-I 15. TEXAS, LOUISIANA, AND ARKANSAS.

The following discussion has been compiled by T. W. Vaughan from the literature and from manuscripts of A. F. Crider and Alexander Deussen. Most of the literature is cited in Chapter XVI (p. 723); other references are given in the discussion.

#### MIOCENE.

No surface outcrops of marine Miocene deposits between Mississippi River and the Rio Grande have yet been described. Buried marine Miocene beds occur in southern Louisiana and in the coastal region of Texas. The two most thoroughly studied occurrences are those of the Jennings oil well, Louisiana, and the deep well at Galveston, Tex.

In the Jennings area the equivalent of the Pascagoula formation of Mississippi was penetrated at depths ranging from 1,040 to 2,183 feet, the variation being due to folding.<sup>407a</sup> In the Crowley field the "*Rangia johnsoni*" zone is from 1,960 to 2,600 feet below the surface.<sup>407b</sup>

Harris<sup>402</sup> has described a large Miocene fauna encountered in the Galveston deep well between 2,158 and 2,920 feet below the surface.

Deussen has discovered in De Witt County, Tex., littoral or fresh-water beds in which the remains of Miocene vertebrates were found. The material consists of cross-bedded coarse gray semi-indurated sands, gray sandstones, and local lenses of clay. The beds grade seaward into a marine phase and are overlain by Pleistocene deposits. Deussen thinks that these beds may be a littoral phase of the marine Miocene encountered in the Galveston well.

Dumble<sup>297c</sup> has proposed the name Oakville for "grits and coarse sands, cross-bedded, with some beds of clay, but oftener with balls, nodules, or lenses of clay embedded in the grit. Some of the sands form a sandrock which is apparently firm and hard, but much of it is so feebly coherent as to fall apart on a slight blow of the hammer. Local beds of conglomerate occur." A few fossil vertebrates were obtained, but they were considered sufficient to determine the age of the formation as "Loup Fork." The formation in which Deussen found Miocene vertebrates in De Witt County may belong to Dumble's Oakville.

Above Dumble's Oakville are formations named by him Lapara and Lagarto,<sup>297d</sup> but they have not been correlated with the geologic time scale.

#### PLIOCENE.

No marine Pliocene deposits are known to outcrop between Mississippi River and the Rio Grande, but a recent discovery of G. C. Matson in Louisiana, 8 miles west of south of Alexandria, indicates that such deposits may have a considerable development in south-central Louisiana and may even extend into Texas.

The problematic Lafayette formation covers extensive areas in northeastern Arkansas, southern Arkansas, northern and central Louisiana (especially over the Catahoula and Fleming formations), and eastern Texas.

The following description for northeastern Arkansas is taken from a manuscript by Crider:

"Overlying the Tertiary in Crowleys Ridge and also on the western border, and extending for a short distance over the Paleozoic rocks, there is a thin blanket of sand and gravel of the Lafayette with a maximum thickness of about 30 feet. The Lafayette has been removed from the lowland regions east and west of Crowleys Ridge, along with the Tertiary.

"Where the loess is absent, as in many places on Crowleys Ridge north of Jonesboro, the Lafayette is present on the highest divide. South of Jonesboro it appears beneath the loess in the railway cuts and deep ravines which have been cut to the middle portion of the ridge. Nearly all the principal streams of Crowleys Ridge have cut through the loess and Lafayette, and their materials have been carried down and spread out on the slopes and the adjacent bottoms. It is probable that most of the Lafayette which was originally deposited on the eastern foothills of the Paleozoic rocks from Missouri to Pulaski County, Ark., has been reworked by the streams and carried farther down the slopes.

"Where undisturbed the Lafayette is made up of chert, quartzite, and white and black quartz pebbles indiscriminately mixed with a coarse, well-rounded reddish sand. The whole is roughly stratified, showing the effects of ever varying currents. At the base of the formation the pebbles are, in places, interbedded with materials reworked from the underlying formation. The cherts constitute a large proportion of the pebbles in the formation. They are much larger and more angular than the quartz pebbles, and many of them contain fossil crinoid stems. They are, therefore, evidently derived from the cherty limestones of the adjacent Paleozoic hills. The quartz pebbles are much smaller than the cherts, and are well rounded and polished.

"Sand everywhere accompanies the gravels and in places forms the bulk of the formation. The grains are well rounded and, like the pebbles, are almost universally stained with oxide of iron. It is probable that some of the sand has been derived from the underlying formations, but a current that would be strong enough to bring in a large amount of foreign gravel would also carry a still larger amount of sand. Much of the sand, therefore, doubtless has the same origin as the pebbles.

"The Lafayette contains a large amount of ferruginous matter. Under favorable circumstances the iron oxide has cemented the sand into a rough, hard brick-red sandstone and the gravels into an ironstone conglomerate which is in few places more than 5 feet thick. These hard ferruginous masses are prone to form where the percolating waters, carrying the iron oxide in solution, come into contact with a compact clay or any other impervious layer. Subsequent erosion exposes these cemented masses, which in places protect the hills from further erosion, while large blocks break loose from the main ledge and cover the slopes."

This description applies well enough to the other areas in Arkansas and Louisiana.

According to Deussen (unpublished manuscript), "A wide area of the Coastal Plain in Texas east of Brazos River is occupied by a series of clays, sands, and gravels, which overlap the Miocene beds and in many places overlie and obscure the Fleming clay and are seen to rest directly on the Catahoula formation. Originally these beds mantled the older rocks over this entire area and the adjacent Black Prairie and extended in broad tongues up the valleys in the region to the west. These exposed portions have been subjected to erosion for so long a time that the interior margin, once very far to the west, has been gradually transferred seaward. In the area of the former extent many outliers persist on the higher divides and plateaus where their isolated position has protected these materials against erosion. These high-level gravels are so common within this area that they generally obscure the older underlying formations. The latter are exposed only in the channels and valleys cut by the streams since the deposition of the Lafayette.

"Toward the coast these sands, clays, and gravels dip beneath the overlying Pleistocene gravels and are recognized in many of the wells put down in this portion of the Coastal Plain.

"These sands and clays and gravels wherever exposed unconformably overlie the lower beds, indicating an erosion epoch between their deposition and that of the underlying beds.

"As a rule the materials carry no fossils indigenous to the strata. Waterworn fragments of fossils from older rocks are sometimes found embedded in the gravels, but these give no

important clues to the age of the formation. At Sour Lake, Texas, they lie beneath beds of known Pleistocene age and above beds of known Miocene age, a position which would fix their age as Pliocene. This is also in accord with evidence from other sources."

In the region of Austin and San Antonio three distinct terraces flanking the rivers are recognizable. The highest and oldest of these occupy the divides, and the material consists almost entirely of flint embedded in a calcareous matrix. This is the Uvalde formation of Hill<sup>446a</sup> and corresponds to the Lafayette of more easterly areas. It consists of the products of destruction of the Edwards limestone. This material is now found only in the divides of the Coastal Plain, but it constitutes the uppermost terrace in the canyons of the Edwards Plateau.

The terraces of the second series occupy a lower level and are therefore younger than the Uvalde terraces. The materials composing these in the vicinity of Austin consist of granitic débris derived from the granites of the Llano region, which was exposed only after the Cretaceous cover was removed. In a terrace along Onion Creek, just west of Pilot Knob, Travis County, occur vertebrate remains of early Pleistocene age.<sup>446b</sup> This would make the upper terraces pre-Pleistocene.

The Uvalde formation is present from Austin to Rio Grande along the interior margin of the Rio Grande plain and extends many miles seaward. For further description see Hill and Vaughan.<sup>446</sup>

#### PLEISTOCENE.

For the areas bordering Mississippi River the brief description given on page 813 will apply. In southern Louisiana the Port Hudson attains a great thickness—usually over 1,000 feet and in places over 2,000 feet. This is also true of the Pleistocene of the coastal region of Texas. Landward from the border of the coastal prairies of Texas there are two systems of terraces between the level of the present flood plains and that of the Uvalde formation.

#### G 17, H 16-17, I 15-17 (EAST OF MISSISSIPPI RIVER), AND J 16. SOUTH ATLANTIC AND EASTERN GULF COASTAL PLAIN AND NORTH END OF MISSISSIPPI EMBAYMENT.

The following discussion (pp. 806-813) has been compiled by T. W. Vaughan from the literature and from unpublished results of G. C. Matson and E. W. Berry in southern Alabama and Mississippi and of his own researches. The principal references to the literature have been listed in Chapter XVI (p. 731). To the list there given may be added Nos. 566, 653, and 693 of the bibliography on pages 840-865.

#### MIOCENE.

Vaughan<sup>834</sup> describes the subdivisions of the Miocene along the Georgia-South Carolina line, their correlation with formations farther north, and their relation to the upper Oligocene:

"The following section of the exposure at Porters Landing is adapted from the description of it given by Mr. Earle Sloan in his 'Catalogue of the mineral localities of South Carolina,' page 273:

|                                                                                                                | Feet.         |
|----------------------------------------------------------------------------------------------------------------|---------------|
| 6. Pleistocene—white, red, and yellow sands, with phosphatic pebbles and vertebrate fragments at the base..... | 64            |
| 5. Miocene—compact yellow fossiliferous marl (Duplin horizon).....                                             | 6             |
| 4. Miocene—grayish fossiliferous marl (Marks Head marl).....                                                   | 29            |
| 3. Fine-grained laminated shale with sandy partings; a line of rounded pebbles at the base...                  | 14            |
| 2. Oligocene—fossiliferous marl (Alum Bluff formation).....                                                    | $\frac{1}{2}$ |
| 1. Laminated drab shale with arenaceous partings.....                                                          | 8             |
|                                                                                                                | 111½          |

"Recent collections made at Porters Landing have rendered possible definite correlation of the two Miocene horizons with those of the area farther north. From bed No. 5 of the section 34 identified species were obtained, 30 of which also occur in the Duplin marl of North

Carolina. The four species which have not as yet been reported from there occur in other localities in horizons the stratigraphic equivalent of the Duplin, or in deposits of later age. Bed No. 5, therefore, can be definitely correlated with the Duplin marl of North Carolina and the fossiliferous Miocene marls of Darlington and Mayesville, S. C.

"The Marks Head marl, which was first named by Sloan and is represented by bed No. 4 of the section, contains specimens of the genus *Carolia*, which suggests an Oligocene age, but every other identifiable species may be Miocene, and only three of them range downward into the Oligocene. Nine of the species are not known below the Miocene, and of these nine, six are confined to the Miocene. The horizon is, therefore, Miocene, while the presence of *Turritella æquistriata* Conrad, *Calliostoma aphelium* Dall, *Ostrea mauricensis* Gabb, and *Pecten marylandicus* Wagner definitely points to a horizon low in the series, approximately equivalent to the Calvert formation of Maryland.

"The recognition of the stratigraphic position of this horizon is of importance, as it is the only low Miocene horizon known south of Virginia. Farther south in Florida, along the western extension, on the Ocklockonee and Apalachicola rivers, the Miocene rests upon the eroded surface of the upper Oligocene. The Miocene deposits of these localities represent a horizon high in the series. Therefore, the Marks Head Miocene is the equivalent in part to the erosion interval between the upper Oligocene and the Miocene of western Florida.

"Bed No. 2 of the section at Porters Landing contains fossils indicative of an upper Oligocene age. Bed No. 3 is very likely of Miocene age, and the line of rounded pebbles at the base suggests that the Miocene may rest upon the eroded surface of the upper Oligocene. It seems probable that along the Savannah River an erosion interval occurred between Oligocene and Miocene depositions, but the interval was of shorter duration than in western Florida."

The Marks Head marl is the oldest Miocene known south of the Hatteras axis. Sloan has applied the name Edisto marl to the indurated phosphatized marl in the vicinity of Charleston, the source of the rich phosphate deposits of that area. This material overlies the Cooper marl (Eocene) and underlies the Pleistocene and is only 2 or 3 feet thick. Although the identifiable fossils from it are few, stratigraphic equivalence with the St. Marys formation of Maryland and Virginia is definitely suggested. The Edisto marl is overlain by a softer, yellow sandy marl near the old Cohen plantation, three-fifths of a mile west of Goodrich station. To this marl Sloan has applied the name Goose Creek marl. According to Sloan it is overlain by the Duplin marl. The following section at Davis Landing, on Peedee River 16½ miles N. 75° E. of Lake City, shows the relations of the beds:

|                                                                                                                      | Feet. |
|----------------------------------------------------------------------------------------------------------------------|-------|
| 5. Pleistocene sands and loam.....                                                                                   | 8     |
| 4. Indurated ledge of dirty yellow marl containing <i>Pecten eboreus</i> , especially at the base.....               | 16½   |
| 3. Compact yellow marl with large numbers of <i>Chama striata</i> and <i>Arca incile</i> .....                       | 8     |
| 2. Friable yellow marl, containing <i>Amusium mortoni</i> and <i>Pecten eboreus</i> (Goose Creek marl of Sloan)..... | 4¾    |
| 1. Dark blue-green marl, with Cretaceous fossils.....                                                                | 23    |
|                                                                                                                      | 60½   |

Beds Nos. 3 and 4 represent the Duplin marl. The faunal affinities of the "Goose Creek" marl have not yet been positively determined. The Duplin marl is an extension of the marl of the same name in North Carolina southward into South Carolina, where it is well developed along Peedee River and in the vicinity of Darlington, Mayesville, and Porters Landing, the last-mentioned locality being on the Georgia side of Savannah River.

Otto Veatch, in the manuscript of a report that has been published since this discussion was compiled, gives the following account of the Miocene in Georgia:

"Miocene strata have been discovered in the bluffs of Savannah River in Screven and Effingham counties; on Altamaha River near Doctortown, Wayne County; at Brunswick; and at Owens Ferry, on Satilla River in Camden County.

"The Marks Head marl is typically exposed near Porters Landing, on Savannah River, Screven County. It has not been differentiated at other localities than the bluffs of this river.

This formation rests unconformably upon the Alum Bluff formation and is also separated from the overlying Duplin marl by a small unconformity represented by an uneven line of quartz pebbles. The strata consist of gray or brownish compact argillaceous sand containing large calcareous nodules and, in places, of friable phosphatic sand containing shells. The formation does not reach a thickness of more than 30 or 35 feet in natural exposures.

"The Duplin marl as exposed along Savannah River overlies the Marks Head marl and is separated from it by a small unconformity indicated by quartz pebbles. It is overlain by Pliocene (Lafayette?) and Pleistocene deposits of sand and clay. It is a shell marl consisting of shells in a matrix of coarse phosphatic sand; in places it consists of a fine gray or brown quartz sand. It probably does not reach a thickness of more than 10 or 12 feet.

"The Duplin on Altamaha River consists of friable sandy and pebbly shell marl and bluish fine-grained argillaceous sand, which is also fossiliferous. The formation unconformably overlies strata of probable Alum Bluff age, and is in turn overlain by varicolored sand and clay which is probably Lafayette (Altamaha). The Duplin reaches a thickness of not over 12 or 15 feet.

"The Miocene at Brunswick is not exposed naturally and was discovered in dredging operations on Brunswick River. The material thrown off the dredge consists of fragments of bones, teeth, sand, quartz pebbles, and compact sandy marl, or shells embedded in a phosphatic sand matrix, together with some argillaceous limestone and hard clay. A study of the fossils has been made by Vaughan and they were found to range from Miocene to Recent.

"Miocene rock is exposed in the bed and banks of Satilla River at low tide, at Owens Ferry, 8 miles west of Woodbine. The rock is a brown or grayish compact sand and calcareous sandstone, containing poorly preserved fossils."

The Miocene in Florida rests upon the eroded surface of the upper Oligocene Alum Bluff formation, as is shown in the exposures at Jackson Bluff, on Ocklockonee River, and at Alum Bluff, on Apalachicola River. The series in this State is divided into two formations that occupy different areas but are probably in large part contemporaneous. The formation in the eastern area is the Jacksonville, that in the western area the Choctawhatchee. Matson and Clapp<sup>580d</sup> describe the Jacksonville as follows:

"From well records and samples obtained along the east coast of Florida, the Jacksonville formation appears to rest unconformably upon the eroded surface of the limestones of the Vicksburg group at Jacksonville, St. Augustine, and other localities. Farther westward it probably rests on the beds belonging to the Apalachicola group, but no contacts were observed.

"When fresh, the limestone of the Jacksonville formation varies in color from light gray to nearly white, but upon weathering it changes to pale yellow or yellowish gray. It usually has a porous texture but occasionally becomes hard and dense. The presence of a large percentage of clear quartz sand may be easily distinguished by the use of an ordinary hand lens, and microscopic examination shows that there is also a large amount of clayey material which varies in color from light gray to pale yellow. In certain horizons fossils are very abundant, the shells having usually been dissolved, leaving nothing but casts or molds; and this fact, together with the friable character of the rock, makes it very difficult to obtain satisfactory collections. However, enough material has been obtained to indicate the Miocene age of the rock. Unlike the Choctawhatchee marl, the Jacksonville formation appears to contain practically no mica. It also differs from the marl in its relatively higher percentage of lime and a correspondingly lower percentage of sand.

"Although the Jacksonville formation is fossiliferous, the organic remains are less numerous and in a much poorer state of preservation than in the Choctawhatchee marl. An examination of well samples shows that limestone forms only a minor part of the formation, a fact which is well illustrated by the log of the well at Jacksonville, where the formation attains a thickness of about 500 feet and is composed largely of arenaceous and siliceous beds. From samples obtained in drilling a well at Jacksonville the clays are known to be siliceous and the hard materials described as gravel found to be chert nodules. Some of the beds consist of a hard gray siliceous rock which

appears to have been formed by the replacement of the calcareous portion of a sandy limestone by silica which was probably derived from organic remains such as sponge spicules and diatoms.

"The exposures of the limestone of the Jacksonville formation seldom exceed 5 or 6 feet in thickness, but there is a maximum exposure of about 15 feet at a locality 2 miles above Middleburg, on Black Creek."

The maximum thickness of the formation is indicated by well borings to be about 500 feet, according to Matson and Clapp. Miocene strata have been identified in well borings as far south as Key Vaca, at depths between 375 and 400 feet.<sup>835a</sup>

The Choctawhatchee marl is described by Matson and Clapp<sup>580e</sup> as follows:

"The Choctawhatchee marl includes the 'Ephora bed' and 'aluminous clay' of Dall. It comprises a grayish sandy shell marl and gray plastic sandy clay of Miocene age. It lies stratigraphically between the Oligocene and Pliocene beds and contains characteristic species of Miocene fossils.

"The Choctawhatchee marl rests unconformably upon the Alum Bluff formation at Alum Bluff, where the contact shows a wavy surface marked by shallow channels due to erosion. At this locality there is also a sharp change from the coarse light-gray sands of the Alum Bluff formation, which contain few fossils, to the bluish-gray shell marl of the Choctawhatchee, with its abundant fauna. Several years ago Dr. Vaughan noted similar evidence of an unconformity between the Oligocene and Miocene at Jackson's Bluff, on the Ocklockonee River. This fact is well shown by his section at that locality. \* \* \*

"The paleontologic evidence indicates a stratigraphic break between the Oligocene and Miocene as is shown by the following quotation:"

"As I have on various occasions insisted, the faunal gap between the uppermost Oligocene (Oak Grove) and the Chesapeake (Choctawhatchee) or Miocene is the most sudden, emphatic, and distinct in the whole post-Cretaceous history of our southeastern Tertiary and indicates physical changes in the surrounding region, if not in Florida itself, sufficient to alter the course of ocean currents and wholly change the temperature of the waters on our southern coast.'

"Lithologically the two members of the Miocene in Florida are very unlike, both in character of the material and state of aggregation. The Choctawhatchee marl varies from greenish gray to light gray in color and consists of quartz sand containing very large admixtures of shells and shell fragments and a smaller percentage of calcareous sand. In some parts of the formation the shells comprise a large percentage of the whole, and they are often in an excellent state of preservation. Elsewhere the organic remains form a very subordinate part of the whole or they may be entirely wanting. One phase of this formation is distinctly plastic and was called 'aluminous clay' by Dall and Stanley-Brown.

"When examined with a microscope the marl is found to consist of clear quartz sand, of medium fineness, coated and partially cemented with calcium carbonate mixed with more or less dark clay. The presence of calcium carbonate may be detected by the effervescence when treated with dilute hydrochloric acid. There is also a certain amount of dark-colored clayey material which appears in the form of a flocculent sediment in water. This material varies from light gray to nearly black and is, without doubt, organic matter. In addition, hydrous iron oxide may be detected, usually in the form of a coating about the sand grains or as a stain along the cracks and on the exposed surfaces of the beds. It is this iron compound which sometimes gives the exposed surfaces a rusty color.

"The Choctawhatchee marl attains a thickness of over 50 feet in the vicinity of Redbay, Walton County, where it is exposed in some small ravines and on the banks of Mill Creek; near Holland post office, Leon County, its thickness exceeds 30 feet. However, from observations elsewhere it appears probable that the average thickness is not more than 25 to 30 feet."

West of Florida Miocene beds have been recognized in the well of the Mobile Oil Co., at Mobile, at a depth of 700 feet, and probably continued to a depth of about 1,100 feet, where upper Oligocene fossils representing the Alum Bluff formation were encountered. Beds of

<sup>a</sup> Dall, W. H., Trans. Wagner Free Inst., vol. 3, p. 1594.

pebbles and conglomerate lying above the Apalachicola group (Oligocene) in this well probably indicate an erosion unconformity between the Apalachicola and the Miocene.

Miocene rocks are exposed at Shell Bluff, on Chickasawhay River, near Merrill, Miss., the type locality of L. C. Johnson's Pascagoula formation. G. C. Matson has discovered that the Miocene along the Alabama-Mississippi line is separated by an erosion unconformity from the underlying upper Oligocene. Across southern Mississippi the Miocene is represented by estuarine deposits that have not yet been definitely discriminated from the underlying upper Oligocene deposits, which are also estuarine and of similar lithology.

#### PLIOCENE.

The marine Pliocene of South Carolina is a southward extension of the Pliocene of North Carolina. The principal area lies along Waccamaw River, near Conway, in Horry County. The material is yellow, brown, and gray shell marl. Sloan gives the thickness at the mouth of Tilly's Lake as 10½ feet.

The Charlton formation of Georgia and Florida, which outcrops along St. Marys River from Stokes Ferry, 11 miles south of St. George, Charlton County, Ga., to Orange Bluff, 2 miles above Kings Ferry, Nassau County, Fla., is probably of Pliocene age. The formation is composed of calcareous shell marl, sand, and clay, having a maximum exposed thickness above low-water level of about 15 feet.

The most extensive development of the marine Pliocene in the Coastal Plain area is in Florida, where it is divided, largely because of its areal distribution, into two formations—the Nashua marl, which occurs along St. Johns River below the town of Nashua, and the Caloosahatchee marl, which takes its name from Caloosahatchee River. Matson and Clapp<sup>580g</sup> give the following description of these formations:

“The Nashua marl bears a strong lithologic resemblance to the Caloosahatchee marl. There is the same alternation of sand beds with shell marl. The matrix of the Nashua marl, while usually calcareous, is always more or less sandy and sometimes consists of nearly pure sand. The shells are commonly well preserved, though locally a marl consisting of broken and eroded fragments of shells is not uncommon. However, the organic remains are so well preserved that it is easy to obtain good collections of fossils from this formation.

“The Nashua marl is much thinner than the Miocene strata. This fact, together with its distribution beneath the lowlands near the coast, indicates that the Pliocene submergence was less extensive than the Miocene; and the presence of shallow-water fossils shows that the Pliocene sea did not attain any great depth over that part of the State where the marine beds are now exposed. The Nashua marl is seldom more than 6 or 8 feet thick, but locally it attains a greater thickness. A series of samples of sand and marl from a well at DeLand indicates that at that locality this marl has a thickness of about 32 feet.

“The Nashua marl occupies the St. Johns Valley, where it underlies a broad terrace bordering the stream. It probably occurs beneath the plain east of St. Johns River, but the overlying Pleistocene forms such a thick mantle that the Nashua marl has no influence on the topography. On the whole, this formation has little or no influence on the topography of the State.

\* \* \* \* \*

“The Caloosahatchee marl consists of a light-gray shell marl which is often interbedded with nearly pure sand. The matrix is usually very calcareous, but locally it consists of sand and even in the most calcareous portion sand is abundant. The shells are remarkable for their excellent state of preservation and their abundance in certain layers makes it possible to secure excellent collections.

“It is difficult to form a correct estimate of the thickness of the Caloosahatchee marl, but its maximum is probably about 25 feet. Single exposures seldom exceed 5 to 10 feet, and the average thickness is probably less than 8 feet. On the whole the Caloosahatchee marl is probably to be regarded as thin, though it may thicken considerably toward the central portion of the peninsula and toward the southern end of the State.

"The Caloosahatchee marl occupies a region of such low altitude that it has only been slightly dissected. In fact, with the exception of the valleys of the streams entering Charlotte Harbor the surface of the region underlain by this formation is an almost unbroken plain. While this is doubtless in part due to the later deposit of Pleistocene sand, it is doubtful if the surface of the Caloosahatchee marl has ever been greatly eroded."

The nonmarine Pliocene of Florida includes the Alachua clay and the Bone Valley gravel. The Alachua is thus described by Matson and Clapp:<sup>580b</sup>

"The Alachua clay is known to occupy depressions such as sinks and gullies in the Oligocene and probably also in the Miocene beds. Observations made by Dall along the banks of Peace River have established the fact that a bone bed ('Peace Creek bone bed'), which he correlates with the Alachua clay, rests upon older Pliocene beds. The relation between the Alachua clay and this bed on Peace Creek has not been observed, but they are believed to be lacustrine or fluviatile deposits which may have been formed at about the same time. The Alachua clay is also thought to be contemporaneous with a part of the Caloosahatchee and Nashua marls. It consists of blue to gray sandy clay which weathers to light yellow or red from the presence of iron oxide. There is usually sufficient clay to give the material a distinct plasticity, and sand is commonly present in considerable quantities. The weathered material is frequently more or less concretionary as a result of the aggregation of the iron oxide. The formation is nearly destitute of fossils except in a few localities where it is filled with vertebrate remains."

As the accumulations took place in depressions of the surface of the Oligocene beds, the thickness is variable. In places it is 15 feet or more, and the average thickness is probably not less than 10 feet.

The Bone Valley gravel, which comprises nearly all the pebble phosphates now being mined in Florida, derives its name from a locality west of Bartow, where the beds are exploited on a large scale. Eldridge designated this deposit land pebble phosphate, while Dall called it simply pebble phosphate, both writers distinguishing between the Tertiary deposits of Pliocene age and the younger pebble phosphates, which vary in age from Pleistocene to Recent. The deposits, according to Matson and Clapp,<sup>580i</sup> "are situated in the valleys of streams and vary in altitude from less than 25 feet to nearly 100 feet above tide. Lithologically the formation is composed of very poorly assorted materials, such as clay and phosphate pebbles, which usually show some evidence of stratification. \* \* \* The poor assortment of the materials and the absence, locally, of distinct stratification point rather to fluviatile than marginal origin. It is, however, probable that some of the deposits were made in the margin of estuaries. The presence of such organic remains as bone fragments and shark's teeth is readily explained by the fact that the phosphatic gravels were derived from older formations in which such materials occurred.

"The Bone Valley gravel rests upon beds of Pliocene or older rocks, and the relation is probably unconformable, but the poor exposures make it impossible to observe contacts except in a few localities. For this reason it may not be safe to postulate an unconformity between the Bone Valley gravel and the underlying Pliocene marls, though the contact with the post-Pliocene beds is certainly unconformable. \* \* \*

"While the exact correlation of this formation is somewhat uncertain, it is believed to be younger than the 'Arcadia marl' and older than the upper beds of the Caloosahatchee marl. It is probably in part contemporaneous with the Alachua clay. \* \* \*

"The exposures frequently reach a depth of more than 30 feet, without encountering the underlying beds, and hence the maximum thickness may be safely fixed at more than 30 feet. The average thickness, however, is probably lower and it may not exceed 15 to 20 feet."

West of Florida the presence of Pliocene rocks has not been definitely determined. It is probable that a portion of the 700 feet of strata above the *Rangia johnsoni* bed in the Mobile well is Pliocene. Berry examined outcrops and collected fossil plants in Alabama at a point

1 mile south of Lambert, Mobile County (elevation about 325 feet), and at Red Bluff, Perdido Bay (just above tide). He bases the following opinions <sup>a</sup> upon studies of the fossil flora:

"Red Bluff is obviously of the same age as the outcrop near Lambert and the same age as the bluffs on Mobile and Pensacola bays. The flora, considered with that of the locality near Lambert, is decidedly modern in its facies as compared with the other so-called 'Grand Gulf' outcrops which contain fossil plants, the difficult question being to differentiate between Pliocene and early Pleistocene. The flora is a mixture of swamp types and those of live-oak barrens and indicates climatic conditions such as occur along the Gulf coast to-day, as, for example, on the Santa Rosa Peninsula.

"In the absence of any American floras for comparison I am disposed to regard the age of the deposits as Pliocene, as the species are nearly all extinct and embrace positively identified genera (for example, *Trapa*) which no longer occur in North America."

The Lafayette formation was first discriminated by E. W. Hilgard in 1855 and 1856, and named by him in manuscript from Lafayette County, Miss., but the name was not published until 1891. This formation was included in the Orange sand of Safford in Tennessee and the Orange sand of Hilgard in Mississippi. In 1888 McGee <sup>565a</sup> applied the name Appomattox to the formation from "the river of typical development in the middle Atlantic slope." McGee's name Appomattox antedates the publication of Hilgard's Lafayette by about three years, but a fact that is perhaps more to the point is that the recent studies of Berry, Lowe, and others around Oxford, Miss., have shown that exposures in Lafayette County, formerly regarded as typical Lafayette formation, are of Wilcox (Eocene) age, rendering very doubtful the propriety of applying the name to deposits of probably late Pliocene age. The nomenclature has, therefore, been unsettled by the attempt to supplant McGee's Appomattox and must temporarily be regarded as only tentative. From the evidence now in hand it seems probable that the term Lafayette for the deposits presently to be described will have to be abandoned, and McGee's Appomattox be revived. However, McGee's usage in his paper "The Lafayette formation" will be followed here.

According to McGee, <sup>566a</sup> "In composition the Lafayette formation is a bed of loam, sand, and gravel, with several minor elements, notably kaolin or kaolinic clay, comminuted silica or siliceous clay, etc. The clay element of the loam and much of the sand are evidently residua derived from decomposition of a variety of older rocks, the local characters generally reflecting the characters of local terranes; the gravel and a part of the sand represent the terranes traversed by the upper reaches of the rivers along which they are found; and the gravel varies in abundance and size with the volume, declivity, etc., of these rivers.

"In geographic distribution the Lafayette formation coincides approximately with the Coastal Plain of the southeastern United States. In hypsographic distribution the formation ranges from altitudes of 700 or 800 feet to probably some distance below tide level.

"In thickness the Lafayette deposits range from a mere veneer over many interstream tracts to 200 feet or more about the mouth of the Mississippi; and in general the thickness varies directly with the volume of neighboring rivers and inversely with the inland extension. The formation has, however, been degraded from considerable areas, particularly along the larger waterways.

"In structural relation it is separated from the newer Columbia formation by the strongest unconformity of the Coastal Plain, an unconformity representing degradation of probably half the volume of the Lafayette formation and profound trenching of subjacent formations along the larger waterways; and it is separated from all of the underlying formations by a noteworthy unconformity of such character as to indicate that during pre-Lafayette time the Coastal Plain was a land surface and was wrought into a configuration much like that existing to-day.

---

<sup>a</sup> Unpublished manuscript.

"In structural composition the formation is a unit, varying from place to place in local characters yet indivisible throughout its area of 250,000 square miles, save on arbitrary grounds."

The formation is important especially in the interstream areas across South Carolina, northern Florida, and each State from Georgia to southern Illinois.

#### PLEISTOCENE.

Marine Pleistocene deposits cover considerable areas along the coasts of South Carolina and Georgia and are greatly developed in Florida, where Pleistocene marls, coquina beds, and limestones underlie over half the present land surface of the State.<sup>a</sup>

Below the Lafayette level in the south Atlantic and Gulf Coastal Plain States are several persistent terraces above the present flood plain, representing McGee's Columbia group. From Georgia to Tennessee there are at least two—(a) one major terrace between the Lafayette and the "second bottoms" and (b) the "second bottoms." The loess of the Mississippi seems correlative with the major terrace below the Lafayette level. The terraces slope coastward and merge with shallow-water and estuarine deposits, to which in Louisiana Hilgard has applied the name Port Hudson group.

#### H-J 13-14. GREAT PLAINS, COLORADO, KANSAS, OKLAHOMA, NEW MEXICO, AND TEXAS.

Darton <sup>238a</sup> maps the Miocene (Ogalalla and Arikaree formations) southward from Nebraska (see p. 822) through Colorado and Kansas into Oklahoma, Texas, and New Mexico. The following notes are taken from a paper by Gould:<sup>373c</sup>

Lying unconformably upon the surface of the red beds and Cretaceous over a large part of western Oklahoma is an extensive deposit of Tertiary rocks, the exact age of which has never been determined with accuracy. Paleontological evidence is rare, but, following the usual classification of beds of apparently the same age in western Kansas and Nebraska, there seems no valid reason for not considering them Miocene or Pliocene. \* \* \*

With the exceptions of the alluvium and sand hills the Tertiary is the uppermost formation in Oklahoma. The red beds underlie it, except that between the red beds and the Tertiary occur sometimes Comanche Cretaceous members. \* \* \*

In general the later Tertiary occupies the uplands of the western half of Oklahoma, almost always occurring on the high divides between the streams. \* \* \*

The Tertiary consists for the most part of clay, sand, and gravel. These materials are in no regular stratigraphic succession. \* \* \* In places the entire thickness of the formation is clay; again sand and gravel predominate, and often deposits of different character will be interbedded. \* \* \*

The clay is usually white or pinkish and sometimes forms steep banks or cliffs along the bluffs or around the heads of canyons. To the harder ledges the name "mortar beds" has been applied. \* \* \*

The sand is of various degrees of fineness and is composed for the most part of quartz, although other minerals are present. The grains, when examined under the microscope, are usually rounded. \* \* \*

"Tertiary pebbles" is the term usually applied by geologists to the smooth, rounded, waterworn pebbles scattered abundantly over the slopes and points throughout western Oklahoma and Kansas. These pebbles have been washed out of the Tertiary deposits, of which they often constitute a moderately large proportion. They are frequently cemented together and form a hard conglomerate rock known as Tertiary grit, which on exposure forms conspicuous ledges. \* \* \*

<sup>a</sup> For detailed information see papers on Florida by Sanford <sup>693</sup> and Vaughan. <sup>835</sup>

The pebbles are of all sizes, from coarse sand to stones several inches in diameter. Quartz is the principal mineral, granite, feldspar, and other minerals also being present. \* \* \*

It is probable that the Tertiary deposits at one time covered the entire western part of Oklahoma. The valleys of the present streams have been carved in these deposits, and in many parts of the Territory all traces of the Tertiary are gone, except scattered quartz pebbles.

The thickness of the formation varies with the locality, being greatest on the high divides. Throughout a large part of western Oklahoma its thickness averages 100 feet or more, while in a few localities distant from the streams it may reach as much as 300 feet. On the other hand, in a great many places there is but a thin blanket of the deposit over the red beds.

#### I 10-11. SANTA BARBARA COUNTY AND SOUTHERN CALIFORNIA.

Arnold and Anderson<sup>32</sup> thus describe the Monterey shale (Miocene) in the Santa Maria oil district, California:

A great series of fine shales, largely of organic origin, overlies conformably the coarse and fine sedimentary deposits of the Vaqueros. These shales make up the Monterey formation and are representative of the whole of middle Miocene time. The formation is of great thickness and is doubly important as the probable source and the present reservoir of the oil. The areal extent of the Monterey is not adequately represented on the map. It doubtless covers as one continuous sheet the whole basin between the Santa Ynez and San Rafael mountains, as well as a large part of these ranges, but it is covered over considerable areas by later deposits, which are in many places very thin. The character, structure, and relations of the Monterey have been the chief subject of the present study.

The name "Monterey" was given by William P. Blake<sup>a</sup> in the early fifties to an organic shale formation typically developed in the vicinity of Monterey, in Central California. It is very extensive in the California Coast Ranges, being the "bituminous shale" series described by Whitney in the reports of the Geological Survey of California as occurring at widely separated points north and south of the Golden Gate. Its age is generally considered to be middle Miocene. It is the source of much of the petroleum found in California. The shale that characterizes this unique formation is not similar to ordinary clay shale but is composed largely of the remains of minute marine organisms. In its unmetamorphosed condition it resembles chalk but is of siliceous instead of calcareous composition.

The Monterey in the part of California treated here may be divided on lithologic grounds into two parts, although there seems to be perfect conformity throughout the formation. There is no definite dividing line to be drawn, but taken as a whole the lower half, composed chiefly of hard, metamorphosed, in places flinty shales, is distinct from the upper half, in which soft shale, giving evidence to the naked eye of its organic origin, is predominant.

The following summary description of the stratigraphy of the Summerland district, Santa Barbara County, is quoted from Arnold:<sup>30</sup>

The formations involved in the geology of the Summerland district are 9,000 ± feet of conglomerate, sandstone, and shale of the Topatopa (Eocene); 4,300 ± feet of conglomerate, sandstone, and shale of the Sespe (Eocene or Oligocene); 2,400 ± feet of sandstone and shale of the Vaqueros (lower Miocene); 1,900 + feet of shale and volcanic ash of the Monterey (middle Miocene); 1,000 + feet of conglomerate, sandstone, and clay shale of the Fernando (upper Miocene-Pliocene); and 50 + feet of gravel, sand, and clay of the Pleistocene—in all, 18,650 ± feet of sediments, practically all of Tertiary age. Unconformities occur between the Monterey and Fernando formations and between the latter and the Pleistocene.

<sup>a</sup> Proc. Acad. Nat. Sci. Philadelphia, vol. 7, 1855, pp. 328-331.

I-J 10-11. COAST RANGE, CALIFORNIA.

Lawson <sup>525</sup> states, in a paper on the geological section of the middle Coast Ranges:

The paper is an attempt to summarize recently acquired information as to the sequence of formations and their respective volumes of sediments in the middle Coast Ranges of California. The results given for the thickness are approximations sufficiently close to afford a general idea of the section. Other features of the paper are the subdivision of the Franciscan into seven stratigraphic subdivisions by the recognition of a persistent horizon of foraminiferal limestone and two important horizons of radiolarian chert; a similar subdivision of the Monterey into seven stages and a summary announcement of the character and history of the post-Monterey Tertiary. The essential features of the paper are given in the following tabulation:

*Geological section of the Coast Ranges of California in the vicinity of the Bay of San Francisco.*

In the hills west of Tulare Lake, southern California, lies the Coalinga oil district studied by Arnold and Anderson,<sup>34d</sup> who thus describe the post-Eocene formations:

The periods following the Eocene are here represented by a great series of sandstone, shale- and conglomerate beds, all tilted at about the same angle, having usually similar character, and presenting an appearance of conformity and intergradation. By means, however, of discontinuous fossil faunas, distinguishable lithologic groups, the absence in some places of formations or zones known elsewhere, as a result of erosion and the overlapping of later beds, and the appearance of fragments of older formations within younger ones, several important breaks

may be definitely made out, which prove the intervention of periods of time during which land conditions existed over wide areas or locally. The important post-Eocene formations that represent the epochs of submergence of the land in the area now occupied by the Coalinga district are the Vaqueros (lower Miocene), the Santa Margarita (?) (upper middle Miocene), the Jacalitos (early upper Miocene), the Etchegoin (late upper Miocene), and the Tulare (Pliocene and lower Pleistocene) formations. The Tulare formation is probably in large part of different origin from the others but is similar to them in the general features of its appearance. These formations are all united into one series in the monocline dipping down the east flank of Joaquin Ridge in the northern part of the district and again in the monocline dipping away from Reef Ridge in the southern portion, but the character of the series is not entirely the same in the two regions.

In the northern part of the district the base of the Miocene-Pliocene is formed of coarse and fine oil-impregnated sands unconformably overlying the whitish and purplish petroliferous Eocene (Tejon) shales, these sands being overlain by prominent sandstone beds (the "reef beds"), a prominent zone of white siliceous shale (the "indicator"), and soft sand up to the base of a zone of bluish-gray and variegated clay, sand, gravel, and serpentine detritus locally known as the Big Blue. Up to this point the beds are fossiliferous, have a thickness of about 550 feet, and are mapped as Vaqueros (lower Miocene). The Big Blue has a thickness of about 300 feet and is nonfossiliferous. It corresponds in stratigraphic position to the Monterey shale (middle Miocene) of regions nearer the coast, but nothing has been discovered to indicate that it may belong to that formation. It is overlain by a thickness of about 175 feet of sand, sandstone, and conglomerate beds full of immense oysters, barnacles (*Tamiosoma*), scallop shells (*Pecten*), and other fossils. These fossiliferous beds will be referred to as the *Tamiosoma* zone. They are overlain by 400 to 500 feet of sand and gravel beds up to the base of a very prominent gravel zone full of petrified wood. The beds from the base of the Big Blue up to this point are mapped as the Santa Margarita (?) formation (upper middle Miocene). The gravel zone with fossil wood forms the base of a succession of sand, sandstone, gravel, and clay beds extending up to the base of a prominent zone of bluish-gray sand beds having near their base a rich fossil bed, the *Glycymeris* zone. The succession of beds up from the base of the fossil-wood gravel zone to this point has a thickness of about 1,600 feet and is mapped as the Jacalitos formation (early upper Miocene). The fossil bed (*Glycymeris* zone) and bluish sands immediately overlying grade upward into sand and clay beds, the whole forming a thickness of about 1,700 feet, which is mapped as the Etchegoin formation (uppermost Miocene), and this finally is overlain by poorly exposed coarse gravel deposits, which are mapped as the Tulare formation (Pliocene-lower Pleistocene). The total thickness of the succession in the Coalinga field thus outlined is about 4,600 feet, exclusive of the Tulare formation, which can not be measured in this portion of the district.

In the southern part of the district the basal portion of the Miocene-Pliocene series consists of about 700 to 900 feet of steeply dipping hard sandstone and conglomerate beds forming the face of Reef Ridge. These overlie, with an important though usually not apparent unconformity, the shale of the Tejon (Eocene) and are locally petroliferous. At the summit they grade into softer beds which are overlain by hard siliceous shale. Up to this shale the beds are fossiliferous and are mapped as the Vaqueros formation. The overlying shales are hard and whitish, form a prominent zone varying up to 1,200 feet in thickness, and are mapped as Santa Margarita (?), although only tentatively referred to that formation. These shales are overlain by a great succession of beds of sandstone, shale, sand, clay, gravel, and conglomerate of many varieties, having a thickness as measured in a section south of Big Tar Canyon of about 9,500 feet. This succession is divided on the map, on the basis of criteria to be discussed later, into three approximately equal divisions corresponding to the formations in the north, namely, the Jacalitos (early upper Miocene), Etchegoin (uppermost Miocene), and the Tulare (Pliocene-lower Pleistocene). The total thickness of the Miocene, Pliocene, and lower Pleistocene series measurable in the above-mentioned single section is over 11,000 feet.

The following table, from Arnold and Anderson's report,<sup>34</sup> gives a correlation of the Mesozoic and Cenozoic formations of the California Coast Range:

*Tentative correlation of formations of Coalinga district with the standard California Coast Range section and those of other localities in California.*

| Era.      | Sys-tem.    | Series.                                                                                                                                | Standard Coast Range section.                                                          | Coalinga district section.                                                                   | Santa Maria district section.                                                     | Santa Clara Valley (Ventura County) section.                                      | Los Angeles and Puente Hills section.                                             | Santa Cruz Mountains section.                                                     |                                                                                   |

## J-K 11. NEVADA, OREGON, AND IDAHO.

The Miocene and Pliocene sediments of Nevada and adjacent parts of Oregon and Idaho have been described by King under the names Truckee and Humboldt, respectively, and Cope has applied the name Idaho formation to certain Pliocene deposits. King<sup>505g</sup> postulates an extensive lake (Pah-Ute Lake) and says:

The beds of this lake, to which, in the Fortieth Parallel area, I have given the name of Truckee Miocene, are made up of, first, detrital rocks and gritty sandstones, with more or less conglomerate, never over 150 feet. Over this lie about 250 feet of palagonite tuff, which, for reasons already described, is referred to the age of the augite andesites; over this, 250 to 300 feet in Nevada, with a greater thickness in Oregon, of infusorial silica, followed by 120 feet of sandy, gritty rocks, purely detrital, but containing always a considerable amount of infusorial silica, succeeded by a fresh-water limestone of about 60 feet, in its turn succeeded upward by 250 feet more of detrital grits, which give way to an enormous formation of volcanic tuffs of the trachytic period. The thickness of these trachyte muds in Nevada can not be less than 2,000 or 3,000 feet; in Oregon, according to the observation of Prof. Marsh, they are even more fully developed. It is in these volcanic muds that the enormously abundant Miocene fauna of this lake is mostly entombed. Out of the grits overlying the limestone in Nevada have been obtained teeth of a rhinoceros, probably *R. pacificus*.

At the close of the Miocene, according to King, the Truckee strata "were thrown into bold folds, their dips reaching angles of 30°." Louderback<sup>547a</sup> recognizes "a certain amount of deformation in later Tertiary."

Ball<sup>54a</sup> gives an account of the relations of igneous rocks and lake beds in southwestern Nevada and eastern California, from which the following partial columnar section and extracts are taken:

*Columnar section [in part] of rocks of southwestern Nevada and eastern California.*

The Tertiary rocks include a number of igneous rocks, lava flows, and fewer intrusive masses, and sediments laid down in lakes. \* \* \*

The oldest of the Tertiary rocks is a rhyolite which occurs in Stonewall Mountain. This occupies a similar stratigraphic position with rhyolites in the Panamint Range, in the Randsburg district, and near Daggett in the Mohave Desert, which, according to Spurr, lie beneath "lake beds which are probably, in part at least, Upper Eocene." This rhyolite in Stonewall Mountain is cut by dikes of quartz monzonite porphyry and quartz syenite, which are probably

contemporaneous with monzonite porphyry, quartz monzonite porphyry, hornblende-biotite latite, and biotite andesite of other ranges. These rocks are in part intrusive masses and in part flows. Prior to the succeeding extrusion of rhyolite these rocks \* \* \* were eroded, unconformities being observed in the Kawich, Amargosa, and Cactus ranges, in the Bullfrog Hills, and in Shoshone and Skull mountains. Then followed an extrusion of rhyolite, with minor siliceous latites and dacites, which was attended by insignificant basalt flows. This period of extrusion of rhyolitic lavas, the most important in this portion of the Great Basin, was not, however, strictly contemporaneous over the whole area. \* \* \* This rhyolite is everywhere separated from the Siebert lake beds by a marked erosional unconformity, and in the Kawich and possibly in the Cactus Range it is separated by an erosional unconformity from the succeeding andesites. The next younger igneous rocks \* \* \* are basic andesites. These two rocks were found in contact only in the area covered by the Goldfield special map, and here Mr. F. L. Ransome found dacites intrusive into the andesites. The succeeding igneous rocks are rhyolites and siliceous latites and dacites which occur only in the Goldfield and Southern Klondike hills and the Silver Peak Range. In the latter two localities at least these rocks are interbedded with the Siebert lake beds without erosional unconformity.

Thick masses of sediment occur in the majority of the ranges of the area and on lithologic and stratigraphic grounds are correlated with the Siebert lake beds of Miocene age at Tonopah described by Spurr. These tuffaceous sandstones and conglomerates, largely composed of rhyolitic material, reach an observed maximum thickness (in the Amargosa Range) of 1,150 feet. \* \* \*

The succession of the lavas of the Great Basin has recently been treated at length by Spurr.<sup>a</sup> His succession for the petrographic province of the Great Basin and that of the writer for the portion of that province here treated are practically identical. Both assign the first rhyolite to the end of Cretaceous and to Eocene time. It is believed, however, from the length of time indicated by the complex history of extrusion and erosion intervening between this rhyolite and the deposition of the Siebert lake beds, that the monzonites and acidic andesites may well also be in part Eocene, while the second rhyolite is believed to be largely of early Miocene age. The andesite and dacite are also of comparatively early Miocene age, while the third rhyolite covers the middle and late Miocene and early Pliocene. The basalts range in age from late Miocene to Pleistocene, the major extrusions occurring in late Pliocene and Pleistocene time. As to the genetic relations of the magmas, the writer is wholly in accord with the views of Spurr in the article already cited. He believes that the Tertiary lavas of the Great Basin are the representatives of two complete cycles of the differentiation of a magma of medium composition into acidic and basic lavas and that probably the end of a still earlier cycle is also represented.

#### K 10. NORTHERN CALIFORNIA.

Miocene and Pliocene deposits occur in the old valleys of upper Sacramento and Trinity rivers, on the southeastern slope of the Klamath Mountains and west of Lassen Peak. They comprise auriferous gravels, fresh-water sediments with some coal, allied to the Ione formation, and tuffs. These deposits have been described by Diller,<sup>272, 276a</sup> Anderson,<sup>28</sup> and Hershey.<sup>436</sup>

#### K 11-12. NEVADA, UTAH, AND IDAHO.

Only the later Tertiary (Pliocene) is represented in the northern and eastern parts of the Great Basin. King<sup>505f</sup> states:

Along the western base of the Wasatch a portion of the terrace country, rising to 700 or 800 feet above the level of the lake, is composed of loose, friable Tertiaries, carrying very

---

<sup>a</sup> Spurr, J. E., Jour. Geology, vol. 8, 1900, pp. 621-646.

recent fresh-water mollusks, the genera at least being chiefly the equivalents of existing types. These beds along the western base of the Wasatch are approximately horizontal. Three considerable depressions east of the main ridge of the Wasatch—Morgan, Cache, and Ogden valleys—which unquestionably represent bays formerly connected with the main Pliocene lake west of the Wasatch, have been receptacles of Pliocene sediments very similar to the fragments of horizontal Pliocene terraces on the west base of the Wasatch. They are all characterized by recent genera of fresh-water mollusks. The height of the Tertiary in all these valleys reaches a full thousand feet above the level of Salt Lake.

With the exception of terrace masses along the western base of the Wasatch, which for the most part are deeply covered by Quaternary deposits, the valley of Salt Lake carries a sheet of Quaternary, through which rise masses of Paleozoic and volcanic rocks. The northern boundary of this great basin is beyond the limits of our map but has been crossed by us in several places, and the members of the exploration have been unanimous in referring to the Pliocene period a considerable series of horizontal rocks which occupy a divide between the waters of the Utah Basin and those of Snake Valley. These rocks are composed chiefly of friable gray, white, and drab sandstones and marly limestones, for the most part horizontal but in places uplifted at low angles. At the northwest boundary of the Salt Lake Basin, near the one hundred and fourteenth meridian, at latitude 40°, are further exposures of horizontal Pliocene rocks, which rise to altitudes of 1,000 to 1,800 feet above the level of the basin.

#### K 13-14. NORTHERN GREAT PLAINS, WYOMING, NEBRASKA, AND SOUTH DAKOTA.

The lower Miocene of the northern Great Plains in the United States is the Arikaree formation, including locally the sediments to which the names Gering, Monroe Creek, and Harrison have been applied.<sup>623k</sup> The Arikaree rests on the Brule clay (Oligocene), in some places unconformably, and is unconformably overlain by the later Miocene Ogallala formation.

Darton<sup>234, 235</sup> originally described the Gering as a distinct formation, rather than as part of the Arikaree. The deposit is locally developed and consists of coarse sands and soft sandstones which contrast with the finer sediments of the Arikaree. It is now<sup>238c</sup> interpreted as a river deposit laid down in the channels of early and possibly somewhat later Miocene streams. Osborn<sup>623l</sup> says:

The typical Gering formation of Darton, 1899, is at Scotts Bluff, western Nebraska; the broad extension by Darton of this formation to other localities is somewhat doubtful. The name Gering formation as used by Darton, Hatcher, and Peterson probably applies to noncontinuous river sandstones and conglomerates (maximum 200 feet), which are in a manner analogous to the "Titanotherium," "Metamynodon," and "Protoceras sandstones" that traverse the lower Arikaree clays or finer beds and partly erode irregular channels in the upper Brule clay (Leptauchenia zone). This formation is thus probably of the same age as the lower parts of the Arikaree, Monroe Creek, and Rosebud. Its known fauna is very limited. The so-called Gering of Hatcher and Peterson is in southeastern Wyoming and northwestern Nebraska; in their section it is said to be lithologically similar to the overlying Monroe Creek.

The typical Arikaree formation of Darton, 1899, is at Pine Ridge Bluffs, in South Dakota; whether or not this extends to southeastern Wyoming rests on future paleontological correlation. The Arikaree as described and mapped by Darton would broadly include the whole of the Rosebud formation of Matthew, as well as the Monroe Creek and Harrison, and broadly cover the whole of the Miocene. The entire Arikaree formation of Darton consists of finer materials, whitish or light-buff sandstones, more continuous and widespread, lying either on the Gering formation or on the Brule clay.

*Approximate correlations of the Arikaree formation.*

<sup>a</sup> Estimated.

Darton<sup>238d</sup> described the Arikaree and Ogalalla as follows:

A large portion of the higher lands of western Nebraska and southeast Wyoming extending south from Pine Ridge is capped by sands and soft sandstones which have been designated the "Arikaree formation." It is the principal component of the series formerly termed "Loup Fork." Generally it lies unconformably on the Brule clay but overlaps the margins of that formation in some portions of the area. It attains a thickness of over 800 feet in southeast Wyoming and, judging from the occurrence of outliers, formerly extended far up the slopes of the mountains to the north and west.

The predominant material is sand loosely cemented into a soft sandstone. The colors vary from white to light gray. Characteristic, partly calcareous concretions occur throughout the formation and greatly predominate in its lower members. They are mostly of elongate cylindrical form, usually occurring in layers connected to a greater or less extent into irregular sheets. \* \* \* From observations by Profs. Barbour and Fisher it has been found that these concretions are due to the growth of calcite crystals in certain portions and layers of the sandstone.

In studying the geology of North Platte Valley in west Nebraska it was discovered that the Arikaree deposits were overlain unconformably by deposits of sand, gravel, and calcareous grits, which, on being traced south, were found to be the north extension of the Tertiary grit and mortar beds of the Kansas and east Colorado region. They were given the local designation Ogalalla formation.

The materials of the Ogalalla formation are mainly sands, merging into gravels, and gravelly sands more or less cemented by carbonate of lime into a grit rock which often has the appearance of rough mortar, from which the name "mortar beds" is derived. Sometimes the lime rock contains but little sand, and usually it varies from grit to conglomerate or conglomeratic grit.

The original descriptions of the Monroe Creek and Harrison are by Hatcher,<sup>413</sup> as follows:

Returning to the Arikaree formation, I have already remarked that in Sioux County, Nebr., and Converse County, Wyo., it is lithologically and faunally divisible into two easily distinguishable horizons. Commencing below, these may be named and characterized as follows:

1. *The Monroe Creek beds.*—These are well shown in the northern face of Pine Ridge, at the mouth of the Monroe Creek canyon, 5 miles north of Harrison, Nebr., where they overlie the Gering sandstones and are composed of some 300 feet of very light-colored, fine-grained, not very hard, but firm and massive sandstones. On account of their usually barren nature they have been neglected by collectors, and very little is known concerning their fauna beyond the fact that toward the top they contain *Promerycochærus*. They decrease in thickness very rapidly to the eastward and increase to the westward.

2. *The Harrison beds.*—These are well shown in the bluffs of all the small streams that head near the summit of Pine Ridge, in the vicinity of Harrison, Nebr. They are also known to cover a considerable area to the east, west, and south of that village, extending well into the State of Wyoming. They are composed of about 200 feet of fine-grained, rather incoherent sandstones, permeated by great numbers of siliceous tubes arranged vertically rather than horizontally. They are further characterized by the presence, often in the greatest abundance, of those peculiar and interesting but as yet not well understood fossils known as *Dæmonelix*, and by a considerable variety of fossil mammals belonging to characteristic Miocene genera. They immediately and conformably overlie the Monroe Creek beds and pass insensibly into them.

Osborn<sup>623m</sup> distinguished the upper Miocene, comprising the *Procamelus* zone, and the "latest Miocene or first phase of the Pliocene," the *Peraceras* zone. He gave an extended homotaxis and synonymy.

#### K 18. LONG ISLAND.

Veatch<sup>837b</sup> mentions a possible occurrence of Miocene strata on Long Island as follows:

In the Long Island region and in the New Jersey region the Miocene sediments were deposited under similar conditions, and as these two areas have been subjected to the same forces, except glacial action, their distribution in both should be similar. The only bed thus far seen on Long Island which is regarded as possibly Miocene is a thin bed of "fluffy sand" which Mr. G. N. Knapp recognized in the upper part of the Melville section, and which is the counterpart of certain sands occurring in the Miocene of New Jersey. A comparison of the sections indicates that if this structure is normal, and there is every reason to believe it is, a Miocene outlier should be expected at this point. The same evidence shows the absence of the Miocene above sea level on southern Long Island, except possibly along a portion of the South Fluke. This line of argument is important, for it shows that the Tertiary deposits can not be expected on the north shore any more than in the Hightstown Vale in New Jersey, and that the occurrences on Long Island are probably limited to erosion outliers, with the embed beneath the Atlantic.

#### K 19. MARTHAS VINEYARD AND NANTUCKET.

Dall<sup>209a</sup> carefully examined the meager occurrences (too small to appear on the map) of Miocene strata on the islands of Marthas Vineyard and Nantucket and the collections which had been made from them and reported lists of species upon which he comments as follows:

It will be observed that this is a distinctly northern assemblage; any of the species might be at home in the waters about Gay Head to-day, as far as we can judge by analogy in the case of extinct species.

As regards correlation with the divisions of the southern Miocene it may be said (1) that the Gay Head Miocene is Chesapeake and not older; and (2) that it belongs in all probability to the upper part of the Chesapeake, certainly not lower than the St. Marys fauna, and probably between that and the Yorktown beds.

For a description of the strata see Chapter XV (pp. 682–683).

In regard to the Pliocene, Dall says that a small collection of shells (for list see the work cited) taken from a "layer of sand unconformably overlying the Miocene" appears to belong to a "more recent fauna than the Miocene and may perhaps be regarded as Pliocene."

## K-L 11. SNAKE RIVER BASIN, OREGON AND IDAHO.

The Payette formation of the Snake River valley is described by Lindgren<sup>537</sup> as follows:

During the earlier part of the Neocene (Miocene) a large fresh-water lake occupied at least the lower part of the Snake River valley, and its sediments are now prominent features of the region. For these lake beds the name Payette formation is proposed, and their age is determined as upper Miocene.

\* \* \* \* \*

It extends over large areas to the north of the Payette, along the flood plains of the Snake River, and is seen to occupy vast areas in Oregon between the mouth of the Owyhee River and Weiser, where the Snake River canyon begins. On both sides of the lower Snake River the bluffs of the Payette formation attain a height of over 800 feet. In the Payette Valley south of Emmett the sharply defined bluff of Payette beds rises 600 feet above the alluvium. Smaller masses, detached by erosion or uplifts, lie in the intermontane valleys, as far east as the Idaho Basin.

Along the Boise Mountains the Payette beds rest against the irregularly eroded and sharply sloping surface of the granite, and the top stratum attains a height of 4,100 feet. A total thickness of 1,000 feet is exposed near Boise, and wells bored show several hundred feet of similar strata below the surface. Over the larger part of its extent the formation lies nearly horizontal or dips only a few degrees. Near the mountains dips of 8° to 10°, generally westward, are noted, and the smaller detached masses in the intermontane valleys are still more disturbed, generally dipping westward at angles up to 50°.

\* \* \* \* \*

As might be expected from the character of the land mass from which the sediments were obtained, the latter consist chiefly of granitic, light-colored sands, locally cemented by hot-spring deposits to hard sandstones or clayey semiconsolidated sandstones. Heavy masses of conglomerates and gravels begin to appear at Table Mountain and reach their greatest development opposite the mouth of Boise River, in the high ridge extending in a westerly direction. Purely clayey deposits are rarer, occurring only in convenient sheltered locations near the shore line or in places where volcanic eruptions took place. The basal part of the formation contains, at Horseshoe Bend, Jerusalem, and other localities along the Payette, small coal seams. In the clay accompanying these coal seams vegetable remains are of frequent occurrence. The following forms were identified by Prof. Knowlton:

|                                                                                                                                                                                |  |                                                                                                                             |
|--------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|--|-----------------------------------------------------------------------------------------------------------------------------|
| <i>Sequoia angustifolia?</i> Lx.<br><i>Quercus consimilis</i> Newb.<br><i>Quercus simplex</i> Newb.<br><i>Acer trilobatum productum?</i> Heer.<br><i>Salix angusta</i> Al. Br. |  | <i>Platanus aspira?</i> Newb.<br><i>Ficus ungeri</i> Lx.<br><i>Ulmus speciosa</i> Newb.<br><i>Betula angustifolia</i> Newb. |
|--------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|--|-----------------------------------------------------------------------------------------------------------------------------|

\* \* \* \* \*

• From these data Prof. Knowlton draws the conclusion that the age is Upper Miocene, contemporaneous with the flora of the auriferous gravels and the Ione formation of California, the Lamar flora of the Yellowstone National Park, and the John Day formation of Oregon. The paleobotanical evidence confirms the conclusion, confidently drawn from the field work, that all these smaller detached masses of lake beds are of practically the same age.

During the time of the maximum extension of the Payette Lake its surface stood at the present elevation of 4,200 feet. Its deposits, over 1,000 feet thick near the shore, rested against the abrupt slope of the Boise Mountains and filled the old canyon of the Boise to the same depth. The canyon must have formed a fiord, the branches of which reached as far back as the Idaho Basin, and in which vast quantities of gravel and sand accumulated. Isolated occurrences of well-washed gravel on the summit of high ridges in the lower Moore Creek drainage, at elevations of 4,500 feet, confirm the above conclusions. The data are not at

present sufficient to determine the extent of the Payette Lake, though it is probable that it was confined to the Snake River valley, inclosed on the west by the Blue Mountains and on the east by the divide toward the Salmon River.

In a subsequent study Lindgren extended the observations on the Payette (Eocene?) and overlying Idaho (Pliocene) formation in the Snake Canyon region. Details of occurrence and notes on the fauna by Dall and flora by Knowlton are given in his report.<sup>539</sup>

Russell<sup>686</sup> gives the following sketch of the Payette formation in Oregon:

The Payette formation, which consists principally of unconsolidated sands, clays, gravel, etc., together with important beds of light-colored and frequently white volcanic dust, and which is widely exposed in southwest Idaho, extends westward into Malheur County, Oreg., where it forms a large portion of the surface. This formation was crossed during my reconnaissance in 1902 and again in 1903, but its entire extent in Malheur County can not as yet be stated. It occupies the Snake River valley, from near Owyhee northward beyond Ontario, and extends westward to a locality about 30 miles southwest of Vale. Similar beds occur also along the courses of Jordan and Succor creeks and in several other valleys. As exploration progresses it will probably be found that many of the valleys of Malheur County are floored to a depth of several hundred feet with soft unconsolidated deposits like those of the Payette formation and probably of the same or of approximately the same age. Whether all of these deposits are portions of one continuous formation, or were laid down in separate and contiguous basins, is not as yet determined. It is probable, however, that they were accumulated in much the same manner that beds of like character are now being spread out on the surface of the valleys of the same region by existing streams. In most of the sediments referred to as being analogous to the Payette formation, however, volcanic dust added materially to the depth of the deposits.

#### L 10. COAST RANGE OF OREGON.

Diller<sup>273a</sup> says:

The Miocene is widely distributed in western Oregon on both sides of the Coast Range. It occurs over a large part of the Willamette Valley \* \* \* and on the coast more or less continuously from Astoria to Coos Bay, and most likely beyond, with interruptions, to California.

Descriptions of local observations and identifications of fossils by Dall follow this general statement. A type section of the Miocene is exposed near Empire City, Oreg., from which the Empire formation takes its name. Diller<sup>275</sup> states that the Empire formation consists chiefly of sandstones and dark shales below with white shales above, in all not more than 500 feet thick at the type locality.

Dall<sup>211</sup> classifies the Empire formation in relation to the Astoria group as follows:

*Empire beds.*—From typical exposures near Empire City, Coos Bay, Oregon. \* \* \* These beds are well exposed between Pigeon Point and Fossil Point, 3 miles southwest of Empire City, and abut unconformably upon the Oligocene beds at Coos Head and the Eocene at Marshfield, in the same region. At Fossil Point they are overlain by the richly fossiliferous Pleistocene beds of the Coos conglomerate. So far as can be judged from the fauna collected, the Empire beds are the exact equivalent of the upper part of the Miocene beds at Astoria, called by Dall, in 1892, the Astoria sandstones, to distinguish them from the (Oligocene?) Astoria shales (formerly called Miocene), which conformably underlie them. The exact place of the Astoria shales in the column must await a better knowledge of the fauna. If the double use of the name

Astoria in this manner is regarded as objectionable, the name Empire beds might be taken for the sandstones.

Dall<sup>213</sup> has made an elaborate report on the fauna, with a discussion of the stratigraphy and the history of investigation of the Empire formation, particularly at Astoria.

#### L 10. CASCADE RANGE AND YAKIMA VALLEY, WASHINGTON.

The Miocene of the Cascade Range and Yakima Valley includes both sedimentary and igneous rocks, but the sediments consist largely of volcanic material. In order of age from older to younger the formations are the Taneum andesite, Yakima basalt, Guye formation (probably contemporaneous with the basalts), Keechelus andesitic series and Ellensburg formation. The following notes are condensed from the accounts by George Otis Smith: <sup>755, 758</sup>

The Guye formation consists of dark shale and gray sandstone, with some chert and limestone. It is interbedded with basalts and rhyolites. The formation is represented in a very small area near Snoqualmie Pass, in the Cascade Range, where it is sharply folded and has been intruded by granodiorite. The black shale contains *Platanus dissecta* Lesq., *Acer æquidentatum* Lesq., *Ficus* n. sp. cf. *F. artocarpoides* Lesq., and *Cinnamomum* n. sp., which are assigned by Knowlton to the Miocene.

The Ellensburg formation occurs extensively in the Yakima Valley. It is composed largely of volcanic sediments, occasionally but rarely containing pebbles of the underlying basalt. The greater part of the conglomerate bed is composed of pebbles of light-gray and purple hornblende andesite and of white pumice of the same composition, while the sandstones and shales consist of finely comminuted andesitic material. The composition of the conglomerate beds and the prevalence of stream bedding indicate that the formation is of fluvial rather than lacustrine origin. The original thickness can not be stated. Individual sections show 1,200 to 1,600 feet in localities where it is evident that the upper part has been removed. The Ellensburg formation carries a flora in which 15 specimens have been identified. Of these 12 or 13 are reported by Knowlton as occurring also in the Mascall beds of the John Day Basin, which are regarded as being upper Miocene.

#### L 10-11. JOHN DAY BASIN, OREGON, AND COLUMBIA PLATEAU.

Merriam<sup>590c</sup> describes the strata of the John Day Basin as follows:

Resting upon the Clarno formation and extending over the greater portion of the John Day Basin is a thick series of sediments which Marsh<sup>a</sup> called the deposits of the "John Day Lake." It has generally been referred to in geological and paleontological literature as the John Day beds. King<sup>b</sup> correlates this series with his Truckee beds as a part of the deposit of his Pah Ute Lake. In the statement regarding this correlation, King has, however, recognized Marsh's name, so that, if a correlation is attempted, Pah Ute should be displaced by John Day.

Nearly the whole of the John Day formation consists of ashy or tuffaceous materials. Only toward the top of the section do we find typical products of erosion. At Haystack, Spray, and in the lower end of Turtle Cove, good exposures show the highest portion of the series to be composed of 100 or 200 feet of hard, blocky tuff, below which is about the same thickness of sand and gravel. The gravels are in some places quite coarse, containing pebbles 4 or 5 inches in diameter. The sands sometimes show cross-bedding. Included in these deposits are worn

<sup>a</sup> Marsh, O. C., Am. Jour. Sci., 2d ser., vol. 9, 1875, p. 52.

<sup>b</sup> King, Clarence, U. S. Geol. Expl. 40th Par., vol. 1, p. 458.

fragments of bones and teeth, which probably represent forms similar to those in the beds immediately below.

Rhyolite flows are found toward the lower part of the Middle John Day at Bridge Creek, near the top of this division in Turtle Cove, and overlying what is probably Middle John Day on Pine Creek, about 3 miles northwest of Spanish Gulch.

The tuffs and ashes seem in some cases to have been worked over somewhat by air or water. At other points beds many feet thick have apparently been deposited directly, without much if any working over by either wind or water.

The source of the ash and tuff is as yet unknown. It probably came from vents not very distant from this basin of deposition.

Excepting the beds of sand and gravel near the top of the section, the stratification throughout the whole thickness of the John Day is very regular. Numerous beds of almost pure ash or tuff compose uniform, hard, and prominent layers, between which in the softer beds the regular deposition of thin layers is plainly indicated by delicate variations in color. Nodular layers, possibly produced in part by contained organic remains, are not infrequent in some localities, and small nodules are usually scattered through a large part of the Middle John Day.

\* \* \* \* \*

Without having accurately measured the John Day section, the writer would not be willing to consider the exposures north of the southern range of mountains as representing a thickness much greater than 2,000 feet. Perhaps it is not more than 1,500 feet thick. At Sheep Rock, near Picture Gorge, the whole section is shown rather sharply tilted, and all but the lower division would be included in the column between the cap rock and the level of the river. At Bridge Creek, also, the section includes the whole of the series. It may reach a thickness somewhat over 2,000 feet at that locality.

\* \* \* \* \*

Wherever the John Day is well exposed in the central and western portion of the basin, it seems to be divisible into three stages, which have been designated <sup>a</sup> the Lower, Middle, and Upper John Day.

The lower division consists usually of highly colored shale, which breaks down readily, forming characteristic mud-covered domes. These beds are in the main a deep red, with occasional alternating strata of buff or white ash. At Bridge Creek alternating beds of red, white, and green, occurring in a group of the typical hills of this division, form a striking feature of the landscape, the colored strata making sharply defined rings about the hills. At Clarno's Ferry numerous alternations of contorted and faulted red and white beds are splendidly exposed in prominent hills at the bottom of the section.

The beds of this group appear usually to show more deformation than those higher up in the series. This may be due in part to their being softer and having offered less resistance to disturbances than the more rigid strata above them.

The Lower John Day is almost barren of fossil remains at all points where it was visited and has never, so far as can be discovered, furnished many good specimens. Diligent search by the writer at several localities has been rewarded by the discovery of two or three fragments of rhinoceros teeth. An *Oreodon* skull was found at this horizon, many years ago, by Mr. L. S. Davis, but definite information regarding it is not now obtainable.

The lower division was estimated to be 250 to 300 feet thick at Clarno's Ferry. Its maximum thickness will probably exceed that limit. It is not impossible that the Lower John Day will some time be found to be separated by an unconformity from the middle division. Such fossil remains as have so far been found in it indicate, however, that it belongs to the John Day series.

The middle portion of the John Day section at Bridge Creek, Clarno's Ferry, and Turtle Cove consists of drab to bluish-green beds, sometimes forming rounded hills but more frequently

<sup>a</sup> Merriam, J. C., *Science*, new ser., vol. 11, Feb., 1900, p. 219.

exposed as steep, pinnaced, and ribbed bluffs. Nodular layers and thick beds with small nodules scattered through them are common in this group, while they are rare, if not entirely absent, in the lower division and are not common in the uppermost beds. The strata of this group are never so sharply contorted as those of the lower division, though they may stand at a fairly high angle and may show considerable faulting.

This stage has probably furnished more fossil remains than the upper division, partly because the remains are here frequently found in hard nodules, which have protected the bones and held them together.

At Bridge Creek a rhyolite flow is interbedded with the lower part of the Middle John Day or possibly separates it from the lower division. In Turtle Cove a similar flow is found at the top of this division and possibly separates it from the upper group. At many places, particularly in Turtle Cove, hard beds of white to greenish ash and tuff are intercalated between the softer and usually more fossiliferous strata.

The middle division is at least 500 feet thick in Turtle Cove and possibly as much as 800 to 1,000 feet at Bridge Creek.

At most John Day localities, including Bridge Creek, Turtle Cove, and the entire region of the North Fork, the uppermost beds in the section are buff tuffaceous or ashy deposits, sometimes with sand and gravels near the top. These beds show a thickness of at least 300 to 400 feet and perhaps much more in some localities.

\*       \*       \*       \*       \*       \*       \*       \*       \*

This division contains the only typical sands and gravels in the John Day, and the only known remains of fresh-water Mollusca occur here. Excepting a single leaf, the only plant remains known to occur in the series are in the upper division.

While it has not been possible for the writer to draw sharp lines between the divisions discussed, the lithologic characters are in general sufficiently well marked so that one is enabled to determine the horizon in the series to which beds in question belong.

\*       \*       \*       \*       \*       \*       \*       \*       \*

The John Day beds are usually slightly disturbed. They are generally tilted  $5^{\circ}$  to  $10^{\circ}$ . From the observations made by the writer, no definite system of folds could be made out, though there seem to be several which trend east and west. Faulting is not uncommon and in some places there has been much friction along the fault planes, so that the soft beds have been changed into hard slate bands several inches in thickness. Both the normal and reverse types of faults are represented. Toward the west end of Haystack Valley a break of unknown extent brings what are probably Middle John Day strata up to the level of the highest beds of the series. At another locality, some miles east of this point, numerous thrusts are beautifully shown in cliff sections. Along the North Fork two systems of fractures were noticed. One trends north and south and the other appears to cross it at nearly a right angle.

As has already been indicated, the series is evidently unconformable upon the Clarno.

In the whole of the region occupied by John Day north of the southern range of the Blue Mountains, it is covered by the Columbian lavas, being accessible only in the deep canyons, where it has been exposed by extensive stream corrasion. At every locality in the basin where the series can be seen, its relations to the overlying formations are beautifully shown. In several places, notably at Sheep Rock in the upper end of Turtle Cove, and on the main river below Spray, residual hills in the middle of the valley are capped by portions of the lower flows, which have served to protect the softer beds beneath.

The Columbia lavas are in some places seen to be decidedly nonconformable to the John Day. Near Haystack the fossil beds form a fairly sharp anticline below lavas which are almost horizontal. At Clarno's Ferry lava flows are seen at one locality to rest upon the middle beds, the typical upper divisions being absent.

The strata thus described are tabulated by Merriam and Sinclair<sup>591</sup> as follows:

*Stratigraphic succession of the Cenozoic formations in the John Day Basin.*

| Age.                 |                        | Section in the John Day Basin.                                                                                                                            | Correlatives.                                                                                          |
|----------------------|------------------------|-----------------------------------------------------------------------------------------------------------------------------------------------------------|--------------------------------------------------------------------------------------------------------|
| Quaternary.          |                        | Terrace deposits with Equus and Elephas remains.                                                                                                          | Later half of Quaternary.                                                                              |
|                      |                        | Erosion interval (tilting of the Rattlesnake and erosion of John Day Canyon).                                                                             | Sierran (?).                                                                                           |
| Pliocene.            |                        | Rattlesnake formation (tuffs, gravels, ashy soil, and rhyolitic lavas).                                                                                   | Not determined.                                                                                        |
|                      |                        | Unconformity (tilting and erosion of the Mascall).                                                                                                        |                                                                                                        |
| Miocene.             | L a t e r Miocene.     | Mascall formation (tuffs, ashes, and possible gravels).                                                                                                   | Pawnee Creek beds, Colorado; Deep River beds, Montana; Ellensburg formation, Washington. <sup>a</sup>  |
|                      | E a r l i e r Miocene. | Columbia lava (basalt and interstratified basaltic tuffs).                                                                                                | Yakima basalt, Ellensburg quadrangle, Washington.                                                      |
|                      |                        | Unconformity. Slight folding of the John Day. Interval of erosion.                                                                                        | Harrison formation.<br>Monroe Creek formation.<br>Rosebud formation.                                   |
| Oligocene.           |                        | Upper John Day (mainly buff-tinted tuffs; sands and gravels near top).                                                                                    |                                                                                                        |
|                      | John Day series.       | Middle John Day (drab and bluish-green tuffs).                                                                                                            |                                                                                                        |
|                      |                        | Lower John Day (red, white, and green tuffaceous shales).                                                                                                 |                                                                                                        |
| Unconformity         |                        |                                                                                                                                                           |                                                                                                        |
| Eocene.              |                        | Clarno formation (shales, tuffs, andesitic and rhyolitic lavas). Osborn<sup>623j</sup> gives the following résumé of the Oregon Tertiary as a whole :

The known mammal fauna of Oregon, as determined partly by Cope and Wortman and more precisely as to levels by Merriam and Sinclair, is found on five levels, partly separated by volcanic overflows, as follows :

|                                                            |                                             |                        |
|------------------------------------------------------------|---------------------------------------------|------------------------|
| Rattlesnake                                                | =upper Miocene                              | =Procamelus zone.      |
| Mascall                                                    | =middle Miocene                             | =Merychippus zone.     |
| Upper part of John Day                                     | =transition, upper Oligocene, lower Miocene | =Promerycochærus zone. |
| Middle (fossils numerous) and (?) lower parts of John Day. | =upper Oligocene, second phase              | =Diseratherium zone.   |

The time of the beginning of the John Day deposition appears to correspond with that of the close of the Leptauchenia zone in the South Dakota region, namely, the upper Oligocene.

\* \* \* \* \*

The volcanic materials of the John Day were chiefly wind blown, as described by Merriam;<sup>a</sup> there is little evidence of fluvial conditions. The Mollusca are terrestrial or air breathing, with the exception of one locality which contains fluvial Mollusca. The Testudinata, genus *Stylomys*, are of the Testudo or terrestrial type; no fluvial types have been recorded. The so-called beavers (*Castoridae*) are not the true river-living beavers (Peterson).

The known fauna of the John Day formation as a whole is chiefly of open-forest and savanna-living type. We note the entire disappearance of the ancient fauna, *Creodonta-Hyænodontidae*, and do not observe the introduction or invasion from Eurasia of any new families of mammals. The major part of the John Day fauna is of upper Oligocene age, but in its latest phases it is perhaps transitional to lower Miocene. The fauna is thus broadly transitional between that of the White River group and the Arikaree formation.

\* \* \* \* \*

The lower John Day fauna is so little known that no deductions can be made from it, except that it appears to be closely related to that of the middle John Day. The faunistic comparison of the John Day formation therefore begins with the middle John Day, which is highly fossiliferous and slightly more advanced than that of the upper portion of the Brule clay and "Protoceras sandstones."

\* \* \* \* \*

The conclusion is that the middle John Day deposition partly overlaps and is partly sequent to the deposition of the upper part of the Brule clay and the "Protoceras sandstones."

\* \* \* \* \*

The upper part of the John Day formation, or *Promerycochærus* zone, of the Mountain region of Oregon, as well as the Gering and Monroe Creek formation of Hatcher, the Gering or lower Arikaree of Darton, the Rosebud of Matthew, all in the plains region of South Dakota, may be regarded as covering the transition between the Oligocene and Miocene epochs, as these divisions are employed in France. They resemble chiefly the upper Oligocene of France.

\* \* \* \* \*

It is concluded that the upper part of the John Day, for the present, may be somewhat arbitrarily separated as the American upper Oligocene, while the partly contemporaneous and partly sequent plains formations may be termed lower Miocene.

The Columbia River basalt (Miocene) is the dominant formation of the Columbia Plateau. Overlying it in Washington are the strata described by Russell<sup>684, 685</sup> as lake beds and assigned by him to the John Day formation, but apparently of later age. Russell states in his later report:<sup>685</sup>

In my report of a reconnaissance in central Washington certain lacustral deposits are described which rest on the surface of the latest extensive lava flow of the Columbia system. This series of lake sediments consists principally of stratified clays, with thick strata of white volcanic dust, and in certain localities contains beds of coarse conglomerate. It is termed the John Day system, for the reason that it is thought to be an extension of a similar formation which occurs in John Day Valley, Oregon. The connection between these two areas has not been actually traced, however, and the correlation just suggested must be considered as provisional.

Beds of light-colored clay and of white volcanic dust, which have been referred to the John Day system, occur at the White Bluffs of the Columbia, 30 miles above Pasco, and are also well exposed in Naches Valley and near Ellensburg, in Yakima County. At these localities the impressions of the leaves of a large variety of plants and the bones of extinct animals have been obtained. The plant remains indicate that the shores of the ancient lake into which they were

<sup>a</sup> A contribution to the geology of the John Day Basin: Bull. Dept. Geology Univ. California, vol. 2, 1901, pp. 269-314.

blown or washed by tributary streams were clothed in a varied and beautiful flora, resembling, in a general way at least, the vegetation of the South Atlantic and Gulf States at the present day. In the ancient forest and about the shores of the old lake, now known as Lake John Day, a veritable menagerie of strange and in part gigantic beasts found a congenial home.

From the White Bluffs of the Columbia southward to the region described in this report there are no barriers, but the surface of the country rises gradually from the broad valley of the Columbia to the basaltic plateau of northeastern Washington. From studies made along the Columbia in 1892, I was led to the conclusion that Lake John Day extended far eastward and covered nearly all of southeastern Washington, even to the base of the Blue Mountains. This view is now known to have been in part erroneous. The sediments of Lake John Day are but poorly exposed to the east of Pasco and Wallula, and their extent in that direction, although not clearly shown, is certainly far short of the Blue Mountains and of the Idaho boundary. They cover the Eureka Flats, however, as is shown by a well 198 feet deep at Eureka Junction, which is all in strata similar to those exposed in the White Bluffs of the Columbia but does not reach the bottom of the formation. Fossil leaves were found in the rock removed in digging the well, similar to those obtained from other portions of the John Day system. With the exception of the rocks found at Eureka Junction, no exposures of the Lake John Day system have been recognized in the region treated in this report. The sediment of the old lake does not occur above the Columbia lava in the vicinity of Walla Walla, Dayton, and Starbuck, and its eastern shore must have been to the west of these localities.

The lacustral deposits described in the preceding section as being interbedded with the Columbia lava are of about the same age as the John Day system and were accumulated under similar conditions. They should perhaps be included in the same system, but further study is necessary before a conclusion in this connection can be reached.

Knowlton made a report on plants collected by Russell from an outcrop near Ellensburg, later placed in the Ellensburg formation by George Otis Smith. (See p. 826.) Regarding the correlation Knowlton<sup>684a</sup> concluded:

The leaves from near Ellensburg, Wash., are preserved in a moderately soft white chalky matrix, that is in general very similar to the well-known material from the auriferous gravels of California and the John Day Valley in Oregon. \* \* \*

Of the ten species enumerated [for list see the work cited], seven, among which are the species most abundant in specimens and the most positive in identification, have been found in the auriferous gravels of California. Seven of the species have also been reported from the John Day Valley, Oregon, of which number three are common to the auriferous gravels. The new species (*Populus russelli*) has great affinities with Upper Miocene species of Europe.

From this examination it appears that there can be no doubt but that the plants from Ellensburg are similar in age to the auriferous gravels and the John Day Valley. The John Day Valley deposit has always been called Miocene. The auriferous gravels, on the other hand, were regarded by Lesquereux and others as Pliocene, but a recent examination of that flora based on extensive collections from Independence Hill, Placer County, Cal., seems to indicate that they also are probably upper Miocene in age.

#### L 12. WESTERN MONTANA.

Calkins, in an unpublished manuscript, has the following to say in regard to the Tertiary in the Philipsburg quadrangle, Montana, which applies equally well to adjacent areas of these rocks:

Rocks of Tertiary age apart from the intrusives occupy relatively small areas, chiefly in the valleys. The evidence at hand indicates that all these rocks are strongly unconformable. \* \* \* They lie on various older formations indiscriminately, are not metamorphosed by the intrusions, and are much less deformed than the Cretaceous and older sediments. The

quadrangle does not afford the best opportunity to determine the absolute age of the Tertiary formations, nor their relation to one another. \* \* \*

In Philipsburg Valley and Willow Creek valley there are exposures of light-colored silty material shown by microscopic examination to be chiefly volcanic ash. These correspond in character to beds well exposed near New Chicago, north of the quadrangle, in which Douglass has collected vertebrate fossils that indicate a late Miocene age. \* \* \*

The soft, pale-tinted, obscurely stratified volcanic ash beds, presumably of Miocene age, occur (1) at the north boundary of the quadrangle west of Flint Creek, (2) on Willow Creek near the west border of the quadrangle, and (3) in Philipsburg Valley with its southern continuation across the east fork of Rock Creek. These beds are perhaps the least resistant to erosion and the most poorly exposed in the quadrangle, being rarely uncovered except on steep slopes below the brinks of terraces capped by protecting gravel. Among the better exposures are some about 3 miles northwest of Philipsburg, whose whitish tint makes them visible from the town, and another in a gully about 1 mile north of Quinlan's ranch, at the head of Philipsburg Valley.

#### L-M 10. OLYMPIC PENINSULA, WASHINGTON.

The reconnaissance of the coast of the Olympic Peninsula in 1904 by Arnold<sup>29c</sup> led to the recognition of a formation covering parts of Oligocene and Miocene time, the Clallam formation. Arnold says:

Resting unconformably upon the Eocene and older rocks of the Olympic Peninsula is a series of conglomerates, sandstones, and shales rich in fossils and extensive in occurrence. The formation is well exposed in the region between Clallam Bay and Pillar Point, to the east, and for that reason is here named the Clallam formation. According to Dr. Dall, the fossils of the formation indicate that the basal portion of the series is Oligocene in age, while the upper part is certainly Miocene. Since the separation of the two members will necessarily have to be made on paleontologic grounds and will require a more detailed study of the material in hand than time has yet permitted, the term "Oligocene-Miocene series" will be used temporarily to designate the age of the beds. A portion of the formation is unquestionably the equivalent of the Astoria sandstones and shales occurring at the mouth of the Columbia River, 130 miles farther south.

All of the pre-Pleistocene deposits along Fuca Strait from Freshwater Bay to Cape Flattery, with the exception of the Eocene basalts and tuffs of Crescent Bay and the Pliocene conglomerate and sandstone of the Clallam Bay-Hoko River region, belong to the Oligocene-Miocene series, and at least the greater part and possibly the whole of the thick series of conglomerates, sandstones, and shales exposed in the Cape Flattery promontory, and also the sandstones and shales exposed in the hills south of the Bogochiel River, come under the same head. The thickness of this series as exposed in sections along the strait, which, by the way, virtually parallels the strike of the beds for most of the distance from Freshwater Bay to Neah Bay, is about 3,650 feet. The Waatch-Neah Bay section, which cuts directly across the strike of the great Cape Flattery monocline, exposes approximately 15,000 feet of conformable strata, most and possibly all of which may be Oligocene-Miocene.

The conglomerates of the series are usually quite coarse and hard and consist of pebbles and cobbles of quartzite, jasper, black slate, and occasional granitics. They are found mostly at the base and near the top of the series along the straits and in the middle of the series on the Cape Flattery promontory. The zone of conglomerate in the middle of the Cape Flattery section may be the equivalent of the basal conglomerates of the series as developed unconformably above the Eocene around Crescent Bay. If so, the sandstones at the base of the Cape Flattery section are older than any of the Oligocene-Miocene beds exposed on the strait. The base of the Cape Flattery section is unknown, as the lowest beds exposed in the section are separated from the subjacent rocks by a fault.

The sandstones of the Clallam formation are for the most part thin bedded, hard, and resistant to erosion and are extremely fossiliferous in certain localities, notably east of Clallam Bay. They are found at the base and near the top of the Cape Flattery section and below the upper conglomerates east of Clallam Bay.

The shale of the Oligocene-Miocene occurs principally in the middle of the formation along the strait. The lower part of the shale is thinly and plainly laminated, but higher up becomes almost massive clay. \* \* \* The overthrusting of the beds exhibited at [one] locality is very unusual, as the strata along this portion of the coast ordinarily lie in low simple folds. The shale is gray in fresh exposures but becomes more or less oxidized upon exposure. Sandstone dikes, probably derived from interbedded sandstones, cut the shales in the region east of the mouth of the Pysht River, and near Gettysburg hydrogen sulphide gas was noticed escaping from cracks in the shale along the beach. \* \* \* Fossils are abundant and beautifully preserved throughout the finer sediments of the series, at least two distinct horizons being recognized.

At least five recognizable faunas have so far been found in the Clallam formation. The oldest comes from the lowest clay shales of the series. [For lists see the work cited.]

Above the clay shale horizon is a series of medium-bedded to fine massive sandstones in which are found fauna apparently transitional from the clay shales to the coarse sandstones.

Still a third fauna [Miocene], later than the last, is represented by species found immediately east of Clallam Bay.

The fourth fauna is that found in sandstone layers interbedded with conglomerates in the upper parts of the formation.

The fifth fauna of the Oligocene-Miocene is that found at the mouth of the Sekiu River in beds the equivalent of the uppermost strata of the Cape Flattery section. The relation of this fauna to those [below it] is somewhat problematical, although it appears quite likely that the former is younger than most of the latter.

Correlations between the different fossiliferous localities of the Oligocene-Miocene series over the whole of the peninsula and Puget Sound region are comparatively easy, as are also correlations with certain of the Oregonian faunas such as those of the Astoria shales and sandstones, but when it comes to making direct correlations with the California or Alaskan faunas much difficulty is encountered. One of the greatest surprises the writer had in all of his work along the straits was his inability to find the characteristic upper Miocene fauna of the Sooke beds which are so well developed only 15 miles to the northward on Vancouver Island. With an almost unbroken series of Miocene faunas one would certainly expect to find the Sooke species somewhere among the lot, but such was not the case and no plausible explanation of their absence has so far presented itself.

#### L-M 11-12. LAKE BASINS OF WESTERN MONTANA.

The valleys which lie within the mountains of western Montana correspond throughout much of their extent with basins that are partly filled by sediments of Miocene and Pliocene age. The deposits were well described by Peale.<sup>632</sup> They were laid down in lakes, in large part at least, and comprise several types of sediment. The lowest are composed of material derived from the shores of the basins, from pre-Cambrian or Paleozoic rocks. They are succeeded by beds of volcanic ash, in part carried by wind and deposited in the lakes without admixture of foreign material, in part washed in from adjacent land surfaces. The sediments were locally covered by basalt. Peale's description applies to the Bozeman and Madison basins, in which the deposits exceed 2,000 feet in thickness.

Douglass<sup>287</sup> describes the general distribution of the Tertiary. In a later article<sup>288</sup> he distinguished the Sage Creek beds (Eocene?), White River formation

(Oligocene), and Fort Logan beds (upper Oligocene, John Day?). (See pp. 775-776.) The Miocene he assigned to the "Loup Fork," and recognized three divisions—Deep River beds (upper Deep River of Scott<sup>717</sup>), Flint Creek beds, and Madison Valley beds. Scott quotes from the first description by Grinnell and Dana (1875). (See Chapter XVI, p. 776.)

**M 12-13. CYPRESS HILLS, SOUTHWESTERN SASKATCHEWAN.**

McConnell<sup>558a</sup> gives the following notes on the Cypress Hills, in Saskatchewan:

The most interesting result of the geological examination of the district has been the discovery of an extensive area of Miocene beds, the first found in Canadian territory east of the Rocky Mountains. These beds cap all the more elevated parts of the range of uplands extending in a direction a little north of east, from the west end of the Cypress Hills to the east end of Swift Current Creek plateau, a distance of 140 miles. They have an average width of 15 miles, and cover altogether an area of nearly 1,400 square miles. They are unconformable to the beds below and in their western extension rest on the Laramie, but near East End Coulee they overlap it and are then underlain by the Fox Hill and Pierre. They have a general easterly dip of about 15 feet per mile, which is somewhat greater than that of the underlying beds, and in their eastern part are affected to some extent by the same depressed fold which has thrown the White Mud River Laramie area into a flattened form.

The Miocene beds are characterized by the great quantity of waterworn pebbles, derived from the quartzite formations of the Rocky Mountains, which are found in every part of the series. The pebbles are usually cemented together into massive beds of hard conglomerate but also occur distributed irregularly through or arranged in layers and lenticular beds in the sands and sandstones. The more massive conglomerate beds are found toward the western part of the area or around its outskirts. The associated beds, consisting of sands, sandstones, marls, and clays, are described in a previous part of the report. They are all very irregular, and seldom remain constant in composition for any distance along their strike.

\* \* \* \* \*

Under the general name of the South Saskatchewan gravels are included the pebble conglomerates and incoherent gravels and silty beds which are found, as valley or lake deposits, in different parts of the district and which, although destitute of organic remains so far as examined, are known by their relative position to be intermediate in age between the Miocene and Quaternary and to belong mostly to the period immediately preceding the latter. They are, however, not all contemporaneous and in one or two places afford evidence, by the admixture of Laurentian and quartzite pebbles toward the top, of a gradual blending with the lowest glacial beds. The deposit is usually confined to a single bed of conglomerate, varying in thickness from 2 up to 50 feet, composed of small quartzite pebbles, precisely similar to those found in the Miocene, and either consolidated by a calcareous or ferruginous cement, or with its constituents lying loose in a sandy matrix. In some places the conglomerate is overlain by a considerable thickness of sandy or silty beds.

Cope's report on the vertebrates<sup>558b</sup> is published as an appendix to McConnell's report.

**N 8-9. GRAHAM ISLAND, QUEEN CHARLOTTE GROUP.**

The Tertiary sediments of Graham Island are described by Ells<sup>316a</sup> as gray cross-bedded quartzose grits, having a calcareous cement and holding scattered pebbles; gray and black shales in thin beds; conglomerates; and lignites. The age of these sediments appears to be Miocene or later but is incorrectly shown as earlier Tertiary on the map of North America. (See also tabular view of formations of Queen Charlotte Islands, by G. M. Dawson, Chapter XII, p. 540.)

## N 10. UPPER PEACE AND FRASER RIVERS, BRITISH COLUMBIA.

Under the title Lignite group Dawson<sup>249b</sup> described the occurrences of sandstone and shale which carry lignite beds and commonly underlie the basalt flows of the upper Fraser Valley, British Columbia. At Quesnel they have yielded a flora of Miocene or earlier age associated with insects.

## N-O 4. ALASKA PENINSULA.

Atwood<sup>42c</sup> thus describes the Miocene of the Alaskan Peninsula:

Miocene sediments appear in Unga and Popof islands and at several places on the north and south sides of Alaska Peninsula. They consist of sandstones, shales, and conglomerates that represent off-shore, shallow-water deposition. An abundance of fossil material was procured and has been identified by Mr. Dall. At Coal Harbor, Unga Island, the Miocene strata conformably overlie the Kenai formation (upper Eocene), but at other localities the Miocene sediments appear to rest unconformably upon different formations and to have been restricted to local basins. They are but little disturbed.

One collection of fossil plants, from the Herendeen Bay district but from a lithologic unit that occupies a very small area, seems to indicate post-Miocene age. The most extensive post-Miocene formations consist of volcanic tuffs and basic lava flows. They are widespread on the mainland in the vicinity of the Balboa-Herendeen Bay district and cover many square miles in the islands to the south and in the region about Chignik Bay.

For Kodiak Island and Katmai Bay, see Chapter XVI (p. 784).

## O 4. BRISTOL BAY.

On the east shore of Nushagak Bay, which enters Bristol Bay from the north, Spurr<sup>771a</sup> observed strata to which he gave the name Nushagak. He says:

The high bluffs which form the east shore of Nushagak Bay are composed of stratified gravels, coarse sands, arkoses, and clays, which in places are slightly consolidated, apparently being cemented by iron which has leached out of the arkoses. These beds, in general horizontal, are frequently distinctly flexed, sometimes dipping as much as 20°, and in places there is even considerable folding and distortion. The strata are often heavily cross-bedded and contain pebbles derived from a great variety of rock, some of which are striated, apparently from ice. This formation is exposed for a number of miles along the shore of Nushagak Bay and around Cape Etolin to Bristol Bay.

Overlying the folded clays and gravels which have been called the Nushagak beds are unconformable horizontally stratified clays and gravels which contain many pebbles and frequently large boulders, often being striated by ice. Near Nushagak these upper beds occupy the tops of the bluffs, which are in places as much as 150 feet high, but where the bluffs become lower and the beds themselves become thicker they often come down to the beach line, so that the underlying unconformable series is not exposed. These upper beds must be referred to the Pleistocene, so that those which underlie are probably Tertiary. In this connection a note made by Dr. Dall<sup>a</sup> concerning fossils collected at Nushagak by C. W. McKay is of interest. According to this, fossils were collected in an "indurated clayey matrix," which evidently refers to the Nushagak beds just described. They include *Modiola multiradiata* Gabb, *Pectunculus patulus* Conrad, *Nucula tenuis* Lamarck, and *Serripes gronlandicus* Beck and determine the age of the clays and gravels in which they occur as Miocene.

Regarding the above Atwood states in a personal communication: "I have not been at this locality. The pebbles and boulders striated by ice, which are reported

<sup>a</sup> Report on coal and lignite of Alaska: Seventeenth Ann. Rept. U. S. Geol. Survey, pt. 1, 1896, p. 847.

as common in the Nushagak beds of Spurr, make me doubt their Tertiary age. I believe they must be younger."

O-P 9. DEASE AND UPPER LIARD RIVERS, BRITISH COLUMBIA.

Dawson,<sup>258b</sup> in a report on explorations in the Yukon district, describes a wide plateau cut on Tertiary rocks, which are unconformable to the underlying Paleozoic rocks.

Q 5-6. YUKON VALLEY.

Spurr<sup>770a</sup> distinguished two occurrences of Tertiary strata in the Yukon Valley—one as the Twelvemile beds and the other as the Palisade conglomerate. According to Brooks the former is now regarded as of Kenai (Eocene) age. Concerning the latter Spurr says:

On the left bank of the Yukon, about 35 miles below the mouth of the Tanana, cliffs of silt and gravel rise to a height of 150 feet. This locality has been named the Palisades, but on account of the occurrence in the silt of abundant bones of the mammoth and other large animals it is more popularly known as the "Boneyard." The silts also contain lignite beds and small land and fresh-water shells and are of Pleistocene age. About a mile below the beginning of the silt bluffs the height of the vertical exposure changes from 150 to 200 feet, the increase being apparently caused by a fault which is visible in the face of the bluffs and which upthrusts the down-river portion. The fault is a normal one, and the silts of the upstream side are seen to be upturned against the fault plane. On the downstream side of the fault there is brought up a lower and more consolidated bed which underlies the silts. This new bed is pure white, being composed of clean sand and well-washed pebbles. It is strongly cross-bedded and contains much woody matter—sticks, logs, etc.—in a condition between wood and lignite. Many of these woody layers are steeply inclined, being cross-bedded with the sandstone. This bed is very gently arched and has a barely perceptible dip downstream. It is partly indurated, so that while it yields with comparative ease to a pick, it is firm enough to stand in solid, nearly perpendicular cliffs and falls in great slabs.

In the materials collected from the woody layers Dr. Knowlton found fragments of dicotyledons, but none sufficiently distinct for identification. Many of the layers are full of finely preserved cones, which, according to Dr. Knowlton, appear to be the same as Heer's *Pinus macclurii*, and from these he infers that the age is Pliocene, or possibly Upper Miocene.

Q 7. UPPER YUKON.

Brooks<sup>103b</sup> states:

No beds have been identified on the Yukon which are positively known to belong to the Pliocene or Miocene. It seems probable, however, that some terrace deposits may be of late Tertiary age. Such interpretation of the facts in hand has been made by both Spurr and Collier.

McConnell<sup>563</sup> thus describes the occurrence east of the international boundary:

Beds referred to the Tertiary occur at several points around the outskirts of the gold district. A wide band follows the Yukon Valley above Dawson, on the northeast side, and continues on in a direction a little south of east to the Klondike, which it crosses a short distance above the mouth of Rock Creek. It then follows the Klondike River to the mouth of Flat Creek and probably underlies the belt of plateau country that borders the latter and extends through to the Stewart.

Exposures of these beds on Rock Creek and the Klondike River consist mostly of soft grayish sandstones, indurated clays and shales, and occasional beds of ironstone. A thick lignite seam is reported to outcrop on one of the branches of Rock Creek, and other seams occur

along the band in its northwesterly extension. A seam, or group of seams, said to be 15 feet in thickness, is being worked on Cliff Creek, about 75 miles below Dawson, for the supply of that place.

A small area of dark sandstones, agglomerates, hardened clays, and shales was found on Last Chance Creek, a tributary of Hunker Creek, lying at angles on the schists. The sandstones contain small particles of carbonaceous matter, but no lignite was noticed.

Tertiary beds were also found along the southern boundary of the district on Indian River. The northern limit of this area follows Indian River Valley from Quartz Creek to a point above New Zealand Creek, and the band extends southward beyond the region examined. The beds lie in easy folds and consist mainly of soft light-grayish sandstone, dark coarse agglomeratic sandstone, soft dark shales, and, at one point, of heavy beds of coarse conglomerate. Fragments of fossil plants occur throughout the formation, but no determinable specimens were found.

#### Q 8. PEEL RIVER.

Camsell<sup>123a</sup> explored Peel River, a western branch of the Mackenzie which joins it at the head of the delta. He says:

The upper canyon of the Peel River is cut in a series of tilted black slates, often dipping upstream. The strata of which it is composed are alternately thick and thin bedded, containing concretionary nodules with crystals and veinlets of pyrite and some bituminous matter disseminated through the rocks. This formation extends for a distance of three-quarters of a mile below the mouth of the Wind River, where it is replaced and overlain by Tertiary clays and sandstones. The contact is not so well shown on the Peel River as it is on the Wind, though the unconformity between the two is plainly evident. These slates outcrop again 15 miles below in the lower canyon of the Peel River, so that they border the Tertiary rocks both to the east and to the west. A small outcrop of bituminous limestone, overlain by the red clay and sandstone of the Tertiary, is exposed 1 mile below the canyon on the south bank of the river.

When cut through by the Peel River, the Tertiary basin is 13 miles in width. The rocks of this basin consist of thick beds of soft sandstone, with some thin seams of lignite, overlain by more sandstone containing pebbles, with clay and some very thick beds of lignite. The whole series has been gently folded into a number of anticlines and synclines. One lignite bed near the top of the series is 30 feet in thickness and fairly persistent, appearing in two exposures 4 miles apart with a shallow syncline between. This bed rises in an anticline, the top of which has been truncated by later erosion, and beyond it dips again and disappears beneath the bed of the Bonnet Plume River.

#### Q 9-10. MACKENZIE VALLEY AND BEAR RIVER.

The "Bear River Tertiary" which outcrops along the Mackenzie above and below Fort Norman is described in some detail by McConnell,<sup>560d</sup> who quotes descriptions of the flora by Sir William Dawson.<sup>265</sup> The original publications should be consulted for details. McConnell states:

After reviewing the evidence afforded by the collections of fossil leaves and fruits which have been brought out by various explorers and examined by Heer and others, Sir William Dawson arrives at the following conclusion:

"The general conclusion indicated by the above facts is the strong resemblance of the flora of the Mackenzie River beds with that of the Laramie of other parts of Canada and the United States and also with the Tertiary of Greenland, Spitzbergen, Alaska, and the Hebrides. They thus confirm the inferences as to this similarity and as to the Lower Eocene age of the Upper Laramie stated by the author in 'The report on the forty-ninth parallel' in 1875, in subsequent 'Reports of the Geological Survey,' and in previous volumes of these Transactions."

The Bear River Tertiary basin, measured along the Mackenzie, has a length of about 40 miles. Its width was not ascertained, but Tertiary beds probably underlie the flat country which borders Bear River for 20 miles above its mouth. They can not extend more than 15 or 20 miles in a westerly direction, as a lofty limestone range runs parallel with the river at about that distance. The distribution of the beds is thus limited to an area 40 or 50 miles in length and 30 or 40 in width and may be considerably less.

The beds of this Tertiary basin are evidently lacustral in their origin and both in lithological character and stratigraphical position have a much closer resemblance to the Miocene (White River) of the Cypress Hills and neighboring areas than to the Laramie, with which their fossil flora correlates them. Like the Cypress Hills beds, they are characterized by their irregular deposition, by their slight induration, and by the large proportion of gravel and pebble beds which they contain, and a further degree of relationship is evidenced by the fact that they both rest unconformably on the beds beneath.

Knowlton, in a personal communication, states that the "Bear River Tertiary" of the Mackenzie Valley is the equivalent of the Fort Union of the United States and is lower Eocene.

#### R 5-6. ARCTIC COASTAL PLAIN, ALASKA.

In traversing the Colville Valley Schrader<sup>708b</sup> distinguished Oligocene and Pliocene strata of the region as the Colville series. For his description of the lower Colville (Oligocene) see Chapter XVI (pp. 792-793). In regard to the upper Colville (Pliocene) he states:

This portion of the section is practically free from indurated rock. It consists of nearly horizontally stratified beds of fine gray, slate-colored, or ash-colored calcareous silts, containing faunal remains. It is tentatively assigned to the Pliocene on the basis of fossils collected in place by the writer in the bluff (near its top) on the west side of the Colville about a mile north of the seventieth parallel. These have been reported on by Dr. Dall. [List follows.]

#### R-U 16-22. ARCTIC ARCHIPELAGO AND WESTERN GREENLAND.

Dawson<sup>257b</sup> in 1886 wrote of the "Arctic Miocene:"

The so-called Miocene of Greenland and Grinnell Land is now regarded as equivalent to the Laramie, or at least not newer than Eocene, by Mr. J. Starkie Gardiner, Sir William Dawson, and other paleobotanists. Our knowledge of the flora of the Banks Land beds is very slight, being confined to that of the structure of a few specimens of fossil woods \* \* \* which have been reported on by Dr. C. Cramer, but, so far as it goes, it presents no features incompatible with the possible Laramie age of these deposits also.

The Tertiary plant-bearing sediments on the west coast of Greenland are described by White and Schuchert<sup>902a</sup> as conformable to the Cretaceous Patoot series.

The Patoot series, which appears lithologically and stratigraphically to be inseparable from the Atane series, contains at the same time many plants common in the upper part of the Amboy clays, with others allied more closely to the higher Cretaceous floras, such as that of the Laramie. The Patoot series may perhaps be safely interpreted as constituting a paleontological as well as sedimentary transition from the Atane series to the Tertiary. The thickness of the Atane and Patoot series (Senonian) is not less than 1,300 feet and may considerably exceed this.

The Tertiary clastics at Atanikerdluk attain a thickness of not less than 1,500 feet, not including the intruded basalts at least 200 feet thick. The horizon of most of the plants described by Heer as Miocene is assumed to be near the base of that series, the demarcation of which appears to be purely arbitrary.<sup>a</sup> It is more probable that the age of the plants now generally conceded by paleobotanists to be Oligocene may even be Eocene instead of Miocene. No remains of marine animals have as yet been discovered with these plants.

The Tertiary clastic zone appears to be thinner west of Atanikerdluk, and at Patoot and Atane it is presumably represented by the upper sandstone horizon 200 to 300 feet in thickness. At the western end of the peninsula its presence is established in the occurrence of "Atanikerdluk" plants. On the north coast east of Niakornat there may be a slight development of this zone, and it evidently is represented in the interior east of Kook.

Tertiary strata of unknown position occur in western Ellesmere Land. Schei<sup>707a</sup> says:

In the depressions between the mountains of Mesozoic sandstones abutting on Heureka Sound are in many places thick deposits of light quartz sand with embedded strata of lignite. The same is also the case in the lowlands east of Blaamanden and at the head of Stenkulfjord in Baumann Fjord. In addition to the lignite, masses of slaty clay were also found at the latter place, in which were well-preserved remains of *Sequoia langsdorfi*, *Taxodium distichum* var. *miocenum*, and some others, well-known witnesses to a southern vegetation in these regions in a geologically late period—that is, the Miocene.

Descriptions of the eruptive rocks follow in the original work.

---

<sup>a</sup> The conglomeratic sandstone at 1,000 feet above tide at Atanikerdluk, assumed by the writers to be the base of the Tertiary at that point, is the only hypothetical lithological bench mark observed in any section.

## CHAPTER XVIII.

### BIBLIOGRAPHY.

The subjoined bibliography comprises the publications cited in the text of this work. References included in quotations have been printed with the quotations as footnotes. The references in the bibliography are arranged alphabetically by authors' names and under each author in the order of dates of publication. Where different pages of a single work are cited letters are used in connection with the number that refers to the work.

MESOZOIC

CRETACEOUS

**MARINE EOCENE**

(Marine deposits of the Atlantic and Gulf, and estuarine deposits of the Mississippi embayment. Mapped with "Earlier Tertiary" on Pacific Coast and in Central America)

**CONTINENTAL EOCENE**

(Puerco, Fort Union, Wasatch, Green River, Bridger, and Tinta of the Interior)

**EARLIEST TERTIARY OR LATEST CRETACEOUS**

(Shoshone, Denver and Arapahoe, "Upper Laramie," "Ceratops" or "Somber" beds, and Edmonton of the Interior)

**UPPER CRETACEOUS**

(Kartan to Maunsquan of the Atlantic; Tuscaloosa to Ripley of the eastern Gulf; Eagle Ford to Navarro of the western Gulf; Dakota to Fox Hills of the Interior; Chico of the Pacific; Montana coal bearing portion and Laramie of the Rocky Mountains and Great Plains mapped separately)

**LOWER CRETACEOUS**

(Potomac of the Atlantic slope; Comanche series of Texas and Mexico; Knoxville and Horsetown of the Pacific; Kootenai of the northern Rocky Mountains)

**JURASSIC**

(Marine deposits of Nevada, California, and Mexico, including Franciscan and Mariposa. Elsewhere mapped with the Triassic)

**TRIASSIC**

(Marine deposits of western North America, Mexico, and the Arctic; red beds of Texas, New Mexico, and Mexico; Newark group of the Atlantic Coast. Marine Triassic in Canadian Rockies mapped with the Paleozoic undivided. Elsewhere combined with the Jurassic)

**EOCENE AND OLIGOCENE**

(Marine deposits of Central America, West Indies, and Pacific Coast, coal bearing Puget and Kenai of Pacific Coast. Mapped separately on the Atlantic and Gulf coasts)

*Rocky Mountain Province*

**LATE UPPER CRETACEOUS LARAMIE**

(Laramie of the Denver Basin; Lower Laramie of southern Wyoming; coal bearing equivalents in Colorado and New Mexico)

**MONTANA (COAL-BEARING PORTION)**

(Mesaverde, Eagle, Claggett, Judith River, and equivalents of the Rocky Mountains and northern Great Plains)

**TRIASSIC AND JURASSIC**

(Red beds and marine deposits of the Cordillera, comprising Jurassic, Triassic, and Permian; marine Triassic and Jurassic of the Pacific where not separated)

**IGNEOUS ROCKS**

24  
22  
20  
18  
16  
14

10

**TRIASSIC**

*(Marine deposits of western North America, Mexico, and the Arctic; red beds of Texas, New Mexico, and Mexico. Newark group of the Atlantic Coast. Marine Triassic in Canadian Rockies mapped with the Paleozoic undivided. Elsewhere combined with the Jurassic)*

**TRIASSIC AND JURASSIC**

*(Red beds and marine deposits of the Cordillera, comprising Jurassic, Triassic, and Permian, marine Triassic and Jurassic of the Pacific where not separated)*

11

**PERMIAN**

*(Limestones and red beds, Kansas to New Mexico and the Black Hills; Dunkard of the northern Appalachians, New Glasgow and associated sandstones of eastern Canada. Elsewhere mapped with Carboniferous undivided. Red beds include some Triassic)*

12

**PENNSYLVANIAN**

*(Coal measures; Pottsville to Monongahela, of eastern North America and their equivalents where separated on the map)*

13

**MISSISSIPPIAN**

*(Lower Carboniferous limestones and their equivalents where separated on the map from the Pennsylvanian)*

15

**DEVONIAN**

*(Helderberg to Chemung, generally mapped with Carboniferous in western North America. Includes Silurian in southern Appalachians)*

16

**SILURIAN**

*(Medina to Cayuga, in the Arctic includes Ordovician, in the southern Appalachians mapped with Devonian, and in the Cordillera generally mapped with Cambrian and lower Ordovician)*

17

**MIDDLE AND UPPER ORDOVICIAN**

*(Chazy to Richmond. Mapped with Silurian in the Arctic and with Cambrian and lower Ordovician in the Rocky Mountains of the United States)*

14

**CARBONIFEROUS, UNDIVIDED**

*(Limestones of western North America, Newfoundland, and the Arctic; doubtful Carboniferous of Central America. Subdivided in eastern North America)*

19

**PALEOZOIC, UNDIVIDED**

*(In northern Cordillera, where data for separation on the map are lacking)*

20

**METAMORPHIC PALEOZOIC UNDIVIDED**

*(Known or supposed Paleozoic rocks in northern Cordillera, northern Appalachians, and Venezuela)*

**IGNEOUS ROCKS**

25

**TERTIARY AND LATER EFFUSIVE ROCKS**

*(Volcanic rocks and lavas throughout the Cordillera, from Central America to Aleutian Islands; Venezuela and Windward Islands; Greenland and Iceland. Includes some intrusive rocks of same age)*

23a

**POST-CAMBRIAN INTRUSIVE ROCKS**

*(Plutonic rocks, chiefly granites, in eastern North America, the Cordillera from South America to Alaska, and San Domingo. Includes some effusive rocks of same age and some older intrusives)*

24

**PRE-CAMBRIAN INTRUSIVE ROCKS**

*(Plutonic rocks in eastern North America and Oklahoma. Includes some effusive rocks of same age. Elsewhere mapped with associated pre-Cambrian rocks)*

23c

**GNEISSES, SCHISTS, AND METAMORPHOSED SEDIMENTS**

*(Supposed pre-Cambrian, possibly in part Paleozoic and Mesozoic)*

**GNEISSES, SCHISTS, AND METAMORPHOSED SEDIMENTS**  
(Supposed pre-Cambrian, possibly in part Paleozoic and Mesozoic)

(Chazy to Richmond. Mapped with Silurian in the Arctic and with Cambrian and lower Ordovician in the Rocky Mountains of the United States)

**CAMBRIAN AND LOWER ORDOVICIAN**  
(Cambrian to Beckmantown; in parts of the Cordillera includes Silurian and upper Ordovician)

*Lake Superior region*

**KEWEENAWAN**

(Lava flows, sediments, and intrusive rocks; includes "Nipigon" series of Lake Superior region)

**UPPER HURONIAN**

(Annikie and equivalents in Lake Superior region and intrusive rocks)

**MIDDLE AND LOWER HURONIAN**

(Sedimentary and intrusive rocks in Lake Superior region)

**KEEWATIN**

(Oldest pre-Cambrian of the Lake Superior region, largely basic lavas)

**LAURENTIAN**

(Acidic plutonic rocks intrusive in Keewatin in Wisconsin, Michigan, and Minnesota)

*Cordilleran region*

**BELT SERIES**

(Belt series of western Rocky Mountains; Needle Mountains group of southwestern Colorado; quartzites of the Uinta and Wasatch mountains)

*Eastern Canada*

**HASTINGS AND GRENVILLE**

(Limestones and associated rocks in eastern Canada)

*Canada*

**LATE ? PRE-CAMBRIAN UNCLASSIFIED**

(Athabasca-Nastopoka series, Avalon group, gold bearing Meguma series, and other little disturbed strata (Cambrian) in Canada)

**EARLIER ? PRE-CAMBRIAN UNCLASSIFIED**

(Metamorphosed iron-bearing rocks, "Huronian", throughout Canada)

**"LAURENTIAN"**

(Gneisses and plutonic rocks throughout Canada and the Arctic; Wisconsin, Minnesota, and North Dakota)

**UNDIFFERENTIATED PRE-CAMBRIAN**

(Gneisses of the Appalachians, Missouri, Texas, Arizona, and the Rocky Mountains of the United States; includes plutonic igneous rocks where not separately mapped)
