Correlation of the Cretaceous deposits of the eastern Gulf region and of the Carolinas	654
Section of older Tertiary formations in Arkansas, Louisiana, and eastern Texas	724

INDEX TO THE STRATIGRAPHY OF NORTH AMERICA.

By BAILEY WILLIS.

CHAPTER I.

INTRODUCTION.

CONTENTS.

The "Index to the stratigraphy of North America" is a compilation designed to explain the geologic map which accompanies it. The compiler has assembled the latest or most authoritative statements of fact and opinion, selected according to his best judgment. He has been most helpfully advised by many colleagues, to whom he is under more obligation than he can here express. In a subjoined list (pp. 30-61) scientific credit is given to each person who has taken part in the work or from whom contributions have been received.

The material selected comprises discussions of stratigraphy, some citations of fossils, and some views on correlation. The aim has been to state stratigraphic facts as fully as the data available or the scope of the work permit and to include as much as space allows relating to faunas and correlation. Quotation is preferred, but where it was not practicable an abstract of facts has been made and the reference given.

The sources from which quotations have been taken include publications of all kinds, official, serial, and occasional. They are listed in the bibliography on pages 840-865. Many more have been consulted. The entries in the bibliography are numbered consecutively and corresponding numbers, printed as "superiors," are used in the text to indicate references.

The method of procedure in selecting material was based on the map, which furnishes the information that strata of a given age occur in a certain locality. If no other clue was available the province or State was looked up in the indexes to the volumes of the "Bibliography of North American geology," ^{616, 617, 870, 871, 872, 874} where the latest writing, at least since 1892, may be traced to the authors. In case a specific formation was in question, its name was followed up in the same indices or lists and all references to it during the last 18 years considered. In the later works earlier ones are usually cited. Occasionally some one geologist is so identified with the investigation of a particular subject or region that immediate reference to his works was suggested, but not in any instance intentionally to the exclusion of other observers.

The Canadian Survey has issued two bibliographies,^{289, 618} which were very useful. In them subjects may readily be traced by locality, geologic division, or geologist.

For North American geology prior to 1892, the bibliography by Darton²³⁰ has been used.

In addition to published material, the compiler has been freely given a very large amount of unpublished information from the records of the United States Geological Survey. Some has been taken from official manuscripts and some from notes prepared for this paper. All this material is credited in the text and in the list on pages 30-61, which shows the names of the contributors and the localities which they have described.

ARRANGEMENT OF MATERIAL.

The material assembled has been arranged arbitrarily according to the index of the map, in order to facilitate reference between the map and the text. Natural divisions and systematic classification have thus been subordinated to convenience.

The map is divided by parallels at intervals of 4 degrees and by meridians at intervals of 6 degrees, according to the plan of sheets of the Standard International Map of the World. Any space thus inclosed is designated by a letter and a number. The letters run from A at the equator to V at the pole, and may be said to designate zones. For example, zone A is bounded by the equator on the south and by the parallel of 4° north latitude on the north; zone H includes northern Mexico and the Gulf coast of the United States; zones L and M are traversed by the boundary of the United States and Canada; zones P, Q, and R comprise Alaska, northern Canada, and southern Greenland.

The spaces between meridians are numbered from west to east, from longitude 180° to Greenwich. In accordance with the usage of European cartographers, these spaces may be called columns. Alaska falls in columns 3 to 7. The eastern United States, Quebec, and the Labrador Peninsula lie in columns 18, 19, and 20.

The letter and number which designate the zone and column in which any division of the map lies define the position of that division and may be employed to designate it. For example, division L 18 comprises the St. Lawrence from Lake Ontario nearly to Quebec; J-K 13 covers the Rocky Mountains of Wyoming and Colorado; and E 14 takes in the City of Mexico and vicinity. The index divisions are employed throughout this work to designate areas.

The division into chapters is based on geologic divisions and in general each chapter corresponds with a geologic system or period defined by the current usage of the United States Geological Survey and named in the legend of the map, but there are departures from a systematic classification which arise partly from the exigencies of cartography and partly from the inaptness of standards. These departures are stated below, in the legend of the map, and in connection with each chapter also.

The order of description follows the alphabetical and numerical sequence—that is, from B 17 to B 20, then from C 16 to C 20, etc., wherever the outcrops of strata or the system under consideration occur. Each zone is followed from west to east

and those divisions in which the system under description is known are taken up in numerical order. The intervening map divisions are skipped. This arbitrary order traverses all natural and political boundaries. The scope of some publications covers more than one zone or one column, in such a way as to necessitate the discussion of two or more divisions under one heading.

It is assumed that the text and map will be used together. To refer from the map to the text, note the letter and number of the map index for the area under examination and look them up in the chapter which describes the geologic system studied. If the reader has simply a certain spot of color on the map in view, the corresponding color in the legend of the map will give the name of the system and chapter.

To refer from the text to the map, note the chapter heading and map index under which a citation occurs and by aid of the legend and index on the margin of the map identify the corresponding spot of color.

GEOLOGIC DIVISIONS MAPPED.

The geologic divisions represented on the map are adjusted to the requirements of cartography. They involve a compromise between the accepted standards of geologic science and the facts of history. The latter point can not be adequately discussed here, but it is true that the European standard (or that of New York in so far as it conforms to that of Europe) is a close approximation to the natural classification in the Atlantic and Gulf provinces only, and that it does not correspond satisfactorily with the natural order of events in the Pacific and interior provinces.

The limitations of cartographic representation are inherent in the scale of the map and the processes of printing. The scale of the map was selected with reference to its use as a wall map and the major features of the continent are intended to be apparent at a distance. They must therefore have at least a certain minimum size and color distinction. The employment of the map for local reference is, however, desirable, and to this end more refined drafting with slighter distinctions of color is desirable. These minor distinctions have been pushed to the limit of lithographic methods.

Whatever geologic systems, series, groups, or formations may be adopted, it will be found that they can not be carried uniformly and with constant value over so broad a territory as North America, for several reasons.

The major problems arise from one or another of several conditions—the scale of the map; differences of knowledge and ignorance; differences among classifications peculiar to the surveys of Canada, Mexico, and the United States; unlike development of the geologic series in diverse provinces.

The scale of the map sets a limit to refinement of possible classification. On a large-scale map may be drawn or printed legibly narrow strips of color, which may represent formations or even subdivisions (members) of formations. On a map of smaller scale a color strip of the same minimum width covers the space representing a thick formation or a group or a series. Thus the desirability of printing a map that shall be legible controls the width of a color band, and the latter in turn determines the least geologic division that can be recognized. The real limitation

in this regard is the space occupied by a least geologic division and it is therefore dependent on structure as well as on classification. Where strata lie flat they present as a rule wide expanses, but where they dip steeply they exhibit narrow edges. The latter is apt to be the case in mountainous regions, where the mosaic is intricate and the difficulty is thus enhanced. Contrast for instance the geologic map of the Great Plains and that of the Rocky Mountains.

The scale of the geologic map of North America is limited by the great scope of the map. Being continental, the scope demands a scale represented by 1 divided by millions, and considerations of convenience led the compilers to fix on 1 : 5,000,000, or approximately 1 inch to 80 miles. One-twentieth of an inch being about as narrow a band of color as can be read distinctly, 4 miles is nearly the narrowest zone of rocks that can be represented without exaggeration. Many zones narrower than 4 miles are of such importance that they must be represented even though exaggerated, but not many adjacent bands can be so treated. The scale therefore imposes severe limitations on classification.

As the limitations are more severe in mountains than in plains a refined set of geologic divisions which can be delineated for plains will be impracticable in mountains, whereas that series of terranes which is practicable for the former is likely to be much too comprehensive for the latter. In maps of moderate scope these differences are usually adjusted in such a manner that a uniform classification may be employed over the entire map; but where the scope is continental the differences become so great that a uniform classification for the continent becomes unsatisfactory. Even though the natural geologic divisions are the same, they must be grouped or separated according to the requirement that the map shall show all possible detail and yet be legible. Cambrian, Ordovician, Silurian, Devonian, and Carboniferous must be distinctly mapped and to some extent individually subdivided in eastern North America; but on the scale adopted they must be grouped where they are upturned on the flanks of the Rocky Mountains. Thus a uniform classification is impracticable for the geologic map of North America, and an elastic or varied classification is required by the conditions of printing and legibility inherent in the scale.

Knowledge contrasted with ignorance imposes a similar condition. In reconnaissance surveys major divisions only are distinguished, and these often but vaguely or along a narrow line of route. There are large areas of North America regarding which present knowledge is no more precise. Within or adjoining these regions are districts of greater or less extent which have been surveyed in detail. The boundaries of these districts may be those of a State or Province, or those of an arbitrary quadrangle. They are sharply defined. Beyond them lies comparative ignorance; within them is displayed the key to an understanding of what the unknown probably is. In depicting the well-known and the little-known side by side on the same map, we can not use one classification for both, without great loss in the one or certainty of error in the other. The only alternative is to map each according to our knowledge of it, using for the well-known district a detailed classification up to the limit set by the scale of the map and for the little-known region a generalized classification adapted to our ignorance. This method has been adopted

in the map of North America, wherever the differences of knowledge are of such a degree as to occasion material difficulties in applying a uniform classification. The instances are readily recognized by the arbitrary boundary which separates several formations or series from a comprehensive major class that comprises them all. Each such occurrence points to an opportunity for investigation.

The legend of the map in detail is as follows:

QUATERNARY.

Color, cream.

Symbol, 1.

Distribution: Shown only where the Quaternary completely conceals the underlying formations.

Content: Alluvial, lacustrine, and desert-basin deposits, glacial drift (in small part only), and beach, dune, and marine deposits of the Atlantic and Gulf coasts; all comprised in one category (Quaternary) and shown by the one color and pattern.

PLIOCENE.

Color, lemon-yellow.

Symbol, 2.

Distribution: The Pliocene is distinguished on the Atlantic and Gulf coasts, so far as surveys permit, in California, and in northern Nevada. Elsewhere on the map it is classed with the Quaternary (1), as in the valley deposits of the Great Basin; or with the Miocene under the heading "Later Tertiary" (4). The Lafayette formation of the Atlantic and Gulf slopes, including the Altamaha of Georgia, is shown only where it completely conceals the underlying formations.

Content: Marine Pliocene of the Coast Ranges of California; Humboldt formation (nonmarine) of Nevada; marine Pliocene and Lafayette of the Atlantic and Gulf slopes east of the Mississippi, including Altamaha of Georgia; also Yucatan.

MIOCENE.

Color, light yellow.

Symbol, 3.

Distribution: The Miocene is separately indicated on the Pacific coast and on the Atlantic and Gulf coasts, so far as surveys permit. Elsewhere on the map it is comprised with Pliocene under the term "Later Tertiary" (4).

Content: Monterey shale and equivalents of the Pacific coast; beds of Carrizo Creek, California; and marine Miocene of the Atlantic and Gulf coasts. Does not include so-called "Arctic Miocene" nor "Old Miocene," both of which are included in the "Marine Eocene."

LATER TERTIARY (MIOCENE AND PLIOCENE).

Color, yellow.

Symbol, 4.

Distribution: Mapped where Miocene or Pliocene are recognized but can not be separated or be individually identified in the present state of knowledge.

Content: Pacific coast marine deposits; Alaskan Arctic coastal plain deposits; fluviatile and lacustrine beds of the Interior; western Gulf coast marine formations; and late marine Tertiary of Mexico, Central America, and South America.

MARINE OLIGOCENE.

Color, light orange (ruling).

Symbol, 5d.

Distribution: Atlantic and Gulf coasts of the United States, where it is separated from the Eocene. Elsewhere combined with the Eocene as "Earlier Tertiary."

Content: Marine Oligocene of the Atlantic and Gulf slopes.

CONTINENTAL OLIGOCENE.

Color, light orange (dots).

Symbol, 5c.

Distribution: Great Plains of Wyoming, the Dakotas, and Colorado.

Content: White River group, including Chadron and Brule formations.

EARLIER TERTIARY (EOCENE AND OLIGOCENE).

Color, orange (horizontal ruling).

Symbol, 5.

Distribution: Central America, West Indies, and Pacific coast to Alaska. Mapped separately on the Atlantic and Gulf coasts, in Greenland, and in the Interior.

Content: Marine Eocene and Oligocene formations of Central America and West Indies; corresponding marine formations on the Pacific coast of California and Oregon; and coal-bearing formations of Puget Sound (Puget group) and Alaska (Kenai formation).

MARINE EOCENE.

Color, orange (vertical ruling).

Symbol, 5b.

Distribution: Atlantic and Gulf coasts, Mississippi embayment, Jamaica, and Greenland, where it is separated from Oligocene. Elsewhere mapped with Oligocene as "Earlier Tertiary."

Content: Marine Eocene of the Atlantic and Gulf coasts, Jamaica, and Greenland, and estuarine deposits of the Mississippi embayment.

CONTINENTAL EOCENE.

Color, orange (dots).

Symbol, 5b-1.

Distribution: Interior basins of the western United States and Canada.

Content: Puerco, Fort Union, Wasatch, Green River, Bridger, and Uinta formations.

EARLIEST TERTIARY OR LATEST CRETACEOUS.

Color, orange-brown.

Symbol, 5a.

Distribution: Colombia, middle western United States, and Canada.

Content: Shoshone group; Denver and Arapahoe and equivalents in Colorado; "Upper Laramie," Lance formation, "Ceratops beds," or "Somber beds" in Wyoming, Montana, and the Dakotas; and Edmonton of Alberta; also "Upper Laramie" of Canadian reports. In Colombia, the Guaduas or Cerro de Oro formation.

LATE UPPER CRETACEOUS; LARAMIE.

Color, yellowish green.

Symbol, 6.

Distribution: Rocky Mountains of the United States, southern Wyoming to New Mexico.

Content: Late Cretaceous coal-bearing formations; Laramie of the Denver Basin; "Lower Laramie" of southern Wyoming; and coal-bearing equivalents in Colorado and New Mexico.

UPPER CRETACEOUS.

Color, light green.

Symbol, 7.

Distribution: South America and West Indies; present but not generally distinguished in Mexico from Lower Cretaceous; Atlantic and Gulf coasts from Mexican boundary to New England; the Interior province, New Mexico to Mackenzie; Pacific coast, Lower California to Alaska; the Arctic coastal plain of Alaska; and the west coast of Greenland.

Content: Marine and coastal-plain deposits of the Atlantic and Gulf coasts and West Indies, comprising Raritan to Manasquan, New Jersey; Black Creek ("Bladen") and Peedee ("Burches Ferry"), North Carolina; Tuscaloosa to Ripley, Alabama; and the Gulf series (Woodbine to Navarro) of Texas and Louisiana. In Mexico, included on map with Lower Cretaceous (8). Marine and coastal-plain deposits of the Interior, Dakota to Fox Hills, inclusive, and equivalents. Marine deposits of the Pacific coast, Chico and its equivalents, Laramie and coal-bearing portion of the Montana of the Rocky Mountains and Great Plains mapped separately.

MONTANA, COAL-BEARING PORTION.

Color, olive-green.

Symbol, 7a.

Distribution: Rocky Mountains and northern Great Plains of the United States and Canada.

Content: Middle Montana, generally coal bearing; Mesaverde of New Mexico, Colorado, and southern Wyoming; Eagle, Claggett, and Judith River of northern Wyoming and Montana, and their equivalents in Canada.

LOWER CRETACEOUS.

Color, medium green.

Symbol, 8.

Distribution: Atlantic, Gulf, and Caribbean coasts, New Jersey to South America; Pacific coast, Alaska to South America. In Mexico, areas mapped include Upper Cretaceous.

Content: Potomac group of the Atlantic slope, Georgia, and eastern Alabama; Comanche series; (comprising Trinity, Fredericksburg, and Washita groups) of Texas, Oklahoma, and Mexico; Shasta series (Knoxville and Horsetown formations) of California and Oregon; Queen Charlotte group of British Columbia; Kootenai formation of the Rocky Mountains, Montana northward to fifty-second parallel and beyond; Lower Cretaceous, Alaska.

TRIASSIC AND JURASSIC.

Color, dark greenish blue.

Symbol, 9.

Distribution: Middle western United States, Rocky Mountains, and High Plateaus, Montana to Arizona; western United States and eastern Alaska, where Triassic and Jurassic can not be separated or can not be separately identified.

Content: Red beds and marine deposits of the Cordillera, comprising Jurassic, Triassic, and Permian, where more or less certainly known to be present but not distinguishable, or too small to map separately; marine Triassic and Jurassic of the Pacific where not separated.

JURASSIC.

Color, greenish blue (horizontal ruling).

Symbol, 9a.

Distribution: Central America, Mexico, California, Oregon, Alberta, and parts of Alaska.

Content: Jurassic limestone and shale of Nevada; Mariposa slate, Sierra Nevada; Franciscan formation, Coast Range, California; Jurassic of Mexico; Chinitna shale and Tuxedni sandstone ("Enochkin formation"), also the Naknek formation, of Alaska Peninsula. The Jurassic of the Humboldt Range, Nevada, and the marine Sundance formation of the Rocky Mountains are not distinguished on the map from Triassic, as the areas are too small to distinguish the system separately.

TRIASSIC.

Color, dark green (horizontal ruling).

Symbol, 10.

Distribution: Central America, Mexico, New Mexico, and Texas; Nevada and California; British Columbia and Alaska; Atlantic slope from North Carolina to Nova Scotia.

Content: Marine Triassic of western Nevada and California; marine Triassic of Zacatecas and red beds in Mexico; red beds of Texas and New Mexico; Newark group, North Carolina to Nova Scotia; marine Triassic of the Arctic. In the Canadian Rockies the marine Triassic is mapped with the "Paleozoic, undivided" (19, 20). In Oregon, Idaho, middle western United States, and part of Alaska the Triassic is combined on the map with Jurassic (9).

PERMIAN.

Color, light gray.

Symbol, 11.

Distribution: Southwestern United States; West Virginia, Ohio, and Pennsylvania; New Brunswick and Nova Scotia. Elsewhere mapped with "Carboniferous, undivided."

Content: Permian limestone and red beds, Kansas to Texas; Permian red beds, New Mexico; Opeche and Minnekahta formations, Black Hills; Dunkard group of the northern Appalachians; red and gray sandstones and subjacent New Glasgow conglomerate of New Brunswick, Nova Scotia, and Prince Edward Island. Includes some Triassic red beds in mapping.

PENNSYLVANIAN.

Color, dark gray.

Symbol, 12.

Distribution: Guatemala, central and eastern United States, New Brunswick, and Nova Scotia. Present, though not distinguished from Mississippian, throughout the Cordillera, the Arctic region, and Newfoundland.

Content: "Coal measures" (Pottsville to Monongahela, inclusive) of eastern North America and their equivalents where distinguished; Carboniferous limestone of Guatemala. Mapped elsewhere with "Carboniferous, undivided" (14).

MISSISSIPPIAN.

Color, light French blue.

Symbol, 13.

Distribution: Guatemala; eastern North America from Oklahoma to Nova Scotia; present but included in the "Carboniferous, undivided," in the Cordillera, Arctic region, and Newfoundland.

Content: "Lower Carboniferous" limestones and their equivalents where they are separated on the map from coal measures of the Pennsylvanian. In Guatemala the Santa Rosa formation.

CARBONIFEROUS, UNDIVIDED.

Color, light blue.

Symbol, 14.

Distribution: Western North America, Arctic region, Newfoundland, and Central America; subdivided into Mississippian, Pennsylvanian, and Permian in eastern North America.

Content: Mississippian and Pennsylvanian limestones of the Cordillera including Devonian where present; Mankomen formation and Nabesna limestone of Alaska; Lisburne formation, Alaska; Carboniferous of the Parry Archipelago, Arctic; Carboniferous of Newfoundland; doubtful Carboniferous or Devonian of Honduras.

DEVONIAN.

Color, dark blue.

Symbol, 15.

Distribution: Eastern central United States and eastern Canada; Cordillera of the United States, Canada, and Alaska; northwestern Canada.

Content: Devonian as commonly defined through the Appalachians, including Helderberg at the base and higher formations to Chemung and Catskill, inclusive; in the northeast, from Gaspé to New York, Helderberg is included with the Silurian in mapping; in the Appalachian zone south of latitude 38° the Devonian color on the map includes Silurian; throughout the Cordillera from Mexico to Alaska the Devonian where present is mapped with "Carboniferous, undivided" (14), except that it is distinguished in the Klamath Mountains, California.

SILURIAN.

Color, violet.

Symbol, 16.

Distribution: General throughout northern and eastern North America east of the Great Plains; represented by the Devonian color (15) in the Appalachian zone south of latitude 38°; known to be present in the Cordillera and Alaska but not generally distinguished by separate color, except in Mexico, Nevada, and British Columbia.

Content: In the Appalachians in general includes Medina to Cayuga; in the southern Appalachians is mapped with Devonian; in eastern Canada and New York Helderberg is included on the map; in the Interior strata of Niagara age; in the Arctic, the Silurian color covers areas of the limestone series, known to include Ordovician and Silurian.

MIDDLE AND UPPER ORDOVICIAN.

Color, light bluish purple.

Symbol, 17.

Distribution: General throughout the continent. In the Arctic mapped with the Silurian (16); in the Rocky Mountains of the United States included in narrow bands of Cambrian and lower Ordovician (18).

Content: Middle to uppermost Ordovician (Chazy to Richmond, inclusive).

CAMBRIAN AND LOWER ORDOVICIAN.

Color, purplish red.

Symbol, 18.

Distribution: General throughout the continent.

Content: In general comprises Lower Cambrian (Georgian) to Lower Ordovician (Beekmantown), inclusive, or so much as may be present. In Appalachian zone, Virginia to Alabama, includes conformable formations below the Olenellus zone; Ocoee and Chilhowee groups of Safford and other terranes. In the Cordillera, includes Upper Ordovician and Silurian where they are present and bands of color are too narrow for distinct mapping.

PALEOZOIC, UNDIVIDED.

Color, light reddish purple.

Symbol, 19.

Distribution: Little-known regions of the northern Cordillera, Montana, and Canada.

Content: Paleozoic in general, where data do not suffice to map the divisions separately. Includes some known marine Triassic in the Canadian Rockies.

METAMORPHIC PALEOZOIC, UNDIVIDED.

Color, light reddish purple with light dashes.

Symbol, 20.

Distribution: Venezuela, Cuba, Santo Domingo, Porto Rico; northeastern Appalachian region; northern Cordillera, California to Alaska.

Content: Metamorphic sedimentary rocks of known or supposed Paleozoic age, together with possibly pre-Paleozoic schists and some igneous intrusive rocks, which have not been separated. Includes some known marine Triassic in the Canadian Rockies.

LATE (?) PRE-CAMBRIAN (UNCLASSIFIED, LITTLE ALTERED).

Color, light brown with blue hachures.

Symbol, 21.

Distribution: Northern Canada (Labrador to Northwest Territories excluding the Lake Superior region); Avalon Peninsula, Newfoundland; Nova Scotia; Uinta and Wasatch ranges, Utah; Needle Mountains, Colorado.

Content: In Canada, sandstones and lava flows that are little disturbed or altered but have no fossils, "Cambrian" of Canadian reports, sometimes tentatively correlated with the Keweenawan series or with the Animikie group (Upper Huronian); Athabasca-Nastopoka series of Adams; gold-bearing Meguma series of Nova Scotia; Random and older formations of the Avalon group of Newfoundland; quartzites of Uinta and Wasatch ranges of Utah (mapped under Belt series); Needle Mountains group of Colorado (mapped under Belt series).

BELT SERIES.

Color, light brown.

Symbol, 21a.

Distribution: Western Rocky Mountains of Idaho, Montana, British Columbia, and Alberta.

Content: The Belt series (late Algonkian) of Idaho, Montana, British Columbia, and Alberta. (The quartzites of the Uinta and Wasatch mountains of Utah and the Needle Mountains group of Colorado, which are regarded as possible equivalents of the Belt series, have also been included under this color on the map, as has the Cherry Creek group of Montana, which is probably of early Algonkian age.)

KEWEENAWAN.

Color, light brown with red dashes.

Symbol, 21b.

Distribution: Lake Superior region, Ontario, Minnesota, Wisconsin, and Michigan.

Content: Keweenawan lava flows and sediments, within the area known to be of Keweenawan age; also "Nipigon" series, but not including possible equivalents in other districts. Areas mapped include intrusive igneous rocks.

UPPER HURONIAN (OF THE LAKE SUPERIOR REGION).

Color, brown (vertical ruling).

Symbol, 21c.

Distribution: Lake Superior region; Ontario, Minnesota, Wisconsin, and Michigan.

Content: Animikie and equivalents in the Lake Superior region only. Areas mapped include intrusive igneous rocks.

EARLIER (?) PRE-CAMBRIAN (UNCLASSIFIED, MUCH ALTERED).

Color, brown with white dashes.

Symbol, 22.

Distribution: Canada in general outside of the districts specially classified; Nova Scotia and Newfoundland; Cherry Creek group of Montana (probably of early Algonkian age, mapped under Belt series, late Algonkian).

Content: Metamorphosed sediments and volcanics, in places richly iron bearing, widely distributed throughout the Canadian shield, and commonly classed as "Huronian;" in Montana the Cherry Creek group (probably early Algonkian), which is mapped under Belt series, late Algonkian.

HASTINGS AND GRENVILLE.

Color, dark reddish brown.

Symbol, 22a.

Distribution: Eastern Canada, Ontario, and Quebec; probably present but not distinguished on the map in Adirondack region, New York.

Content: Limestone and associated rocks of the Hastings and the Grenville series in the type areas.

MIDDLE AND LOWER HURONIAN.

Color, brown with red dashes.

Symbol, 22b.

Distribution: Lake Superior region; Ontario, Minnesota, South Dakota, Wisconsin, and Michigan.

Content: Sedimentary and intrusive rocks in the Lake Superior region only; Sioux quartzite of South Dakota and Baraboo quartzite of Wisconsin. Areas mapped include intrusive igneous rocks.

“LAURENTIAN” (CANADIAN USAGE).

Color, pink and red hachures.

Symbol, 23.

Distribution: Throughout Canada and the Arctic.

Content: Gneisses and associated plutonic rocks throughout Canada, the Laurentian of Canadian geologists; included in Archean of Dana. (Areas of undifferentiated pre-Cambrian in Michigan, Wisconsin, Minnesota, and North Dakota have also been mapped under this color.)

LAURENTIAN (OF THE LAKE SUPERIOR REGION).

Color, pink with red hachures.

Symbol, 23d.

Distribution: Wisconsin, Michigan, and Minnesota.

Content: Acidic plutonic rocks intrusive in Keewatin, separately indicated only within the United States.

KEEWATIN.

Color, dark red with white hachures.

Symbol, 23a.

Distribution: Lake Superior region; Ontario, Michigan, Minnesota, and Wisconsin.

Content: Oldest pre-Cambrian of the Lake Superior region. Largely basic lavas.

UNDIFFERENTIATED PRE-CAMBRIAN.

Color, pink with red dashes.

Symbol, 23b.

Distribution: Appalachian province, Vermont to Alabama; Missouri, Texas, Arizona, New Mexico, California, and the Rocky Mountains of the United States; in Michigan, Wisconsin, Minnesota, and North Dakota is mapped under “‘Laurentian’ (Canadian usage).”

Content: Gneisses known to be of pre-Cambrian age, but not otherwise correlated; included in Archean of Dana. Includes plutonic igneous rocks where not separately mapped, and some sediments of Paleozoic age.

GNEISSES, SCHISTS, AND METAMORPHOSED SEDIMENTS (SUPPOSED PRE-CAMBRIAN; POSSIBLY IN PART PALEOZOIC AND MESOZOIC).

Color, pink with blue dashes.

Symbol, 23c.

Distribution: In the Cordillera from South America to Alaska.

Content: Highly metamorphosed schists and associated plutonic rocks, apparently of great antiquity but not known to be pre-Cambrian; possibly in part Paleozoic or Mesozoic.

PRE-CAMBRIAN INTRUSIVE ROCKS.

Color, dark violet.

Symbol, 24.

Distribution: Plutonic igneous rocks in eastern Canada, eastern United States, and Oklahoma. Includes some effusive rocks of same age. Elsewhere mapped with associated pre-Cambrian rocks.

POST-CAMBRIAN INTRUSIVE ROCKS.

Color, dark red.

Symbol, 24a.

Distribution: The Cordillera from South America to Alaska; Santo Domingo; eastern United States, New Brunswick, Nova Scotia, and Newfoundland.

Content: Plutonic rocks of all kinds, chiefly granites, occurring in masses of sufficient size to be mapped. Mostly of Paleozoic and Mesozoic age. Includes some effusive rocks of same age and some older intrusives. Tertiary intrusives mapped with "Tertiary and later effusive rocks."

TERTIARY AND LATER EFFUSIVE ROCKS.

Color, scarlet.

Symbol, 25.

Distribution: Volcanic rocks and lava flows, chiefly of Tertiary age, of the Cordillera from Central America to Aleutian Islands; Venezuela and Windward Islands; Greenland and Iceland. Includes some intrusive rocks of same age.

In applying the preceding legend to the map adjustments to scale and to knowledge have been made by the compilers, but adjustments of classifications adopted by different surveys could be made only by authority of the responsible officers, and to bring them about has necessitated correspondence or required special conferences. The classification of the pre-Cambrian was discussed at two formal conferences at which the Canadian and Federal surveys were represented, with results that are stated in Chapter II.

Some other difficult questions may be enumerated here.

In applying the distinction indicated by the categories 23b and 23c, the compilers have placed in the former all areas where Cambrian sediments rest unconformably upon the pre-Cambrian. In 23c are classed those areas which contain highly metamorphic rocks overlain by later Paleozoic or Mesozoic strata and which may include masses that were deposited and metamorphosed in some post-Cambrian epoch. This is the case throughout the Cordillera, except in the southwestern United States.

The "Archean" of the southern Appalachian Mountains has been separated by Keith into undifferentiated pre-Cambrian, pre-Cambrian intrusives, and post-Cambrian intrusives. The undifferentiated pre-Cambrian is carried northward through New Jersey, New York, and New England to the international boundary. In the Adirondacks this division presumably comprises the "Laurentian" of Canada and also the Hastings and Grenville representatives.

The pre-Cambrian rocks of Sutton Mountain, Quebec, are mapped as igneous and undifferentiated pre-Cambrian, after Dresser. The distinction can not yet be carried across the international boundary.

The Random formation of Newfoundland is placed in the late pre-Cambrian by Walcott, and the rest of the Avalon group is mapped with it.

The gold-bearing Meguma series of Nova Scotia is classed as pre-Cambrian on the recommendation of C. K. Leith and because of the resemblance which the rocks bear to the Avalon group of Newfoundland, as noted by Selwyn, Murray, Howley, and Faribault.

The Belt series, though regarded as Cambrian by R. A. Daly, is retained in the Algonkian in accordance with the observations of Willis, confirmed by the later work of Walcott.

Most of the Paleozoic in New England is represented as undivided, because the metamorphism which the rocks have suffered has so far prevented recognition of divisions. In northwestern Maine it is rather the drift covering and the monotony of the black slates of the several terranes distinguished in Canada that has interfered with mapping.

In the northern Cordillera from Idaho to Alaska the unknown or little-known strata are generally classed as Paleozoic, but the few areas that have been worked up in detail indicate that the region really is a fine mosaic of many formations.

In the West Indies and in Venezuela the pre-Mesozoic sediments are classed as Paleozoic.

The systems of the lower Paleozoic (Cambrian and Ordovician) can not be mapped on this scale as separate terranes divided by the boundary which paleontologists have generally recognized, for the line in many areas falls in a great thickness of limestone which is not readily divisible. It has been found practicable to distinguish Cambrian and lower Ordovician from middle and upper Ordovician, the former including all below the Chazy and its equivalents, whereas the latter takes in the Chazy and all later Ordovician terranes.

The Helderberg of the New York and eastern Canada sections is classed as Devonian in the text and in the legend but is included with Silurian on the map. The difference arises from the facts that the Geological Survey of Canada has not yet recognized the Devonian age of the Helderberg and that the United States Geological Survey has only recently done so. The map would in most places not be perceptibly changed, however, by shifting the lines to accord with the text.

In the eastern United States the Carboniferous is readily divisible and the divisions (Mississippian, Pennsylvanian, and Permian) are easily shown upon the map. In western North America the Carboniferous has a different development and the areas are, moreover, too small to be subdivided on the scale of this map. Thus, although the equivalents of the Mississippian and Pennsylvanian are known in western North America, they are not separated on the map.

The Permian is not yet clearly distinguished from the older Carboniferous in some areas or from the Triassic in others. The adjustment of uncertainties can best be followed by referring to the authors quoted in the chapters on the Carboniferous and Triassic.

The Triassic of the Arctic is mapped according to Schei and extended to the Cape Rawson beds, which lie in the strike.

The Jurassic occupies but very small areas. Although it is widely represented in the central Rocky Mountains and thence northward, it occurs in such narrow belts that it can not be mapped separately from the Triassic in that province. It was not possible to insert another band of color between those representing the Triassic and Cretaceous.

The line between Jurassic and Cretaceous in the Coast Range of California is drawn by different observers below the Franciscan, at the base of the Knoxville, or in the upper part of the Knoxville. The mapping expresses the line at the base of the Knoxville, the only one that can be readily traced.

FIGURE 1.—Sketch map showing the distribution of post-Cambrian intrusive rocks represented on the geologic map of North America.

FIGURE 2.—Sketch map showing the distribution of Tertiary and later effusive rocks represented on the geologic map of North America.

The distinction between Upper and Lower Cretaceous in the United States is based on the natural divisions which are regarded as characteristic of North American Cretaceous. The Mexican Survey recognizes a threefold division, Eo-, Meso-, and Neo-Cretaceous, which is adjusted to European standards but which can not yet be carried out on the geologic map of Mexico, because not enough detailed work has been done in that country. The Lower Cretaceous is most widely distributed in Mexico, and the areas which are colored accordingly include also those of the Upper Cretaceous.

The line of division between the Cretaceous and Tertiary is everywhere in doubt from South America to Canada. The positions of the Laramie and its supposed equivalents and of those formations which have been placed in the Shoshone group of Cross have been controverted and are still matters of opinion. The data for the map assembled by the most recent work of the United States Geological Survey in Utah, Colorado, Wyoming, and Montana were compiled by Willis, who placed the Laramie in the Cretaceous, in accordance with the decision of the Survey, and assigned the Shoshone group to the "Paleocene," after Scott. "Paleocene" has not, however, been accepted by the Survey's committee on geologic names, and the group is here described as "earliest Tertiary or latest Cretaceous." The Canadian Survey stated that the corresponding line in western Canada should be drawn at the base of the Edmonton.

Many other questions will present themselves to the student, who is referred to the text for the data on which the map is constructed.

As this work includes no chapters describing the igneous rocks, figures 1 and 2, showing the distribution, as indicated on the geologic map, of the post-Cambrian intrusive rocks and the Tertiary and later effusive rocks, respectively, are inserted here. With the post-Cambrian intrusive rocks are included extrusive rocks of the same age, and with the Tertiary effusives are included associated intrusive rocks.

ACKNOWLEDGMENTS.

The chapters have been read by geologists of the United States Geological Survey and revised in accordance with their suggestions. The writer owes special acknowledgment to Messrs. C. D. Walcott, Charles Schuchert, E. O. Ulrich, and A. W. Grabau, who have read the citations on the lower Paleozoic; to Mr. E. M. Kindle, who read the Silurian and Devonian chapters in the original and also in the revised drafts; to Messrs. G. H. Girty, David White, and G. H. Ashley, for criticism of the Carboniferous chapters; to Mr. J. Perrin Smith, for revision of the Triassic chapter; to Mr. T. W. Stanton, for revision of the Jurassic and Cretaceous chapters; to Mr. F. H. Knowlton, for comments on Mesozoic paleobotany; to Mr. W. H. Dall, for consideration of the several chapters on the Tertiary; and to Mr. T. Wayland Vaughan, for contributions to the discussion of the Tertiary of the Atlantic, Gulf, and West Indian provinces.

The suggestions made by these able critics have been followed so far as the scope of the work permitted, but the responsibility for the substance and form of the text rests none the less with the compiler.

The preparation of the manuscript geologic map has been difficult and tedious. It is a task requiring peculiar skill and experience to prepare suitable copy of so

complex a map and to engrave and lithograph it according to the high standards of modern cartography. The writer has been fortunate in being associated with the Survey's editor of geologic maps, Mr. G. W. Stose, and aided by the chief engraver, Mr. S. J. Kübel. To them in particular and also to Mr. H. S. Selden, who drew the manuscript geologic map, and to the cartographic section of the Survey he would express his indebtedness.

The names of the contributors to the map are given in the list at the close of this introduction. There are, however, certain portions of the geologic map which are strikingly different from any previously published and which represent original contributions from geologists who are familiar with special districts. These contributions are especially acknowledged as follows:

Mr. Robert T. Hill prepared an original map of Sonora and Chihuahua, Mexico, and of portions of adjacent areas in the United States.

Messrs. T. W. Vaughan and A. C. Spencer furnished the map of Cuba according to published data and their own unpublished notes.

Mr. W. P. Blake supplied material for the little-known districts of Arizona and his map was adjusted to notes and maps supplied by other geologists.

Mr. Ralph Arnold prepared for the geologic map of North America issued by the International Geological Congress in 1906 the map of California south of San Francisco, and for the map accompanying this volume Mr. Robert Anderson reviewed this material and supplemented it from his own notes.

Mr. A. C. Lawson supplied a manuscript map of the northern Coast Ranges, which was adjusted to other data in hand.

Mr. T. Wayland Vaughan and Mr. L. W. Stephenson drew the map of the Atlantic and Gulf coastal plains according to cooperative work in progress in the several States.

Mr. Arthur Keith prepared the map of the Appalachian Mountains from Maryland to Georgia, east of the Appalachian Valley, after his own surveys, supplemented by the original work of other geologists.

Messrs. George Otis Smith and E. S. Bastin compiled the map of the New England region from surveys by several geologists, supplemented by their own original notes.

Mr. N. H. Darton, Mr. M. R. Campbell, and the geologists assisting Mr. Campbell supplied the data for the Mesozoic and Tertiary of Colorado, Wyoming, and Montana.

COLOR SCHEME.

PRINCIPLES.

Color is used on geologic maps to delineate the distribution of various rocks. Legibility is the first requirement, economy in printing the second, and good taste the third. Custom may prescribe certain associations of color with particular implications, which, being thus established, control other associations.

The requirement of legibility determines the first principle. Distinctions of color should be so marked as to be clearly recognized. As contrast depends on hue and tint or shade in flat colors, and also on pattern where devices are employed, distinctions of hue, tint, shade, or pattern may be used to produce it.

In order to discuss contrasts it is necessary to have in mind certain facts about colors. There are three primary colors—red, blue, and yellow, which may be more accurately spoken of in terms of pigments as crimson lake, cobalt blue, and cadmium yellow. If pairs of these colors are combined in equal volumes they yield the standard secondary colors purple, orange, and green. Again if the standard secondaries are mixed in equal volumes in pairs standard tertiary colors are obtained—russet from purple and orange; olive from purple and green; and citrine from orange and green. Red predominates in russet, blue in olive, and yellow in citrine; each primary forms one-half of the respective tertiary color, but the presence of the other two primaries modifies its brilliancy.

Although the above statements are true in a general way, they are not mathematically exact. A name does not define a color. There are various reds, blues, and yellows, and various secondaries and tertiaries result according to the choice of primaries with which to start. Given three primaries, however, corresponding standard secondaries and tertiaries may be produced in the manner above described.

If graduated proportions are mixed instead of equal parts a series of slightly differing tints are obtained. For instance, 9 volumes of red to 1 of blue, 8 of red to 2 of blue, 7 of red to 3 of blue, and so on to 1 of red to 9 of blue will yield a range of purples which are scarcely distinguishable one from the next, yet which run the gamut from red to blue. A similar range of greens from blue to yellow and one of oranges from yellow to red complete a circle of closely graded secondaries.

The tertiary mixtures may be graded in the same manner to produce a sequence of russets, olives, and citrines which range from purple through green and then through orange back to purple without a break.

If we call the primary, secondary, and tertiary colors thus mixed hues, we may distinguish tints and shades of any one of them. The normal *hue* has the full available strength of its constituent colors. A *tint* is lighter. It may be mixed by adding more of the medium, water or oil, or by adding white. On the other hand a *shade* is darker—that is, it reflects less light than the normal hue. It may be produced by adding black, but more artistically by mixing a complementary tertiary color with the normal hue. In color printing tints result where the white of the paper shines through the hue, which is thereby diluted, and shades are produced by overprinting grays, which are usually tints of olives or russets strong in blue.

Contrast depends on the juxtaposition of unlike hues. It is strongest between any two of the pure primaries. It is equally striking but less likely to be offensive between a primary and the secondary which is composed of the other two primaries. Contrast in general is less pronounced between secondary hues and is materially less between tertiaries. There is no stronger contrast than that of white and black; in relation to colors it enters in a subdued degree into the distinction between tints and shades. Hence where strong contrast is desired we may juxtapose primary hues, or a primary with its complementary secondary, or a light tint of a hue against a dark shade of the same or another hue. The requirement of distinctness may usually be met by lesser contrasts and in general the greater contrasts are reserved for small areas or for emphasis.

A second principle follows from the requirement of economy in printing: The color scheme should be devised to accomplish the required distinctions with the least practicable number of impressions or printings.

As the lithographic press prints but one color at a time, it might seem that there must be as many printings as colors; but printing one color over another has the effect of combining them as if they were mixed and therefore a small number of printings may yield many distinctions. In colored illustrations three colors—red, yellow, and blue or green—usually suffice, reinforced sometimes by black.

On assuming that we proceed with the three primaries, it is evident that by overprinting we may obtain the three secondaries and also one combination of all three primaries in the full strength of their several hues. This combination will be almost black. These seven effects are strong unmodified hues. To produce tints the lithographer substitutes fine lines or dots in place of flat colors. Many of the patterns employed are almost invisible, but they permit the white of the paper to shine through and lighten the hue. Several distinct tints of any one primary hue may be produced at one printing, and their various combinations constitute a wide range of secondaries and tertiaries. Only an experienced lithographer can know in advance what the effects of the combinations will be and how distinct they will be. They fall into groups and of each group some are too closely similar to one another for practical distinction and others are undesirable because they are distasteful. But a large number of good distinctions is possible with three printings, the number is very greatly increased by a fourth printing, and only very numerous and very refined differences require many printings. The geologic colors on the map of North America are produced by 12 printings, which yield 42 distinct effects. Two more printings are required for the black and blue of the base map.

Conspicuous patterns are more or less used in geologic maps and greatly increase the range of recognizable distinctions. They are, however, a concession to technical requirement and offend good taste unless they are very skillfully designed.

The third requirement, that of good taste, is commonly little considered, but if it is satisfied the prime requirement of proper distinctness will also have been met; for the essential of good taste is adaptation to purpose. In general it may be said that pleasing maps result from an association of light tints, particularly light tints of tertiary hues in large areas, with appropriate contrasts of bright primary or secondary hues which may be proportionately more brilliant as the areas covered by them are smaller.

USAGES.

If entire freedom of choice and arrangement in devising a color scheme is allowed, the principles stated above may easily be applied in most cases to produce a thoroughly satisfactory map; but usage has established certain associations of colors with definite meanings, and it is misleading to contravene those associations. Whether the difficulty thus occasioned in the mind of a reader is such as to overbalance the advantages that may be gained by using colors arbitrarily instead of according to custom is determinable only with reference to each particular case and is then often a matter of personal judgment.

Some familiar usages are those of red, the color of fire, for igneous rocks; pink for the ancient crystalline rocks; blue, the color of the rock, for limestone; yellow, by similar association, for sandstone; and many others in which the suggestion of the color has a mnemonic value.

Another class of usages comprises those established officially by the practice of a government survey or by agreement among such surveys. Among those which have been developed to meet a general application and which are therefore most comprehensive in character, there are two that have been considered for the map of North America—the color scheme adopted by the International Geological Congress for the general map of Europe, and that designed by the United States Geological Survey for the Geologic Atlas of the United States. The following table shows their resemblances and differences:

Colors and color schemes.

Natural order of tints, hues, and shades.	International European color scheme.	United States Geological Survey.	
		Geologic Atlas of the United States.	Geologic map of North America.
Yellow, orange-tinted (cream)...	Quaternary.....		Quaternary.
Yellow, light.....	Pliocene.....		Miocene.
Yellow, medium.....	Miocene.....		Pliocene.
Yellow, dark.....	Oligocene.....	Pliocene and Miocene...	
Yellow, greenish.....			
Citrine, yellowish brown.....		Eocene and Oligocene...	
Citrine, medium brown.....	Permian.....		
Citrine, greenish brown.....		Cretaceous, upper part...	
Green, yellowish.....	Eocene.....		Cretaceous, late Upper.
Green, light.....	Cretaceous, Upper.....		Cretaceous, Upper.
Green, medium.....	Cretaceous, Lower.....	Cretaceous.....	Cretaceous, Lower.
Green, dark.....	Wealden.....	Cretaceous, lower part...	Triassic.
Green, bluish.....	Volgian.....	Jurassic.....	
Olive, greenish.....	Cambrian (dark).....		
Olive, medium.....	Devonian (dark).....	Archean.....	
Olive, bluish.....			
Blue, greenish.....	Silurian (dark).....	Triassic.....	{Jurassic (light). Triassic and Jurassic (dark). Permian (light). Pennsylvanian (dark).
Blue, gray.....	Carboniferous (dark).....	Carboniferous.....	Carboniferous.
Blue, light.....	Jurassic, Upper.....	Carboniferous, upper part.....	Carboniferous.
Blue, medium.....	Jurassic, Middle.....	Carboniferous, lower part.....	Mississippian.
Blue, dark.....			Devonian.
Blue, purplish.....	Jurassic, Lower.....		Ordovician, middle and upper.
Purple, bluish.....	Triassic.....	Devonian.....	Silurian.
Purple, light.....			Paleozoic.
Purple, medium.....			
Purple, dark.....			Eruptives.
Purple, reddish.....	Gneiss and protogine.....	Silurian.....	Cambrian and lower Ordovician.
Russet, purplish.....		Ordovician (reddish).....	
Russet.....		Algonkian.....	Late pre-Cambrian.
Russet, reddish.....	Eruptives.....		Earlier pre-Cambrian.
Red, russet.....		Cambrian.....	
Red, light.....	Schists.....		Pre-Cambrian.
Red, medium.....			
Red, dark.....	Eruptives.....		Eruptives.
Red, yellowish.....	Effusives.....		
Orange, reddish.....	Effusives.....		Effusives.
Orange, medium.....	Effusives.....		Eocene.
Orange, light.....			Oligocene.
Orange, yellowish.....			

The European international geologic color scheme embodies the results of prolonged consideration by the international committee who were charged by the Geological Congress with the duty of preparing the map of Europe. In it can be recognized some elements of the French usage, particularly in the colors employed for the Mesozoic and Tertiary terranes. German influence appears in the selection of tones for Paleozoic terranes, and the familiar association of gray with Carboniferous and of pink with the ancient crystalline schists is an obvious result of general practice. So also is the use of strong, brilliant colors for the igneous rocks. The writer is not definitely informed regarding the discussion of principles through which the result was reached, but by a study of the color schemes in the light of what is published concerning the controlling principles, it would seem that the committee recognized (1) established usage, (2) the order of prismatic colors from purple through blue and green to yellow for that portion of the scheme relating to the Triassic and post-Triassic terranes, and (3) the arbitrary principle that Mesozoic terranes should be distinguished from Paleozoic by a very decided contrast of light and shade, the Paleozoic terranes being indicated by dark colors.

The European color scheme is exceedingly well adapted to delineate the geology of Europe and would apply well to that portion of western North America in which the Mesozoic and Tertiary formations occupy large areas in contrast to the Paleozoic terranes, as they do in Europe also. The map of Europe is very clear and legible, the base map having been kept free from confusing details and the colors having been selected and printed with great skill. The color scheme thus commends itself through the beautiful appearance of the map. It must not be forgotten, however, that Europe presents a special form of geologic structure. The continent is made up of extensive areas of Mesozoic and Tertiary strata surrounding relatively small exposures of Paleozoic terranes. This arrangement of younger strata about older nuclei is, from the point of view of the cartographer, the most important feature which the continent presents. The committee with good reason sought to emphasize the fact, and through that emphasis the map of Europe gains in expression and educational value. The greater part of the map is easily legible, being covered only by the light colors which are used for the Mesozoic and Tertiary, and the difficulties which arise in attempting to read the geology of the minor Paleozoic areas are not forced upon the attention.

But the international color scheme is unfitted to lands in which the Paleozoic terranes predominate and are minutely subdivided, for the density of the colors selected for the Paleozoic would produce a map that would offend good taste and be illegible. Moreover, inasmuch as the range of prismatic colors from purple, blue, and green to yellow is preempted in the European color scheme for Mesozoic and Tertiary terranes and the reds are assigned to the ancient crystalline and eruptive rocks, the choice of colors remaining available for the Paleozoic is much too limited for satisfactory discriminations. This is at once evident on an examination of the Paleozoic areas as represented on the international map—such, for instance, as the coal fields of Belgium and France, or the peninsula of Brittany, or Wales and Scotland. Although the distinctions are limited to a few great systems they are recognizable only on close inspection and the areas are indistinguishable from one another

at a little distance. A geologic map of eastern North America printed in these dark colors with so little difference of hue or shade would fail to present adequately the great Appalachian zone as distinguished from the broad plateaus of the coal measures and the domelike uplifts of the Cincinnati axis. In the pre-Cambrian also the number of formations recognized in North America is greatly in excess of those distinguished in Europe, and the simplicity of the European scheme renders it insufficient to delineate the geology of the Lake Superior region and the Canadian shield.

For these reasons, after very careful consideration, the compilers of the geologic map of North America found it necessary to abandon the European international scheme not only for the map issued by the International Geological Congress in 1906 but also for the map accompanying the present volume.

The color scheme adopted by the United States Geological Survey for the Geologic Atlas of the United States is based on three essential principles—(1) that the order of the colors shall be that of their natural association, (2) that there shall be a standard color for each of the great geologic periods, and (3) that subordinate distinctions under each color shall be obtained by the use of obvious patterns. To these may be added the practice of using dull, subdued tones for the sedimentary and brilliant colors for the igneous rocks, as well as the mnemonic association of patterns which assigns parallel lines to the sedimentary rocks, angular patterns to igneous rocks, hachure patterns to metamorphic rocks, and dotted patterns to the surficial deposits. This color scheme has been developed and applied in the office and engraving division of the United States Geological Survey, where special facilities and skill in technical processes have been available. In attempting to apply the scheme to geologic maps printed under contract with private firms, difficulties have been encountered both in technical execution and in cost. Experience shows that the applicability of any color scheme which requires a precise use of patterns is affected by the necessity of developing a different use of patterns to secure economy in printing. For this reason primarily the color scheme of the United States Geological Survey is unavailable in general practice.

As color schemes that employ definite associations of colors and time divisions are limited in application to provinces that have had a certain historic development, and as patterns that may occasion excessive cost are unpractical, it follows that neither of these usages can be adopted for a universal color scheme except to a qualified degree. Nevertheless, a color scheme which shall serve as the universal language of geologic cartography is extremely desirable. The writer has sought, therefore, to devise certain principles which would occasion as little departure from current usage as might be practicable and which should yet be of general application in all continents. The adoption of such general principles would not find favor in England, France, or Germany, as may readily be foreseen if we consider how long established the several usages of those countries are; nor can it hope to supersede the international color scheme already applied to a large part of the geologic map of Europe and to be extended to the incomplete portions of the map. But Europe represents only a small part of the earth's surface and the Americas, Africa, and Asia need not be governed by its practice. It may be hoped that in making local

geologic maps of other continents than Europe, even European cartographers will strive toward uniformity of expression, especially in color schemes, and that the American nations which are not yet committed by established practice to diverse usages will unite upon common principles.

In order to promote this desirable end, the following principles, suggested by the writer, have been proposed by the United States Geological Survey for discussion with a view to the development of a common usage among the official surveys of the Americas and for application to the geologic maps of the world published on the standard 1:1,000,000 base. These principles have already been indorsed in a general way by the Geological Survey of Canada and the Instituto Geológico de México.

PRINCIPLES FOR COLORING GEOLOGIC MAPS.

The first principle shall be that the relations of color and relative age shall be invariable—that is, when applied to distinguish divisions of a sequence of strata, colors shall always be used in a definite succession which shall express relative age.

Let it be agreed that the sequence red, purple, violet, blue, green, and yellow shall be adopted to represent succession of formations, groups, or series of sedimentary rocks from older to younger and let the order of colors be invariable according to the principle stated above, no matter what part or how much of the geologic column is represented. Then red will always represent something older than that which is shown in purple, or violet, or blue, etc. Blue will always stand for something older than that shown in green or yellow. In looking at any geologic map thus colored the student would at once know which were the older and which the younger sedimentary rocks. The essential features of sequence and structure would be immediately obvious.

The second principle is that color and geologic time divisions shall be measurably independent; in other words, no color shall be regarded as precisely indicative of any particular time division.

This principle is a radical departure from general usage in any one of the several countries which have well-established color schemes, but it is simply a recognition of general practice if we take account of the differences of these established schemes. For instance, in Europe blue means Jurassic, but in the United States it stands for Carboniferous. Thus blue in each country represents something different, and to a student of one country examining the maps of the other it suggests something other than it should. Let us agree that blue shall not necessarily mean Jurassic or Carboniferous, but that it may represent either Jurassic or Carboniferous, or in general some Mesozoic or Paleozoic time division. Such an agreement will give that elasticity of usage which is essential to a general color scheme designed for application to different provinces. If applied with appropriate recognition of the first principle the elasticity thus introduced will not occasion confusion, because we will always know the relative age of those formations represented by blue as compared to those represented by green on the one side and violet on the other. Indeed, a certain orderliness will take the place of the disorder that is forced by arbitrary usages upon any student of the maps of several countries. This principle is not intended, however, to give license to use any color whatever for any period, nor to

contravene the principle of utility, which requires that a color scheme for a given province shall be as nearly uniform as practicable.

To illustrate the application of the first and second principles that have been proposed, we may consider certain examples. A general geologic map of North America requires few distinctions in the Mesozoic but many in the Proterozoic, Paleozoic, and Cenozoic. We may therefore allot the colors as follows:

Cenozoic	}	Yellow.
		Green.
Mesozoic	}	Blue.
		Violet.
Paleozoic	}	Purple.
		Red.
Proterozoic		

A general geologic map of Europe makes different requirements—very few distinctions in the Proterozoic, few in the Paleozoic, but very many in the Mesozoic and Cenozoic. Hence for such a map we may allot the colors as follows:

Cenozoic	}	Yellow.
		Green.
Mesozoic	}	Blue.
		Violet.
Paleozoic	}	Purple.
		Red.
Proterozoic		

The braces are overlapped to avoid too precise an assignment—for it is the purpose of the second principle to preserve that elasticity which alone can make the scheme available everywhere. Yet through the first principle we secure an orderly sequence, which will always convey the idea of relative age.

The preceding considerations apply to general maps on a small scale, for instance, the accompanying geologic map of North America, or maps on the scale of 1:1,000,000, the standard international base. A cartographer having such a map to construct should consider the geologic development of the province which the map is to represent in whole or in part and should devise the application of his color scheme in such a way that it accords with the two principles suggested and yet gives the greatest range of colors where there is the greatest development of the geologic column.

Detailed maps, on larger scales than 1:1,000,000, present special conditions; they may be simple or comprehensive.

If they are simple, it is desirable that the colors used should correspond with those that represent the same general time divisions on the general map. Where one or two effects suffice for the latter, there may be two or three times as many on the simple detailed map, but the range of colors may not need to be greatly increased.

If the detailed map shows terranes that are greatly subdivided, the range of colors must be increased; but in that case the dominant effects may be and should be selected to correspond with colors indicating the general time divisions on the general map and only so many of the colors above and below as may be needed should be used. The reader will then know that (*a*) if warm ruddy tones predominate, the earlier periods are represented; (*b*) if cold blue tones are most evident,

the rocks of middle geologic periods are shown; and (c) if bright greenish or yellowish tones prevail, the map indicates rocks of later geologic periods. If the greens are wanting, so that the yellow tones are in contact with blues, he will recognize a hiatus; and similarly if any other color in the sequence is omitted.

The first and second principles discussed above embody the essential suggestions for a general color scheme, but there are other considerations which may be stated as supplementary rules that are at least desirable. Thus, in regard to contrasts, if we recognize pure hues, tints, shades, and tertiary hues, as explained on a previous page, we may provide that the invariable sequence of colors shall apply equally to pure hues, tints, shades, and tertiary hues; that pure, brilliant hues shall as a rule be reserved for igneous rocks; and that shades and tints belonging to a single minor division of the color sequence shall preferably be so used that darker effects represent the lower and lighter effects the upper terranes, in such manner that gradations from dark to light correspond with conformable sequences and contrasts indicate systemic distinctions, so far as practicable.

These provisions establish certain usages which have become common—the use of strong, bright effects for igneous rocks as contrasted with subdued effects for sedimentary rocks, and the employment of darker tones for the older and lighter tones for the younger divisions of a group or series. They support the first principle but emphasize contrast.

Contrast is as necessary to good geologic coloring as harmony. The eye catches a line between contrasted values and identifies the horizon in the various associations that may be occasioned by complex structures. Among the contrasts available for mapping sedimentary rocks, those which occur between light tints of one hue and dark shades of the next hue in the natural order of colors are the most useful and most consistent with harmony.

With regard to patterns we may recognize that they are desirable in many cases, for they afford distinctions that otherwise may not be clearly made, and if used consistently they serve to suggest at once the igneous, sedimentary, metamorphic, or surficial character of the rocks. But as patterns may be costly and unless skillfully employed fail in desirable effects, we may agree that the use of patterns shall not be obligatory, yet that if visible patterns are used, it shall be according to an established classification. The experience of the United States Geological Survey indicates that this classification should be patterns in circular figures for surficial rocks, patterns in parallel lines for sedimentary rocks, patterns in hachures for metamorphic rocks, and patterns in angular figures for igneous rocks. Patterns so used must be such as are obvious to the eye at the usual reading distance for which the map is designed. The use of patterns that are not obvious but may be seen on close inspection is a method of combining colors to economize in printing and may modify the mnemonic suggestion of the origin of the rock. For instance, by close examination of many of the patterns employed for sedimentary rocks on the accompanying map of North America, it will be seen that they are made up of crossed lines which would suggest igneous rocks, but these patterns are so fine that they will not be seen at the distance at which the map will ordinarily be read if hung upon the wall. Where conspicuous patterns are employed, either in parallel lines or in hachures, they signify the character of the rock.

Although for some maps these visible patterns may be costly there may also be economy in their use, as stated below. A consideration which rises to the importance of a principle in devising any general color scheme relates to economy. Economy in reproduction is usually secured by limiting the number of printings. There are two ways in which this may be done—(a) by using patterns of one color which produce distinctions of tint; (b) by overprinting two or more colors. In applying the former method the preparation of a lithographic stone so that it shall print many devices in one color, yet shall give different effects, may occasion greater cost than would be involved in printing from two or more simpler stones. In applying the second method, the combinations secured by overprinting two or more colors are numerous and may be less monotonous than those obtained by patterns of one color. The lithographer has always to balance the cost of preparing stones and that of printing, and the calculation of least expense involves not only the number of effects required but also the size of the edition and other factors. The conditions vary with individual maps, and an economical color scheme for general use must permit the employment of either or both methods.

By coloring geologic maps according to the proposed principles, we may secure (a) legibility, because the invariable order of colors will indicate the order of age; (b) common usage of colors within limits, which may be wide, for freedom is imperative, but which are nevertheless significant; (c) recognition of customary usages that now exist but are often disregarded; and, consequently, (d) the equivalent of a universal language in the coloring of all maps that follow the accepted principles.

The accompanying geologic map of North America represents an application of the proposed principles to a general case of great complexity. It is hoped that it may serve to encourage consideration and adoption of a universal color language on geologic maps.

CONTRIBUTORS.

The list of contributors to the geologic map of North America and of the sources from which it has been compiled follows.^a

In this list are included the names of authors of geologic maps, published and in manuscript, used in compiling the map of North America, and those who furnished data, published and unpublished, for the correction of previously existing maps, or contributing to the knowledge of little-known regions. The sources of information from which published maps were originally derived are not given except where specifically credited on the maps. The term "folio" in the citations refers to the Geologic Atlas of the United States, published by the United States Geological Survey.

Adams, F. D.

Member of the committee on pre-Cambrian nomenclature.

Data on Victoria, Peterborough, and Hastings counties: Ann. Rept. Geol. Survey Canada for 1892-93, vol. 6, Rept. J.

Montreal sheet: Ann. Rept. Geol. Survey Canada for 1894, vol. 7, Rept. J.

Geologic map of Laurentian area north of the Island of Montreal: Ann. Rept. Geol. Survey Canada for 1895, vol. 8, Rept. J.

^a This list has been prepared by G. W. Stose and (for the Canadian contributors) J. M. Nickles, from notes and lists by Bailey Willis and the Canadian Geological Survey and from other sources.

Adams, F. D.—Continued.

- Data on Haliburton district, Ontario: *Summ. Rept. Geol. Survey Canada* for 1899, pp. 122-131 (with A. E. Barlow).
 Data on Haliburton and Bancroft areas, Ontario: *Summ. Rept. Geol. Survey Canada* for 1901, pp. 145-148.
 Geologic map of Island of Montreal and vicinity: *Ann. Rept. Geol. Survey Canada* for 1901, vol. 14, pt. O (with O. E. LeRoy).
 Geologic map of central Ontario: *Proc. Roy. Soc. Canada*, 3d ser., vol. 2, sec. 4, p. 3, 1908 (with A. E. Barlow).
 Geologic map of Haliburton and Bancroft areas, Ontario: *Mem. Geol. Survey Canada* No. 6, 1910 (with A. E. Barlow).

Adams, G. I.

- Geologic map of the Ozark region of Missouri and Arkansas: *Twenty-second Ann. Rept. U. S. Geol. Survey*, pt. 2, 1901, pp. 69-94.
 Geologic map of Louisiana and eastern Texas: *Bull. U. S. Geol. Survey* No. 184, 1901.
 Geologic map of part of the eastern Choctaw coal field, Oklahoma: *Twenty-first Ann. Rept. U. S. Geol. Survey*, pt. 2, 1901, pp. 257-311 (with J. A. Taff).
 Fayetteville folio, Missouri-Arkansas (with E. O. Ulrich).

Adán de Yarza, Ramón.

- Geologic map of Cuba: *Bol. Com. del Mapa Geol. de España*, vol. 20, 1895, pp. 71-88.

Aguilera, J. G.

- Furnished geologic map of Mexico compiled for the map of North America published by the International Geological Congress, 1906, and later compiled manuscript maps of parts of Mexico for the present map.

Alden, W. C.

- Chicago folio, Illinois-Indiana; Milwaukee folio, Wisconsin (with T. C. Chamberlin).
 Corrections to southeastern portion of geologic map of Wisconsin published in 1881, from unpublished notes on this area.

Ami, H. M.

- Manuscript contributions; Paleozoic formations of St. Lawrence Valley.

Anderson, F. M.

- Notes on the Cretaceous of California, used by Ralph Arnold and Robert Anderson in compilation of map of California: *Proc. California Acad. Sci.*, 3d ser., *Geology*, vol. 2, 1902, pp. 1-154.

Anderson, Robert.

- Compiled manuscript geologic map of Coast Ranges of California south of San Francisco, for this map.
 Geologic maps of Santa Maria and Coalinga districts, Cal.: *Bull. U. S. Geol. Survey* Nos. 322, 1907, and 398, 1910 (with Ralph Arnold).
 Manuscript geologic maps of parts of Diablo Range and Salinas Valley region, California.

Arnold, Ralph.

- Compiled manuscript geologic map of Coast Ranges of California south of San Francisco for map of North America published by International Geological Congress, 1906; used in part in this map.
 Geologic map of part of Olympic Peninsula, Washington: *Bull. Geol. Soc. America*, vol. 17, 1906, pp. 451-468.
 Santa Cruz folio, California (with J. C. Branner and J. F. Newsom).
 Geologic maps of Santa Clara Valley, Puente Hills, and Los Angeles oil districts (with G. H. Eldridge); of Summerland district; of Santa Maria and Coalinga districts (with Robert Anderson), and McKittrick-Sunset region (with H. R. Johnson): *Bull. U. S. Geol. Survey* Nos. 309, 321, 322, 398, and 406.
 Manuscript geologic maps of San Luis Obispo County, Santa Monica and Pasadena quadrangles, and part of San Diego County, Cal.

Ashley, G. H.

- Compiled detailed map of the Pennsylvanian and Permian series in the Appalachian region, from northern Pennsylvania to Alabama.
 Notes on the distribution of the Pennsylvanian series in the Appalachian and central coal fields.
 Ditney folio, Indiana (with M. L. Fuller).

Atwood, W. W.

- Data on Alaska Peninsula, used in compiling manuscript map of Alaska.

Bailey, L. W.

- Data on Queens, Sunbury, and York counties, New Brunswick: *Rept. Prog. Geol. Survey Canada* for 1872-73, pp. 180-230 (with G. F. Matthew).
 Data on New Brunswick: *Rept. Prog. Geol. Survey Canada* for 1874-75, pp. 84-89 (with G. F. Matthew).
 Data on southern New Brunswick: *Rept. Prog. Geol. Survey Canada* for 1870-71, pp. 13-240; idem for 1875-76, pp. 348-368 (with G. F. Matthew); idem for 1878-79, *Rept. D* (with G. F. Matthew and R. W. Eells).
 Data on Albert and Westmoreland counties, New Brunswick: *Rept. Prog. Geol. Survey Canada* for 1876-77, pp. 351-395, with geologic map of lower Carboniferous rocks (with R. W. Eells).
 Data on and geologic map of Carleton, Victoria, York, and Northumberland counties, New Brunswick: *Ann. Rept. Geol. Survey Canada* for 1885, vol. 1, *Rept. G*.
 Geologic map of southwestern Nova Scotia: *Ann. Rept. Geol. Survey Canada* for 1892-93, vol. 6, *Rept. Q*; idem for 1896, vol. 9, *Rept. M*.
 Data on the pre-Silurian of southern New Brunswick: *Rept. Prog. Geol. Survey Canada* for 1877-78, *Rept. DD*.

Bailey, L. W.—Continued.

Data on York and Carleton counties, New Brunswick: Rept. Prog. Geol. Survey Canada for 1882-84, Rept. G; Summ. Rept. idem for 1900, pp. 146-150.

Geologic map of Victoria, Northumberland, and Restigouche counties, New Brunswick: Ann. Rept. Geol. Survey Canada for 1886, vol. 2, Rept. N (with W. McInnes).

Data on northern New Brunswick and adjacent areas in Quebec and in Maine: Ann. Rept. Geol. Survey Canada for 1887-88, vol. 3, Rept. M (with W. McInnes).

Bain, H. F.

Geologic map of Illinois, compiled by Stuart Weller: Bull. State Geol. Survey Illinois No. 6, 1907.

Geologic map of the zinc and lead region of the upper Mississippi Valley: Bull. U. S. Geol. Survey No. 294, 1906.

Ball, M. W.

Data on Little Snake River coal field, Wyoming; used in compiling map of the Cretaceous and Tertiary.

Geologic map of eastern part of Little Snake River coal field, Wyoming: Bull. U. S. Geol. Survey No. 381, 1910, pp. 186-213 (with E. Stebinger).

Geologic map of western part of Little Snake River coal field, Wyoming: Bull. U. S. Geol. Survey No. 341, 1909, pp. 243-255.

Ball, S. H.

Geologic map of southwestern Nevada and adjacent parts of California; Bull. U. S. Geol. Survey No. 308, 1907.

Manuscript geologic map of part of Silver City quadrangle, New Mexico.

Bancroft, Howland.

Geologic map of part of Yuma County, western Arizona: Bull. U. S. Geol. Survey No. 451, 1911.

Bancroft, J. A.

Data on coast of British Columbia from Powell River to Kingcome Inlet: Summ. Rept. Geol. Survey Canada for 1907, pp. 16-18.

Barbour, E. H.

Notes on details of geology in Nebraska.

Bard, D. C.

Unpublished notes on details of lava of Snake River Plains, Elko County, Nev.

Barlow, A. E.

Data on Haliburton district, Ontario: Summ. Rept. Geol. Survey Canada for 1896, pp. 43-53; idem for 1899, pp. 122-131 (with F. D. Adams).

Data on Hastings and Renfrew counties, Ontario: Summ. Rept. Geol. Survey Canada for 1897, pp. 44-56.

Geologic map of Nipissing district, Ontario, and Pontiac County, Quebec: Ann. Rept. Geol. Survey Canada for 1897, vol. 10, Rept. I.

Data on Temagami district, Ontario and Quebec: Summ. Rept. Geol. Survey Canada for 1903, pp. 120-133; idem for 1904, pp. 190-194; idem for 1906, pp. 113-118.

Geologic map of Sudbury mining region, district of Algoma, Ontario: Ann. Rept. Geol. Survey Canada for 1901, Rept. H.

Lake Timiskaming sheet, Ontario-Quebec: Geol. Survey Canada, 1907.

Geologic map of central Ontario: Proc. Roy. Soc. Canada, 3d ser., vol. 2, sec. 4, 1908, p. 3 (with F. D. Adams).

Geologic map of Haliburton and Bancroft areas, Ontario: Mem. Geol. Survey Canada No. 6, 1910 (with F. D. Adams).

Barlow, Scott.

Data on Springhill coal field, Cumberland County, Nova Scotia: Rept. Prog. Geol. Survey Canada for 1873-74, pp. 147-160; idem for 1875-76, pp. 343-347.

Barnett, V. H.

Data on Smith River coal field, Montana, and on Cheyenne River and Standing Rock Indian reservations, South and North Dakota, used in compiling map of the coal-bearing Cretaceous and Tertiary.

Bascom, Florence.

Philadelphia and Trenton folios, Pennsylvania and New Jersey, and manuscript maps of neighboring regions.

Bastin, E. S.

Geologic map of New England, compiled by G. O. Smith and E. S. Bastin for geologic map of North America, Intern. Geol. Congress, 1906.

Geologic map of the granites of Maine: Bull. U. S. Geol. Survey No. 313, 1906 (with G. O. Smith and C. W. Brown).

Geologic map of part of southern Maine: Bull. U. S. Geol. Survey No. 420, 1910.

Penobscot Bay and Rockland folios, southeastern Maine, and manuscript maps of adjacent areas in Maine.

Manuscript geologic map of the Eastport quadrangle, Maine.

Bauerman, Hilary.

Data on country near forty-ninth parallel of north latitude west of the Rocky Mountains: Rept. Prog. Geol. Survey Canada for 1882-84, Rept. B.

Bayley, W. S.

Passaic folio, New Jersey, and manuscript for Raritan folio.

Becker, G. F.

Data on Kodiak Island used in compiling manuscript map of Alaska.

Geologic maps of the quicksilver districts of the Pacific slope: Mon. U. S. Geol. Survey, vol. 13, 1888.

Beede, J. W.

Cottonwood Falls folio, Kansas (with C. S. Prosser).

Beekly, A. L.

Data on Glenwood Springs coal field, Colorado, and on Cheyenne River and Standing Rock Indian reservations, South and North Dakota, used in compiling map of the coal-bearing Cretaceous and Tertiary.

Bell, J. M.

Data on country from Great Bear Lake to Great Slave Lake: Ann. Rept. Geol. Survey Canada for 1899, vol. 12, Rept. C.

Bell, Robert.

Data on Manitoulin Islands: Rept. Prog. Geol. Survey Canada for 1863-1866, pp. 165-169; idem for 1866-1869, pp. 109-116.

Data on country northwest of Lakes Superior and Nipigon: Rept. Prog. Geol. Survey Canada for 1866-1869, pp. 313-364.

Data on region north of Lake Superior between Nipigon and Michipicoten rivers: Rept. Prog. Geol. Survey Canada for 1870-71, pp. 322-351.

Data on country between Lake Superior and Albany River, Ontario: Rept. Prog. Geol. Survey Canada for 1871-72, pp. 101-114.

Data on country between Lake Superior and Lake Winnipeg: Rept. Prog. Geol. Survey Canada for 1872-73, pp. 87-111.

Data on country between Red River and south Saskatchewan, and region between Lake Superior and Red River: Rept. Prog. Geol. Survey Canada for 1873-74, pp. 66-90.

Data on country west of Lake Manitoba and Winnipegosis, and vicinity of Lake Winnipeg: Rept. Prog. Geol. Survey Canada for 1874-75, pp. 24-56.

Data on country between James Bay and Lakes Superior and Huron: Rept. Prog. Geol. Survey Canada for 1875-76, pp. 294-342.

Data on region north of Lake Huron and east of Lake Superior: Rept. Prog. Geol. Survey Canada for 1876-77, pp. 193-220.

Data on east coast of Hudson Bay: Rept. Prog. Geol. Survey Canada for 1877-78, Rept. C.

Data on country between Lake Winnipeg and Hudson Bay: Rept. Prog. Geol. Survey Canada for 1877-78, Rept. CC (with geologic map).

Geologic map of the Lake of the Woods region, Ontario: Rept. Prog. Geol. Survey Canada for 1880-1882, Rept. C.

Data on basin of Athabasca River, Alberta: Rept. Prog. Geol. Survey Canada for 1882-1884, Rept. CC.

Data on Labrador coast, Hudson Strait, and Hudson Bay: Rept. Prog. Geol. Survey Canada for 1882-1884, Rept. DD.

Data on Hudson Strait and Hudson Bay: Ann. Rept. Geol. Survey Canada for 1885, vol. 1, Rept. DD.

Data on Attawapishkat and Albany rivers, Lonely Lake to James Bay: Ann. Rept. Geol. Survey Canada for 1886, new ser., vol. 2, Rept. G.

Geologic map of Algoma and Nipissing districts, Ontario: Ann. Rept. Geol. Survey Canada for 1890-91, vol. 5, Rept. F.

French River sheet, Ontario: Ann. Rept. Geol. Survey Canada for 1896, vol. 9, Rept. I.

Geologic map of northern side of Hudson Strait: Ann. Rept. Geol. Survey Canada for 1898, vol. 11, Rept. M.

Data on Michipicoten district, Ontario: Summ. Rept. Geol. Survey Canada for 1898, pp. 99-106; idem for 1900, pp. 109-121.

Data on Churchill and Nelson rivers and around God's and Island lakes: Rept. Prog. Geol. Survey Canada for 1878-79, Rept. C.

Data on region west of Hudson Bay: Rept. Prog. Geol. Survey Canada for 1879-80, Rept. C.

Geologic map of Moose River basin: Rept. Prog. Geol. Survey Canada for 1880-82, Rept. C.

Data on Great Slave Lake region, Northwest Territory: Summ. Rept. Geol. Survey Canada for 1899, pp. 103-110.

Geologic map of basin of Nottaway River: Ann. Rept. Geol. Survey Canada for 1900, vol. 13, Rept. K.

Cobalt mining district, Ontario: Summ. Rept. Geol. Survey Canada for 1905, pp. 94-104; idem for 1906, pp. 110-112.

Manuscript geologic map of Newfoundland, furnished by Geological Survey of Canada for the map of North America published for the International Geological Congress, Mexico, 1906.

Berry, E. W.

Data on the Cretaceous of Maryland, Delaware, New Jersey, Pennsylvania, Virginia, North Carolina, South Carolina, Georgia, and Alabama and the Tertiary of Alabama and Mississippi, used in the compilation of the map of the Atlantic and Gulf Coastal Plain.

Bibbins, A. B.

Data on the Cretaceous of Maryland, Delaware, New Jersey, Pennsylvania, Virginia, and North Carolina, used in compilation of the map of the Atlantic Coastal Plain.

Blackwelder, Eliot.

Data on Yakutat Bay and Alsek River region, used in compiling manuscript map of Alaska, making use of earlier work of I. C. Russell.

Laramie-Sherman folio, Wyoming (with N. H. Darton and C. E. Siebenthal).

Blake, W. P.

Manuscript map of southern Arizona, used in part.

Böse, E.

Geologic map of Chiapas and Tabasco: Bol. Inst. geol. México No. 20, 1905.

Boutwell, J. M.

Geologic map of the Bingham district, Utah: Prof. Paper U. S. Geol. Survey No. 38, 1905 (with Arthur Keith).

Manuscript map of Park City district, Utah, on file in office of U. S. Geol. Survey.

Bowman, Amos.

Geologic map of Cariboo mining district, British Columbia: Ann. Rept. Geol. Survey Canada for 1887-88, vol. 3, pt. 1, Rept. C.

Bownocker, J. A.

Geologic map of Ohio, based on maps by Newberry and Orton, Ohio Geol. Survey, 1909.

Branner, J. C.

Geologic map of Arkansas: Am. Jour. Sci., 4th ser., vol. 2, 1896, pp. 229-236.

Map of novaculite area, central Arkansas: Third Ann. Rept. Geol. Survey Arkansas, 1890 (with L. S. Griswold).

Santa Cruz folio, California, and manuscript maps of San Jose and Mount Hamilton quadrangles, used in compilation by Ralph Arnold and Robert Anderson.

Brock, R. W.

Member (part of the time) of committee on classification of the pre-Cambrian. Furnished geologic map of Canada compiled for the map of North America published by the International Geological Congress, 1906, and later notes and sketch maps for the present map. Adjusted several points which arose between the Canadian and United States surveys.

Data on West Kootenay district, British Columbia: Summ. Rept. Geol. Survey Canada for 1898, pp. 62-71; idem for 1899, pp. 75-86; idem for 1900, pp. 62-84.

Data on the Boundary Creek district, British Columbia: Summ. Rept. Geol. Survey Canada for 1901, pp. 49-67; idem for 1902, pp. 92-138.

Data on the Lardeau mining district, British Columbia: Summ. Rept. Geol. Survey Canada for 1903, pp. 42-81; idem for 1904, pp. 80-91; idem for 1907, pp. 84-90.

Data on Rossland mining district, British Columbia (preliminary report): Geol. Survey Canada, 1906.

West Kootenay sheet, British Columbia: Ann. Rept. Geol. Survey Canada for 1901, vol. 14 (portfolio) (with R. G. McConnell).

Geologic map of Canada, including Labrador and Newfoundland, scale 100 miles to 1 inch (accompanies a descriptive sketch of the geology and economic minerals of Canada, by G. A. Young): Geol. Survey Canada, 1909.

Brooks, A. H.

Furnished geologic map of Alaska compiled from published maps and manuscript data.

Data on southeastern Alaska, upper Tanana and White River basins, Susitna basin, Alaska Range, Seward Peninsula, and Yukon-Tanana region (the last based on earlier work of Spurr), used in compiling manuscript map of Alaska.

Buckhannon folio, West Virginia (with J. A. Taff).

Brown, C. W.

Penobscot Bay folio, Maine (with G. O. Smith and E. S. Bastin).

Manuscript geologic map of Frenchmans Bay quadrangle, Maine.

Unpublished notes on the geology of Rhode Island.

Geologic map of the granites of Maine: Bull. U. S. Geol. Survey No. 313, 1906 (with E. S. Bastin and G. O. Smith).

Buckley, E. R.

Geologic map of Missouri: Rept. Missouri Bureau of Geol. and Mines for 1903-4.

Sketch manuscript map showing corrections to map of Missouri, 1904 (1907).

Buehler, H. A.

Notes on details of geology of Missouri.

Burchard, E. F.

Lancaster-Mineral Point folio, Wisconsin-Iowa-Illinois (with U. S. Grant).

Butler, B. S.

Unpublished notes on certain Devonian areas in Utah.

Manuscript geologic map of Frisco and adjacent region of western Utah.

Butts, Charles.

Rural Valley, Ebensburg, and Warren folios, Pennsylvania, and Birmingham folio, Alabama.

Cairnes, D. D.

- Data on the foothills of Rocky Mountains south of main line of Canadian Pacific Railway: *Summ. Rept. Geol. Survey Canada* for 1905, pp. 62-67.
 Whitehorse and Tantalus regions, Yukon: *Summ. Rept. Geol. Survey Canada* for 1906, pp. 22-30; *idem* for 1907, pp. 10-15; *idem* for 1908, pp. 26-32.
 Geologic map of Moose Mountain district of southern Alberta: *Geol. Survey Canada*, 1907.
 Geologic map of lower Lake Laberge and vicinity, Yukon Territory, scale 1 mile to 1 inch: *Geol. Survey Canada*, 1908.
 Geologic map of Conrad and Whitehorse districts, Yukon: *Geol. Survey Canada*, 1908.

Calkins, F. C.

- Geologic map of part of northern Washington: *Bull. U. S. Geol. Survey* No. 235, 1904 (with G. O. Smith).
 Geologic map of the Cœur d'Alene district, Idaho: *Prof. Paper U. S. Geol. Survey* No. 62, 1908 (with F. L. Ransome).
 Geologic map of part of east-central Washington: *Water-Supply Paper U. S. Geol. Survey* No. 118, 1905.
 Geologic map of part of northern Idaho: *Bull. U. S. Geol. Survey* No. 384, 1909.
 Manuscript map of Philipsburg quadrangle, Montana.
 Snoqualmie folio, Washington (with G. O. Smith).

Calvert, W. R.

- Geologic map of the vicinity of Judith Mountains, Montana: *Bull. U. S. Geol. Survey* No. 390, 1909.
 Data on Lewistown and Livingston coal fields, Montana, used in compiling map of the coal-bearing Cretaceous and Tertiary.

Campbell, H. D.

- Manuscript maps of Lexington and Natural Bridge quadrangles, Virginia.

Campbell, M. R.

- Data on Black Mesa coal field, Arizona, used in compiling map of the coal-bearing Cretaceous and Tertiary.
 Geologic map of the coal-bearing Cretaceous and Tertiary of the central Western States, compiled by Bailey Willis and M. R. Campbell.
 Estillville, Pocahontas, Tazewell, London, Richmond, Standingstone, Bristol, Huntington, Charleston, and Raleigh folios, southern Appalachians, and manuscript maps of adjacent areas; Danville folio, Illinois; and Masontown-Uniontown, Brownsville-Connellsville, and Latrobe folios, Pennsylvania.
 Geologic map of Deer Creek coal field, Arizona: *Bull. U. S. Geol. Survey* No. 225, 1904, pp. 240-258.

Camsell, Charles.

- Data on the region southwest of Fort Smith, Slave River, Northwest Territory: *Summ. Rept. Geol. Survey Canada* for 1902, pp. 151-169.
 Data on the headwater region of Severn River, Northwest Territory: *Summ. Rept. Geol. Survey Canada* for 1904, pp. 143-152.
 Data on Peel and Wind rivers: *Ann. Rept. Geol. Survey Canada* for 1904, vol. 16, Rept. CC.
 Data on Peel River, in the Yukon and Mackenzie districts: *Summ. Rept. Geol. Survey Canada* for 1905, pp. 36-46.
 Data on Osoyoos and Similkameen mining divisions, British Columbia: *Summ. Rept. Geol. Survey Canada* for 1907, pp. 24-31; *idem* for 1908, pp. 61-64.
 Geologic map of Similkameen district, British Columbia: *Geol. Survey Canada*, 1907.

Chamberlin, T. C.

- Member of committee on pre-Cambrian nomenclature.
 Geologic map of Wisconsin: *Wisconsin Geol. Survey*, 1881.
 Milwaukee folio, Wisconsin (with W. C. Alden).

Clapp, C. H.

- Data on southeastern part of Vancouver Island: *Summ. Rept. Geol. Survey Canada* for 1908, pp. 52-60.

Clapp, F. G.

- Amity and Rogersville folios, Pennsylvania; Patoka folio, Indiana-Illinois (with M. L. Fuller).
 Geologic map of Florida: *Ann. Rept. Geol. Survey Florida*, 1909 (with G. C. Matson and Samuel Sanford).

Clark, W. B.

- Geologic map of Maryland: *Maryland Geol. Survey*, vol. 6, 1906.
 Furnished geologic map of the Atlantic Coastal Plain north of North Carolina, from cooperative surveys with States. Trenton and Philadelphia folios, New Jersey and Pennsylvania (with Florence Bascom and others).

Clarke, J. M.

- Corrections to geologic map of New York published in 1901.
 Geologic map of eastern part of Gaspé Peninsula, Quebec: *Mem. New York State Mus.* No. 9, 1908.
 Manuscript map of other parts of Gaspé Peninsula, Quebec.

Collier, A. J.

- Data on Miles City coal field, Montana, used in compiling map of the coal-bearing Cretaceous and Tertiary.
 Geologic map of Arkansas coal field: *Bull. U. S. Geol. Survey* No. 326, 1907.
 Data on Yukon Valley, St. Lawrence Island, Cape Lisburne region, and Seward Peninsula, used in compiling manuscript map of Alaska.

Collins, W. H.

- Data on Montreal River district, Ontario: Summ. Rept. Geol. Survey Canada for 1908, pp. 115-120.
- Geologic map of northwestern Ontario traversed by the Transcontinental Railway between Lake Nipigon and Sturgeon Lake: Geol. Survey Canada, 1908.
- Geologic map of northwestern Ontario traversed by National Transcontinental Railway between Lake Nipigon and Clay Lake, Ontario: Geol. Survey Canada, 1909.
- Geologic map of Gowganda mining division, district of Nipissing, Ontario: Geol. Survey Canada, 1909.
- Geologic map of the region north of Lake Superior between Pic and Nipigon rivers, Ontario: Geol. Survey Canada, 1909.

Cook, G. H.

- Geologic map of New Jersey: Geol. Survey New Jersey, 1890.

Crandall, Roderic.

- Unpublished data on geology of Mount Hamilton region, California.

Crider, A. F.

- Data on the Tertiary and Cretaceous of Mississippi and on the Tertiary of Arkansas, used in compilation of the map of the Atlantic and Gulf Coastal Plain.
- Geologic map of Mississippi: Bull. Mississippi State Geol. Survey No. 4, 1908.

Crosby, W. O.

- Maps of the Boston Basin, used in compiling map of New England: Occas. Papers Boston Soc. Nat. Hist., 4th ser., vol. 1, pt. 1, 1893, pp. 1-177; pt. 2, 1894, pp. 179-288; pt. 3, 1900, 289-563.

Cross, Whitman.

- Telluride, La Plata, Silverton, Rico, Needle Mountains, Ouray, and Engineer Mountain folios, southwestern Colorado, and manuscript maps of the adjacent Lake City and Durango quadrangles.
- Notes for correction of the Hayden map of Colorado.
- Geologic map of the Denver Basin, Colo.: Mon. U. S. Geol. Survey, vol. 27, 1896 (with S. F. Emmons and G. H. Eldridge).
- Pikes Peak and Anthracite-Crested Butte folios, central Colorado.
- Geologic map of Silver Cliff and Rosita Hills, Colorado: Seventeenth Ann. Rept. U. S. Geol. Survey, pt. 2, 1896, pp. 269-403.

Cummins, W. F.

- Geologic map of Staked Plain and adjacent area, Texas: Third Ann. Rept. Geol. Survey Texas, 1891 (with E. T. Dumble).

Dale, T. N.

- Manuscript maps of Housatonic, Taconic, and Mettawee quadrangles, Massachusetts, Vermont, and New York.
- Geologic map of Greylock and Hoosac mountains, Mass.: Mon. U. S. Geol. Survey, vol. 23, 1894 (with Raphael Pumpelly and J. E. Wolff).
- Geologic map of the slate belt of eastern New York and western Vermont: Nineteenth Ann. Rept. U. S. Geol. Survey, pt. 3, 1899, pp. 153-308.

Dall, W. H.

- Data on Kodiak Island and Nunivak Island, used in compiling manuscript map of Alaska.

Daly, R. A.

- Member (part of the time) of the committee on pre-Cambrian nomenclature.
- Data on the western part of the international boundary: Summ. Rept. Geol. Survey Canada for 1901, pp. 37-49; idem for 1902, pp. 136-147; idem for 1903, pp. 91-100; idem for 1904, pp. 91-100; Rept. Chief Astronomer Canada, Dept. Interior, for 1905, appendix 8, 1906, pp. 278-283; idem for 1906, appendix 5, 1907, pp. 131-135. Also manuscript geologic map of the region.

Darton, N. H.

- Camp Clark and Scotts Bluff folios, Nebraska; Oelrichs, Newcastle, Edgemont, Sundance, Devils Tower, Belle Fourche, and Aladdin folios, Black Hills, South Dakota; Bald Mountain-Dayton and Cloud Peak-Fort McKinney folios, Bighorn Mountains; and Laramie-Sherman folio, Rocky Mountains of Wyoming.
- Geologic maps of the Black Hills, South Dakota; Bighorn Mountains, Wyoming; and Great Plains: Prof. Paper U. S. Geol. Survey Nos. 17, 32, 51, 52, and 65; Twenty-first Ann. Rept. U. S. Geol. Survey, pt. 4, 1901, pp. 497-599; Water-Supply Paper U. S. Geol. Survey No. 227, 1909.
- Fredericksburg, Nomini, Staunton, Franklin, Piedmont, Monterey, Washington, New York City, Passaic, Philadelphia, and Trenton folios, Appalachian region; manuscript maps of parts of Lewisburg, Dublin, Christiansburg, Roanoke, Hillsville, Huntsville, Hinton, and Harrisonburg quadrangles, Virginia.
- Reconnaissance map of northwestern New Mexico and northern Arizona: Bull. U. S. Geol. Survey No. 435, 1910.
- Geologic map of Owl Creek Mountains, Wyoming: Senate Doc. 219, 59th Cong., 1st sess., 1906.
- Geologic map of central Wyoming, Wind River to Owl Creek: Bull. Geol. Soc. America, vol. 19, 1908, pp. 403-470.
- Manuscript map of Deming quadrangle, New Mexico.
- Geologic map of Laramie Basin, Wyoming: Bull. U. S. Geol. Survey No. 364, 1909 (with C. E. Siebenthal).
- Notes on Cambrian and pre-Cambrian areas in San Bernardino County, Cal.

Davis, W. M.

Geologic map of the Triassic area of Connecticut: Eighteenth Ann. Rept. U. S. Geol. Survey, pt. 2, 1898, pp. 1-192.

Dawson, G. M.

Data concerning Tertiary lignite formation in the vicinity of the forty-ninth parallel: Geol. Rept. Prog. Brit. North America Boundary Comm. for 1873 (in part).

Geologic sections and data on region between Lake of the Woods and the Rocky Mountains: Rept. Geol. 49th Par. Brit. North America Boundary Comm., 1875.

Data on British Columbia: Rept. Prog. Geol. Survey Canada for 1875-76, pp. 233-265; idem for 1876-77, pp. 95-102.

Geologic map of British Columbia between Fraser River and the Coast Range: Rept. Prog. Geol. Survey Canada for 1876-77, with report, pp. 17-94.

Data on Leech River region, British Columbia: Rept. Prog. Geol. Survey Canada for 1876-77, pp. 95-102.

Geologic map and data on southern portion of interior of British Columbia: Rept. Prog. Geol. Survey Canada for 1877-78, Rept. B.

Data on Queen Charlotte Islands: Rept. Prog. Geol. Survey Canada for 1878-79, Rept. B. (with geologic map).

Data on region from Souris River to one hundred and eighth meridian: Rept. Prog. Geol. Survey Canada for 1879-80, Rept. A, appendix I.

Data on northern part of British Columbia and Peace River country, from Port Simpson on Pacific coast to Edmonton on Saskatchewan: Rept. Prog. Geol. Survey Canada for 1879-80, Rept. B.

Data on Bow and Belly rivers region, Alberta: Rept. Prog. Geol. Survey Canada for 1880-82, Rept. B; idem for 1882-84, Rept. C (with geologic map).

Geologic map of Rocky Mountains between latitudes 49° and 51° 30': Ann. Rept. Geol. Survey Canada for 1885, new ser., vol. 1, Rept. B.

Geologic map of northern part of Vancouver Island and adjacent coasts: Ann. Rept. Geol. Survey Canada for 1886, vol. 2, Rept. B.

Geologic map of northern portion of the Dominion of Canada east of the Rocky Mountains: Ann. Rept. Geol. Survey Canada for 1886, vol. 2, Rept. R.

Data on southern interior of British Columbia: Summ. Rept. Geol. Survey Canada for 1887-88, pp. 60-66.

Data on Yukon Territory and northern British Columbia: Ann. Rept. Geol. Survey Canada for 1887-88, vol. 3, pt. 1, Rept. B.

Data on West Kootenay district, British Columbia: Ann. Rept. Geol. Survey Canada for 1888-89, vol. 4, Rept. B.

Kamloops map sheet, British Columbia: Ann. Rept. Geol. Survey Canada for 1894, vol. 7, Rept. B.

Notes on Yukon district and adjacent northern part of British Columbia, compiled from report of 1898.

Geologic map of Dominion of Canada (western sheet), scale 50 miles to 1 inch: Geol. Survey Canada, edition of 1901.

Data on Nunivak Island, used in compiling manuscript map of Alaska.

Denis, Theodore.

Data on the country around Bruce mines, Ontario: Summ. Rept. Geol. Survey Canada for 1904, pp. 179-190.

Diller, J. S.

Geologic map of the Klamath Mountains, Oregon and northern California, compiled for this map.

Geologic map of Crater Lake region, Oregon: Prof. Paper U. S. Geol. Survey No. 3, 1902.

Geologic map of Taylorsville region, California: Bull. U. S. Geol. Survey, No. 353, 1908.

Lassen Peak, Coos Bay, Roseburg, Port Orford, and Redding folios, Oregon and California, and manuscript maps of adjacent Riddles, Granite Pass, Red Bluff, and parts of Ashland and Shasta quadrangles.

Notes on the geology of northwestern Oregon: Seventeenth Ann. Rept. U. S. Geol. Survey, pt. 1, 1896, pp. 447-520.

Deussen, Alexander.

Manuscript geologic map of the Tertiary of the Gulf coast of Texas west of Galveston.

Dobbs, W. S.

Data on the region south of Cape Tatnam, Northwest Territory: Summ. Rept. Geol. Survey Canada for 1905, pp. 69-73.

Dowling, D. B.

Data on vicinity of Red Lake and part of the basin of Berens River, Keewatin: Ann. Rept. Geol. Survey Canada for 1894, vol. 7, Rept. F.

Geologic map of Lake Winnipeg and vicinity: Ann. Rept. Geol. Survey Canada for 1898, vol. 11, Rept. G (with J. B. Tyrrell).

Data on Nipigon Lake district, Ontario: Summ. Rept. Geol. Survey Canada for 1898, pp. 94-99.

Data on Saskatchewan district: Summ. Rept. Geol. Survey Canada for 1899, pp. 110-115.

Geologic map of Athabasca, Saskatchewan, and Keewatin, including Moose Lake and the route from Cumberland Lake to Churchill River and the upper parts of Burntwood and Grass rivers: Ann. Rept. Geol. Survey Canada for 1900, vol. 13, Rept. FF.

Data on the west side of James Bay: Summ. Rept. Geol. Survey Canada for 1901, pp. 107-115.

Dowling, D. B.—Continued.

- Data on Ekwan River, Sutton Mill lakes, and west coast of James Bay: Ann. Rept. Geol. Survey Canada for 1901, vol. 14, Rept. F.
- Data on Rocky Mountains, Sheep Creek and Cascade troughs northward to Panther River: Summ. Rept. Geol. Survey Canada for 1903, pp. 83-91.
- Geologic map of Costigan coal field: Ann. Rept. Geol. Survey Canada for 1904, vol. 16, Rept. A.
- Data on the Cascade and Costigan coal basins, Alberta: Summ. Rept. Geol. Survey Canada for 1904, pp. 105-121.
- Data on the northern extension of Elk River coal basin: Summ. Rept. Geol. Survey Canada for 1905, pp. 59-62.
- Data on the Rocky Mountains between Bow and Yellowhead passes: Summ. Rept. Geol. Survey Canada for 1906, pp. 66-73; idem for 1907, pp. 32-34; idem for 1908, pp. 77-86.
- Geologic map of Cascade coal basin, Alberta: Geol. Survey Canada, 1907.
- Geologic map of coal fields of Manitoba, Saskatchewan, Alberta, and eastern British Columbia: Geol. Survey Canada, 1909 (and later manuscript corrections).
- Data on and geologic map of country between Athabasca Lake and Churchill River: Ann. Rept. Geol. Survey Canada for 1895, vol. 8, Rept. D (with J. B. Tyrrell).
- Geologic map of Lake Winnipeg and vicinity: Ann. Rept. Geol. Survey Canada for 1898, vol. 11, Rept. G (with J. B. Tyrrell).
- Boundaries of Eocene against Upper Cretaceous in M 12, N 11-12.

Drake, N. F.

- Nampa folio, Idaho-Oregon, and Silver City folio, Idaho (with Waldemar Lindgren).

Dresser, J. A.

- Data on Shefford and Brome mountains, Quebec: Summ. Rept. Geol. Survey Canada for 1901, pp. 183-187; Ann. Rept. for 1900, vol. 13, Rept. L; idem for 1904, vol. 16, pt. G.
- Geologic map of Brome Mountain, Brome County, Quebec: Ann. Rept. Geol. Survey Canada for 1904, vol. 16, Rept. G.
- Geologic map of eastern townships of Quebec: Geol. Survey Canada, Report on copper deposits, 1907.
- Data on Lake Megantic and vicinity, Compton County, Quebec: Geol. Survey Canada, 1908.
- Data on country along National Transcontinental Railway from St. Lawrence River to interprovincial boundary: Summ. Rept. Geol. Survey Canada for 1908, pp. 124-128.
- Geologic map of St. Bruno Mountain, Chambly County, Quebec: Mem. Geol. Survey Canada No. 7, 1910.

Dumble, E. T.

- Geologic map of Staked Plain and adjacent area, Texas: Third Ann. Rept. Geol. Survey Texas, 1891 (with W. F. Cummins).
- Geologic map of part of southwestern Texas: Trans. Am. Inst. Min. Eng., vol. 33, 1903, pp. 914-987.
- Notes on eastern New Mexico: Trans. Am. Inst. Min. Eng., vol. 31, 1902, pp. 696-715.

Dutton, C. E.

- Atlas of High Plateaus of Utah: U. S. Geog. and Geol. Survey Rocky Mtn. Region, 1880.
- Geologic map of Grand Canyon district, Arizona: Mon. U. S. Geol. Survey, vol. 2, 1882.
- Geologic map of northwestern New Mexico: Sixth Ann. Rept. U. S. Geol. Survey, 1885, pp. 106-198.

Eakin, H. M.

- Data on Yukon River-Norton Bay regions, used in compiling manuscript map of Alaska.

Eldridge, G. H.

- Anthracite-Crested Butte folio, Colorado (with Whitman Cross and S. F. Emmons). Manuscript geologic maps of Santa Paula and Santa Susana quadrangles, California.
- Data on Susitna basin, used in compiling manuscript map of Alaska.
- Manuscript maps covering portions of Ventura, Los Angeles, and Orange counties, Cal.
- Geologic map of Santa Clara Valley, Puente Hills and Los Angeles oil districts, California: Bull. U. S. Geol. Survey No. 309, 1907 (with Ralph Arnold).
- Geologic map of Denver Basin, Colo.: Mon. U. S. Geol. Survey, vol. 27, 1896 (with S. F. Emmons and Whitman Cross).
- Geologic map of northwestern Wyoming: Bull. U. S. Geol. Survey No. 119, 1894.
- Geologic map of the Uinta Basin, Utah and Colorado: Twenty-second Ann. Rept. U. S. Geol. Survey, pt. 1, 1901, p. 332.
- Geologic map of San Luis Obispo district, California: Twenty-second Ann. Rept. U. S. Geol. Survey, pt. 1, 1901, p. 412.

Ells, R. W.

- Boring operations at Newcastle Bridge, New Brunswick: Rept. Prog. Geol. Survey Canada for 1872-73, pp. 231-237; idem for 1874-75, pp. 90-96.
- Geologic map and data on Carleton County, New Brunswick: Rept. Prog. Geol. Survey Canada for 1874-75, pp. 97-104.
- Data on Albert, eastern Kings, and St. John counties, southern New Brunswick: Rept. Prog. Geol. Survey Canada for 1877-78, Rept. D.
- Data on northern New Brunswick, embracing portions of Restigouche, Gloucester, and Northumberland counties: Rept. Prog. Geol. Survey Canada for 1879-80, Rept. D.

Ells, R. W.—Continued.

- Geologic map of northern and eastern New Brunswick to the north side of the Bay of Chaleur: Rept. Prog. Geol. Survey Canada for 1880-1882, Rept. D.
- Data on Gaspé Peninsula and Prince Edward Island: Rept. Prog. Geol. Survey Canada for 1880-1882, Rept. DD; idem for 1882-1884, Rept. E.
- Data and geologic map of eastern Albert and Westmoreland counties, New Brunswick, and portions of Cumberland and Colchester counties, Nova Scotia: Ann. Rept. Geol. Survey Canada for 1885, vol. 1, Rept. E.
- Geologic map of Compton, Stanstead, Beauce, Richmond, and Wolfe counties, Quebec: Ann. Rept. Geol. Survey Canada for 1886, vol. 2, Rept. J.
- Three Rivers sheet, northwestern sheet of the eastern townships map, Quebec: Ann. Rept. Geol. Survey Canada for 1898, vol. 11, Rept. J.
- Geologic map of city of Ottawa and vicinity, Ontario and Quebec: Ann. Rept. Geol. Survey Canada for 1899, vol. 12, Rept. G.
- Grenville sheet, geologic map of Argenteuil, Ottawa, and Pontiac counties, Quebec, and Carleton, Russell, and Prescott counties, Ontario: Ann. Rept. Geol. Survey Canada for 1899, vol. 12, Rept. J.
- Data on Kingston district, Ontario: Summ. Rept. Geol. Survey Canada for 1901, pp. 170-183.
- Perth geologic sheet, Renfrew, Addington, Frontenac, Lanark, and Carleton counties, Ontario: Ann. Rept. Geol. Survey Canada for 1901, vol. 14, Rept. J.
- Data on Gaspé, Québec: Summ. Rept. Geol. Survey Canada for 1902, pp. 339-361.
- Data on Albert and Westmoreland counties, New Brunswick: Summ. Rept. Geol. Survey Canada for 1902, pp. 363-369.
- Geologic map of Prince Edward Island: Summ. Rept. Geol. Survey Canada for 1902, p. 369.
- Data on Charlotte County, New Brunswick: Summ. Rept. Geol. Survey Canada for 1903, pp. 150-160; idem for 1904, pp. 271-279.
- Data on southern New Brunswick: Summ. Rept. Geol. Survey Canada for 1906, pp. 131-139; idem for 1907, pp. 74-76.
- Geologic map of Pontiac, Carleton, and Renfrew counties (Pembroke sheet, No. 122): Rept. Geol. Survey Canada, 1907.
- Data on Megantic, Beauce, Dorchester, Levis, Bellechasse, and Montmagny counties, Quebec: Ann. Rept. Geol. Survey Canada for 1887-88, vol. 3, pt. 2, Rept. K.
- Montreal sheet: Ann. Rept. Geol. Survey Canada for 1894, vol. 7, Rept. J.
- Geologic map of Graham Island, British Columbia: Ann. Rept. Geol. Survey Canada for 1904, vol. 16, Rept. B.
- Geologic map of coal basins of Quilchena Creek, Coldwater River, Coal Gully, and Guichon Creek, Nicola Valley, Yale district, British Columbia: Ann. Rept. Geol. Survey Canada for 1904, vol. 16, pt. A.
- Data on southern New Brunswick: Rept. Prog. Geol. Survey Canada for 1878-79, Rept. D (with L. W. Bailey and G. F. Matthew).
- Data on Albert and Westmorland counties, New Brunswick: Rept. Prog. Geol. Survey Canada for 1876-77, pp. 351-395, with geologic map of lower Carboniferous rocks of Albert and Westmorland counties (with L. W. Bailey).

Emerson, B. K.

- Geologic map of Franklin, Hampshire, and Hampden counties, Mass.: Mon. U. S. Geol. Survey, vol. 29, 1898.
- Geologic map of part of Rhode Island from Woonsocket to Narragansett Bay: Bull. U. S. Geol. Survey No. 311, 1907.
- Furnished manuscript geologic map of Massachusetts.
- Holyoke and Hawley folios, Massachusetts-Connecticut, and manuscript maps of adjacent Housatonic, Ware, and Quinsigamond quadrangles.

Emmons, S. F.

- Geologic map of Leadville, Colo., and vicinity: Mon. U. S. Geol. Survey, vol. 12, 1886.
- Geologic map of the southern end of the Oquirrh Mountains, Utah: Sixteenth Ann. Rept. U. S. Geol. Survey, pt. 2, 1895, pp. 343-455 (with J. E. Spurr).
- Contributions to maps of the Fortieth Parallel Survey.
- Geologic map of Denver Basin, Colorado: Mon. U. S. Geol. Survey, vol. 27, 1896 (with Whitman Cross and G. H. Eldridge).
- Anthracite-Crested Butte, Butte, Tenmile district, and Tintic folios, Rocky Mountains (with Whitman Cross and others).

Emmons, W. H.

- Geologic map of part of northern Nevada: Bull. U. S. Geol. Survey No. 408, 1910.

Fairbanks, H. W.

- San Luis folio, California.

Faribault, E. R.

- Data on Nova Scotia: Summ. Repts. Geol. Survey Canada, 1894-1906.
- Geologic map of Nova Scotia (to illustrate report on the gold fields of Nova Scotia): Geol. Survey Canada, 1906.
- Data on Lunenburg County, Nova Scotia: Summ. Rept. Geol. Survey Canada for 1907, pp. 78-83; idem for 1908, pp. 150-158.

Faribault, E. R.—Continued.

Data on Guysborough, Antigonish, Pictou, Colchester, and Halifax counties, Nova Scotia: Ann. Rept. Geol. Survey Canada for 1886, vol. 2, Rept. P (with Hugh Fletcher).

Fenneman, N. M.

Geologic map of the Boulder district, Colorado: Bull. U. S. Geol. Survey No. 265, 1905.

Data on Yampa coal field, Colorado, used in compiling map of the coal-bearing Cretaceous and Tertiary.

Geologic map of Yampa coal field and vicinity, Colorado: Bull. U. S. Geol. Survey No. 297, 1906 (with H. S. Gale).

Manuscript geologic map of St. Louis quadrangle, Missouri.

Fernández de Castro, Manuel.

Geologic map of Cuba. Bol. Com. del Mapa Geol. España, vol. 8, 1881, pl. G (with Pedro Salterain y Legarra).

Fisher, C. A.

Data on Great Falls coal field, Montana, used in compiling map of the coal-bearing Cretaceous and Tertiary.

Nepesta folio, Colorado.

Geologic map of the Roswell basin, southeastern New Mexico: Water-Supply Paper U. S. Geol. Survey No. 158, 1906.

Geologic map of Great Falls region, Montana: Water-Supply Paper U. S. Geol. Survey No. 221, 1909.

Geologic map of the Bighorn Basin, Wyoming: Prof. Paper U. S. Geol. Survey No. 53, 1907.

Fletcher, Hugh.

Data on Cape Breton, Nova Scotia: Rept. Prog. Geol. Survey Canada for 1875-76, pp. 369-418; idem for 1877-78, Rept. F; idem for 1882-1884, Rept. H.

Data on Victoria, Cape Breton, and Richmond counties, Nova Scotia: Rept. Prog. Geol. Survey Canada for 1876-77, pp. 402-456, with geologic map of part of Cape Breton.

Geologic map of Springhill coal field, Cumberland County, Nova Scotia: Ann. Rept. Geol. Survey Canada for 1902-3, vol. 15, Rept. A.

Geologic map of the Nictaux and Torbrook iron district, Annapolis County, Nova Scotia: Ann. Rept. Geol. Survey Canada for 1904, vol. 16, Rept. A.

Data on Pictou and Colchester counties, Nova Scotia: Ann. Rept. Geol. Survey Canada for 1890-91, vol. 5, pt. 2, Rept. P.

Data on Nova Scotia: Summ. Repts. Geol. Survey Canada for 1894-1908.

Geologic map of parts of Kings and Hants counties, Nova Scotia: Ann. Rept. Geol. Survey Canada for 1901, vol. 14, Rept. A.

Data on Richmond, Inverness, Guysborough, and Antigonish counties, Nova Scotia: Rept. Prog. Geol. Survey Canada for 1879-80, Rept. F.

Data on Guysborough, Antigonish, Pictou, Colchester, and Halifax counties, Nova Scotia: Ann. Rept. Geol. Survey Canada for 1886, vol. 2, Rept. P (with E. R. Faribault.)

Foerste, A. F.

Geologic map of Narragansett Basin, Rhode Island: Mon. U. S. Geol. Survey, vol. 33, 1899 (with N. S. Shaler and J. B. Woodworth).

Fuller, M. L.

Manuscript map of Crowleys Ridge, Missouri and Arkansas.

Ditney and Patoka folios, Indiana and Illinois; Gaines and Elkland-Tioga folios, Pennsylvania and New York.

Gale, H. S.

Geologic maps of part of northwestern Colorado and northeastern Utah: Bull. U. S. Geol. Survey No. 341, 1909, pp. 283-315; Bull. No. 415, 1910.

Geologic map of Raven Park and vicinity, western Colorado: Bull. U. S. Geol. Survey No. 350, 1908.

Geologic maps of phosphate areas in southeastern Idaho, northeastern Utah, and adjacent parts of Wyoming: Bull. U. S. Geol. Survey No. 430, 1910, pp. 457-551 (with R. W. Richards).

Geologic map of Yampa coal field and vicinity, Colorado: Bull. U. S. Geol. Survey No. 297, 1906 (with N. M. Fenneman).

Data on Buffalo (Wyoming), Yampa, Grand Hogback, and White River (Colorado), and Vernal (Utah) coal fields, used in compiling map of the coal-bearing Cretaceous and Tertiary.

Garde, Victor.

Geologic map of southeastern Greenland: Meddelelser om Grönland, vol. 9, 1889, pp. 53-144 (with G. F. Holm).

Gardner, Miss J. A.

Data on the Tertiary of Virginia and North Carolina, used in compiling map of Atlantic Coastal Plain.

Gardner, J. H.

Geologic map of coal field between Cuba and San Mateo, N. Mex.: Bull. U. S. Geol. Survey No. 381, 1910, pp. 461-473.

Data on San Juan coal region, New Mexico, used in compiling map of the coal-bearing Cretaceous and Tertiary.

Geologic map of parts of the San Juan coal field, New Mexico: Bull. U. S. Geol. Survey No. 341, 1909, pp. 335-378.

Geiger, H. R.

Manuscript geologic maps of Romney, Winchester, Woodstock, Harrisonburg, and Luray quadrangles, Virginia. Revised by Arthur Keith.

- George, R. D.**
Notes on the details of geology of Colorado.
- Gilbert, G. K.**
Contributed to the map of the Wheeler Survey.
Pueblo folio, Colorado.
Manuscript geologic map of Apishapa quadrangle, Colorado.
Geologic map of the Henry Mountains, Utah: U. S. Geog. and Geol. Survey Rocky Mtn. Region, 1880.
Map of Lake Bonneville Quaternary deposits of Utah and adjacent parts of Nevada and Idaho: Mon. U. S. Geol. Survey, vol. 1, 1885.
- Girty, G. H.**
Notes on distribution of marine Carboniferous in the United States, for this map.
- Glenn, L. C.**
Data on the Cretaceous of Tennessee and the Tertiary of Tennessee, Kentucky, and Illinois, used in compiling the map of the Atlantic Coastal Plain.
Geologic map of parts of Tennessee, Kentucky, and Illinois: Water-Supply Paper U. S. Geol. Survey No. 164, 1906.
- Goldman, M. I.**
Data on Colorado Springs coal field, Colorado, used in compiling map of the coal-bearing Cretaceous and Tertiary.
Geologic map of Colorado Springs coal field, Colorado: Bull. U. S. Geol. Survey No. 381, 1910, pp. 317-340.
- Goldthwait, J. W.**
Geologic map of Toqueville district, Utah: Bull. Mus. Comp. Zool. Harvard Coll. No. 42, 1904 (with Ellsworth Huntington).
- Gorby, S. S.**
Geologic map of Indiana: Geol. and Nat. Hist. Survey Indiana, 1893.
- Gordon, C. H.**
Data on the Cretaceous of Texas and Oklahoma, used in compiling the map of the Atlantic and Gulf Coastal Plain.
Geologic map of part of San Mateo and the Black, Caballos, and Cristobal ranges, New Mexico: Prof. Paper U. S. Geol. Survey No. 68, 1910, pp. 213-285.
- Gould, C. N.**
Geologic map of Oklahoma: Water-Supply Paper U. S. Geol. Survey No. 148, 1905.
Geologic map of parts of northern Texas: Water-Supply Paper U. S. Geol. Survey No. 191, 1907.
- Grabau, A. W.**
Geologic map of Becraft Mountain, New York: Bull. New York State Mus. No. 69, 1903, pp. 1030-1079.
Geologic map of Schoharie and Cobleskill valleys, New York: Bull. New York State Mus. No. 92, 1906.
- Graham, R. P. D.**
Data on the coast of British Columbia, from Kingcome Inlet to Dean Channel, including the adjacent islands: Summ. Rept. Geol. Survey Canada for 1908, pp. 38-40.
- Grant, U. S.**
Lancaster-Mineral Point folio, Wisconsin-Iowa-Illinois (with E. F. Burchard).
Data on Prince William Sound and eastern half of Kenai Peninsula, used in compiling manuscript map of Alaska.
- Gregory, H. E.**
Data on Black Mesa coal field, Arizona, used in compiling map of the coal-bearing Cretaceous and Tertiary.
Geologic map of Connecticut: Connecticut Geol. and Nat. Hist. Survey, 1906 (with H. H. Robinson).
Manuscript map of northeastern Arizona, 1910.
- Griswold, L. S.**
Geologic map of novaculite area, central Arkansas: Third Ann. Rept. Geol. Survey Arkansas, 1890 (with J. A. Branner).
- Gwillim, J. C.**
Geologic map of Atlin mining district, British Columbia: Ann. Rept. Geol. Survey Canada for 1899, vol. 12, Rept. B.
- Hague, Arnold.**
Geologic map of Yellowstone Park and adjacent part of Wyoming: Mon. U. S. Geol. Survey, vol. 32, 1904.
Geologic map of the Eureka district, Nevada: Mon. U. S. Geol. Survey, vol. 20, 1892.
Yellowstone National Park and Absaroka folios, Wyoming.
- Hall, C. M.**
Alexandria and De Smet folios, South Dakota: Casselton-Fargo folio, North Dakota-Minnesota.
- Hamlin, Homer.**
Manuscript geologic map of part of Monterey County, Cal.
- Hammer, R. R. I.**
Geologic map of part of the west coast of Greenland: Meddelelser om Grönland, vol. 4, 1893, pp. 173-242 (with K. J. V. Steenstrup).
Geologic map of part of northwestern Greenland: Meddelelser om Grönland, vol. 8, 1889, pp. 1-32.
- Harder, E. C.**
Geologic map of Iron Spring district, southwestern Utah: Bull. U. S. Geol. Survey No. 338, 1908 (with C. K. Leith).
Unpublished notes on part of southeastern California.

Harris, G. D.

Data on the Tertiary of Louisiana, used in compiling the map of the Gulf Coastal Plain.
Geologic map of Louisiana: Geol. Survey Louisiana, pt. 4, 1902.

Hartley, Edward.

Data on Pictou County, Nova Scotia: Rept. Prog. Geol. Survey Canada for 1866-1869, pp. 55-107, 365-442.
Geologic map of Pictou coal field (with W. E. Logan).

Haworth, Erasmus.

Geologic map of Kansas: Kansas Univ. Geol. Survey, vol. 9, 1908.

Haycock, Ernest.

Data on west coast of Vancouver Island: Summ. Rept. Geol. Survey Canada for 1902, pp. 76-92.
Data on Ottawa County, Quebec: Summ. Rept. Geol. Survey Canada for 1904, pp. 232-239.
Data on Labelle and Wright counties, Quebec: Summ. Rept. Geol. Survey Canada for 1905, pp. 105-112.

Hayden, F. V.

Geologic maps of Colorado and parts of Idaho, Montana, Utah, Wyoming, Arizona, New Mexico, South Dakota, and Nebraska: Repts. U. S. Geol. and Geog. Survey Terr., 1867-1882.

Hayes, C. W.

Member (part of the time) of committee on pre-Cambrian nomenclature.
Ringgold, Kingston, Chattanooga, Sewanee, Stevenson, Cleveland, Pikeville, McMinnville, Gadsden, Rome, and Columbia folios; southern Appalachians.
Manuscript maps of Anniston, Tallapoosa, Marietta, Dalton, Cartersville, Fort Payne, and Murphy quadrangles, southern Appalachians.
Unpublished notes on the geology of eastern Mexico.
Geologic reconnaissance of Cuba: Rept. Military Governor Cuba for 1901 (with T. W. Vaughan and A. C. Spencer).
Data on geology of region adjacent to the Nicaragua Canal route: Bull. Geol. Soc. America, vol. 10, 1899, pp. 285-348; Science, new ser., vol. 10, 1899, p. 97.

Heikes, V. C.

Geologic map of Fort Hall mining district, southeastern Idaho: Bull. U. S. Geol. Survey No. 340, 1908 (with F. B. Weeks).

Herrick, C. L.

Geologic maps of parts of Bernalillo and Valencia counties, N. Mex.: Am. Geologist, vol. 25, 1900, pp. 331-346.

Hershey, O. H.

Manuscript geologic map of part of southern California north of Los Angeles and San Bernardino.

Hess, F. L.

Notes on the Randsburg district, California.
Manuscript geologic map of the Randsburg quadrangle, southern California.

Hettner, Alfred.

Geologic map of central Colombia, Kordillere von Bogota: Petermanns Mitt., Ergänzungsband 22, Heft 104, 1892.

Higgins, D. F.

Data on Prince William Sound and eastern half of Kenai Peninsula, used in compiling manuscript map of Alaska.

Hill, B. F.

Geologic map of portion of southwestern Texas, from Lone Mountains to Chisos district: Repts. Univ. Texas Min. Survey, 1904 (with J. A. Udden).

Hill, J. M.

Manuscript geologic map of Patagonia and Nogales quadrangles, southern Arizona (with F. C. Schrader).

Hill, R. T.

Manuscript map of Chihuahua, Sonora, and part of Coahuila, Mexico, used in part.
Manuscript map of southern Arizona, southern California, southern and eastern New Mexico, and Texas, used in part.
Map of eastern Texas: Twenty-first Ann. Rept. U. S. Geol. Survey, pt. 7, 1901.
Austin and Nueces folios, Texas.
Notes on the geology of the West Indies and Central America, used in compiling map of these areas: Cuba and Porto Rico, 1898; Nat. Geog. Mag., vol. 9, 1898, pp. 193-242; vol. 10, 1899, pp. 93-112; Bull. Mus. Comp. Zool. Harvard Coll., vol. 16, 1895, pp. 241-288.

Hills, R. C.

Walsenburg, Spanish Peaks, and Elmore folios, southern Colorado.

Hitchcock, C. H.

Geologic map of Vermont: Final Rept. Vermont Geol. Survey, vol. 2, 1861; used by G. O. Smith and E. S. Bastin in compiling New England map.

Hoeing, J. B.

Geologic map of Kentucky, compiled for Kentucky Geol. Survey, 1907.

Holm, G. F.

Geologic map of part of southern Greenland: Meddelelser om Grönland, vol. 2, 1881, pp. 27-41 (with K. J. V. Steenstrup).
Geologic map of southeastern Greenland: Meddelelser om Grönland, vol. 9, 1889, pp. 53-144 (with Victor Garde).

Howe, Ernest.

Compiled geology of Panama, South America, and parts of the West Indies for the map of North America published by the International Geological Congress, 1906; in part incorporated in present map.

Data on the Canal Zone: Rept. Isthmian Canal Comm. for 1907, pp. 108-138.

Silverton and Needle Mountains folios, Colorado:

Howley, J. P.

Manuscript geologic map of Avalon Peninsula, Newfoundland, furnished by Geological Survey of Canada for geologic map of North America published for the International Geological Congress, Mexico, 1906.

Huntington, Ellsworth.

Geologic map of Toqueville district, Utah: Bull. Mus. Comp. Zool. Harvard Coll., 1904 (with J. W. Goldthwait).

Iddings, J. P.

Livingston folio, Montana (with W. H. Weed): Yellowstone National Park folio, Wyoming (with Arnold Hague and W. H. Weed).

Ingall, E. D.

Data on the Bruce mines district, Algoma, Ontario: Summ. Rept. Geol. Survey Canada for 1902, pp. 244-254; idem for 1904, pp. 179-190.

Ireland, William.

Geologic map of California: California State Min. Bur., 1891, used in part.

Jaggard, T. A., jr.

Bradshaw Mountains folio, Arizona (with Charles Palache).

Geologic map of the northern Black Hills, South Dakota: Prof. Paper U. S. Geol. Survey No. 26, 1904.

Jessen, A.

Geologic map of part of the southwestern coast of Greenland: Meddelelser om Grönland, vol. 16, 1896, pp. 123-170.

Johnson, H. R.

Geologic map of McKittrick-Sunset oil region, California: Bull. U. S. Geol. Survey No. 406, 1910 (with Ralph Arnold).

Manuscript geologic map of San Joaquin Valley, California.

Johnston, J. F. E.

Data on the Abitibi Lake district, Ontario: Summ. Rept. Geol. Survey Canada for 1901, pp. 128-141.

Data on Ottawa County, Quebec: Summ. Rept. Geol. Survey Canada for 1904, pp. 239-250.

Johnston, R. A. A.

Data on Aspen Grove and Aberdeen camp, British Columbia: Summ. Rept. Geol. Survey Canada for 1904, pp. 74-80.

Data along route of Transcontinental Railway in New Brunswick: Summ. Rept. Geol. Survey Canada for 1906, pp. 127-130.

Johnston, W. A.

Data on the Peterborough, Prince Edward, and Simcoe sheets, Ontario: Summ. Rept. Geol. Survey Canada for 1905, pp. 92-94; idem for 1906, pp. 124-126; idem for 1907, pp. 56-58; idem for 1908, pp. 97-102.

Karsten, Hermann.

Geologic map of part of Colombia, South America: Géologie de l'ancienne Colombie bolivarienne, Vénézuéla, Nouvelle-Grenade et Ecuador, Berlin, 1886, p. 62.

Katz, F. J.

Data on Iliamna and Lake Clark region, used in compiling manuscript map of Alaska.

Kay, F. H.

Manuscript geologic map of Llano and Burnet quadrangles, Texas (with A. C. Spencer and Sidney Paige).

Keele, Joseph.

Geologic map of upper Stewart River: Ann. Rept. Geol. Survey Canada for 1904, vol. 16, Rept. C.

Data on Duncan Creek mining district: Summ. Rept. Geol. Survey Canada for 1904, pp. 18-42.

Data on Stewart River: Summ. Rept. Geol. Survey Canada for 1905, pp. 32-36.

Data on Pelly, Ross, and Gravel rivers, Yukon and Northwest Territory: Summ. Rept. Geol. Survey Canada for 1908, pp. 33-37.

Keith, Arthur.

Harpers Ferry, Knoxville, Loudon, Morristown, Briceville, Wartburg, Washington, Maynardsville, Cranberry, Asheville, Greenville, Mount Mitchell, Nantahala, Roan Mountain, and Pisgah folios, Appalachian region, and manuscript maps of adjacent areas.

Compiled and adjusted data of his own and others for parts of New England.

Manuscript geologic maps of Frederick, Mount Vernon, Abingdon, Mount Guyot, Murphy, Saluda, Morganton, Cowee, Kings Mountain, and Gaffney quadrangles, central and southern Appalachians.

Compiled and furnished data for map of pre-Cambrian and Paleozoic Appalachian Mountain and Piedmont Plateau region of Georgia, South Carolina, North Carolina, Tennessee, and Virginia, for this map.

Geologic map of Bingham mining district, Utah: Prof. Paper U. S. Geol. Survey No. 38, 1905 (with J. M. Boutwell).

Geologic map of Catoctin belt, Maryland and Virginia: Fourteenth Ann. Rept. U. S. Geol. Survey, pt. 2, 1893, pp. 285-395.

Kemp, J. F.

Geologic map of Elizabethtown and Port Henry quadrangles, New York: Bull. Univ. New York No. 138, 1910 (with Rudolph Ruedemann).

Keyes, C. R.

Geologic map of central New Mexico: Water-Supply Paper U. S. Geol. Survey No. 123, 1905, modified by data from W. T. Lee.

Geologic map of Missouri: Missouri Geol. Survey, vol. 14, 1894.

Kindle, E. M.

Data on Cape Lisburne region and Porcupine River, used in compiling manuscript map of Alaska.

Watkins Glen-Catatonk folio, New York (with H. S. Williams and R. S. Tarr).

King, Clarence.

Geologic maps of parts of Utah, Colorado, Wyoming, and Nevada: Repts. U. S. Geol. Expl. 40th Par., 1871-1878.

Knopf, Adolph.

Data on southeastern Alaska, upper Tanana and White River basins, and Matanuska Valley, used in compiling manuscript map of Alaska.

Kornerup, A.

Geologic map of part of southwestern coast of Greenland: Meddelelser om Grönland, vol. 1, 1879, pp. 77-140; vol. 2, 1881, pp. 49-194.

Kümmel, H. B.

Passaic, Franklin Furnace, Trenton, Philadelphia, and Raritan folios, New Jersey and Pennsylvania.

Corrections to geologic map of New Jersey of 1890.

Lafamme, J. C. K.

Data on Saguenay region, Quebec: Rept. Prog. Geol. Survey Canada for 1882-1884, Rept. D.

La Forge, Laurence.

Manuscript geologic map of Ellijay quadrangle, Georgia (with W. C. Phalen).

Lane, A. C.

Geologic map of Michigan: Geol. Survey Michigan, 1905.

Corrections to map of Michigan, 1905, by later correspondence.

Lawson, A. C.

Geologic map of San Francisco Peninsula, California: Fifteenth Ann. Rept. U. S. Geol. Survey, 1895, pp. 399-476.

Furnished manuscript geologic map of California, north of San Francisco Bay, used in part.

Manuscript geologic maps of Tamalpais, San Francisco, Concord, San Mateo, and Haywards quadrangles, California.

Geologic map of Lake of the Woods region, Ontario and Manitoba: Ann. Rept. Geol. Survey Canada for 1885, vol. 1, Rept. CC.

Geologic map of the Rainy Lake region, Ontario: Ann. Rept. Geol. Survey Canada for 1887-88, vol. 3, pt. 1, Rept. F.

Leach, W. W.

Data on Crows Nest coal field, British Columbia: Summ. Rept. Geol. Survey Canada for 1901, pp. 67-79.

Geologic map of Blairmore-Frank coal fields, southern Alberta: Summ. Rept. Geol. Survey Canada for 1902, p. 169; Ann. Rept. Geol. Survey Canada for 1902-3, vol. 15, Rept. A.

Geologic map of Telkwa Valley, British Columbia: Geol. Survey Canada, 1907.

Data on Bulkley Valley and vicinity, British Columbia: Summ. Rept. Geol. Survey Canada for 1907, pp. 19-23; idem for 1908, pp. 41-45.

Lee, W. T.

Geologic map of part of western Arizona: Bull. U. S. Geol. Survey No. 352, 1908.

Manuscript map of central New Mexico, from El Paso, Tex., to Santa Fe, N. Mex.

Data on coal fields of Grand Mesa and Crested Butte, Colorado, and Raton, New Mexico, used in compiling map of the coal-bearing Cretaceous and Tertiary.

Geologic map of part of Salt River Valley, Arizona: Water-Supply Paper U. S. Geol. Survey No. 136, 1905.

Leith, C. K.

Geologic map of Lake Superior region: Mon. U. S. Geol. Survey, vol. 52, 1911 (with C. R. Van Hise).

Geologic map of the Iron Springs district, southwestern Utah: Bull. U. S. Geol. Survey No. 338, 1908 (with E. C. Harder).

Unpublished notes on the pre-Cambrian in Canada.

Leonard, A. G.

Geologic map of North Dakota: Fourth Rept. North Dakota Geol. Survey, 1906.

Bismarck folio, North Dakota.

LeRoy, O. E.

Map of and data on Nanaimo and New Westminster districts, British Columbia: Geol. Survey Canada, 1908.

Data on Phoenix camp and Slocan district, British Columbia: Summ. Rept. Geol. Survey Canada for 1908, pp. 65-68.

Geologic map of Island of Montreal and vicinity: Ann. Rept. Geol. Survey Canada for 1901, vol. 14, Rept. O (with F. D. Adams).

Lesley, J. P.

Geologic map of Pennsylvania, compiled by A. D. W. Smith, under direction of J. P. Lesley: *Summ. Rept. Second Geol. Survey Pennsylvania*, 1893.

Leverett, Frank.

Ann Arbor folio, Michigan (with I. C. Russell).

Lewis, J. V.

Geologic map of western North Carolina based on data furnished by Arthur Keith: *North Carolina Geol. Survey*, vol. 1, 1905 (with J. H. Pratt).

Lindgren, Waldemar.

Geologic map of Idaho Basin and Boise Ridge, Idaho: *Eighteenth Ann. Rept. U. S. Geol. Survey*, pt. 3, 1898, pp. 625-736.

Geologic map of Silver City, De Lamar, and other mining districts in Idaho: *Twentieth Ann. Rept. U. S. Geol. Survey*, pt. 3, 1900, pp. 65-256.

Placerville, Sacramento, Marysville, Smartsville, Nevada City, Pyramid Peak, Truckee, and Colfax folios, Sierra Nevada, California and Nevada; and manuscript maps of adjacent Sierraville, Carson, and Markleeville quadrangles; Boise, Nampa, and Silver City folios, southern Idaho; Clifton folio, southern Arizona.

Geologic map of part of Bitterroot Range and Clearwater Mountains, Montana and Idaho: *Prof. Paper U. S. Geol. Survey No. 27*, 1904.

Geologic map of part of eastern Oregon: *Twenty-second Ann. Rept. U. S. Geol. Survey*, pt. 2, 1901, pp. 551-776.

Geologic map of the lower Snake River valley, Idaho: *Eighteenth Ann. Rept. U. S. Geol. Survey*, pt. 3, 1898, pp. 617-735.

Lines, E. F.

Foxburg-Clarion folio, Pennsylvania (with E. W. Shaw and M. J. Munn).

Logan, W. E.

Data on Ottawa River region: *Rept. Prog. Geol. Survey Canada for 1845-46*, pp. 5-98.

Data on Lake Superior region, Ontario: *Rept. Prog. Geol. Survey Canada for 1846-47*, pp. 5-46.

Data on the country on the south side of St. Lawrence, from Montreal and Lake Champlain to River Chaudiere: *Rept. Prog. Geol. Survey Canada for 1847-48*, pp. 5-92.

Data on region about Bay St. Paul and Murray Bay, and eastern townships, Quebec, from Chaudiere River to Temiscouata Portage Road: *Rept. Prog. Geol. Survey Canada for 1849-50*, pp. 5-72.

Data on Chaudiere River region, Quebec: *Rept. Prog. Geol. Survey Canada for 1850-51*, pp. 5-11.

Geologic map of Pictou coal field: *Rept. Prog. Geol. Survey Canada for 1866-1869* (with Edward Hartley).

Geologic map and data on Argenteuil and Two Mountains counties (Grenville district), Quebec: *Rept. Prog. Geol. Survey Canada for 1853-1856*, pp. 5-57.

Data on River Rouge district: *Rept. Prog. Geol. Survey Canada for 1858*, pp. 5-66.

Geologic map of Canada, scale 125 miles to 1 inch: *Geol. Survey Canada*, 1864.

Notes on Ontario and Quebec: *Prelim. Rept. Geol. Survey Canada for 1842*; *Rept. Prog. for 1843*.

Notes on the Joggins, Nova Scotia: *Rept. Prog. Geol. Survey Canada for 1843*.

Data on Chat and Cascapedia rivers, Gaspé, and part of Chaleur Bay: *Rept. Prog. Geol. Survey Canada for 1844*, pp. 5-66.

Data on counties of Beauharnois and Lake of Two Mountains and Chaudiere district, Quebec: *Rept. Prog. Geol. Survey Canada for 1851-52*, pp. 5-56.

Data on region along north shore of St. Lawrence, between Montreal and Cape Tourmente: *Rept. Prog. Geol. Survey Canada for 1852-53*, pp. 5-74.

Geologic map of Pictou coal field, Nova Scotia: *Rept. Prog. Geol. Survey Canada for 1866-69*.

Louderback, G. D.

Data for manuscript geologic map of Coast Ranges of California, compiled by Robert Anderson.

Low, A. P.

Member (part of the time) of committee on pre-Cambrian nomenclature.

Geologic map of the Arctic Archipelago and northwestern Greenland, based on cruise of the *Neptune*: *Geol. Survey Canada*, 1906.

Data on Gaspé Peninsula: *Rept. Prog. Geol. Survey Canada for 1882-1884*, Rept. F.

Data on Mistassini region, Quebec: *Ann. Rept. Geol. Survey Canada for 1885*, vol. 1, Rept. D.

Data on country between Lake Winnipeg and Hudson Bay: *Ann. Rept. Geol. Survey Canada for 1886*, vol. 2, Rept. F.

Data on James Bay and country east of Hudson Bay, drained by the Big, Great Whale, and Clearwater rivers: *Ann. Rept. Geol. Survey Canada for 1887-88*, vol. 3, pt. 1, Rept. J.

Data on Portneuf, Quebec, and Montmorency counties, Quebec: *Ann. Rept. Geol. Survey Canada for 1890-91*, vol. 5, Rept. L.

Data on and geologic map of Labrador Peninsula along Eastmain, Koksoak, Hamilton, Manikuagan, and other rivers: *Ann. Rept. Geol. Survey Canada for 1895*, vol. 8, Rept. L.

Data on Labrador Peninsula, Richmond Gulf to Ungava Bay: *Ann. Rept. Geol. Survey Canada for 1896*, vol. 9, Rept. L.

Low, A. P.—Continued.

- Geologic map of south shore of Hudson Strait and of Ungava Bay: Ann. Rept. Geol. Survey Canada for 1898, vol. 11, Rept. L.
 Geologic map of east coast of Hudson Bay from Cape Wolstenholme to the south end of James Bay: Ann. Rept. Geol. Survey Canada for 1900, vol. 13, Rept. D.
 Data on Nastapoka Islands, Hudson Bay: Ann. Rept. Geol. Survey Canada for 1900, vol. 13, Rept. DD.
 Geologic map of Chibougamau region, Quebec: Geol. Survey Canada, 1906.
 Geologic map of the northeastern part of the Dominion of Canada: Cruise of the *Neptune*, Ottawa, 1906.

Lupton, C. T.

- Data on the Bull Mountains (Montana) and Powder River (Wyoming) coal fields, used in compiling map of the coal-bearing Cretaceous and Tertiary.

McCallie, S. W.

- Geologic map of Georgia: Bull. Geol. Survey Georgia No. 15, 1908.

McConnell, R. G.

- Geologic map of Cypress Hills, Wood Mountain, and adjacent country, Saskatchewan: Ann. Rept. Geol. Survey Canada for 1885, vol. 1, Rept. C.
 Data on and geologic section of Rocky Mountains near fifty-first parallel: Ann. Rept. Geol. Survey Canada for 1886, vol. 2, Rept. D.
 Data on Yukon and Mackenzie basins: Ann. Rept. Geol. Survey Canada for 1888-89, vol. 4, Rept. D.
 Data on northern Alberta, comprising the country between Peace River and Athabasca River, north of Lesser Slave Lake: Ann. Rept. Geol. Survey Canada for 1890-91, vol. 5, Rept. D.
 Geologic map of Finlay and Omenica rivers region, British Columbia: Ann. Rept. Geol. Survey Canada for 1894, vol. 7, Rept. C.
 Data on West Kootenay district, British Columbia: Summ. Rept. Geol. Survey Canada for 1895, pp. 23-37; idem for 1896, pp. 19-31; idem for 1897, pp. 27-34.
 Data on Yukon and adjacent parts of British Columbia: Summ. Rept. Geol. Survey Canada for 1898, pp. 46-55.
 West Kootenay sheet, British Columbia: Ann. Rept. Geol. Survey Canada for 1901, vol. 14 (portfolio) (with R. W. Brock).
 Geologic map of Klondike mining region: Ann. Rept. Geol. Survey Canada for 1901, vol. 14, Rept. B.
 Data on Macmillan River, Yukon: Summ. Rept. Geol. Survey Canada for 1902, pp. 22-38.
 Geologic map of Kluane mining district, Yukon Territory: Ann. Rept. Geol. Survey Canada for 1904, vol. 16, Rept. A.
 Data on the headwaters of White River: Summ. Rept. Geol. Survey Canada for 1905, pp. 19-32.
 Data on Windy Arm, Tagish Lake, Yukon: Rept. Geol. Survey Canada, 1905.
 Data on Texada Island, British Columbia: Summ. Rept. Geol. Survey Canada for 1908, pp. 46-50.
 Geologic map of Whitehorse region, Yukon Territory: Rept. Geol. Survey Canada, 1909.

McEvoy, James.

- Geologic map of Yellowhead Pass route from Edmonton to Tête-Jaune Cache, comprising portions of Alberta and British Columbia: Ann. Rept. Geol. Survey Canada for 1898, vol. 11, Rept. D.
 Data on Alberta: Summ. Rept. Geol. Survey Canada for 1898, pp. 71-86.
 Geologic map of East Kootenay district, British Columbia: Ann. Rept. Geol. Survey Canada for 1899, vol. 12.

Macfarlane, Thomas.

- Data on county of Hastings, Ontario: Rept. Prog. Geol. Survey Canada for 1863-1866, pp. 91-113.
 Data on Lake Superior region, Ontario: Rept. Prog. Geol. Survey Canada for 1863-1866, pp. 115-164.

McInnes, William.

- Data on Nipigon Lake district, Ontario: Summ. Rept. Geol. Survey Canada for 1894, pp. 48-51.
 Geologic map of Seine River and Lake Shebandowan map sheets, comprising portions of the Rainy River and Thunder Bay districts, Ontario: Ann. Rept. Geol. Survey Canada for 1897, vol. 10, Rept. H.
 Data on district east of Manitou, Ontario: Summ. Rept. Geol. Survey Canada for 1898, pp. 87-94.
 Data on Rainy River district, Ontario: Summ. Rept. Geol. Survey Canada for 1899, pp. 115-122.
 Data on the region southeast of Lac Seul, Ontario: Summ. Rept. Geol. Survey Canada for 1901, pp. 87-93.
 Data on the region northwest of Lake Nipigon, Ontario: Summ. Rept. Geol. Survey Canada for 1902, pp. 208-213.
 Data on Winisk River, Keewatin district: Summ. Rept. Geol. Survey Canada for 1902, pp. 100-108.
 Data on Hudson Bay Railway route, Northwest Territory: Summ. Rept. Geol. Survey Canada for 1906, pp. 87-98.
 Data on the Pasquia Hills and lower Carrot River region, Saskatchewan: Summ. Rept. Geol. Survey Canada for 1907, pp. 41-47.
 Data on Churchill River and South Indian Lake, Northwest Territory: Summ. Rept. Geol. Survey Canada for 1908, pp. 87-92.
 Geologic map of part of Northwest Territory drained by Winisk and upper Attawapiskat rivers: Rept. Geol. Survey Canada, 1910.
 Boundaries of Paleozoic against pre-Cambrian, and of Cretaceous against Paleozoic and pre-Cambrian in N 13-14.
 Geologic map of Victoria, Northumberland, and Restigouche counties, New Brunswick: Ann. Rept. Geol. Survey Canada for 1886, vol. 2, Rept. N (with L. W. Bailey).

McInnes, William—Continued.

Data on northern New Brunswick and adjacent areas in Quebec, and in Maine: *Ann. Rept. Geol. Survey Canada* for 1887-88, vol. 3, Rept. M (with L. W. Bailey).

McOuat, Walter.

Data on country between Lake St. John and Lake Mistassini, Quebec: *Rept. Prog. Geol. Survey Canada* for 1871-72, pp. 115-119.

Data on country between Lakes Timiskaming and Abitibi, Quebec: *Rept. Prog. Geol. Survey Canada* for 1872-73, pp. 112-135.

Data on Cumberland County, Nova Scotia: *Rept. Prog. Geol. Survey Canada* for 1873-74, pp. 161-170.

Macoun, John.

Data on lower Peace and Athabasca rivers: *Rept. Prog. for Geol. Survey Canada* 1875-76, pp. 87-95.

Maddren, A. G.

Data on Controller Bay region, Chitina Valley, Porcupine River, Chandalar and upper Koyukuk and Innoko region, used in compiling manuscript map of Alaska.

Malloch, G. S.

Data on the Cascades, Palliser, and Costigan coal basin, Alberta: *Summ. Rept. Geol. Survey Canada* for 1907, pp. 35-40.

Data on Bighorn coal basin, Alberta: *Summ. Rept. Geol. Survey Canada* for 1908, pp. 70-76.

Martin, G. C.

Data on Controller Bay region, Kachemak Bay region, Alaska Peninsula, Iliamna and Lake Clark region, and Matanuska Valley, used in compiling manuscript map of Alaska.

Accident-Grantsville folio, Maryland-Pennsylvania-West Virginia.

Matson, G. C.

Data on the Tertiary of Florida, Alabama, and Mississippi, used in compiling map of Atlantic and Gulf Coastal Plain.

Geologic map of Florida; *Second Ann. Rept. Florida State Geol. Survey*, 1909 (with F. G. Clapp and Samuel Sanford).

Matthews, E. B.

Geologic map of the crystalline rocks of Maryland and adjacent part of Pennsylvania: *Am. Jour. Sci.*, 4th ser., vol. 17, 1904, pp. 141-159.

Matthew, G. F.

Data on Charlotte County, New Brunswick: *Rept. Prog. Geol. Survey Canada* for 1876-77, pp. 321-350.

Data on southern New Brunswick: *Rept. Prog. Geol. Survey Canada* for 1877-78, Repts. E and EE.

Data on Cape Breton Island, Nova Scotia: *Rept. Geol. Survey Canada*, 1903.

Data on Queens, Sunbury, and York counties, New Brunswick: *Rept. Prog. Geol. Survey Canada* for 1872-73, pp. 180-230 (with L. W. Bailey).

Data on New Brunswick: *Rept. Prog. Geol. Survey Canada* for 1874-75, pp. 84-89 (with L. W. Bailey).

Data on southern New Brunswick: *Rept. Prog. Geol. Survey Canada* for 1870-71, pp. 13-240; *idem* for 1875-76, pp. 348-368 (with L. W. Bailey).

Data on southern New Brunswick: *Rept. Prog. Geol. Survey Canada* for 1878-79, Rept. D (with L. W. Bailey and R. W. Ells).

Meinzer, O. E.

Manuscript geologic map of Estancia Valley and vicinity, New Mexico.

Manuscript geologic map of the pre-Quaternary rocks of southwestern Minnesota.

Mendenhall, W. C.

Manuscript geologic map of San Bernardino Valley in San Bernardino County and Corona quadrangle, California.

Data on Chitina Valley, upper Copper River region, Chandalar and upper Koyukuk, main Koyukuk Valley, and Kobuk Valley, used in compiling manuscript map of Alaska.

Merriam, J. C.

Notes on the geology of Berkeley Hills region, California.

Notes on the geology of John Day Basin, Washington.

Merrill, F. J. H.

Geologic map of New York: *Rept. New York State Geologist*, 1901.

New York City folio.

Merritt, W. M.

Geologic map of Ontario.

Miller, B. L.

St. Marys folio, Maryland-Virginia; Patuxent folio, Maryland-District of Columbia (with G. B. Shattuck); and Dover folio, Delaware-Maryland-New Jersey.

Data on and manuscript maps of the Cretaceous of Maryland, New Jersey, Pennsylvania, Virginia, and North Carolina, used in compiling map of Atlantic Coastal Plain.

Miller, W. G.

Member (part of the time) of committee on pre-Cambrian nomenclature.

Moffit, F. H.

Data on Chitina Valley, upper Tanana and White River basins, eastern half of Kenai Peninsula, and Seward Peninsula, used in compiling manuscript map of Alaska.

Munn, M. J.

Burgettstown-Carnegie, Foxburg-Clarion, Sewickley, and Claysville folios, Pennsylvania.

Murray, Alexander.

Data on district between Georgian Bay and the lower extremity of Lake Erie: Rept. Prog. Geol. Survey Canada for 1843.

Data on Bonaventure River district: Rept. Prog. Geol. Survey Canada for 1844, pp. 67-77.

Data on region of Matane, Ste. Anne, and St. John rivers, Gaspé: Rept. Prog. Geol. Survey Canada for 1845-46, pp. 99-118.

Data on Kaministikwia and Michipicoten rivers, Lake Superior region, Ontario: Rept. Prog. Geol. Survey Canada for 1846-47, pp. 47-57.

Data on Lake Huron region: Rept. Prog. Geol. Survey Canada for 1847-48, pp. 93-124; idem for 1848-49, pp. 7-46; idem for 1850-51, pp. 13-33.

Data on region between Ottawa, St. Lawrence, and Rideau rivers, Ontario: Rept. Prog. Geol. Survey Canada for 1851-52, pp. 57-91.

Data on region between Kingston and Lake Simcoe, Ontario: Rept. Prog. Geol. Survey Canada for 1852-53, pp. 75-152.

Data on region between Lake Huron and Ottawa River: Rept. Prog. Geol. Survey Canada for 1853-56, pp. 59-190; idem for 1857, pp. 13-27; idem for 1858, pp. 67-104.

Geologic map of Newfoundland, Montreal, 1877.

Nathorst, A. G.

Geologic map of part of northeastern Greenland: Förhandl. Geol. Fören. Stockholm, No. 207, bd. 23, hft. 4, 1901, pp. 275-306.

Newsom, J. F.

Santa Cruz folio, California (with J. C. Branner and Ralph Arnold).

Unpublished data on geology of Mount Hamilton region, California.

Nordenskjöld, Otto.

Geologic map of eastern Greenland: Meddelelser om Grönland, vol. 28, 1909, pp. 151-284.

Norwood, C. J.

Geologic map of Kentucky, compiled by J. B. Hoeing; Kentucky Geol. Survey, 1907.

O'Harra, C. C.

Aladdin, Devils Tower, and Belle Fourche folios, Black Hills, South Dakota (with N. H. Darton).

Ordóñez, Ezequiel.

Contributed to geologic map of Mexico compiled under the direction of J. G. Aguilera.

Osann, A.

Data on Ottawa Valley: Ann. Rept. Geol. Survey Canada for 1899, vol. 12, Rept. O.

O'Sullivan, Owen.

Data on the west coast of James Bay, Ontario, Quebec, and Northwest Territory: Summ. Rept. Geol. Survey Canada for 1904, pp. 173-179.

Data on the coast of Hudson Bay from York Factory to Severn River, Northwest Territory and Quebec: Summ. Rept. Geol. Survey Canada for 1905, pp. 73-76.

Data on Canadian Northern Railway route between Split Lake and Fort Churchill, Northwest Territory: Summ. Rept. Geol. Survey Canada for 1906, pp. 99-102.

Data on National Transcontinental Railway route, from La Tuque westward, Quebec: Summ. Rept. Geol. Survey Canada for 1907, pp. 67-68.

Data on west coast of Hudson Bay from Severn River to Cape Henrietta Maria, Northwest Territory: Summ. Rept. Geol. Survey Canada for 1908, pp. 93-94.

Pack, R. W.

Manuscript geologic map of part of Diablo Range, California.

Paige, Sidney.

Manuscript geologic maps of Llano and Burnet quadrangles, Texas (with A. C. Spencer and F. H. Kay).

Data on Matanuska Valley, used in compiling manuscript map of Alaska.

Palache, Charles.

Bradshaw Mountains folio, Arizona (with T. A. Jaggar, jr.), and Franklin Furnace folio, New Jersey (with A. C. Spencer, R. D. Salisbury, and H. B. Kümmel).

Pardee, J. T.

Unpublished notes on western Montana.

Parks, W. A.

Data on country east of Nipigon Lake and River, Ontario: Summ. Rept. Geol. Survey Canada for 1901, pp. 105-107.

Data on region northeast of Lake Nipigon, Ontario: Summ. Rept. Geol. Survey Canada for 1902, pp. 213-222.

Data on region north of Lake Timiskaming, Ontario: Summ. Rept. Geol. Survey Canada for 1904, pp. 198-225.

Data on valley of Tobique River, New Brunswick: Summ. Rept. Geol. Survey Canada for 1905, pp. 115-117.

- Peale, A. C.**
Three Forks folio, Montana.
- Pepperberg, L. J.**
Unpublished notes on the Sweetgrass Hills, Bearpaw Mountains, and Little Rocky Mountain districts of northern Montana.
Data on Milk River coal field, Montana, used in compiling map of the coal-bearing Cretaceous and Tertiary.
Geologic map of Milk River coal field, Montana: Bull. U. S. Geol. Survey No. 381, 1910, pp. 82-107.
- Phalen, W. C.**
Johnstown folio, Pennsylvania.
Manuscript geologic map of Ellijay quadrangle, Georgia (with Laurence La Forge).
Manuscript geologic map of Kenova quadrangle, Ohio-West Virginia-Kentucky.
- Pirsson, L. V.**
Geologic map of Little Rocky Mountains, Montana: Jour. Geology, vol. 4, 1896, pp. 399-428 (with W. H. Weed).
Geologic map of Judith Mountains, Montana: Eighteenth Ann. Rept. U. S. Geol. Survey, pt. 3, 1898, pp. 446-616 (with W. H. Weed).
Notes on the Bearpaw Mountains, Montana: Am. Jour. Sci., 4th ser., vol. 1, 1896, pp. 283-301, 351-362; vol. 2, 1896, pp. 136-148, 188-199 (with W. H. Weed).
- Fishel, M. A.**
Data on Cheyenne River and Standing Rock Indian reservations, North and South Dakota, used in compiling map of the coal-bearing Cretaceous and Tertiary.
- Poole, H. S.**
Geologic map of Pictou coal field, New Brunswick: Ann. Rept. Geol. Survey Canada for 1901, vol. 14, Rept. M.
Data on Chignecto Bay, New Brunswick and Nova Scotia: Summ. Rept. Geol. Survey Canada for 1902, pp. 379-384.
Data on the Nanaimo-Comox coal field, British Columbia: Summ. Rept. Geol. Survey Canada for 1905, pp. 55-59.
- Powell, J. W.**
Geologic maps of part of Arizona, Utah, Colorado, Wyoming, and South Dakota: Repts. U. S. Geog. and Geol. Survey Rocky Mtn. Region, 1872-1880.
- Pratt, J. H.**
Geologic map of western North Carolina, based on data furnished by Arthur Keith: North Carolina Geol. Survey, vol. 1, 1905 (with J. V. Lewis).
- Prindle, L. M.**
Data on Alaska Range and on Yukon-Tanana region (based on earlier work of J. E. Spurr) used in compiling manuscript map of Alaska.
- Prosser, C. S.**
Cottonwood Falls folio, Kansas (with J. W. Beede).
- Pumpelly, Raphael.**
Geologic map of Greylock and Hoosac mountains, Massachusetts: Mon. U. S. Geol. Survey, vol. 23, 1894 (with T. N. Dale and J. E. Wolff).
- Purdue, A. H.**
Winslow folio, northern Arkansas; and manuscript maps of adjacent Eureka Springs, Harrison, Hot Springs, and Caddo Gap quadrangles.
- Ransome, F. L.**
Manuscript geologic map of Ray quadrangle, southeastern Arizona (with J. B. Umpleby).
Globe and Bisbee folios, southern Arizona.
Geologic map of Cœur d'Alene district, Idaho: Prof. Paper U. S. Geol. Survey No. 62, 1908 (with F. C. Calkins).
Mother Lode district folio, California.
- Reagan, A. B.**
Geologic map of part of Olympic Peninsula, Washington: Trans. Kansas Acad. Sci., vol. 22, p. 160.
- Richards, R. W.**
Geologic maps of phosphate areas in southeastern Idaho, northeastern Utah, and adjacent parts of Wyoming: Bull. U. S. Geol. Survey No. 430, 1910, pp. 457-551 (with H. S. Gale).
Data on Bull Mountains coal field, Montana, used in compiling map of the coal-bearing Cretaceous and Tertiary.
- Richardson, G. B.**
Data on Trinidad, Colorado, and Book Cliffs coal fields, Colorado and Utah, and on Colob Plateau, southern Utah, used in compiling map of the coal-bearing Cretaceous and Tertiary.
Reconnaissance map of the trans-Pecos region, Texas and New Mexico: Bull. Univ. Texas Min. Survey No. 9 (23), 1904.
Indiana folio, Pennsylvania; El Paso folio, Texas; and manuscript map of Van Horn quadrangle, Texas.
Geologic map of part of the Book Cliffs coal field, Colorado and Utah: Bull. U. S. Geol. Survey No. 371, 1909.
Geologic map of Franklin Mountains, Texas and New Mexico: Bull. U. S. Geol. Survey No. 285, 1906, pp. 146-149.
- Richardson, James.**
Geologic map of region south of St. Lawrence River, between Chaudiere and Trois Pistoles rivers, Quebec: Rept. Prog. Geol. Survey Canada for 1866-69, pp. 119-141.

Richardson, James—Continued.

- Data on region along north shore of lower St. Lawrence: Rept. Prog. Geol. Survey Canada for 1866-1869, pp. 305-311.
- Data on country north of Lake St. John, Quebec: Rept. Prog. Geol. Survey Canada for 1870-71, pp. 283-308.
- Map of coal fields of east coast of Vancouver Island: Rept. Prog. Geol. Survey Canada for 1871-72, pp. 73-98.
- Data on Vancouver and Charlotte Islands: Rept. Prog. Geol. Survey Canada for 1872-73, pp. 32-65, 84-86.
- Data on British Columbia: Rept. Prog. Geol. Survey Canada for 1873-74, pp. 94-102; idem for 1874-75, pp. 71-83; idem for 1876-77, pp. 160-192, with geologic map of coal fields of northeastern part of Vancouver Island.
- Data on Magdalen Islands: Rept. Prog. Geol. Survey Canada for 1879-80, Rept. G.
- Data on Anticosti and Mingan islands: Rept. Prog. Geol. Survey Canada for 1853-56, pp. 191-245.
- Data on Gaspé Peninsula: Rept. Prog. Geol. Survey Canada for 1857, pp. 29-93; idem for 1858, pp. 105-169.
- Data on eastern townships of Quebec: Rept. Prog. Geol. Survey Canada for 1863-66, pp. 29-45.

Robb, Charles.

- Geologic map of York, Carleton, and Victoria counties, New Brunswick: Rept. Prog. Geol. Survey Canada for 1866-1869, pp. 173-209.
- Data on northwestern New Brunswick: Rept. Prog. Geol. Survey Canada for 1870-71, pp. 241-251.
- Data on Sydney coal field, Cape Breton, Nova Scotia: Rept. Prog. Geol. Survey Canada for 1872-73, pp. 238-290.
- Data on Cape Breton, Nova Scotia: Rept. Prog. Geol. Survey Canada for 1873-74, pp. 171-188; idem for 1874-75, pp. 166-266 (with geologic map of Cape Dauphin district).

Robinson, H. H.

- Geologic map of Connecticut: Connecticut Geol. and Nat. Hist. Survey, 1906 (with H. E. Gregory).

Rogers, W. B.

- Geologic map of Virginia and West Virginia: Geology of the Virginias, 1884.

Ruedemann, Rudolph.

- Geologic map of Elizabethtown and Port Henry quadrangles, New York: Bull. Univ. New York No. 138, 1910 (with J. F. Kemp).

Russell, I. C.

- Geologic map of part of Cascade Mountains, northern Washington: Twentieth Ann. Rept. U. S. Geol. Survey, pt. 2, 1900, pp. 83-210.
- Geologic maps of Newark system in eastern United States: Bull. U. S. Geol. Survey No. 85, 1892.
- Ann Arbor folio, Michigan (with Frank Leverett).
- Geologic map of Lake Lahontan Quaternary deposits of western Nevada and adjacent parts of California and Oregon: Mon. U. S. Geol. Survey, vol. 11, 1885.
- Geologic map of central Washington: Bull. U. S. Geol. Survey No. 108, 1893.
- Geologic map of part of southern Idaho: Bull. U. S. Geol. Survey No. 199, 1902.

Sanford, Samuel.

- Geologic map of Florida: Second Ann. Rept. Florida Geol. Survey, 1909 (with G. C. Matson and F. G. Clapp).

Safford, J. M.

- Geologic map of Tennessee, published by the State geologist, 1896.

Salterain y Legarra, Pedro.

- Geologic map of Cuba: Bol. Com. del Mapa Geol. de España, vol. 7, 1880, pp. 161-225; vol. 8, 1881 (with Manuel Fernández de Castro).

Sapper, Carl.

- Geologic maps of Central America and adjacent portions of Mexico: Petermanns Mitt., Ergänzungsband 24, 27, and 32; Bull. Geol. Inst. México No. 3, p. 7.

Savage, T. E.

- Geologic map of Iowa, compiled for Iowa Geol. Survey for report of 1905 (1906).

Schrader, F. C.

- Data on lower Copper River, Prince William Sound, Chitina Valley, upper Tanana and White River basins, upper Copper River region, Chandalar and upper Koyukuk, main Koyukuk Valley, Endicott Range, and Anaktuvuk and Colville River valleys, used in compiling manuscript map of Alaska.
- Geologic map of part of western Arizona: Bull. U. S. Geol. Survey No. 397, 1909.
- Manuscript geologic map of Patagonia and Nogales quadrangles, southern Arizona (with J. M. Hill).
- Data on San Juan coal region, New Mexico, used in compiling map of the coal-bearing Cretaceous and Tertiary.
- Geologic map of Durango-Gallup coal field, New Mexico and Colorado: Bull. U. S. Geol. Survey No. 285, 1906, pp. 241-257 (with M. K. Shaler).
- Independence folio, Kansas.

Schultz, A. R.

- Geologic map of southern part of Rock Springs coal field, southern Wyoming: Bull. U. S. Geol. Survey No. 381, 1910, pp. 214-281.
- Geologic map of northern part of Rock Springs coal field, Sweetwater County, Wyoming: Bull. U. S. Geol. Survey No. 341, 1909, pp. 256-282.

Schultz, A. R.—Continued.

Data on northern Uinta County and Rock Springs coal fields, Wyoming, used in compiling map of the coal-bearing Cretaceous and Tertiary.

Geologic map of part of central Uinta County, Wyoming: Bull. U. S. Geol. Survey No. 316, 1907, pp. 212-241.

Sellards, E. H.

Geologic map of Florida, by G. C. Matson, F. G. Clapp, and Samuel Sanford: Second Ann. Rept. Florida Geol. Survey, 1909.

Selwyn, A. R. C.

Data on Quebec and Nova Scotia: Rept. Prog. Geol. Survey Canada for 1870-71, pp. 252-282.

Data on British Columbia: Rept. Prog. Geol. Survey Canada for 1871-72, pp. 16-72.

Data on country from Lake Superior to Fort Garry, by English and Winnipeg rivers: Rept. Prog. Geol. Survey Canada for 1872-73, pp. 8-18.

Data on Colchester County, Nova Scotia: Rept. Prog. Geol. Survey Canada for 1872-73, pp. 19-31.

Data on Saskatchewan and Alberta: Rept. Prog. Geol. Survey Canada for 1873-74, pp. 17-62.

Data on British Columbia: Rept. Prog. Geol. Survey Canada for 1875-76, pp. 28-86.

Data on Quebec group: Rept. Prog. Geol. Survey Canada for 1877-78, Rept. A.

Data on Souris River valley, Manitoba: Rept. Prog. Geol. Survey Canada for 1879-80, Rept. A.

Data on southeastern portion of Province of Quebec: Rept. Prog. Geol. Survey Canada for 1880-82, Rept. A.

Geologic map of the Dominion of Canada, from surveys 1842-1882, scale 45 miles to 1 inch.

Shaler, M. K.

Data on San Juan coal region, New Mexico, used in compiling map of the coal-bearing Cretaceous and Tertiary.

Geologic map of the western part of the Durango-Gallup coal field, New Mexico and Colorado: Bull. U. S. Geol. Survey No. 316, 1907, pp. 376-426.

Geologic map of Durango-Gallup coal field, New Mexico and Colorado: Bull. U. S. Geol. Survey No. 285, 1906, pp. 241-257 (with F. C. Schrader).

Shaler, N. S.

Geologic map of Narragansett Basin, Rhode Island: Mon. U. S. Geol. Survey, vol. 33, 1899 (with A. F. Foerste and J. B. Woodworth).

Geologic map of Richmond area, Virginia: Nineteenth Ann. Rept. U. S. Geol. Survey, 1899, pp. 385-520 (with J. B. Woodworth).

Shattuck, G. B.

St. Marys folio, Maryland-Virginia, and Patuxent folio, Maryland-District of Columbia (with B. L. Miller).

Shaw, E. W.

Data on Big Muddy coal field, Wyoming, used in compiling map of the coal-bearing Cretaceous and Tertiary. Burgettstown-Carnegie and Foxburg-Clarion folios, Pennsylvania.

Sieenthal, C. E.

Geologic map of Laramie Basin, Wyoming: Bull. U. S. Geol. Survey No. 364, 1909 (with N. H. Darton).

Joplin (Missouri) and Laramie-Sherman (Wyoming) folios.

Notes on San Luis Valley, Colorado: Water-Supply Paper U. S. Geol. Survey No. 240, 1910.

Manuscript geologic map of Uncompahgre Valley, Colorado.

Sievers, Wilhelm.

Geologic maps of northern Venezuela, South America: Petermanns Geog. Mitt., vol. 42, pt. 6, p. 127, 1896; Geog. Abhandl., Bd. 3, 1889, p. 239.

Sloan, Earle.

Data on the Tertiary and Cretaceous of South Carolina, used in compiling map of Atlantic Coastal Plain.

Geologic map of South Carolina: Bull. South Carolina Geol. Survey, 4th ser., No. 2, 1908.

Smith, A. D. W.

Geologic map of Pennsylvania, compiled under direction of J. P. Lesley: Summary Rept. Second Geol. Survey Pennsylvania, 1893.

Smith, C. D.

Data on Fort Peck Indian Reservation and Miles City coal fields, Montana, used in compiling map of the coal-bearing Cretaceous and Tertiary.

Geologic map of Fort Peck Indian Reservation lignite field, Montana: Bull. U. S. Geol. Survey No. 381, 1910, pp. 40-59.

Smith, E. A.

Geologic map of Alabama: Geol. Survey Alabama, 1894.

Smith, E. E.

Data on Great Divide Basin coal field, Wyoming used in compiling map of the coal-bearing Cretaceous and Tertiary.

Geologic map of eastern part of Great Divide Basin coal field, Wyoming: Bull. U. S. Geol. Survey No. 341, 1909, pp. 220-242.

Smith, G. O.

Geologic map of Perry Basin, southeastern Maine: Prof. Paper U. S. Geol. Survey No. 35, 1905 (with David White).

Map of the granites of Maine: Bull. U. S. Geol. Survey No. 313, 1906 (with E. S. Bastin and C. W. Brown).

Smith, G. O.—Continued.

Geologic map of part of northern Washington: Bull. U. S. Geol. Survey No. 235, 1904 (with F. C. Calkins).

Geologic map of New England, compiled by G. O. Smith and E. S. Bastin, for geologic map of North America: International Geological Congress, 1906; used in part.

Ellensburg, Mount Stuart, and Snoqualmie folios, Cascade Range, Washington; Tintic folio, central Utah; Penobscot Bay folio, southeastern Maine; and Tacoma folio, Washington.

Geologic map of Fox Islands, Maine: Bull. Colby Coll., vol. 1, supplement, 1901, pp. 1-53.

Smith, P. S.

Data on Yukon River and Norton Bay regions and Seward Peninsula, used in compiling manuscript map of Alaska.

Smith, W. H. C.

Geologic map of Rainy River district, Ontario: Ann. Rept. Geol. Survey Canada for 1890-91, vol. 5, Rept. G.

Smith, W. S. T.

Geologic map of Santa Catalina Island, southern California: Proc. California Acad. Sci., 3d ser., vol. 1, 1897, pp. 1-71.

Geologic map of San Clemente Island, southern California: Eighteenth Ann. Rept. U. S. Geol. Survey, pt. 2, 1898, pp. 465-494.

Hartville folio, Wyoming; Joplin folio, southwestern Missouri (with C. E. Siebenthal); and Edgemont folio, South-Dakota-Nebraska (with N. H. Darton).

Spencer, A. C.

Manuscript geologic maps of Llano and Burnet quadrangles, Texas (with Sidney Paige and F. H. Kay).

Geologic reconnaissance of Cuba (with C. W. Hayes and T. W. Vaughan): Rept. Military Governor Cuba for 1901. La Plata and Rico folios, Colorado; Franklin Furnace folio, New Jersey.

Geologic map of Encampment district, southern Wyoming: Prof. Paper U. S. Geol. Survey No. 25, 1904.

Data on southeastern Alaska, lower Copper River, Prince William Sound, and Chitina Valley, used in compiling manuscript map of Alaska.

Spencer, J. W.

Data on country between upper Assiniboine River and Lakes Winnipegosis and Manitoba: Rept. Prog. Geol. Survey Canada for 1874-75, pp. 57-70.

Spurr, J. E.

Geologic map of south end of Oquirrh Mountains, Utah: Sixteenth Ann. Rept. U. S. Geol. Survey, pt. 2, 1895, pp. 343-455 (with S. F. Emmons).

Geologic map of Aspen district, Colorado: Mon. U. S. Geol. Survey, vol. 31, 1898.

Geologic map of Silver Peak quadrangle, Nevada, based on data furnished by H. W. Turner: Prof. Paper U. S. Geol. Survey No. 55, 1906.

Data on Alaska Peninsula, Susitna Basin, Kuskokwim Valley, and Bristol Bay region, used in compiling manuscript map of Alaska.

Reconnaissance map of Nevada south of fortieth parallel: Bull. U. S. Geol. Survey No. 208, 1903.

Stanton, T. W.

Data on Kachemak Bay region and Alaska Peninsula, used in compiling manuscript map of Alaska.

Notes on distribution of Triassic, Jurassic, and Cretaceous throughout western United States from northern Mexico to Canada and in Alaska, for this map.

Stebinger, Eugene.

Geologic map of eastern part of Little Snake River coal field, Wyoming: Bull. U. S. Geol. Survey No. 381, 1910, pp. 186-213 (with M. W. Ball).

Steenstrup, K. J. V.

Geologic map of part of the west coast of Greenland: Meddelelser om Grönland, vol. 4, 1893, pp. 173-242 (with R. R. I. Hammer).

Geologic map of part of southern Greenland: Meddelelser om Grönland, vol. 2, 1881, pp. 27-41 (with G. F. Holm).

Stephenson, L. W.

Data on and manuscript maps of the Cretaceous of South Carolina, Georgia, and Alabama, and of Tertiary of South Carolina, used in compiling map of Atlantic and Gulf Coastal Plain.

Sterrett, D. B.

Manuscript geologic map of Kings Mountain and Gaffney quadrangles, North Carolina-South Carolina.

Stone, R. W.

Elders Ridge and Waynesburg folios, Pennsylvania.

Data on Musselshell River (Montana) and Powder River (Wyoming) coal field, used in compiling map of the coal-bearing Cretaceous and Tertiary.

Data on Kachemak Bay region, used in compiling manuscript map of Alaska.

Stose, G. W.

Assisted largely in compiling the map of North America and directing its drafting and publication.

Mercersburg-Chambersburg and Pawpaw-Hancock folios and manuscript maps of Carlisle, Fairfield, and Gettysburg quadrangles, southern Pennsylvania, Maryland, and West Virginia.

Geologic map of part of South Mountain, Pennsylvania: Bull. U. S. Geol. Survey No. 430, 1910, pp. 54-63.

Manuscript map of Apishapa quadrangle, Colorado.

Swartz, C. K.

Pawpaw-Hancock folio, West Virginia-Maryland-Pennsylvania (with G. W. Stose).

Taff, J. A.

Data on Sheridan coal field, Wyoming, on Book Cliffs and Wasatch Plateau coal fields, Utah, and on San Juan coal region, New Mexico, used in compiling map of the coal-bearing Cretaceous and Tertiary.

Geologic map of the McAlester-Lehigh coal field, Oklahoma: Nineteenth Ann. Rept. U. S. Geol. Survey, pt. 3, 1899, pp. 423-602.

Geologic maps of Arbuckle and Wichita mountains, and coal fields of Oklahoma: Nineteenth Ann. Rept. U. S. Geol. Survey, pt. 3, 1899, pp. 423-583; Prof. Paper U. S. Geol. Survey No. 31, 1904.

Geologic map of part of the eastern Choctaw coal field, Oklahoma: Twenty-first Ann. Rept. U. S. Geol. Survey pt. 2, 1900, pp. 257-311 (with G. I. Adams).

Buckhannon and Piedmont folios, Appalachian region; Coalgate, Atoka, Tishomingo, Tahlequah, and Muscogee folios, and manuscript maps of McAlester, Winding Stair, Antlers, Tuskahoma, Canadian, Sansbois, and Sallisaw quadrangles, Oklahoma.

Tarr, R. S.

Watkins Glen-Catatonk folio, New York (with H. S. Williams and E. M. Kindle).

Data on Yakutat Bay and Alsek River region (making use of earlier work of I. C. Russell), used in compiling manuscript map of Alaska.

Thoroddsen, Th.

Geologic map of Iceland, London, 1901.

Tippenhauer, L. G.

Notes on Haiti used in compiling map of West Indies: Petermanns Mitt., Bd. 45, 1899, pp. 25-29, 153-155, 201-204; Bd. 47, 1901, pp. 121-127, 169-178, 193-199.

Todd, J. E.

Olivet, Parker, Mitchell, Alexandria, Huron, De Smet, Elk Point, and Aberdeen-Redfield folios, South Dakota.

Torrance, J. F.

Data on Ottawa County, Quebec: Rept. Prog. Geol. Survey Canada for 1882-1884, Rept. J.

Torre, Carlos de la.

Notes on the paleontology of Cuba: Anales Acad. ciencias médicas, físicas y naturales de la Habana, Revista científica, vol. 47, July, 1910, pp. 1-33, with plates.

Tower, G. W.

Butte folio, Montana, and Tintic folio, Utah.

Turner, H. W.

Geologic map of Tertiary deposits in Silver Peak region, Nevada: Twenty-first Ann. Rept. U. S. Geol. Survey, pt. 2, 1901, pp. 191-226.

Geologic map of older formations of Sierra Nevada, California: Seventeenth Ann. Rept. U. S. Geol. Survey, pt. 1, 1896, pp. 521-761.

Placerville, Jackson, Marysville, Smartsville, Downieville, Sonora, Bidwell Bar, and Big Trees folios, Sierra Nevada, California.

Manuscript maps of Silver Peak quadrangle, Nevada, and Yosemite quadrangle, California.

Tyrrell, J. B.

Geologic map of central Alberta: Ann. Rept. Geol. Survey Canada for 1886, vol. 2, Rept. E.

Data on northwestern Manitoba: Ann. Rept. Geol. Survey Canada for 1887-88, vol. 3, Rept. E.

Geologic map of northwestern Manitoba: Ann. Rept. Geol. Survey Canada for 1890-91, vol. 5, Rept. E.

Data on and geologic map of country between Athabasca Lake and Churchill River: Ann. Rept. Geol. Survey Canada for 1895, vol. 8, Rept. D (with D. B. Dowling).

Data on Doobaunt, Kazan, and Ferguson rivers and northwest coast of Hudson Bay: Ann. Rept. Geol. Survey Canada for 1896, vol. 9, Rept. F.

Data on northern Manitoba: Summ. Rept. Geol. Survey Canada for 1897, pp. 34-38.

Data on Yukon and adjacent parts of British Columbia: Summ. Rept. Geol. Survey Canada for 1898, pp. 36-46.

Geologic map of Lake Winnipeg and vicinity: Ann. Rept. Geol. Survey Canada for 1898, vol. 11, Rept. G (with D. B. Dowling).

Geologic map of northeastern Saskatchewan and adjacent parts of Keewatin: Ann. Rept. Geol. Survey Canada for 1900, vol. 13, Rept. F.

Udden, J. A.

Data on the Cretaceous of Texas, used in compiling the map of the Atlantic and Gulf Coastal Plain.

Geologic map of portion of southwestern Texas, from Lone Mountains to Chisos district: Repts. Univ. Texas Min. Survey, 1904 (with B. F. Hill).

Ulrich, E. O.

Notes on distribution of Paleozoic formations, particularly Cambrian, Ordovician, and Silurian, in eastern United States.

Columbia folio, Tennessee, and Fayetteville folio, Missouri-Arkansas.

- Umpleby, J. B.**
 Manuscript geologic map of Lemhi County, Idaho.
 Manuscript geologic map of Ray quadrangle, southeastern Arizona (with F. L. Ransome).
- Van Hise, C. R.**
 Member of committee on pre-Cambrian nomenclature.
 Geologic map of Lake Superior region, compiled by C. R. Van Hise and C. K. Leith: Mon. U. S. Geol. Survey, vol. 52, 1911.
- Vaughan, T. W.**
 Nueces, Uvalde, and Austin folios, and manuscript map of Brackett quadrangle, southern Texas.
 Geologic map of south Atlantic and Gulf Coastal Plain, compiled under the direction of T. W. Vaughan from cooperative surveys with States.
 Geologic reconnaissance of Cuba: Rept. Military Governor of Cuba for 1901 (with C. W. Hayes and A. C. Spencer).
- Veatch, A. C.**
 Data on southern Uinta County and Hanna coal fields, Wyoming, used in compiling map of the coal-bearing Cretaceous and Tertiary.
 Geologic map of northern Louisiana and southern Arkansas: Prof. Paper U. S. Geol. Survey No. 46, 1903.
 Geologic map of part of southwestern Wyoming: Prof. Paper U. S. Geol. Survey No. 56, 1907.
 Geologic map of east-central Carbon County, Wyoming: Bull. U. S. Geol. Survey No. 316, 1907, pp. 244-260.
- Veatch, Otto.**
 Data on the Cretaceous and Tertiary of Georgia, used in compiling map of Atlantic Coastal Plain.
- Vennor, H. G.**
 Geologic map of parts of Hastings, Peterborough, Addington, and Frontenac counties, Ontario: Rept. Prog. Geol. Survey Canada for 1866-1869, pp. 143-171.
 Data on Frontenac, Leeds, Lanark, and Addington counties, Ontario: Rept. Prog. Geol. Survey Canada for 1870-71, pp. 309-315; idem for 1871-72, pp. 120-141; idem for 1872-73, pp. 136-179; idem for 1873-74, pp. 103-146; idem for 1874-75, pp. 105-165.
 Data on Renfrew, Pontiac, and Ottawa counties: Rept. Prog. Geol. Survey Canada for 1876-77, pp. 244-320.
 Geologic map of Lanark County, Ontario: Rept. Prog. Geol. Survey Canada for 1874-75.
- Walcott, C. D.**
 Notes on Rocky Mountains of northern Montana: Bull. Geol. Soc. America, vol. 17, 1906, pp. 1-28.
 Geologic map of Belt terrane in Montana: Bull. Geol. Soc. America, vol. 10, 1899, pp. 199-244.
 Geologic map of eastern part of Colorado Canyon: Fourteenth Ann. Rept. U. S. Geol. Survey, pt. 2, 1894, pp. 497-519.
- Walker, T. L.**
 Data on Muskoka district, Ontario: Summ. Rept. Geol. Survey Canada for 1905, pp. 84-86.
- Wall, G. P.**
 Geologic maps of Trinidad and part of Venezuela: Jour. Geology, London Geol. Soc., 1860, p. 470; Appendix M, Geology of Trinidad (with J. G. Sawkins).
- Washburne, C. W.**
 Data on South Park and Canon City coal fields, Colorado, and on Bighorn Basin coal fields, Wyoming and Montana, used in compiling map of the coal-bearing Cretaceous and Tertiary.
 Geologic map of South Park coal field, central Colorado: Bull. U. S. Geol. Survey No. 381, 1910, pp. 307-316.
 Geologic map of Canon City coal field, Colorado: Bull. U. S. Geol. Survey No. 381, 1910, pp. 341-378.
- Watson, T. L.**
 Unpublished data on Paleozoic and Cambrian rocks in Virginia.
- Weaver, C. E.**
 Manuscript map of Napa quadrangle, California.
- Webster, Arthur.**
 Data on west coast of Vancouver Island: Summ. Rept. Geol. Survey Canada for 1902, pp. 54-76.
- Weed, W. H.**
 Geologic map of Little Rocky Mountains, Montana: Jour. Geology, vol. 4, 1896, pp. 399-428 (with L. V. Pirsson).
 Geologic map of Judith Mountains, Montana: Eighteenth Ann. Rept. U. S. Geol. Survey, pt. 3, 1898, pp. 446-616 (with L. V. Pirsson).
 Notes on Bearpaw Mountains, Montana: Am. Jour. Sci., 4th ser., vol. 1, 1896, pp. 283-301, 351-362; vol. 2, 1896, pp. 136-148, 188-199 (with L. V. Pirsson).
 Geologic map of Elkhorn district, Montana: Twenty-second Ann. Rept. U. S. Geol. Survey, pt. 2, 1901, pp. 399-550.
 Livingston, Butte, Yellowstone Park, Fort Benton, and Little Belt Mountains folios, Montana.
 Manuscript maps of parts of Fort Logan and Helena quadrangles, Montana.
- Weeks, F. B.**
 Manuscript map of part of northwestern Utah.
 Geologic map of Uinta Range, Utah: Bull. Geol. Soc. America, vol. 18, 1907, pp. 427-448.
 Notes on Silver Peak quadrangle and other portions of Nevada.
 Geologic map of Fort Hall mining district, southeastern Idaho: Bull. U. S. Geol. Survey No. 340, 1908, pp. 175-183 (with V. C. Heikes).

Wegemann, C. H.

Data on Buffalo coal field, Wyoming, used in compiling map of the coal-bearing Cretaceous and Tertiary.

Weller, Stuart.

Geologic map of Illinois: Bull. Illinois State Geol. Survey No. 6, 1907.

Raritan folio, New Jersey (with H. B. Kummel, W. S. Bayley, and R. D. Salisbury).

Wheeler, G. M.

Geologic maps of parts of Nevada, Arizona, Utah, Colorado, and New Mexico: Repts. U. S. Geog. Surveys W. 100th Mer.

White, David.

Geologic map of Perry Basin, southeastern Maine: Prof. Paper U. S. Geol. Survey No. 35, 1905 (with G. O. Smith).

Notes on distribution of continental Carboniferous.

White, I. C.

Geologic maps of parts of West Virginia: West Virginia Geol. Survey, county reports, 1906-1910.

White, James.

Member (part of the time) of committee on pre-Cambrian nomenclature.

Wilder, F. A.

Geologic map of Iowa compiled by T. E. Savage: Rept. Iowa Geol. Survey for 1905 (1906).

Willard, D. E.

Jamestown-Tower, and Casselton-Fargo folios, North Dakota-Minnesota.

Williams, H. S.

Watkins Glen-Catatonk folio, New York (with E. M. Kindle and R. S. Tarr).

Willis, Bailey.

Compiler of map of North America; contributed local details in many districts.

Geologic map of part of Rocky Mountains, northern Montana: Bull. Geol. Soc. America, vol. 13, 1902, pp. 305-352.

Chairman of committee on pre-Cambrian nomenclature.

Manuscript map of Jonesville quadrangle, Tennessee-Kentucky.

Geologic map of coal-bearing Cretaceous and Tertiary of central-western States (compiled by Bailey Willis and M. R. Campbell).

Geology of Lower California, compiled from published notes of Gabb, Merrill, Emmons, Lindgren, Fairbanks, and Lawson.

Piedmont folio, Appalachian region (with N. H. Darton and J. A. Taff); Tacoma folio, Washington (with G. O. Smith).

Wilson, A. W. G.

Data on country west of Nipigon Lake and River, Ontario: Summ. Rept. Geol. Survey Canada for 1901, pp. 96-103.

Data on region about headwaters of Albany River, Ontario: Summ. Rept. Geol. Survey Canada for 1902, pp. 203-206.

Data on Lake Nipigon and Thunder Bay region, Ontario: Summ. Rept. Geol. Survey Canada for 1908, pp. 95-96.

Wilson, M. E.

Data on region east of Lake Timiskaming, Quebec: Summ. Rept. Geol. Survey Canada for 1907, pp. 59-63.

Data on Lake Opasatika and the Height of Land, Quebec: Summ. Rept. Geol. Survey Canada for 1908, pp. 121-123.

Wilson, W. J.

Data on rivers southwest of James Bay, Ontario: Summ. Rept. Geol. Survey Canada for 1902, pp. 222-240.

Data on the western part of Abitibi region, Ontario: Summ. Rept. Geol. Survey Canada for 1901, pp. 115-128.

Data on Nagagami River and other branches of the Kenogami, Ontario: Summ. Rept. Geol. Survey Canada for 1903, pp. 109-120.

Data on Little Current and Drowning rivers, Ontario: Summ. Rept. Geol. Survey Canada for 1904, pp. 164-173.

Data on region between Lake Temagami and Spanish River, Ontario: Summ. Rept. Geol. Survey Canada for 1905, pp. 82-84.

Data on the Transcontinental Railway route from Lake Abitibi eastward, Quebec: Summ. Rept. Geol. Survey Canada for 1906, pp. 119-123.

Data on the National Transcontinental Railway from Bell River eastward, Quebec: Summ. Rept. Geol. Survey Canada for 1907 pp. 64-66.

Geologic map of Algoma and Thunder Bay districts, northwestern Ontario: Rept. Geol. Survey Canada, 1909.

Winchester, D. E.

Data on Eaton quadrangle, Colorado, used in compiling map of the coal-bearing Cretaceous and Tertiary.

Notes on the Wind River Basin, Wyoming (with E. G. Woodruff).

Wolff, J. E.

Geologic map of Greylock and Hoosac mountains, Massachusetts: Mon. U. S. Geol. Survey, vol. 23, 1894 (with Raphael Pumpelly and T. N. Dale).

Woodruff, E. G.

Data on Red Lodge (Montana), Bighorn Basin and Wind River Basin (Wyoming) coal fields, and the Eaton quadrangle, Colorado, used in compiling map of the coal-bearing Cretaceous and Tertiary.

Woodworth, J. B.

Geologic map of Narragansett Basin, Rhode Island: Mon. U. S. Geol. Survey, vol. 33, 1899 (with N. S. Shaler and A. F. Foerste).

Geologic map of Richmond area, Virginia: Nineteenth Ann. Rept. U. S. Geol. Survey, 1899, pp. 385-520 (with N. S. Shaler).

Woolsey, L. H.

Data on Bull Mountains coal field, Montana, used in compiling map of the coal-bearing Cretaceous and Tertiary. Beaver folio, Pennsylvania.

Wright, C. W.

Data on southeastern Alaska, used in compiling manuscript map of Alaska.

Wright, F. E.

Data on southeastern Alaska, used in compiling manuscript map of Alaska.

Data on Unuk River mining region, British Columbia: Summ. Rept. Geol. Survey Canada for 1905, pp. 46-53.

Yeates, W. S.

Geologic map of Georgia: Rept. Geol. Survey Georgia for 1906.

Young, G. A.

Data on Lake St. John district, Quebec: Summ. Rept. Geol. Survey Canada for 1900, pp. 143-146.

Geologic map of Yamaska Mountain, Rouville County, Quebec: Ann. Rept. Geol. Survey Canada for 1904, vol. 16, Rept. H.

Data on Temagami and Rabbit lakes, district of Nipissing, Ontario: Summ. Rept. Geol. Survey Canada for 1904, pp. 195-198.

Data on Bathurst district and the Tobique country, Victoria County, New Brunswick: Summ. Rept. Geol. Survey Canada for 1908, pp. 129-131.

In the subjoined list, arranged by localities, only the names of the authors of data used in compiling the map are given. The sources of the data are given in the preceding list.

CHAPTER II.
PRE-CAMBRIAN.

The pre-Cambrian of North America has been described in detail and with exhaustive consideration of the literature in the revised correlation bulletin on the pre-Cambrian by Van Hise and Leith.⁸²⁸ That work makes any description of the terranes superfluous in this paper, which will confine itself to a list of the areas colored as pre-Cambrian (see fig. 3) and an account of the efforts made to reach a satisfactory classification for the purposes of the geologic map of North America.

Pre-Cambrian areas.

Keewatin (23a).^a

L-M 15-16.....Minnesota, Wisconsin, Michigan, Ontario.

"Laurentian" (23).

L 14-16.....Wisconsin, Michigan, Minnesota, and North Dakota (undifferentiated pre-Cambrian, which is mapped with "Laurentian").

N 20-21.....	Quebec, Northwest Territories.
N-O 17-18, P 17-19.....	Northwest Territories.
O-P 22-24.....	Southern Greenland.
R 22.....	West coast of Greenland.

PRE-CAMBRIAN CLASSIFICATION.

The problem of pre-Cambrian classification has been difficult of adjustment under the requirements of the map of North America. The Canadian Survey adheres to its long-established divisions Laurentian and Huronian, which rest upon the work of Logan and his successors. The modifications developed by modern studies have not in the opinion of Canadian authorities rendered these terms less useful or justified substitutes or material changes of definition. The United States Survey adopted the divisions Archean and Algonkian in 1889 and they have been earnestly advocated by the geologists working in the Lake Superior region in their earlier as well as in their latest publications. These geologists maintain that the terms Archean and Algonkian stand for two great major divisions which constitute a "dual classification" of the pre-Cambrian that is thought probably to be of general occurrence and to distinguish two grand eras of the earth's history. The points of view of the Canadian and United States geologists have been presented by F. D. Adams^{1,2} and C. R. Van Hise^{826, 827} and are also set forth in the report of the special (international) committee for the Lake Superior region.³

The classification of the pre-Cambrian which the compiler introduced in the map of 1906 was the result of an attempt to adjust differences of interpretation to the requirements of a general map, in which the number of distinctions was limited. In conformity with the terminology of the international congress the prefixes neo and eo were used for two major divisions of the post-Archean, both of which, according to the nomenclature employed by the United States Geological Survey, belonged to the Algonkian. Thus arose neo-Algonkian and eo-Algonkian. The classification could not, however, be carried through with perfect separation of the several systems—Archean, eo-Algonkian, and neo-Algonkian—and it became necessary to state that each of these systems *as represented on the map of 1906* might include masses belonging to one of the other two. The wording of the explanation in the legend of the map did not make it plain that the Keewatin was included under eo-Algonkian, for instance, only because of the requirements of cartography and in spite of the well-known fact that the two are separated by a great unconformity, and the classification was therefore criticized by American as well as by Canadian geologists. The latter objected to the term Algonkian; the former objected to the confusion of distinct systems in one.

These objections were entirely just from the point of view of the systematic geologist. The Keewatin does not belong to the Algonkian and is separated from the lowest terrane of that system by an unconformity which is regarded as equivalent to a long interval of time. But this interval and the distinction between these terranes can not be expressed on the map so long as it is true, as stated by Dr. Adams, that "It is impossible for us as yet to separate the Keewatin from the Huronian, these two divisions having been, up to the present time, both classed as Huronian." The legend of the map of 1906 does not, however, adequately express the fact that the mapping is less advanced than investigation. It should have stated plainly that eo-Algonkian comprised Lower and Middle Huronian, and that the areas so mapped included some undifferentiated Keewatin which belongs to the Archean.

In preparing the revised edition of the geologic map of North America, effective agreement on problems of classification and nomenclature was sought by the officers of the United States Survey. An international committee, composed of geologists representing the surveys of Canada and the United States, had brought about an understanding in regard to questions relating to the geology of the Lake Superior region and to that of eastern Canada and New York. At a meeting of that committee in New York on December 29, 1906, it was voted that a subcommittee consisting of three representatives from Canada and three from the United States be appointed to consider questions of classification and nomenclature in connection with the preparation of a geologic map of North America by the United States Geological Survey. Bailey Willis was designated chairman of this subcommittee, the other members to be selected later by correspondence between Messrs. Low and Hayes. The subcommittee thus nominated consisted of F. D. Adams, R. A. Daly, and James White, representing the Canadian Survey, and T. C. Chamberlin, C. R. Van Hise, and Bailey Willis (chairman), for the United States Survey. A meeting was held at Toronto March 7, 1907, and the entire scheme of nomenclature for the map was considered from Quaternary to pre-Cambrian. The following classification of the older rocks was agreed to:

Paleozoic.....	Cambrian and latest pre-Cambrian.
Proterozoic.....	} Later Proterozoic, including unseparated earlier Proterozoic.
	} Earlier Proterozoic, including unseparated later Proterozoic.
	Ancient schists and igneous rocks.
	Laurentian gneiss.

The action of the committee was a compromise which was designed to meet the needs of a legend for the general map but which did not go beyond that point in attempting to adjust existing differences of opinion. Prof. Van Hise dissented from the proposed division of the Proterozoic. The subcommittee did not indicate any areas to be mapped under any particular designation, that selection being left to the compiler, Mr. Willis.

From studies which followed the meeting at Toronto, the compiler concluded that a map prepared on the compromise there reached would not adequately present the known facts or express the existing uncertainties regarding the pre-Cambrian sequence and classification. At his instance a further conference was proposed and held at Chicago, February 21, 1908. The conferees were R. W. Brock, Acting Director, and F. D. Adams, for the Canadian Survey; W. G. Miller, for the Ontario

Bureau of Mines; and T. C. Chamberlin, C. R. Van Hise, and Bailey Willis (chairman), for the United States Survey. The discussion of the problem of pre-Cambrian classification was earnest and prolonged. It clearly developed the fact that knowledge of the pre-Cambrian terranes is not yet adequate to furnish criteria by which even some of the major divisions may be surely correlated or to offset the differences of opinion which spring from historical associations or personal experience. The discussion was in part as follows:

Mr. Willis presented as a basis for discussion a tentative classification of the pre-Cambrian, which is shown in figure 4 by the names printed in Roman type. It embodied Archeozoic and Proterozoic without definite delimitation; undifferen-

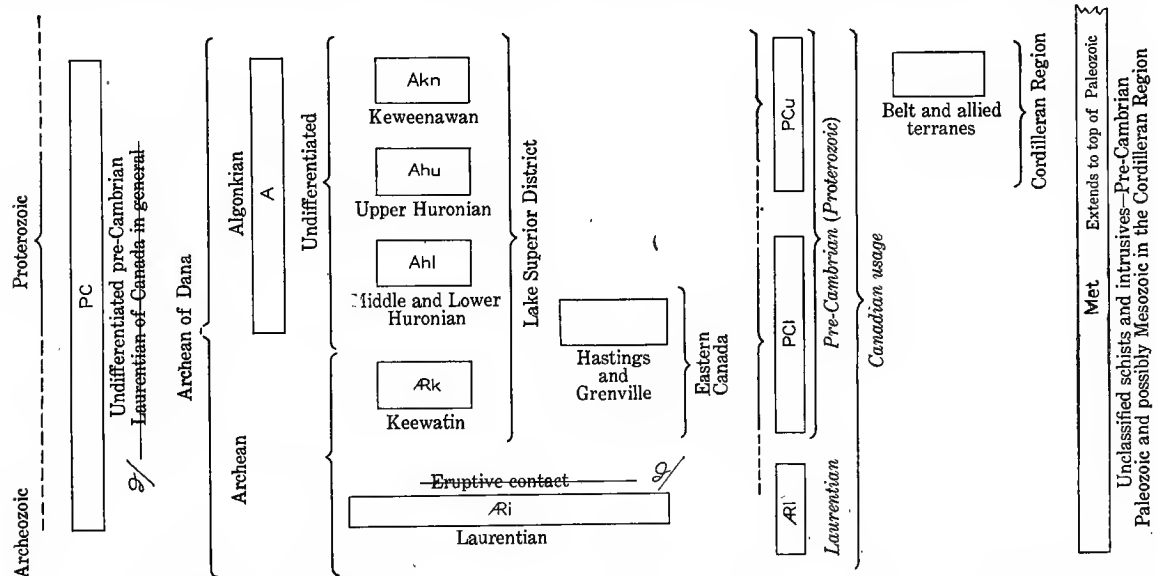

FIGURE 4.—Classification of the pre-Cambrian adopted by the international committee. The portion in roman type represents the table as originally presented by Mr. Willis. The corrections made by the committee are shown, the additions being in italics.

tiated pre-Cambrian, which was also designated Laurentian of Canada in general and Archean of Dana; Archean and Algonkian of the United States Geological Survey; the classification adopted by the international committee for the Lake Superior district; the Hastings and Grenville series of eastern Canada; the Belt series and allied terranes; and the unclassified schists and intrusives of the Cordillera.

Prof. Van Hise took up the discussion and emphasized the point that it is desirable in such a map as that under discussion to make clear the relation of the adopted color scheme to the various classifications in use by different organizations and in different textbooks, in order that the matter might be plainly understood.

Prof. Adams, speaking for the Canadian geologists, stated that if the requirements of cartography limited the classification to three divisions, they would wish one to indicate Laurentian and two others to represent two different parts of the Proterozoic. The divisions of the Proterozoic have to be made on grounds which seem valid now, but they may have to be shifted as the work goes on. The map represents the distinctions essentially as the Canadian geologists would like to have them made, even though in the course of eight or ten years the colors will have to be revised. Some great areas that are little metamorphosed lie in the

neighborhood of areas that are highly metamorphosed, and it may be that those which are considered older may prove to be newer, but as we have no very definite line to divide newer from older, the Canadian Geological Survey would undertake to state how the distinctions should be made.

Mr. Willis called attention to the classification of the Paleozoic into metamorphic and nonmetamorphic and suggested that the same distinction might be applied to the Proterozoic of the northern shield.

After some discussion, in which Prof. Chamberlin urged that metamorphism was but one factor in discriminating older and newer Proterozoic and that the classification should be based on several factors, Prof. Adams stated that throughout northern Canada there are patches of rock that resemble very closely the Keweenawan. There is a very strong presumption, which Dr. George Dawson believed, that it is the most extensive of the Proterozoic formations of North America. In other places occur formations which resemble Huronian. There is a distinction of metamorphism which is also very largely a distinction of age.

The discussion also brought out the fact that in the region northwest of Hudson Bay the Keweenawan facies is predominant; whereas in the Labrador Peninsula, east of Hudson Bay, the resemblances to the Animikie appear to be closer. It appeared therefore that a classification into older and newer Proterozoic must be one which separates the Animikie and Keweenawan from the Huronian.

As a result of the discussion it was agreed that the Canadian Geological Survey should be responsible for the classification of the Proterozoic in two groups which should in a general way express a relation of older formations to younger ones but which should be clearly explained to be somewhat indefinite and subject to future revision.

The use of the term Laurentian in general was then considered at length. By reference to figure 4 it will be seen that four different interpretations were represented in the committee. The most comprehensive allied Laurentian in general with the Archean of Dana, Laurentian in general being understood to mean the pre-Cambrian rocks of the great northern shield, regarding which it is not definitely known whether they are prevalingly pre-Huronian or include also large areas of Huronian. The second interpretation of the Laurentian in general is that which relates it to the Archean according to the restricted definition comprising Keewatin and intrusives into the Keewatin—that is, the pre-Huronian formations to which Logan originally gave the name Laurentian. The third interpretation is that which is represented in the Canadian classification (*italics in fig. 4*) and which is closely related to the second but leaves the upper limit of the Laurentian in general somewhat indefinite, it being recognized that throughout the Canadian shield there are many intrusives whose age can never be precisely determined on account of the absence of overlying sedimentary rocks. The fourth interpretation is the restricted Laurentian of the international committee on the Lake Superior and Adirondack regions, which limits the term to acidic rocks intrusive into the Keewatin, except as it may be employed, “preferably with an explanatory phrase,” to designate some “associated granites of large extent which cut the Huronian or whose relations to the Huronian can not be determined.”

The first interpretation (Laurentian in general considered as the equivalent of undifferentiated pre-Cambrian), was found to be unacceptable to the Canadian representatives. Prof. Adams had earlier in the discussion expressed the opinion that the Laurentian in the sense of pre-Huronian constituted essentially 99 per cent of the northern part of the Canadian shield.

In answer to a question by Mr. Willis as to whether the Canadians were prepared to restrict Laurentian to the equivalent of pre-Huronian, Dr. Brock responded:

I think we were all agreed at Ottawa that this would be the most desirable thing to do if possible, but we overruled it on account of the difficulty in separating the Keewatin and Huronian. It was necessary to have some color which would indicate Keewatin and Lower Huronian for purposes of mapping. Economically they go together. If we could possibly do it we would very much prefer to have a general color to cover the lower part, but in mapping I do not think we can do it. We have many areas in which we can not differentiate the Keewatin and Lower Huronian.

Prof. Chamberlin asked:

What is your preference, Mr. Brock, in regard to the lower formation? Should it represent undifferentiated pre-Cambrian or should it represent Archean?

Dr. Brock responded:

We would prefer to see it represent the Archean. There is, of course, undifferentiated Huronian in that probably, but the main fact is that the great part of the northern area represents what Logan called Laurentian.

Prof. Chamberlin urged the recognition of Logan's definition of Laurentian. He said:

From my point of view I should like to see the general color [adopted for the Canadian shield] represent pretty closely Logan's idea, which involves Keewatin, Laurentian intrusive into Keewatin, and rocks of general Laurentian aspect—the old gneiss groups as confessedly an undifferentiated series but as a great series representing one of the greatest of the eras of the earth's history; so that if this conception is true we have the great nucleus of the continent. I am thinking of something more fundamental than pre-Cambrian, something nucleal to Huronian, Animikie, and Keweenawan. We need to find the general nucleus from which the Canadian formations have been derived.

Prof. Van Hise granted the fact that the nucleus described had existed for Paleozoic formations but did not admit that the Canadian region was a nucleus for the pre-Cambrian.

As a result of further discussion the term Laurentian in general as applied to the unclassified pre-Cambrian was stricken out. The use of Laurentian in general as equivalent to Archean in the restricted sense of pre-Huronian was recognized as one having a theoretical significance, but one which in the present state of knowledge does not represent a mappable thing. There remain the two usages, namely, (1) Laurentian equivalent to the Keewatin and the intrusive rocks cutting the Keewatin and including probably some Huronian^a and (2) the Laurentian intru-

^a In commenting on these minutes of the conference, Prof. Adams, under date of March 9, 1908, wrote: "In this usage the Laurentian includes not only rocks which are equivalent to Keewatin but any portion of the protaxis which may be found to be older than Keewatin; that is to say, if in the great northern protaxis the base exists on which the Keewatin has been deposited, this also is of Laurentian age. It may easily be that a not inconsiderable proportion of the Laurentian protaxis is really pre-Keewatin in date."

sive in the Keewatin, which is restricted, in mapping at least, to areas that have been surveyed in detail. It was determined to recognize both of these divisions of the Laurentian to the extent that present knowledge justifies such distinction.

The arrangement of the classifications agreed upon was then taken under consideration and the schedule was corrected as shown in figure 4. The revised classification showing the various usages which are there set forth was then unanimously adopted on motion of Prof. Chamberlin, seconded by Prof. Adams.

The classification thus drawn up comprises the usage accepted for this publication by the Canadian Survey and the United States Survey, also the local sequence of eastern Canada, of the Lake Superior region, and of the Cordillera. It presents the presumed correlation of these various classes according to present knowledge and fixes the responsibility for the mapping of different sections upon that organization which has done most of the work in either district.

I 16-17, J 17-18. SOUTHERN APPALACHIAN MOUNTAINS.

The revision of the pre-Cambrian rocks of the Appalachian Mountains by Arthur Keith and the sources of information used by him are stated in the following memorandum, which he prepared for this work.

The geologic formations of the area between the Blue Ridge and the Coastal Plain and from Maryland to Alabama have been revised from those shown in published maps, according to detailed and reconnaissance work that I have done during the last 20 years.

In Virginia the boundary at the base of the Cambrian near the Blue Ridge and all boundaries east of that, except for the Richmond and the Danville Triassic basins, are new. They are based on detailed work as far south as latitude $38^{\circ} 30'$; south of that latitude they are founded upon reconnaissance work.

In North Carolina the detailed geology of the published folios for the western part of the State is supplemented by reconnaissance in the central part of the State; for the eastern part of the crystalline rocks, the mapping is based on the old map of North Carolina by W. C. Kerr, with some modification and reinterpretation of the areas.

In the western part of the State also the detailed but yet unpublished work extends from the mountains and the Blue Ridge 20 to 40 miles into the Piedmont Plateau.

In South Carolina the northwestern margin of the State has been mapped in detail and a detailed survey has been made of the Kings Mountain region in northern-central South Carolina and in North Carolina. The remainder of the mapping in the State is based on the old county maps of Lieber, somewhat modified by my reconnaissance.

For Georgia manuscript maps of C. W. Hayes have been used west of longitude $84^{\circ} 30'$ and north of $33^{\circ} 30'$. My detailed and reconnaissance work affords the basis for mapping formations north and northeast of Atlanta, including the belt of probable Cambrian strata (Brevard schist). Southeast and south of that line I have used the map of the granites of Georgia published by T. L. Watson, with slight modifications.

In the rocks southeast of the main Cambrian belt three divisions are made—(1) Paleozoic igneous rocks of post-Cambrian age; (2) undivided pre-Cambrian gneisses and schists; and (3) pre-Cambrian igneous rocks, mainly granites and granitoid rocks. Of the pre-Cambrian igneous rocks, only the granites are mapped in class 3, the Roan gneiss being omitted, although mainly igneous, because most of its areas are too small to show with the present map scale. The effusive pre-Cambrian igneous rocks are included with the granites in the mapping, as no provision is made in the color scheme to separate them.

Although most of the boundaries shown are those between different pre-Cambrian formations, considerable areas of Paleozoic intrusive rocks are distinguished, especially in Georgia and the Carolinas. In the areas so shown there are known to be minor areas of pre-Cambrian rocks,

mainly granites, and similarly there are Paleozoic granites in the areas shown as pre-Cambrian. Separation of these minor areas is difficult, even with detailed work, and is not warranted by the present state of our knowledge. It is believed, however, that the present mapping is sufficiently accurate to give a fair idea of the distribution of the various igneous and metamorphic rocks of the Piedmont—a matter which has not previously been attempted. The divisions used consist of groupings of formations that have been distinguished in the detailed work in the Appalachian Mountains. . . I have described these in full in folios of the United States Geological Survey and my summary of them is given in Survey Bulletin 360 ("Pre-Cambrian geology of North America," by Van Hise and Leith), page 701.

CHAPTER III.
CAMBRIAN AND LOWER ORDOVICIAN.

Color, purplish red.

Symbol, 18.

Distribution: General throughout the continent. (See fig. 5.)

Content: In general comprises Lower Cambrian (Georgian) to Lower Ordovician (Beekmantown), inclusive, or so much as may be present; in the Appalachian zone, Virginia to Alabama, includes conformable formations below the Olenellus horizon; Ocoee group and other terranes; Brevard, Weverton, Harpers, and others not named. In the Cordillera includes upper Ordovician and Silurian where they are present and the bands of color are too narrow for distinct mapping.

Cambrian and lower Ordovician areas.

H 12. BISBEE DISTRICT, ARIZONA.

In southeastern Arizona, in the Bisbee district, Ransome⁶⁵⁸ distinguishes the probable equivalents of the Tonto group as the Bolsa quartzite and Abrigo limestone. He says:

FIGURE 5.—Sketch map showing the distribution of Cambrian and lower Ordovician rocks represented on the geologic map of North America and the key to references in the text.

The Bolsa quartzite is constant in its lithological character and is readily recognized wherever it occurs. The base of the formation is exposed at many places along Escabrosa Ridge. It is invariably marked by a bed of conglomerate from 6 inches to a foot in thickness, resting upon the eroded edges of the pre-Cambrian schists. Most of the pebbles of this basal conglomerate are composed of white vein quartz and are rarely over 3 inches in diameter. This conglomerate is overlain by hard pebbly grits in beds from 10 to 20 feet in thickness, the change from conglomerate to grit being, as a rule, not very definitely marked. The scattered pebbles in these thick-bedded grits are usually white quartz, but their matrix frequently contains abundant small fragments of pink feldspar mingled with the predominant quartz grains. Cross-bedding is often a conspicuous feature in the lower part of the formation. The pebbly grits in turn pass upward into thinner bedded, more vitreous, fine-grained quartzites showing no feldspathic material, which are conformably overlain by the Abrigo limestone.

The Bolsa quartzite was deposited during an advance of the sea over a subsiding basement of pre-Cambrian crystalline rocks which had been worn down by long-continued erosion to a nearly level plain. The arkose character of some of the lower beds of the quartzite shows that this ancient crystalline basement is composed in part of granitic rocks. None of the latter, however, are exposed in the Bisbee quadrangle, where fine-grained sericitic schists are the only pre-Cambrian rocks known. The basal conglomerate of the Bolsa formation is a littoral deposit made up of the most durable materials of this schist terrane, chiefly fragments of quartz derived from the numerous irregular veins that occur within the schists, while the finer particles of quartz and flakes of mica were probably transported by currents into deeper water and contributed to the formation of the overlying quartzite beds. The general nature of the Bolsa formation, particularly the pebbly and cross-bedded character of its lower portion, indicate that deposition took place in comparatively shallow water, with probably a gradual increase in depth as the upper beds were laid down. The conditions were apparently not favorable to marine life, as no organic remains have yet been found in the Bolsa quartzite.

As no fossils have been found in the Bolsa quartzite its exact geological age is not directly determinable. It will presently be shown, however, that the Bolsa formation is conformably overlain by the Abrigo limestone which contains a middle Cambrian fauna. It is thus without very much doubt, the stratigraphic equivalent of the Tonto sandstone of the Grand Canyon section, considered by Walcott as also included within the middle Cambrian, the lower Cambrian being there represented by the unconformity between the Tonto and the Grand Canyon series. It is possibly the equivalent of at least the lower part of the thicker and more varied Apache group of the Globe district in central Arizona, about 110 miles north-northwest of the Bisbee quadrangle, and also correlated provisionally with the Tonto group. * * *

The Abrigo limestone is named from Abrigo Canyon, 3 miles southwest of Bisbee, where the beds composing the formation are well exposed. Like the Bolsa quartzite, the Abrigo limestone occurs principally in the northwestern part of the quadrangle, although a few small areas are found within the attenuated belt of Paleozoic rocks extending southeastward past Gold Hill toward Glance Creek. The most satisfactory occurrence, and the only one in the quadrangle where the entire sequence of the beds from base to top may be studied in a single continuous exposure, is that of the Mount Martin section, $1\frac{1}{2}$ miles west of Bisbee. As measured in this section the Abrigo limestone is 770 feet thick. It rests conformably upon the Bolsa quartzite and is overlain by the Martin limestone (Devonian). * * *

The Abrigo limestone is distinguished from the other calcareous formations of the local Paleozoic section by its prevailing thin bedding, and particularly by a conspicuous laminated structure produced by the alternation of thin irregular sheets of chert with layers of gray limestone. The layers of limestone may be 2 or 3 inches in thickness, while those of chert are usually less. This cherty lamination is eminently characteristic of the Abrigo limestone in the Mule Mountains and serves as a ready means of identifying the beds belonging to this formation within the various fault blocks into which the region is dissected. Chert also occurs occasionally in the Devonian and Carboniferous limestones of the Bisbee quadrangle, but as irregular bunches, never in the form of the thin, more or less anastomosing sheets peculiar to the Cambrian Abrigo limestone.

The beds are commonly from 1 to 2 feet in thickness. Their dominant color as seen in large exposures is dark greenish yellow, whereas the prevailing tint of the overlying Martin limestone is dark gray, and of the still higher Escabrosa and Naco limestones white or light gray.

In the typical Mount Martin section the Bolsa quartzite is immediately overlain by about 40 feet of thin-bedded, very cherty limestones, which break up, on weathering, into thin rusty plates. Above this occur a few beds of gray limestone up to 2 feet in thickness, alternating with fissile yellowish calcareous shales, and with laminated cherty beds, such as have just been described. The upper 100 feet of the formation is made up of rather soft, sandy, thin-bedded gray limestone, with one bed of harder gray limestone 6 feet in thickness about 40 feet from the top. The upper limit of the Abrigo formation is defined in the Mount Martin section by a bed of pure white quartzite about 8 feet in thickness.

This quartzite is a persistent stratum and is always found immediately underlying the Martin limestone, which carries Devonian fossils. Its thickness, however, is variable and it sometimes grades downward into the upper sandy limestones of the Abrigo formation. It apparently records the consummation of an increasing supply of sandy sediments during the later phases of the deposition of the Abrigo limestone and contrasts with the more purely calcareous beds of the overlying Devonian formation. * * *

The fossils collected from the Abrigo limestone were submitted to Dr. Charles D. Walcott, who kindly examined them and reported that they are middle Cambrian, indicating a fauna closely resembling that of the middle Cambrian of Texas.

H 13. TRANS-PECOS TEXAS.

With reference to the Cambrian and Lower Ordovician in the district about El Paso and to the southeast, Richardson⁶⁶⁸ states :

The formations which are the subject of this paper outcrop in the Franklin and Hueco mountains in the El Paso quadrangle, and in the Sierra Diablo, Delaware Mountains, and associated groups of hills in the Van Horn quadrangle. These two quadrangles, which have recently been mapped by the United States Geological Survey, are situated about 60 miles apart and they include practically all of the known occurrences of lower Paleozoic rocks in trans-Pecos Texas. The following table summarizes the Paleozoic formations in the El Paso and Van Horn quadrangles:

Paleozoic formations in the El Paso and Van Horn quadrangles, Texas.

El Paso quadrangle.		System.	Series.	Van Horn quadrangle.	
Formation.	Thickness (feet).			Thickness (feet).	Formation.
Absent.		Carboniferous.	Permian? (Guadalupian).	500+	Capitan limestone.
Absent.				2,000+	Delaware Mountain formation.
Hueco limestone.	3,000		Pennsylvanian.	2,500+	Hueco limestone.
Absent.			Mississippian.		Absent.
Absent.		Devonian.			Absent.
Fusselman limestone.	1,000	Silurian.	(Niagara [fossils]).		Absent.
Montoya limestone.	250	Ordovician.	Upper and Middle Ordovician.	250	Montoya limestone.
El Paso limestone.	1,000		Lower Ordovician.	750	El Paso limestone.
Bliss sandstone.	0-300	Cambrian.	Saratogan or Acadian.	0-700	Van Horn sandstone.

The main occurrence of the Bliss sandstone is along the eastern slopes of the Franklin Mountains, but the considerable faulting to which the range has been subjected causes its distribution to be very irregular. The Bliss is a massive, fine-textured, brownish sandstone that varies from a few feet to slightly more than 300 feet in thickness. The lower beds are indurated and are practically quartzites and at the base of the formation the strata are coarser textured, locally are conglomeratic and contain pebbles of the underlying rocks. The sandstone is composed of small grains of quartz embedded in a matrix of sericite and kaolin. In places the Bliss sandstone is in contact with granite of post-Carboniferous age and elsewhere it rests on rhyolite porphyry, of which it contains rounded pebbles in the basal beds. In the central part of the Franklin Mountains the sandstone thins out and locally disappears, and the overlying limestone, containing a basal conglomerate, lies directly on the rhyolite porphyry.

Annelid borings both perpendicular and parallel to the bedding occur abundantly in the Bliss sandstone. Other fossils are rare, but in places in the lower strata some brachiopod shells have been found. Of these Mr. Walcott has identified *Lingulepis acuminata*, *Obolus matinalis*(?), and fragments of *Lingulella* which determine the Cambrian age of the rocks and indicate that either the upper or middle division of the system is here represented.

The Van Horn is a medium to coarse-textured cross-bedded sandstone that is banded with thin lenses of conglomerate. The formation is of a prevailing brick-red color in its lower part, which becomes paler toward the top, where the color fades away and the sandstone is white. The conglomerate lenses vary from a few inches to about a foot in thickness and are irregularly distributed throughout the formation. At the base the pebbles are composed of fragments of the underlying rocks and consist of quartz schist, fine-textured red sandstone, cherty limestone, porphyry, and quartz, while the conglomerate in the upper part of the formation consists chiefly of well-rounded quartz pebbles. The sandstone likewise varies in composition, its lower part being composed of quartz and decomposed feldspar grains while the upper portion is prevailingly quartzose. The formation varies from a few feet to 700 feet in thickness and averages about 400 feet.

The Van Horn sandstone unconformably overlies highly tilted metamorphosed rocks and is overlain in places by the El Paso limestone (Ordovician), and elsewhere by the Hueco limestone (Carboniferous). The upper part of the formation contains numerous annelid borings and fucoid-like remains, but no characteristic fossils have been found in the sandstone and its age therefore is undetermined.

The presence of sandstone at the base of the Paleozoic section in southwestern United States has been noted wherever observations have been made, and it is suggested that the Bliss and Van Horn sandstones are the probable equivalent of the Tonto sandstone of the Grand Canyon, the Bolsa quartzite of Bisbee, the Coronado quartzite of Clifton, the Reagan sandstone of Oklahoma, and the Cambrian sandstone of the central Texas Paleozoic area.

The El Paso limestone outcrops in the Franklin and Hueco mountains in the El Paso quadrangle and in Beach and Baylor mountains in the Van Horn quadrangle. The formation is typically a massive gray magnesian limestone which contains the same fauna in both regions. In the El Paso area the formation is about 1,000 feet thick, the lower 100 feet of which is characteristically arenaceous and weathers brownish. A distinctive feature of the middle portion of the formation is the presence of thin connected nodules of brown chert arranged in irregular steaks parallel to the bedding. This limestone lies apparently conformably on the Bliss sandstone, but, as already stated, in the central part of the Franklin Mountains the Bliss sandstone is locally absent and the El Paso limestone rests directly on pre-Cambrian (?) rocks with a basal conglomerate varying up to 20 feet thick composed of rounded pebbles of rhyolite porphyry in a calcareous matrix. In the Van Horn quadrangle the El Paso limestone does not contain the cherty layers that are characteristic of the middle parts of the formation in the Franklin Mountains, and 50 feet above the base of the formation a thin bed of white sandstone is present. In this region there are indications of an unconformity at the base of the limestone marked by a slight undulatory contact between the El Paso and Van Horn formations.

Mr. Ulrich reports that the fossils obtained from the El Paso limestone in both the El Paso and Van Horn quadrangles represent essentially the same Beekmantown fauna. Most of the species are undescribed, but all are of unmistakable types. The more characteristic forms are the following:

Calathium sp. nov. (coral-like sponge), *Maclurea?* sp. nov. The small hornlike opercula are very common. The shell itself is of the type of *M. oceana* Billings. Solid siphuncles of endoceratoid cephalopod, evidently a close ally of *Cameroceras brainardi*. Besides these there are a number of less easily recognized small gastropods.

H 14. LLANO DISTRICT, TEXAS.

In Mason, Llano, and Burnet counties, Tex., the pre-Cambrian rocks are unconformably overlain by Upper Cambrian sediments. Shumard^{854c} originally described the section. During 1908 and 1909 detailed surveys have been carried out by A. C. Spencer and Sidney Paige, and the following description is abstracted from notes furnished by them.

UPPER CAMBRIAN.

The Upper Cambrian of this area is essentially the equivalent of the Reagan sandstone in Oklahoma, agreeing with that formation not only in age but in lithologic succession.

The Cambrian sediments rest upon a complex of metamorphic rocks which include schists, gneisses, and enormous masses of granitic intrusives.

The Cambrian beds have been divided into three formations, namely, from the base upward, the Hickory sandstone, the Cap Mountain formation, and the Wilberns formation.

Conglomerate and sandstone reaching a maximum thickness of about 250 feet constitute the lower formation. Following, but with a gradual transition from sandstone to limestone, are beds consisting predominantly of limestone, capped by 15 to about 75 feet of cross-bedded glauconitic sandstone. These strata, about 90 feet thick, constitute the second formation. The third formation includes limestones and shales from 170 to 220 feet thick, the shales occupying approximately the upper third of the formation.

The following section is characteristic of the lithology of the formations, though the thickness of the basal beds varies considerably, owing largely to the unevenness of the pre-Cambrian floor.

Section of Hickory, Cap Mountain, and Wilberns formations on Packsaddle Mountain.

	Feet.
Grayish slabby, slaty crystalline limestone; very little glauconite; more massive beds toward top of peak.....	40
Thinner-bedded crystalline limestone; some glauconite.....	20
Heavy-bedded pink limestone, somewhat oolitic; contains some glauconite.....	10
Yellow and white sandstone with small percentage of glauconite, grading up into pink sandy limestone.....	14
Glauconite sand and coarse quartz sands; iron concretions on surface.....	6
Massive-bedded grayish-brown crystalline limestone, somewhat oolitic; glauconite increasing toward top.....	35
Flaggy subcrystalline limestone with small amount of glauconite; yellowish discolorations.....	30
Grading into purer limestone. Several red bands of sandstone alternating with beds of hard subcrystalline limestone and fine-grained whitish sandy limestone; crystalline limestone contains some glauconite grains.....	35
Thin-bedded calcareous dirty-white sandstone, grading upward into very fine-grained hard reddish-brown sandstone. Weathers rough but generally shows a brown sand on surface. Broken surface shows reddish-brown sandstone with crystalline faces of calcite. Makes cliffs which weather irregularly and show bands of red, yellow, and dirty-brown cross-bedded sandstone alternating with very calcareous beds.....	200
Ledge of calcareous sandstone, conglomeratic and containing a few shell fragments, also few glauconite grains.....	2
Massive and thin-bedded red and yellow sandstone, with some shale, probably covered.....	35

	Feet.
Covered; mostly sandy shales. At bottom a 2½-foot bed of red conglomerate sandstone with flat pebbles; a few shell fragments in this ledge.....	10
Mostly fine-grained dirty-white, brown, yellow, and red sandstone.....	45
Massive pink and white, conglomerate sandstone, with white quartz pebbles mostly one-half inch in diameter; cross-bedded; prevailing reddish tones. Near top grains are smaller and more rounded. Secondary infiltration of quartz in cross fractures gives honeycomb structure on weathering.....	85
	567

It will be noted that the sections are not complete. The following measurements include the upper portion of the Cambrian, or the Wilberns formation:

Generalized section of Wilberns formation on east bank of Colorado River about one-third mile above old Tanyard Crossing.

Ellenburger limestone at top.	Feet.
Impure limestone.....	30
Heavy-bedded limestone containing abundant exceedingly small shell fragments, also abundant minute globular remains.....	10
Impure sandy limestone having conglomerate aspect in the hard layers.....	10
Débris-covered slope.....	10
Débris-covered slope; contains layers of shale conglomerate consisting of cemented flat fragments of thin shale accompanied by layers containing boulder-like forms composed of limy mud.....	60
Slope of impure limestone layers breaking down to 1 inch in thickness, carrying fine sand, weathering light brown.....	30
Pink flaggy semicrystalline limestone.....	10
Crystalline and semicrystalline bedded limestone, weathering into hard layers.....	11
Heavy layer of mottled light-brown impure limestone.....	4
Alternating beds of crystalline limestone, 4 inches to 1 foot thick, with crinkly-weathering beds that are slightly more sandy, the whole carrying finely disseminated glauconite, locally concentrated in layers.....	23
Base, recent silt of Colorado River.	

Another section of the Wilberns is as follows:

Generalized section of Wilberns formation near head of Little Llano River.

Ellenburger limestone at top.	Feet.
Calcareous shale, with subcrystalline to crystalline oolitic limestone bands; alternating hard and soft.....	39
Thin flaggy limestone with some sandy layers.....	10
Shale and shaly limestone and subcrystalline layer with shell fragments.....	11
Conglomerate containing slightly rounded half-inch to 1-inch pebbles, weathering yellow, with limestone matrix.....	1
Greenish-gray shales.....	6
Two beds of conglomerate, about 8 inches each, separated by 8 inches of shale; small, slightly rounded calcareous pebbles weathering yellow.....	2
Fine-grained greenish-gray shaly limestone.....	3
Conglomerate of long, flat, thin, shaly calcareous fragments, overlain by fine-grained calcareous muds.....	3
Greenish shaly limestone.....	5
Conglomerate composed of small, slightly rounded calcareous pebbles weathering yellow.....	1½
Light-gray shaly limestone, weathering to a covered slope.....	25
Thicker-bedded gray crystalline limestone, with scattered grains of glauconite; a few hard layers about 9 inches thick.....	20
Light-pink to gray thin-bedded flaggy crystalline limestone, mottled brown by fine-grained sand..	17
Pink and gray crystalline limestone; glauconite grains at base.....	6
Pinkish subcrystalline limestone.....	7
Sandy limestone and a little glauconite.....	2
Base at top of glauconite sand.	

This section was measured in dipping beds and the total thickness as stated is believed to be somewhat short of the actual thickness. The section is of value, however, as indicating the succession.

Certain characteristics of these formations deserve a more detailed description.

A wide diversity exists in the basal members. Locally they are fine-grained, cleanly washed sands; elsewhere they are coarse conglomerates with pebbles ranging from 6 to 8 inches in diameter. A marked relation was noted between the underlying pre-Cambrian and the basal layer. Certain coarse granites rich in pink feldspar have produced a pinkish-white conglomerate, in which the rounded quartz grains average a quarter of an inch in diameter and which contains numerous angular fragments of feldspar. A clean white cement consisting of small quartz grains and feldspar fragments with calcium carbonate binds the whole. In another place a coarser conglomerate stained red contains subangular quartz fragments as large as half an inch and feldspar fragments an inch long. A fine-grained quartz cement which included particles of iron oxide was the matrix. In another place a coarse sandstone containing 1 to 2 inch fragments of hematite makes up the basal layer, the iron having been derived from the underlying schists probably in the form of magnetite and later altered to hematite. In yet another place where the underlying formation is rich in pegmatite dikes, large angular masses of quartz are abundant in the lower beds. Here and there the lower member, where resting on a coarse-grained granite surface, is a granite arkose.

In different localities the conditions of sedimentation undoubtedly varied, and this variation is expressed in the inadequacy of a hard and fast line between the Hickory sandstone and the Cap Mountain formation. The sandstones become gradually more limy, until the beds are predominantly limestone. In drawing a boundary line between two such formations, it is often difficult to decide upon a satisfactory line, though taken as a whole the two sets of beds fully justify such a separation.

The distribution of glauconite in the Cambrian strata is interesting. Beginning in the Cap Mountain formation, it appears in scattered grains in the pure limestones and reaches its greatest development in cross-bedded sandstones, the top of which is used as the boundary between the Cap Mountain formation and the Wilberns formation. Above this sand the glauconitic material gradually disappears. Though where observed in limestones the glauconitic grains exist essentially as such, in the sandstones the material is more likely to form the matrix in which the well-rounded clean quartz grains are embedded.

UPPER CAMBRIAN AND LOWER ORDOVICIAN.

The rocks overlying the Wilberns formation are of late Cambrian and early Ordovician age and have not been subdivided. They have been given the local name Ellenburger limestone. They are regarded by Ulrich as equivalent to a small portion of the rocks of similar age in the Missouri section and also to the lower part of the Arbuckle limestone of Oklahoma. In the greater number of places where the base of the Ellenburger limestone was observed, it is apparently conformable with the Wilberns formation. Many observations were made where no unconformity could be detected and where an apparent transition between the two formations could be followed. It must be noted, however, that the basal beds of the Ellenburger limestone vary in texture and appearance, and that this phenomenon is in itself a suggestion of unconformity. Any decision, therefore, must for the present remain tentative.

At the top of the Ellenburger limestone there is usually, though not always, a conglomerate limestone bed, succeeded by the lowest portion of the Pennsylvanian (upper Carboniferous). The upper surface of the Ordovician on Doublehorn Creek just south of the road crossing half a mile north of the mouth of Cordova Creek gives an excellent example of the pre-Carboniferous surficial conditions.

The upper 25 feet of the Ordovician is composed of large angular blocks, very irregularly disposed, revealing a condition of peculiar surface breakage prior to submergence beneath the

sea. As no coarse sediment is present, shallow, quiet Carboniferous seas must be inferred. The same type of breakage may locally be observed in stream channels and must not be confused with the basal conglomerate. Beds including the Mississippian (lower Carboniferous), Devonian, Silurian, and later Ordovician are therefore absent.

As the Ordovician rocks lie immediately above the Cambrian, they occur at the crest of the Paleozoic scarp (unless faulting has intervened) and form the greater part of the Paleozoic surface in Llano and Burnet counties.

Complete sections of the Ellenburger limestone are not easy to obtain. The general massiveness of the beds and the gentle folds and faults combine to prevent continuous record. Thicknesses up to 600 feet may be observed in the bluffs of the Colorado between Tanyard Crossing and Deer Creek. It is probable that the formation is 1,000 feet or more thick.

The following section represents the upper portion measured near the mouth of Flat Rock Creek, Burnet County.

Section measured in the upper part of the Ellenburger limestone near the mouth of Flat Rock Creek.

	Feet.
Carboniferous.....	50
Grayish crystalline limestone with much chert.....	15
Crystalline limestone, brown and gray, sugar-grained texture, with light-colored chert; coarsely crystalline near top, greenish stains in calcite crystals.....	25
Massive, hard, smooth-textured beds at base, grading up into brown crystalline and coarse gray limestone; some chert.....	22
Alternating sugary and smooth-grained beds; at top a bed of cherty limestone, weathering honey-comb fashion.....	11
Alternating sugary and smooth-grained beds; but little chert.....	11
Brown, sugary banded limestone with some chert.....	5
Smooth light-gray limestone with whitish chert, weathering bluish gray; smooth rounded pieces simulating waterworn bowlders on surface.....	50
Light-gray smooth limestone, conchoidal fracture; contains some chert which weathers out into rough surface; alternating thin and massive.....	22
Brown, sugar-grained limestone containing layer of white chert.....	2
Irregularly bedded dark and light brown, sugar-grained limestone; tessellated weathering in cliff.....	11
Brown and gray crystalline limestone; lowest portion contains some chert.....	3½
Rough-weathering, somewhat concretionary limestone, sugar-grained, brown and mottled pink..	2
Massive beds of brownish-gray smooth limestone, irregular fracture.....	4
Gray crystalline limestone, massive bedded, sugar-grained, mixed with smooth noncrystalline variety.....	5½
Brown and light-colored fine sugar-grained crystalline limestone, mostly thin and irregularly bedded.....	17
Local bowlder bed resembling conglomerate, sandy material.....	1½
Brown and light-colored fine sugar-grained crystalline limestone, mostly thin and irregularly bedded but makes jagged cliff.....	27½
Bottom at level of Colorado River.	

Certain characteristics of the Ellenburger limestone are pronounced. The bedding as a rule is ill defined, preventing correlation by lithologic units. Repetitions of coarse or fine grained phases of the limestone occur in alternating succession, but the position of individual beds, because of their great similarity, was not determined. An abundance of white and yellow chert characterizes the series, though some layers are free from this material. Where relief is considerable and dissection of the plateau has taken place, the surface of the formation is exceedingly rough, and in general the formation may be recognized by this irregularity of surface. This condition does not apply to the high rolling grass lands to the north. In certain layers the chert has evidently been dissolved and replaced by crystalline quartz filling irregular cavities.

I 12. ARIZONA.^a

The Tonto group is recognized by Reagan,⁶⁶³ who states:

The Tonto formation is composed of coarse to fine grained, often cross-bedded vitreous sandstones and sandy shales, varying in color from brown to red, purple, and white. The formation is the surface rock of a large area. The Sierra Ancha Mountains are capped with it. It is exposed all around the rim of the Tonto-Cherry Creek basin and continues on the east from that basin beyond the headwaters of Oak Creek in the latitude of Chiddesky on Canyon Creek. From this point it extends in an ever-widening strip along the plateau south across Salt River to the Apache and Nantan mountains. Patches of it also occur in the Apache and Pinal mountains. In short, the Tonto exposures completely encircle the Archean and Algonkian areas of the Salt River and Canyon Creek region. That it once covered the entire Archean and Algonkian area is attested by the vitreous sandstone points and buttes scattered over the country, among which are points Chiddesche and the Twin and Sombrero buttes.

I 13. NEW MEXICO.

Lindgren^{542a} gives the following account of the Cambrian and Ordovician of New Mexico:

The pre-Cambrian history of the Territory, though imperfectly known, indicates a period of sedimentation followed by mountain building and igneous intrusion, which was in turn succeeded by long-continued erosion that exposed the intrusive cores. At the base of the Paleozoic section is a strongly pronounced unconformity. In general it has a fundamental appearance, as, for instance, where sandstones and limestones rest horizontally on vertical gneisses.

In the whole of northern New Mexico the Pennsylvanian or upper Carboniferous rests directly on the pre-Cambrian, and these conditions appear to continue as far south as Socorro. Cambrian rocks were first definitely recognized in New Mexico in 1905 by C. H. Gordon,^b who found fossils of this age in the Caballos Range, along the thirty-third parallel. The thickness of the Cambrian quartzite and shales, which here underlie the Ordovician limestone, is only 55 feet. In the Mimbres Mountains, near Kingston, the thickness is 75 feet, and in the Florida Range, southeast of Deming, 135 feet of quartzites were measured in the same stratigraphic position. Toward the west, near Silver City, L. C. Graton measured a thickness of nearly 1,100 feet of quartzitic sandstones, including some strata of limestone. Across the Arizona line in the same latitude Waldemar Lindgren^c found 280 feet of quartzites, with some shales, resting on granite underneath the Ordovician and obtained near the top of these rocks some fossils suggestive of the Cambrian. In the Franklin Mountains G. B. Richardson^d found 150 feet of sandstone containing Upper Cambrian fossils. At Bisbee, in southern Arizona, F. L. Ransome measured 400 feet of nonfossiliferous, probably Cambrian sandstone, covered by 750 feet of fossiliferous Middle Cambrian limestone. This is the only known occurrence of heavy Cambrian limestone in this region, although it is possible that some of the limestone which in southwestern New Mexico covers the quartzite may also be of Cambrian age.

All this indicates beyond doubt that during the period preceding the Cambrian the whole of western New Mexico, so far as available exposures permit a judgment, was a land area which gradually became planed down from a very high to a more moderate relief. During the Cambrian period the sea appears to have advanced northward, but only to about latitude 33° 30', where the Cambrian deposits seem to thin out. The greatest thickness of sediments is found

^a See also I-J 12, Grand Canyon, Arizona (pp. 88-89).

^d Tin in the Franklin Mountains, Texas: *Bull. U. S. Geol. Survey* No. 285, 1906, pp. 146-149.

at Silver City. In the Caballos Range there appears to exist a gradual transition between quartzitic sandstone and underlying granite, suggestive of secular decay of the granite, preceding deposition.

It is interesting to note that the Ordovician, Silurian, Devonian, and lower Carboniferous (Mississippian) are likewise lacking in northern New Mexico, and that they begin to appear prominently at about latitude $33^{\circ} 30'$; some exposures of the Mississippian have been recognized at about the latitude of Socorro, or 34° . * * *

The Ordovician rests conformably on the Cambrian and consists of 450 to 1,200 feet of usually cherty limestone, very poor in fossils. It has been recognized in the Caballos Range, in the Mimbres Range, and at Silver City and other places.

I 14-15. OKLAHOMA.

In the Arbuckle Mountains of Oklahoma the Upper Cambrian and Lower Ordovician are represented by the Reagan sandstone and Arbuckle limestone. Taff⁸⁰⁸ gives the following descriptions:

In pre-Cambrian [late Cambrian] time the region of the Arbuckle uplift was submerged, and the Reagan sandstone, the lowest Cambrian sediment, was laid down upon the eroded surface of the granite and porphyry as a beach and off-shore deposit. The pre-Cambrian land, composed of igneous rocks, possessed some relief at the time of submergence, as is shown by the uneven contact of the igneous rocks with the Reagan sandstone and also by the variable nature of the sandy deposits. The land in the immediate vicinity of the uplift was soon submerged, however, as is shown by the presence of fossiliferous horizons representing the same mid-Cambrian time in the upper member of the Reagan sandstone wherever it is exposed.

CAMBRIAN ROCKS.

Reagan sandstone.—This sandstone is a variable formation, as regards both its thickness and the nature of its materials. In the eastern part of the uplift, in contact with the granite, it varies in thickness from a few thin beds to approximately 500 feet, with an average thickness of about 300 feet. In its thickest portion, at the western end of the granite, the lowest beds are composed for the most part of coarse arkose grit. The following is a record of the thickest section of the Reagan sandstone as it occurs at the western end of the granite area, beginning at the base:

Section of Reagan sandstone.

	Feet.
Quartzite and arkose conglomerate, composed of poorly sorted granitic materials.....	30
Coarse grit and sand, with some clay and green sand in upper part, generally well stratified....	370
Thin-bedded and laminated sandstone, becoming calcareous in the upper part.....	60

This section is followed by generally thin-bedded siliceous limestone and shaly strata through several hundred feet to the top of the middle Cambrian. The calcareous beds at the top and above the Reagan contain numerous fossils of well-defined middle Cambrian forms.

The Reagan sandstone overlying the porphyry in the southern sides of the East and West Wooded hills has a section similar to that in contact with the granite. The coarse materials which make lentils of conglomerate near the base, however, are here composed of porphyry and associated dike rock. In the upper part of the formation greenish clays are probably more abundant, and the green sand continues higher up into the more calcareous beds. As in the occurrence near the granite, here the calcareous rocks contain numerous middle Cambrian fossils.

CAMBRO-ORDOVICIAN ROCKS.

Arbuckle limestone.—The Arbuckle limestone, with the exception of thin, shaly strata and occasional siliceous and cherty beds, is composed entirely of light-blue and white limestone and cream-colored to white crystalline dolomite. The section ranges in thickness from 4,000

to 6,000 feet, and includes the whole of the upper Cambrian and the Calciferous of the Ordovician. From the base of the formation upward to the top of the middle Cambrian the rocks are composed of thin-bedded and, in part, intraformational conglomerate and shaly limestones. While pursuing stratigraphic field work in connection with the study and collection of the fossils, Mr. E. O. Ulrich noted the occurrence of what appeared to be shaly lentils at the top of the middle Cambrian, indicating to his mind an unconformity between the upper and lower Cambrian.

Beginning with the upper Cambrian the rocks are composed of massive and hard, pink to yellow crystalline limestone and dolomite, which weather to various shades of brown and almost black. Rocks of this character have a thickness of 500 to 600 feet, and are followed by lighter-colored massive dolomite and limestone, without any indication of time interval, up into the Ordovician. Beginning approximately 450 feet below the top of the Arbuckle formation the limestones become more thinly bedded and are associated with thin and, in places, shaly strata. Very near the top occasional sandy beds occur.

In the massive beds in the central part of the formation fossils are found, but not in great abundance. Near the top, however, where the rocks become argillaceous, fossils are more common. Fossils of a number of genera, mostly undescribed, occur in the upper 1,250 feet of the Arbuckle limestone.

The Reagan sandstone and the Arbuckle limestone in the Wichita Mountains of Oklahoma are described by Taff⁸⁰⁸ as follows:

The Reagan sandstone is the lowest Cambrian formation in the Wichita region, and it rests on the eroded uneven surface of the granite porphyry, from which most of its materials have been derived. * * *

The Reagan sandstone is approximately 300 feet thick and is composed of hard and soft sandstone, grit, conglomerate, shales, and siliceous shell limestones. The section of the formation is essentially the same as in the western end of the Arbuckle Mountains. In each case porphyry is beneath it, and the limestone which overlies the Reagan is of the same nature and contains the same fossil fauna. In both localities the Reagan formation is made up of conglomerate composed of porphyry pebbles and included basic rocks, gritty light-brown to gray and greenish sandstones, greenish clay shales, and siliceous limestones, interstratified. The limy layers contain many species of Cambrian fossils, which were carefully collected, but which have not yet been thoroughly studied. The conglomerate occurs invariably near the base as local beds or lentils, while the calcareous sandstone and limestone beds are without exception in the upper part of the formation. * * *

Above the Reagan formation in conformable succession is a great limestone section essentially the same as the Arbuckle formation in the Arbuckle Mountains, where the lower part, practically the lower third, was found to be Cambrian and the upper two-thirds Ordovician in age. Near the transition zone, between the rock of the two periods, very few fossils have been found, so that precise distinctions as to age can not be made at the present time. The same conditions of deposition seem to have occurred in the Wichita region as in the Arbuckles, and the rocks must be classified in the same manner. There seems to be no reason to doubt that the formation is continuous from one region to the other beneath "Red Beds" deposits.

E. O. Ulrich contributes the following note regarding the Reagan sandstone:

The Reagan sandstone includes most of the Cambrian deposits exposed in the uplifts of the Arbuckle and Wichita mountains, in south-central and southwestern Oklahoma, respectively. The formation as described by J. A. Taff^a and as observed by me consists of two members. The lower is a brown sandstone, coarse grained and ill bedded below; finer grained, laminar, and slightly calcareous above; varying greatly in thickness because it rests directly on the uneven pre-Cambrian granite floor. The upper member, though not sharply separated

^a Tishomingo folio (No..98), Geol. Atlas U. S., U. S. Geol. Survey, 1903.

from the lower, is the more persistent and is readily distinguished lithologically, being composed of interbedded thin glauconite limestones and thin layers of greenish shale, together making up a thickness of about 80 feet. Some of the limestone layers in the upper half are conglomeratic and many of those in the lower half are filled with fossils. This upper member is an easily recognized and widely distributed division.

A basal sandstone, overlain by a thin-bedded limestone carrying glauconite and containing the same fauna as that found in this upper member of the Reagan sandstone, occurs at the base of the eo-Paleozoic column in the Llano and Burnet quadrangles, in central Texas. Very similar, apparently contemporaneous deposits and faunas are found also in New Mexico, Arizona, and the Bighorn Mountains of Wyoming. Further, the same fauna, though the rocks depart somewhat lithologically, is yet easily recognized in the Lamotte sandstone and Bonnetterre limestone, perhaps also in the Elvins formation of the Ozark uplift and in the "St. Croix group" of the upper Mississippi Valley.

I 16. ALABAMA AND GEORGIA.^a

The Cambrian of the southern Appalachian Valley region is represented by the Weisner quartzite, Beaver limestone, and Rome formation, by the Conasauga shale, and by part of the Knox dolomite. The upper part of the latter is of Lower Ordovician age. Hayes ^{428a} described these formations as follows:

The Weisner quartzite includes the oldest rocks that come to the surface within the limits of the Rome quadrangle. It is confined to the extreme southwest corner; and since it contains the most resistant rocks, the areas of its outcrop are marked by the greatest elevation within the quadrangle—that is, Indian Mountain. The most prominent member of the formation is a hard, vitreous quartzite, but it contains also conglomerates, sandstones, and sandy shales. The coarser elements of the formation constitute a series of lenses, variable in extent and thickness, which are interbedded with the finer-grained rocks. The latter make up the bulk of the formation, although they are much less prominent than the more resistant coarser beds. The quartzite when exposed to atmospheric agencies breaks up into angular blocks, which nearly everywhere cover the surface, and exposures of the beds in place are rarely seen. For this reason, and also because of the enormous faults which intersect the formation, its thickness is difficult to determine. On a section from Bluffton to Rockrun its apparent thickness is over 10,000 feet, but it is by no means certain that this apparent thickness is not due in some measure to repetition by faulting and the minute folding of the less resistant beds. The section is limited by a fault on the west, and the foundation upon which the formation was originally deposited is nowhere exposed. Some of the conglomerate beds contain numerous feldspar pebbles, showing that the material composing the conglomerate was derived, in part at least, from granites. It probably came from a source to the southeast, and the beds which form Indian Mountain have the appearance of massive delta deposits. No fossils have as yet been found in these beds, but their relations to adjacent formations are such that there is little hesitation in correlating them with the lower Cambrian.

The beds of the Weisner quartzite generally dip to the southeast and, where not limited by a fault, pass under a narrow belt of red clay soil containing many angular fragments of quartzite and a few masses of cellular chert. This red soil is derived from the decay of the Beaver limestone, which is itself rarely seen. It is a gray, semicrystalline, dolomitic limestone, generally massive, but sometimes slightly shaly. The exposures of this limestone are so infrequent that its thickness can not be determined, but, judging from the width of its outcrop and the prevailing dip of the adjoining beds, it is probably between 800 and 1,200 feet thick. The principal areas of the Beaver limestone are in the vicinity of Indian Mountain, but a small area is found at a considerable distance from any outcrop of the quartzite, a few miles southwest of Rome.

^a See also I-J 16-17, Tennessee and North Carolina (pp. 89-98).

The Rome formation consists of thin-bedded, fine-grained sandstones and sandy shales. Its most striking peculiarity is the brilliant coloring of its beds. The prevailing colors are various shales of red, purple, green, yellow, and white. The changes in color are often very abrupt and the exposures of the formation present a distinctly banded appearance. The base of the formation, where it is found resting upon the underlying Beaver limestone, consists of thin-bedded red sandstones, and the top of the formation is characterized by a rather heavy bed of white sandstone. Northeast of Rome the upper portion of the formation consists chiefly of shale and is distinguished on the map as a lentil in the formation. In its type locality, south of Rome, the formation is between 700 and 1,000 feet in thickness. Its beds are always more or less folded, so that it is impossible to make exact measurements of its thickness. The formation is confined to a narrow belt crossing the quadrangle diagonally from northeast to southwest at the eastern margin of the Coosa Valley. Its rocks are somewhat more resistant than the limestones which occur above and below, and it forms a line of low ridges between the lowlands on either side.

The Conasauga formation presents a number of widely differing phases within the limits of this quadrangle. At its type locality, in the Dalton quadrangle to the northeast, it consists of a great thickness of fine clay shales with occasional beds of limestone. The latter vary in thickness from a few inches to several hundred feet, and are always rather pure, blue limestone. In the vicinity of Rome and northeastward to the margin of the quadrangle, the formation consists at the base of several hundred feet of fine olive clay shale, then beds of oolitic limestone, and finally 1,000 or more feet of calcareous shales, interbedded toward the top with blue limestones. Southward from Rome the formation changes considerably by an increase in the amount of limestone. A typical section is exposed on Big Cedar Creek, where it crosses Vans Valley. The lower part of the formation consists of olive shales, above which are oolitic limestones, the same as at Rome. The upper portion of the formation, however, consists largely of heavy beds of limestone. Some of these limestone beds are gray and crystalline, closely resembling the Knox dolomite, but free from the compact nodular chert of the latter formation. Other beds contain considerable earthy matter, which often retains the form of the rock after the calcareous matter has been removed, and also masses of characteristic cellular chert. The two phases of the Conasauga formation above described are confined to the strip of lowland between the Rome sandstone ridges and the Knox dolomite plateau which occupies the southeastern half of the quadrangle.

Northwest of the Rome sandstone ridges there is a much larger area of the Conasauga formation, occupying the greater part of the Coosa Valley. The formation here varies somewhat widely from the type to the east, and is capable of subdivision into three rather distinct phases. The upper portion of the formation, along the eastern margin of the Coosa Valley, consists of characteristic greenish siliceous shales. These have been separately mapped and are indicated on the sheet as a lentil in the formation. In some cases the shales are replaced by greenish micaceous sandstone, which is always highly contorted and crushed into a series of lenticular masses from a fraction of an inch to 4 or 5 inches in thickness. The sandstone is always filled with cracks or fissures, which have the appearance of having been produced by contraction of the bed. These cracks are partially filled with quartz, and where they are unweathered the remaining space is occupied by calcite. The sandstone is confined to the southeastern margin of the valley. Northwestward the siliceous beds become fewer, being replaced by fine olive-green shales, and throughout the central portion of the valley this division is represented by olive shales, in which occur numerous flat concretions composed of gray siliceous rock intermediate in character between fine-grained quartzite and chert. Along the northwestern border of the valley this division becomes very much more calcareous. The concretions are similar in appearance to those above described, but are composed of siliceous limestone. As the shale holding these siliceous concretions weathers they collect upon the surface and resemble deposits of waterworn gravel. The intermediate division of the Conasauga as it occurs in the Coosa Valley is composed of clay shales containing varying amounts of limestone. The limestone appears in some places as a few thin beds scattered through the shales,

and in others as massive beds, frequently several hundred feet in thickness. In some places the limestone, instead of forming continuous beds, occurs as flat lenticular masses, an inch or less in thickness, rather closely crowded in the fine shales. The lower portion of the formation consists wholly of fine clay or slightly sandy shales, which appear yellow or brown at the surface and dark bluish gray or black below drainage.

These three subdivisions merge into one another without sharp boundaries. The formation contains no single stratum sufficiently characteristic to be identified at different outcrops and thereby used as a datum for the subdivision of the formation, so that the siliceous beds are represented only as a lentil in the formation. The rocks of the Coosa Valley are everywhere highly contorted and are probably also intersected by numerous faults. For these reasons, and also because large areas in the valley are deeply covered by recent gravels, it is impossible to estimate even approximately the thickness of the formation as a whole or of any of its subdivisions. The fact that the formation occupies such a broad area suggests, however, that its thickness must be very considerable, probably several thousand feet. In addition to the areas already described, the Conasauga forms a number of narrow belts in the northwestern portion of the quadrangle. These occupy the axes of narrow anticlinal rolls or are brought to the surface by faults. The formation here has much the same character as in the type locality; that is, it consists of fine clay shales with occasional beds of blue limestone. The Conasauga formation differs so widely in character in the closely adjoining regions that, except for the evidence derived from the fossils, the two phases would scarcely be correlated. Nothing resembling the upper siliceous division occurs in the region east of the Rome sandstone belt, and, on the other hand, the characteristic oolitic limestone of this eastern region is wholly wanting in the Coosa Valley.

Two explanations of these differences are suggested. The first is that there may have been a barrier of land between the two areas of deposition, so that the rocks of the Coosa Valley and those south of the Coosa fault were laid down in separate, though contiguous, basins. Deriving their sediments from different sources, they would differ in lithologic character, while the faunas might be essentially the same. No trace of such a land barrier, however, has yet been found, and the rocks in question contain none of the characteristic marks of littoral deposition. The second explanation is that the rocks now occupying adjacent areas at the surface were originally deposited in comparatively remote parts of the same sea, but have been brought side by side by folding and faulting, and that the observed lithologic differences are due to the gradual change which is always found upon tracing a bed for a considerable distance. The contrast in character is greatly heightened by the elimination of the intermediate varieties and by the most widely different types being brought into immediate contact, where comparison reveals differences which in the normal relation of the beds might escape notice. The two regions are separated by the Coosa fault, which will be more fully described later. It is quite possible that rocks now in contact on opposite sides of this fault were originally separated by an interval of 10 or 15 miles, and that the intervening rocks, now entirely concealed, would, if restored, present all the intermediate varieties between the two sharply contrasted phases of the formation.

The Knox dolomite consists of from 4,000 to 5,000 feet of massively bedded and somewhat crystalline gray magnesian limestone. From the few fossils which have been found it appears probable that a transition from Cambrian to Silurian occurs in the lower third of the formation, but it is generally impossible to determine this line of division, so the whole formation is classed as Silurian on the historical-geology sheet. This limestone, or, more properly, dolomite, contains a large amount of silica in the form of nodules and layers of chert, an impure variety of flint. Upon weathering, that part of the rock which consists of the carbonates of lime and magnesia is dissolved, leaving behind the chert, usually embedded in red clay. This residual material covers the surface to a great depth, and the dolomite is seldom seen except in the stream channels. Unlike the underlying Conasauga formation, the Knox dolomite affords some indication of having been deposited in proximity to land toward the east. In a few places the chert beds are replaced by coarse sand disseminated through the dolomite, in some

cases making it a calcareous sandstone. This sand increases in abundance toward the east, in which direction, therefore, its source probably lays.

The Knox dolomite occurs in a number of belts, from 1 to 3 miles in breadth, in the northwestern portion of the quadrangle, and also forms the surface in a much broader area which occupies nearly the whole of the southeastern third of the quadrangle. These areas are characterized by a hilly surface which is usually several hundred feet above the adjoining lowlands. Since exposures of the dolomite are rare, the extent of the formation is determined by means of the residual chert which covers its outcrops. In the vicinity of faults the chert is frequently altered by partial recrystallization of the silica and converted into a white granular rock which readily crumbles on exposure to the air. Hence, those portions of the formation which have undergone this alteration weather to a red siliceous clay soil. This can not be easily distinguished from the soil derived from the Beaver limestone and from portions of the Conasauga formation. Considerable uncertainty, therefore, pertains to the mapping of these three formations, particularly in a much faulted region, as in the vicinity of Indian Mountain.^a

The Ocoee group of Safford, which comprises a great thickness of coarsely clastic strata, together with some finer sediments, is very widely developed in Alabama and Georgia. The strata are in general much metamorphosed. Hayes^{428b} states:

The Ocoee series, whose age is not definitely known, was deposited for the most part near the margin of the sea, where the supply of land waste was abundant but subject to great fluctuations. Fine sediments alternate with coarse material, and few of the formations retain the same characteristics for long distances, except in a very general way. During a part of the Ocoee epoch there were in this region several granite islands, whose waste was deposited about them as basal conglomerates. Later these islands were entirely covered by the sea and by the sediments derived from more distant lands and spread over the sea bottom. The extreme metamorphism which the rocks of this series have undergone toward the east renders it difficult to determine their original limit in that direction or their relation to the older rocks beyond.

Hayes and Eckel⁴²⁹ give the following more detailed account of certain aspects and relations of Safford's Ocoee in Bartow County, Ga.:

The rocks on the opposite side of the Cartersville fault, occupying the eastern half of the district, present considerable variety in composition and age. A large area, extending from Stamp Creek southward across the Etowah River, to the Atlantic & Western Railroad, is occupied by the Corbin granite, which is, for the most part, a massive coarse-grained rock, containing large porphyritic crystals of feldspar (microcline), in a groundmass of plagioclase feldspar, muscovite mica, and blue quartz. Some portions of the rock have undergone considerable alteration, by which it has been converted into an augen gneiss. This area of Corbin granite at one time probably formed an island, since it is surrounded, in part at least, by rocks derived from its waste. These are feldspathic conglomerates in which the blue quartz and the porphyritic crystals of microcline, which characterize the granite, can be readily distinguished. In some places the transition from granite to conglomerate is so gradual that it is difficult to determine the exact boundary between the two formations. The development of the gneissoid structure in the granite evidently took place after it was deeply buried by sediment, for the alteration of the latter is even more marked than that of the granite itself. Wherever the granite is not bordered by coarse conglomerate or quartzite it is in contact with black graphitic slates, which generally overlie the coarser sediments.

These conglomerates and slates associated with the granite belong to the Ocoee series, which reaches its greatest development in eastern Tennessee and western North Carolina. No fossils have yet been found in the rocks of this series, although many of them are only slightly altered. They contain limestones and slates similar to portions of the adjacent valley forma-

^a See also quotation from report on the Birmingham district, pp. 164-165.

tions, but the latter are always found to contain more or less abundant traces of life. In the absence of fossil evidence their age can not be definitely determined, but on structural evidence, obtained chiefly in Tennessee, they are believed to be Lower Cambrian with possibly some pre-Cambrian.

The rocks of the Ocoee series generally show an increasing degree of metamorphism toward the southeast; and within a few miles of this region they pass into schists and gneisses, the original form of which, whether igneous or sedimentary, can not be readily determined. This increased metamorphism toward the southeast is due in part to the greater compression which that region has suffered, and in part to the presence of considerable bodies of various igneous rocks which have been intruded into the sedimentary beds. These intrusive rocks present considerable variety in composition, varying from extremely basic diabase to acid granites. The most common variety is a diorite, which was among the earlier intrusions, and has been subsequently converted for the most part into amphibolite schist. Two belts of this basic schist pass across the southeastern corner of the district. Its southeastern corner is occupied by the Acworth gneiss, which, like the Corbin granite, is probably Archean in age, and formed the foundation on which the oldest sediments of the region were deposited.

Among these probably pre-Cambrian schists occur some strata which, though highly metamorphosed, are of late Paleozoic age. Thus E. A. Smith records the discovery of plant remains near Mosely, Clay County, Ala., in "semicrystalline (sericite) slates of the Ocoee type * * * at the eastern base of the main range of the Talladega Mountains * * * 8 miles or more from the contact of the 'Ocoee' with the unaltered Cambrian of the valley." David White⁷⁴⁷ reported on the plants as follows:

Your specimens represent several fragments of large cones in which the axes, the basal, sporangiferous portions of the spirally arranged bracts, the rhomboidal compressed sporangia, and the megaspores are well defined. Precise identification of the material is deferred pending the study of thin sections and the determination of certain points regarding the sporangial walls and their attachment to the basal portions of the bracts. It is clear, however, that we have here fragments of cones whose superficial features appear to represent the common *Lepidostrobus* type of the upper Paleozoic. Beds containing lepidophytic remains of this type can hardly be older than Devonian at earliest, and should not antedate the Middle Devonian.

The general proportions and aspect of the cones are suggestive of some of the Carboniferous forms. Although the internal structure of the strobili may be found to indicate a more highly organized genus than *Lepidostrobus*, we may rest assured that the material is not older than the upper Paleozoic lepidophytes.

I-J 12. GRAND CANYON, ARIZONA.

The Tonto group comprises a sandstone at the base and shales and limestones above. Walcott^{851a} gives the following section:

The Tonto section at the head of Nunkoweap Valley is as follows, from top downward:

	Feet.
1. Massive mottled limestone.....	60
Fossils: <i>Lingulepis</i> and <i>Ptychoparia</i> .	
2. Evenly bedded yellowish sandstone.....	25
3. Mottled and variegated calcareo-arenaceous rocks.....	340
4. Thin-bedded sandstones.....	325
Fossils (near base): <i>Lingulella</i> , <i>Acrothele</i> , <i>Iphidea ornatella</i> , <i>Hyalolithes</i> , <i>Leperditia</i> (three species), <i>Dilichometopus</i> , <i>Olenoides</i> , and <i>Ptychoparia</i> .	
5. Fine-grained passing into coarse reddish-brown sandstone in layers.....	300
	1,050

The base rests unconformably upon the Chuar shales, etc. Nos. 4 and 5 are referred to the Middle Cambrian, and the strata above to the Upper Cambrian.

In 1883 Walcott⁸⁴⁶ wrote:

The geologic age of the Tonto group is determined by the presence of numerous specimens representing the genera *Cruziana*, *Lingulepis*, *Iphidea*, *Conocephalites*, *Crepicephalus* and *Dicelloccephalus* that occur at various horizons in the upper 700 feet of sandstone, shales and limestone. No fossils were obtained from the coarse sandstone forming the lower 300 feet. The fauna above, however, shows close relations to that of the Potsdam sandstone horizon of central Nevada, the Mississippi Valley, and Saratoga County, N. Y.

The base line of the Tonto is quite uniform and rests unconformably on the varied strata beneath; here and there a knoll, point or ridge is seen on the pre-Tonto surface that rises nearly through the massive Tonto sandstones that were deposited against and over them, the sea breaking off, and burying with the drifting sand, fragments of the rocky islands.

The great unconformity beneath the Tonto has been described by Prof. J. W. Powell, who examined it in his boat trips down through the Grand Canyon, and by Capt. C. E. Dutton, who viewed it from the summit of the Kaibab Plateau, 5 miles away. Prof. Powell estimated the strata beneath the Tonto and above the Archean at 10,000 feet, and as this is all cut across the unconformity is very great. A detailed study adds to the thickness of the strata; it shows that the original summit of the pre-Tonto group had undoubtedly been cut away more or less before the deposition of the Tonto group; that the plane of erosion cut deeply into the Archean, and that besides the 13,000 feet of strata, that have been planed off, of which the record is found in the section preserved, there was also a problematical amount of considerable thickness.

I-J 16-17. TENNESSEE AND NORTH CAROLINA.

In eastern Tennessee and North Carolina two distinct sequences of strata are assigned to the Cambrian. One consists of the sparsely fossiliferous siliceous group to which Safford applied the name Chilhowee sandstone but which has been subdivided by Keith into several formations, and the overlying richly fossiliferous, generally calcareous deposits which constitute the Apison, Beaver, Rome, Conasauga, and Knox formations and some minor divisions of local extent; these are found in the valley region of east Tennessee. The other sequence is the more or less metamorphosed unfossiliferous Ocoee group of Safford, composed in part of coarse clastic deposits with slate and subordinate limestone, which form large masses of the Great Smoky Mountains. Keith⁴⁸⁰ has demonstrated the conformity of Safford's Ocoee to the fossiliferous Cambrian and classes it as Cambrian on grounds of physical relationship. He says:

With the deposition of the Cambrian rocks there came a great change in the physical aspect of this region. The sea encroached upon areas which were until then dry land. Eruptions of lava and erosion of the surface were replaced by deposition of sediments beneath a sea. Extensive beds of these were laid down in some areas before others were submerged. Here the sediments lapped over lavas and plutonic granites alike, and the waste from them all was combined in one sheet of gravel and coarse sand which now appears as sandstone, conglomerate, and quartzite. Some of this waste consists of epidote and jasper, the products of alteration in the Linville meta-diorite. It is thus seen that the interval between the Algonkian and Cambrian was at least long enough to permit dynamic movements and chemical changes to effect considerable results, even before the period of erosion and reduction began.

The two sequences generally do not occur in their original relations, which are therefore indeterminate over wide areas. The Ocoee of Safford is usually overthrust from the east upon younger strata to an extent which obliterates the normal

sequence. An exception to this general fact occurs in northeastern Tennessee, where a complete conformable sequence from Safford's Ocoee into the fossiliferous Cambrian has been worked out by Keith. (See section, Greeneville and Roan Mountain quadrangles, pp. 95-96.) The discovery of Carboniferous plants near Mosely (now Erin), in Clay County, Ala., in metamorphosed rocks which have been regarded as a part of Safford's Ocoee (see Chapter VIII, p. 363), shows that the metamorphic terrane of which his Ocoee there has been considered a part locally comprises rocks of various ages.

The fossiliferous Cambrian formations of Tennessee range from Lower Cambrian (Georgian) up through the entire system and pass into Lower Ordovician in the Knox dolomite. Beneath the fossiliferous strata occur others which have no fossils but which are conformable to those that have. The strata vary along the valley from southwest to northeast and more markedly across the valley from southeast to northwest. Some typical sequences are as follows:

Generalized section west of Southern Railway.^{42a}

Period.	Formation.	Thickness (feet).	Character of rocks.
Silurian. [Ordovician.]	Chickamauga limestone.	1,800-2,100	Blue flaggy limestone with some mottled, earthy beds.
	Knox dolomite.	3,800-4,200	Magnesian limestone, white, gray, or light blue; generally granular and massively bedded, containing nodules and layers of chert.
Cambrian.	Conasauga shale.	500-1,600	Blue seamy limestone. Greenish clay shale. Thin beds of oolitic limestone.
	Rome formation. (Rome sandstone.)	1,800-2,600	Greenish or brown shale with thin siliceous layers. Purple, brown, and white sandstone interbedded with sandy shale.
	Apison shale.	1,500+	Sandy shale or clay shale in brightly colored bands.

Generalized section east of Southern Railway.^{424a}

Period.	Formation.	Thickness (feet).	Character of rocks.
Silurian. [Ordovician.]	Chickamauga limestone.	300-650	Blue flaggy limestone.
	Knox dolomite.	4,200-4,400	Magnesian limestone, white, gray, or light blue; generally granular and massively bedded, containing nodules, layers of chert, and beds of coarse sand.
Cambrian [fossiliferous to Nichols shale, inclusive]. [Chilhowee of Safford.] [Ocoee of Safford.]	Conasauga shale.	1,100-6,000	Blue seamy limestone. Greenish calcareous clay shale and beds of limestone. Thin beds of oolitic limestone in shale.
	Rome formation. (Rome sandstone.)	1,600 (1,100)	Brownish shale. Purple, brown, or white sandstone interbedded with sandy shale.
	Murray shale.	200+	Sandy shale.
	Nebo sandstone.	250-600	White quartzite or quartzose sandstone.
	Nichols shale.	440-1,140	Micaceous sandy shale.
	Cochran conglomerate.	200-1,500	Quartzite, quartzose sandstone, and conglomerate.
	Sandsuck shale.	750-1,900	Blue shale, locally calcareous.
	Starrs conglomerate.	0-660	Conglomerate, generally feldspathic.
	Sandsuck shale.	(?)	Blue shale.

Generalized section west of Clinch and Tennessee rivers.^{420a}

Period.	Formation.	Thickness (feet).	Character of rocks.
Silurian. [Ordovician.]	Chickamauga limestone.	1,300-1,700	Blue flaggy limestone.
	Knox dolomite.	3,300-3,500	Magnesian limestone; white, gray, or light blue; generally granular and massively bedded; containing nodules and layers of chert.
Cambrian.	Conasauga shale.	300-500	Blue seamy limestone. Greenish clay shales. Thin beds of oolitic limestone.
	Rome formation. (Rome sandstone.)	2,800-3,400 (1,800-2,200)	Greenish or brown shales with thin siliceous layers. Purple or brown sandstones interbedded with sandy shales.
	Apison shale.	1,000+	

Generalized section southeast of Bays Mountain.^{475a}

Period.	Formation.	Thickness (feet).	Character of rocks.
Silurian [Ordovician.]	Athens shale.	1,000-1,200	Light-blue calcareous shale, black calcareous shale.
	Chickamauga limestone.	0-50	Gray argillaceous limestone.
Cambrian [fossiliferous to Nichols shale, inclusive]. [Chilhowee of Safford.]	Knox dolomite.	3,500	Magnesian limestone, white, gray, light and dark blue, with nodules of chert.
	Nolichucky shale.	450-550	Yellow and brown calcareous shale and limestone beds.
	Maryville limestone.	350-550	Massive dark-blue limestone.
	Rogersville shale.	180-220	Bright-green clay shales, with a limestone bed.
	Rutledge limestone.	350-450	Massive dark-blue limestone.
	Rome formation. Rome formation sandstone.	250 500-700	Red, green, yellow, and brown shales and sandy shales. Red, white, and brown sandstones and sandy shales.
	Beaver limestone.	300	Massive blue limestone.
	Apison shale.	{ 200 900+	Green argillaceous shale. Bright-red, green, and brown sandy shales.
	Hesse sandstone.	500+	Fine white massive sandstone.
	Murray shale.	300	Grayish-blue sandy shale.
	Nebo sandstone.	500	Massive white sandstone, coarse and fine.
	Nichols shale.	550-800	Grayish-blue sandy shale.
	[Ocoee of Safford.]	Cochran conglomerate.	600-900 0-100 500-700
Sandsuck shale.		1,000+	Grayish-blue argillaceous shale.

Generalized section for the Briceville quadrangle.^{478a}

Period.	Formation.	Thickness (feet).	Character of rocks.
Silurian. [Ordovician.]	Chickamauga limestone.	1,600-2,000	Blue and gray limestone, argillaceous limestone, flaggy limestone, and calcareous shale. Blue and gray massive limestone with a few nodules of black chert.
	Knox dolomite.	2,800-3,500	Magnesian limestone, white, gray, light blue, and dark blue, with nodules of chert.
Cambrian.	Conasauga shale: {Nolichucky shale. Maryville limestone.	650-800 (250)	Yellow, red, and brown calcareous shale with thin beds of limestone, those at the base assuming the importance of a separate formation in the extreme southeast.
	Rome formation.	600-800	Bright-colored red, green, and brown sandy shale interbedded with layers of thin sandstone.
	Rome sandstone lentil.	500+	Red, yellow, and brown sandy shale with thick beds of sandstone.

Generalized section of the sedimentary rocks in the Great Valley (Greeneville quadrangle).^{481a}

System.	Formation.	Thickness (feet).	Character of rocks.	
Ordovician.	Athens shale.	1,000±	Black and bluish-black calcareous shale.	
	Moccasin limestone.	450-500	Red, blue, gray, and drab massive and shaly limestone.	
	Chickamauga limestone.	0-450	Blue and gray limestone, shaly in part, and variegated marble.	
?	Knox dolomite.	3,000-3,500	Magnesian limestone, light and dark blue, white, and gray, with nodules and layers of chert and a few beds of calcareous sandstone.	
Cambrian.	Nolichucky shale.	500-750	Yellow, green, and brown calcareous shale, with limestone beds.	
	Honsaker limestone.	Maryville limestone.	700-950	Massive dark-blue and dark-gray limestone.
		Rogersville shale.	180-200	Bright-green clay shales, with thin limestone beds.
		Rutledge limestone.	400-450	Massive dark-blue limestone, with shale beds at bottom.
	Rome formation. Sandstone lentil.	200± 400±	Red, green, and brown shale and sandy shale. Red, white, and brown sandstone and sandy shale.	

Generalized section for portion of Bristol quadrangle south of Clinch Mountain.^{125a}

Period.	Formation.	Thickness (feet).	Character of rocks.
Silurian. [Ordovician.]	Athens shale.	1,000-1,200	Sandy shale and thin sandstones, with occasional beds of impure limestone and limestone conglomerate. Dark argillaceous shale at the base.
	Knox dolomite.	2,800-3,500	Blue and gray limestone. Very cherty along Walker Mountain, but farther toward the southeast the chert disappears and the formation merges with and becomes indistinguishable from the Honaker limestone beneath, and the whole is called the Shenandoah limestone.
Cambrian.	Nolichucky shale.	0-300	Blue calcareous and sandy shale. Toward the east this changes to limestone.
	Honaker limestone.	1,200-1,400	Blue and gray limestone. Toward the east this formation merges with the Knox dolomite and the whole is known as the Shenandoah limestone.
	Russell formation.	400+	Red and green shales and thin-bedded sandstones.

The development of the Ocoee group in part of eastern Tennessee and North Carolina is shown in the following six sections, which represent the group from southeastern to northeastern Tennessee:

Generalized section east of Beans Mountain.^{424a}

Period.	Formation.	Thickness (feet).	Character of rocks.
Ocoee series, age unknown. [Cambrian of Keith, Ocoee of Safford.]	Thunderhead conglomerate. Thunderhead slate.	300± 1,500±	Massive conglomerate interbedded with black slate. Black slate, with beds of conglomerate and sandstone, generally schistose.
	Thunderhead conglomerate.	800-1,000	Massive conglomerate of blue quartz and feldspar.
	Pigeon slate.	(?)	Blue or black slate, with local beds of sandstone and conglomerate, generally schistose.
	Citico conglomerate.	500-1,100	Conglomerate and sandstone, with beds of sandy shale.
	Wilhite slate.	(?)	Blue slate with lenses of quartz conglomerate, sandy limestone, and limestone conglomerate.

Generalized section southeast of Chilhowee Mountain.^{475a}

Period.	Formation.	Thickness (feet).	Character of rocks.
Age unknown. [Cambrian of Keith, Ocoee of Safford.]	Clingman conglomerate.	1,000+	Gray sandstone and coarse and fine conglomerate, with blue quartz and feldspar.
	Hazel slate.	600-800	Black slate, with small beds of sandstone and fine conglomerate.
	Thunder Head conglomerate.	3,000+	Gray sandstone and coarse and fine conglomerate, with blue quartz and feldspar.
	Cades conglomerate.	2,400+	Gray sandstone and fine conglomerate, with many beds of sandy slate.
	Pigeon slate.	1,300-1,700	Banded gray and bluish-gray slate and sandy slate; a few gray sandstone beds.
	Citico conglomerate.	50-800	Coarse quartz conglomerate. Fine quartz conglomerate. Coarse white sandstone. Fine white sandstone.
	Wilhite slate.	0-1,000	Limestone conglomerates and sandy limestone. Bluish-black argillaceous and calcareous slate.

Generalized section of the sedimentary rocks in the Bald Mountains, Greeneville quadrangle.^{481a}

System.	Formation.	Thickness (feet).	Character of rocks.
Cambrian. [Knox of Safford.] [Chilhowee of Safford.] [Ocoee of Safford.]	Shady limestone.	1,000±	Gray, bluish-gray, mottled gray, and white limestone, with nodules and masses of chert.
	Hesse quartzite.	700-800	Massive white quartzite and sandstone.
	Murray slate.	300-400	Bluish-gray to gray argillaceous and sandy shale and slate, with thin sandstone seams.
	Nebo quartzite.	200-900	Massive white quartzite and sandstone, coarse and fine, with a few layers of sandy shale and reddish sandstone.
	Nichols slate.	400-700	Bluish-gray to gray argillaceous and sandy shale and slate, with thin sandstone layers.
	Cochran conglomerate.	200-1,600	Massive quartz conglomerate and quartzite, light and dark gray, with seams of dark slate.
	Hiwassee slate.	1,200-1,500	Blue, gray, black, and banded slate, with a little fine mica schist. Includes layers of sandstone and conglomerate and beds of calcareous sandstone.
	Snowbird formation.	700-2,000	Gray and white feldspathic quartzite and sandstone, with dark slate beds. Locally becomes conglomerate and dark-purplish sandstone. Coarse and fine quartz conglomerate and arkose.
Archean.	Unconformity.		
	Granites.		

Generalized section of the sedimentary rocks of the Roan Mountain quadrangle in the vicinity of Erwin.⁴⁸⁴

System.	Formation.	Thickness (feet).	Character of rocks.
Ordovician.	Athens shale.	800-1,600	Black and bluish-black calcareous shale below, blue-gray banded slaty shale above.
	Knox dolomite.	3,000-3,700	Magnesian limestone, light and dark blue, white, and gray, with nodules and layers of chert and a few beds of calcareous sandstone.
Cambrian [fossiliferous to Hesse quartzite, inclusive].	Nolichucky shale.	50-600	Yellow, green, and brown calcareous shale with limestone beds.
	Honaker limestone.	1,800-2,200	Massive dark-blue and dark-gray limestone. White and blue limestones.
	Watanga shale.	1,000-1,100	Purplish, red, green, and variegated shales, sandy shales, and thin sandstones, with calcareous shales and thin blue limestones interbedded.
	Shady limestone.	750-1,000	Gray, bluish-gray, mottled-gray, and white limestone, with nodules and masses of chert.
	Hesse quartzite.	700-1,000	Massive white quartzite and sandstones.
	Murray slate.	300-400	Bluish-gray to gray argillaceous and sandy shale and slate, with thin sandstone seams.
	Nebo quartzite.	200-900	Massive white quartzite and sandstone, coarse and fine, with layers of sandy shale, slate, and reddish sandstone.
	Nichols slate.	400-700	Bluish-gray to gray argillaceous and sandy shale and slate, with thin sandstone layers.
	Cochran conglomerate.	200-1,600	Massive quartzite, sandstone, and conglomerate, white or gray, with seams of dark slate.
	Hiwassee slate.	300-1,500	Bluish-gray to black and banded slates, with a little fine mica schist. Includes layers of sandstone and conglomerate.
[Knox of Safford.]	Snowbird formation (amygdaloid).	700-2,000	Gray and white feldspathic quartzite and sandstone, with dark slate beds and lentils of amygdaloid. Locally becomes conglomerate and dark-purplish sandstone. Fine quartz conglomerate and arkose at base.
[Chilhowee of Safford.]			
[Ocoee of Safford.]			
Archean.	Granites.		

Generalized section of the sedimentary rocks of the Cranberry quadrangle.^{480a}

Period.	Formation.	Thickness (feet).	Character of rocks.
Cambrian.	[Knox of Safford.] Watauga shale.	1,000-1,100	Purplish, reddish-brown, and yellow shales, sandy shales, and thin sandstones, with calcareous shales and thin blue limestones interbedded.
	Shady limestone.	750-800	Gray, bluish-gray, and mottled-gray limestone, with nodules and masses of black chert.
	[Chilhowee of Safford.] Erwin quartzite.	500-700	Massive white quartzite and sandstone.
	Hampton shale.	600-800	Bluish-gray and gray argillaceous and sandy shales, with thin sandstone layers.
	[Ocoee of Safford.] Unicoi formation.	1,500-2,500	Massive white sandstone, feldspathic sandstone, and quartzite, with interbedded shales and sandy shales in the upper part, a thin bed of amygdaloid near the middle, and conglomerate, arkose, and graywacke in the lower part.
	Unconformity.		
Pre-Cambrian.	Gneisses, granites, and ancient volcanic rocks.		

*Generalized section of the sedimentary rocks of the Mount Mitchell quadrangle.*⁴⁸²

System.	Formation.	Thickness (feet).	Character of rocks.
Cambrian.	[Chilhowee of Safford.] Shady marble.	600+	White and blue massive banded marble.
	Erwin quartzite.	600+	Massive white quartzite.
	Hampton shale.		Blue and gray shale and slate.
	[Ocoee of Safford.] Brevard schist.	1,000+	Fine-grained black schist, in places graphitic.
	Unconformity.		
Archean.	Gneisses and granites.		

A somewhat different development of Safford's Ocoee group is found in extreme southwestern North Carolina, as shown by the following section:

*Generalized section of the sedimentary rocks of the Nantahala quadrangle.*⁴⁸³

System.	Formation.	Thickness (feet).	Character of rocks.
Cambrian [Ocoee of Safford].	Nottely quartzite.	150+	Fine white quartzite.
	Andrews schist.	200-350	Light-colored calcareous schist with ottrelite and iron ore.
	Murphy marble.	150-500	Thick-bedded white, blue, and blue and white banded marble.
	Valleytown formation.	900-1,200	Graywacke and fine-grained gneiss, interbedded with dark garnet and ottrelite schists.
	Brasstown schist.	1,200-1,500	Blue and black banded ottrelite schist, garnet schist, and slates, with a few layers of fine graywacke. Black slate usually at the base.
	Tusquitee quartzite.	20-500	Coarse and fine white quartzite with some quartz conglomerate.
	Nantahala slate.	1,400-1,800	Black, bluish-black, and gray slate; in places altered to fine black schist with some fine ottrelite and garnet. Contains a few beds of gray sandstone and graywacke. Thick bed of staurolite-garnet schist usually at the base.
	Great Smoky conglomerate.	5,500-6,000	Blue quartz and feldspar conglomerate. Massive beds of quartz and feldspar conglomerate and coarse gray sandstone with beds and seams of black slate. Altered toward the southeast into coarse and fine graywacke and quartzite with beds of black schist and ottrelite schist.
	Hiwassee slate.	500	Blue and gray banded slate.
Archean.	Unconformity.		
	Gneisses and granite.		Light-gray granite, fine granite, and gneissoid granite.

J 11-12. CALIFORNIA, NEVADA, AND UTAH.

In 1890, with reference to the Great Basin province in general, Walcott⁸⁵¹ summed up the Cambrian stratigraphy as follows:

In this province there appears to have been a large accumulation of more or less coarse, arenaceous sediment, commingled with considerable argillaceous material, before the deposition of the sediments of the Olenellus zone. As far as shown, the Olenellus fauna appeared at the time the character of the sediments was changing to finer sands and argillaceous clays, and then to calcareous clays. The sedimentation is unlike that of the sections on the eastern side of the continent. The southern portion of the province is found in the Great Basin region of Utah and Nevada, between the Wasatch range and the Sierra Nevada range. In the eastern or Wasatch area *Linguella ella*, *Olenellus gilberti*, and *Cruziana* sp.? occur in a thin band of fine micaceous sandstone, about 200 feet from the summit of the Cambrian rocks, which are conformably subjacent to strata of Ordovician age. The Olenellus-bearing sandstones are covered with trails of annelids, etc., and are evidently a littoral or shore deposit.

In the Eureka district of central Nevada the fauna is confined to a narrow belt of arenaceous shales, with some intercalated limestone. The fauna consists of but seven species: *Girvanella?* sp.?, *Kutorgina prospectensis*, *Scenella conula*, *Olenellus gilberti*, *O. iddingsi*, *Olenoides quadriceps*, *Ptychoparia subcoronata*, and *Anomocare parvum*. Of these, two species, *Olenoides quadriceps* and *Scenella conula*, are found 500 feet higher up in the section. In the Highland Range section of Nevada the rocks are essentially of the same character as in the Eureka section; the two species, *Olenellus gilberti* and *O. iddingsi*, occur in an arenaceous shale associated with *Cruziana* sp.? In the Pioche section more limestone is interbedded in the arenaceous shale and the fauna of the *Olenellus* zone is larger. It includes *Eocystites??*, *Lingulella ella*, *Kutorgina pannula*, *Acrothele subsidua*, *Acrotreta gemma*, *Orthis highlandensis*, *Olenellus gilberti*, *Zacanthoides levis*, *Crepicephalus augusta*, *C. liliana*, and *Oryctocephalus primus*. Of these, *Kutorgina pannula*, *Acrothele subsidua*, *Acrotreta gemma*, and *Hyolithes billingsi* pass to the zone above that carrying *Olenellus*. In limestones of the *Olenellus* zone at Silver Peak, in western Nevada, the following species were collected by Mr. Clayton: *Girvanella?* sp.?, *Spirocyathus atlanticus*, *Ethmophyllum meeki*, *E. whitneyi*, *Kutorgina cingulata*, *Hyolithes princeps*, *Olenellus gilberti*.

Detailed sections are given in a bulletin by Walcott⁸⁴⁸ published in 1886. In 1895 Walcott⁸⁵⁶ stated:

The only Lower Cambrian rocks of California known to me occur in the White Mountain Range of Inyo County, east of Owens Valley, with the single exception of one small mass west of Big Pine, which is in the foothills of the Sierra Nevada.

*. * * * * *

During the summer of 1894, accompanied by Mr. F. B. Weeks, I crossed the range over the toll road leading from Big Pine to Piper's ranch, in Fish Lake valley, and penetrated into it from the western side in Waucobi, Black, and Silver canyons.

The ascending section exposed in the ridge on the north side of Black Canyon is as follows:

	Feet.
1. Gray and yellowish arenaceous limestone, occurring in low hills above the Quaternary.....	200
2. Massive-bedded compact fine-grained, often saccharoidal light-gray siliceous and arenaceous limestone (strike N. 10° W. (mag.), dip 20° E.). At 100 feet from base of this division a dike of basalt 40 feet in thickness cuts through and displaces the limestone in the vicinity of the dike, so as to give it a dip of from 70° to 80° E. Above the dike the dip of 20° is very quickly resumed. At 160 feet from the base a band of white limestone occurs, which contains numerous small concretions of limestone. At 230 feet above the dike occurs a band of shaly limestone, which has buff-colored partings; and irregular, buff-colored, sandy laminations occur in thin layers in the thick-bedded limestone.	
No. 2 may be subdivided as follows:	
a. Light-gray and white limestone.....	500
b. Buff and gray, more arenaceous limestone, with a band of cherty limestone 20 to 25 feet thick at 125 feet from its base.....	170
c. Gray arenaceous limestone, cherty at top.....	115
d. Shaly and thick-bedded sandy limestone, cross-bedded in places, with yellowish-buff layers, also with two bands of brown thick-bedded and shaly quartzite..	145
e. Massive-bedded coarse arenaceous gray limestone, passing into buff-colored and cherty beds above.....	85
f. Buff-colored shaly limestone.....	5
g. Bluish-gray banded limestone.....	30
h. Gray arenaceous limestone, with bands of buff-colored, mostly thick-bedded limestone.....	70
i. Thick-bedded bluish-gray limestone.....	10
j. Brownish and buff-colored calcareous sandstone, with inclosed brecciated thin-bedded brown sandstone.....	5
k. Dark banded quartzite.....	30
l. Massive-bedded gray arenaceous limestone.....	225
3. Dark irregular thin-bedded siliceous slates with interbedded dark quartzitic sandstone (dip 25°-30° E. (mag.), strike north and south).....	1, 525 635

The section is terminated at this point by a fault line.

On the north side of Silver Canyon, No. 3 is well exposed and is estimated to have a thickness of 2,000 feet. Above this a series of limestones and calcareous and siliceous shales occurs and some interbedded dark quartzitic sandstones, that extend upward 1,000 feet. Near the base a massive-bedded limestone 100 feet in thickness occurs, in which great quantities of Lower Cambrian corals (*Archæocyathinæ*) occur. This series is capped by about 200 feet of compact thin-bedded arenaceous argillite, with interbedded layers of dark-brown fine-grained quartzite.

The entire section, briefly summarized from summit downward, is as follows:

	Feet.
4. Upper arenaceous beds.....	200
3. Alternating limestones and shales.....	1,000
2. Siliceous slates and quartzites.....	2,000
1. Siliceous limestones.....	1,700
	4,900

In round numbers the section exposed in the White Mountain Range, between White Mountain Peak and Waucobi Canyon, is 5,000 feet in thickness.

No fossils were found in the lower limestone. Numerous annelid trails occur in the lower siliceous series, and in the slaty portion near the summit heads of *Olenellus* were found. In places the lower portion of the upper limestone series is almost a solid bed of different forms of the *Archæocyathinæ*. *Ethmophyllum whitneyi* Meek is very abundant, and the genera *Protopharetra*, *Coscinocyathus*, and probably *Archæocyathus* occur. *Ethmophyllum* ranges throughout the limestone series into the base of the shales in Tollgate Canyon, where it is associated with cystidean plates and fragments of *Olenellus*. On the north side of Silver Canyon the *Archæocyathinæ* are so abundant in the limestone that it may practically be called a Lower Cambrian coral reef. This reef was traced for nearly 30 miles, and the same types are also known to occur in the Silver Peak Range, about 25 miles to the eastward.

So far as known to me, this is the oldest of the Cambrian faunas known in the western portion of the United States. Just what its relations to the *Olenellus* fauna of central Nevada and British Columbia are I am unable at present to state, except that I believe it to be older than the *Olenellus* fauna of central Nevada.

It is not impossible that a fauna will be found in the lower limestone, but in the hasty reconnaissance in which I was engaged only a portion of one day was given to the examination and measurement of the section. I hope in the future to extend the study of the White Mountain Range, as Mr. Fairbanks has written me that he has discovered *Fusilina cylindrica* in the southern end of the range, east of Keeler, which is about 50 miles south of Tollgate Canyon. If the section is unbroken, the Middle and Upper Cambrian and Ordovician faunas should be found before reaching the Carboniferous horizon discovered by Mr. Fairbanks.

In recent papers Walcott²⁶¹ has supplemented the data regarding the earliest Cambrian stratigraphy and faunas as follows:

The oldest known Cambrian fossils are found deep down in the Lower Cambrian strata of southwestern Nevada and the adjoining Inyo County area of eastern California. In sections 120 miles apart the Lower Cambrian has a thickness of over 5,000 feet, with a great limestone forming the upper 700 to 2,000 feet. Below this limestone calcareous strata occur, but the predominating rocks are sandstones and arenaceous, siliceous, and calcareous shales. In the lower 400 feet of the Waucoba Springs section and the Barrel Spring section south of Silver Peak in western Nevada the fauna includes—

Annelid trails.
Protopharetra sp. undt.
Archæocyathus sp. undt.
Ethmophyllum cf. *whitneyi* Meek.
Mickwitzia occidentis Walcott.

Trematobolus excelsis Walcott.
Obolella sp. undt.
Orthotheca sp. undt.
Holmia rowei n. sp.
Holmia weeksi n. sp.

Although this fauna, according to our present knowledge, is the oldest known Cambrian fauna, it includes representatives of the several classes of invertebrates which I will enumerate.

Actinozoa.—The corals are represented by a very primitive form of *Protopharetra*, a small form of cup-shaped *Archæocyathus*, and a small *Ethmophyllum* closely allied if not identical with *Ethmophyllum whitneyi* (Meek), which occurs higher in the section. The latter is not a notably simple or primitive form of the *Archæocyathinæ*; on the contrary, it is nearly as far advanced as any species known in the Cambrian.

Vermes.—The annelid borings and trails that occur in and on the sandstones and shales are much like those of the Middle and Upper Cambrian.

Molluscoidea.—The two species of brachiopods represent widely separated genera. *Mickwitzia occidentis* Walcott is one of the primitive forms of the *Paterinidæ*, while *Trematobolus excelsis* Walcott is a typical form of the *Siphonotretidæ*. The interval represented by the relative development of *Mickwitzia* and *Trematobolus* is sufficient to convince us that we must look far back in Cambrian or it may be pre-Cambrian time for the progenitors of the inarticulate brachiopods.

Pteropoda.—The forms representing *Orthotheca* are abundant, large, strong, and evidently as well developed as those of the Middle Cambrian.

Crustaceans.—The trilobites thus far found at this horizon are confined to two species of the genus *Holmia*. One of them, *Holmia weeksi* n. sp., has many segments and is more primitive than such forms as *Olenellus thompsoni* Hall and *Holmia bröggeri* (Walcott), of the upper portions of the Lower Cambrian section. The other species, *Holmia rowei* n. sp., is of the same general type as *Holmia bröggeri*. The absence of all other trilobite genera is the most marked feature of this early Cambrian fauna.

In the section 100 miles to the south, at Resting Springs, Inyo County, Cal., a brachiopod closely related to *Billingsella highlandensis* Walcott occurs 2,800 feet below the upper limestone in association with the trilobite *Holmia rowei*.

Comparing the species in the early Lower Cambrian fauna with the *Olenellus* fauna, in strata 5,000 feet higher in the section, we find a marked advance in the variety of the later fauna, but we do not know how much of this may be due to the absence, from our collections, of genera and species that may have existed during the deposition of the earlier sediments. In the earlier fauna of the Waucoba section the class characters of the *Arthropoda*, *Mollusca*, *Molluscoidea*, *Vermes*, and *Cœlenterata* were developed, and while the study of the genera and species adds a little more to our knowledge of the rate of convergence backward in geologic time of the lines representing the evolution of animal life, it, at the same time, proves that a very long time interval elapsed between the beginnings of life and the epoch represented by the *Olenellus* fauna.

This fauna is described by Walcott,⁸⁶⁰ in the Smithsonian Miscellaneous Collections. In his latest contribution Walcott⁸⁶² says:

The evidence afforded by the few traces of pre-Cambrian fossils is inconclusive as far as determining whether their habitat was in marine, brackish, or fresh water.

The fossils from the Chuar group of Arizona are not sufficiently characterized to prove their origin or habitat. The protozoan *Cryptozoon? occidentale* Dawson is very abundant in Arizona, also in the Belt series of Montana, Alberta, and British Columbia. It occurs in limestones similar to those deposited in the fresh-water lagoons of Florida, and similar to the limestones of the lake deposits of the Tertiary formations of the Great Plains region of North America. The fossils of the Beltina zone of Montana and Alberta could as readily have been developed in fresh or brackish waters. There is nothing about the crustacean remains incompatible with their living in fresh water, in fact, the fragments indicate a form more nearly related to the fresh-water *Brachiopoda* with very thin test, rather than the strong *Merostome* (*Euryp-terus*, etc.).

The oldest Cambrian fauna now known, with *Nevadina weeksi* and *Holmia rowei*, is limited to a few forms, but with a careful examination of the region where it occurs in southwestern Nevada it is highly probable that a considerable fauna will be found. The strata in which it occurs were deposited in a depression opening out toward the Pacific Ocean, where southwestern California is now located; this depression soon extended northward and presumably connected through to British Columbia and Alberta, as the same species of *Olenellus* occur in the central and upper portions of the Lower Cambrian both in Nevada and Alberta.

I do not know of a Cambrian fauna as old as that of *Nevadina weeksi* on the eastern side of the continent, or on the European continent. It appears to be a portion of the older fauna that is missing everywhere except in southwestern Nevada. I think it was brought in by the advancing Lower Cambrian sea from a sea to the west, the sediments of which are buried beneath later strata or are off the present shore line of the continent beneath the sea.

The theory that life originated and developed in fresh-water ponds and lakes does not appeal to me. More uniform conditions of temperature and environment would be present in the ocean and the sediments of the fresh-water deposits of pre-Cambrian and Cambrian time, if such exist, do not show sufficient evidence of life having existed at the time of their deposition. The Algonkian fossils of the Belt and Grand Canyon series (Walcott, 1899, pp. 227-239) probably came from the marine fauna when a temporary connection existed between the interior fresh or brackish water lakes and the ocean.

Spurr⁷⁷² gathered in one volume the observations made by himself and others on the occurrences of Cambrian strata and faunas in 25 widely distributed ranges of the Great Basin. Ball⁵⁴ supplemented Spurr's descriptions for southwestern Nevada and eastern California and gave a columnar section showing the relations of the Paleozoic strata among themselves and to the post-Carboniferous and Tertiary igneous rocks.

Darton²⁴³ has noted the occurrence of Cambrian strata resting on older granite at Iron Mountain, in eastern San Bernardino County, Cal. He observed 1,200 feet of shale and limestone with quartzite at the base and collected "fragments of trilobites and mollusks which proved not to be specifically determinable," but which according to Walcott are "undoubtedly Cambrian, probably Middle Cambrian."

J 13. COLORADO.

The Upper Cambrian is represented in southwestern Colorado in Animas Valley by the Ignacio quartzite, a basal deposit, unconformable on the Algonkian. Cross¹⁸⁸ describes the Ignacio as follows:

The lowest lithologic division of the Paleozoic section in the Animas Valley is made up of quartzites and varies in thickness, in the area thus far examined, from a few feet to 200 feet. In layers near the middle of these quartzites a single generically determinable shell has been found. From the stratigraphic relations and the evidence of this fossil it is assumed that in this region the Cambrian system is represented only by a thin series of quartzites belonging probably to its upper division, and for those the name Ignacio formation or quartzite is proposed, from the lakes in the Animas Valley about 18 miles west of south from Silverton, near which the formation is well exposed. It is at present believed that all of the Paleozoic quartzites beneath the "Salt shales" belong to the Ignacio.

The Ignacio consists of nearly pure siliceous strata, with some feldspar locally in the lowest beds. The greater part is fine grained, white, gray, or pinkish, and highly indurated. The lower portion is commonly a massive quartzite of prevalent pink or reddish color, while the succeeding strata are nearly white. Distinct bedding is common, as is an irregular jointing.

Above this the strata are often wavy in bedding, with shale partings, in which mud cracks, trails, and other markings are common. These layers are friable sandstones in places. More massive quartzite layers generally succeed this series, but not in a thickness equal to those below.

At the very base of the formation a true basal conglomerate is often found but only in hollows of the granite, schist, or Algonkian quartzite floor. The hard Algonkian quartzites are most abundant among the pebbles, which range in size up to a diameter of (rarely) 1 foot.

The only identifiable fossil invertebrate yet obtained from the Ignacio beds was found on a remnant capping Overlook Point, one of the hills of Mountain View Crest, in the Needle Mountains quadrangle, south of Needle Creek. Specimens of this fossil were found scattered through a hard, dark quartzite above the middle of the formation, which was there 110 feet thick. Mr. Walcott identifies this shell as an *Obolus* but is unable, from the material at hand, to determine its species. Three forms that are much like this are *Obolus matinalis*, *O. tetonensis*, and *O. loperi*, the latter occurring in the passage beds between the Cambrian and the Ordovician in the Crested Butte quadrangle, Colorado. Since the Cambrian is known in Colorado only in thin representatives of the upper division, it seems best to assume for the present that the Ignacio quartzite also belongs in that series.

A common apparent fossil of the Ignacio is thought by Mr. Walcott to be *Cruziana*, a problematic plant remain.

J 15. MISSOURI AND NORTHERN ARKANSAS.

The "Magnesian Limestone series" of Missouri is thus described in general terms by Broadhead:⁹⁸

The chief rocks of the Ozark Plateau include a series of magnesian limestones and sandstones amounting to 1,000 feet in thickness. In 1891 I applied to these rocks the name "Ozark series." The lower one-half to two-thirds may be Cambrian, including rocks of the age of the Potsdam of New York. The upper portion may be the equivalent of Dana's Canadian, or the lower part of the Lower Silurian. The evidence shows that the life of the Cambrian sea in Missouri was limited to but a few species. We find a few *Orthocerata*, a *Lituite*, a small *Orthis*, a *Pleurotomaria*, a *Maclurea*, two species of *Ophileta*, two or three species of *Straparollus*, probably two species of *Murchisonia*, an *Obolella*, three or four species of trilobites, while in the Potsdam of Wisconsin and Minnesota several other trilobites may be found. Where the waters were shallow sea worms lived and left their track in irregular windings in the rocks. In the later seas seaweeds abounded, as shown by certain beds of the Second Magnesian limestone. That the Ozark series was subject to erosions and slight elevations and depressions is shown by the occasional appearance of a few feet of sandstone at intervals of a few feet to over a hundred. Near the close of the Ozark terrane it is probable that a large area of the plateau was elevated above water.

The general stratigraphy is stated as follows by the same authority:

	Feet.
Trenton limestone.....	100
First Magnesian limestone.....	130
First or St. Peters (saccharoidal) sandstone.....	200
Second Magnesian limestone.....	125
Second sandstone.....	300
Third Magnesian limestone.....	300
Lower Magnesian limestone and sandstone.....	300
	1,155

Several classifications of this series of rocks have been proposed, but the variable character and lenticular form of many of the formations or members have

rendered generalization difficult. A systematic study of the whole area was made in 1905 by Ulrich,⁵² who arranges the formations as follows:

Classification and synonymy of the formations of the "Magnesian" or "Ozark series" in Missouri.

System.	Series.	Formation.	Thickness (feet).	Synonyms.
Ordovician.	Saratogan and Lower Ordovician.	Joachim limestone.	0-150	First Magnesian limestone. Folley limestone. ^a
		St. Peter ("Crystal City") sandstone.	0-200	First or Saccharoidal sandstone. Cap-au-Grès sandstone. Pacific sandstone. "Key sandstone" in Yellville district of Arkansas.
		Jefferson City limestone.	50-250	Second Magnesian limestone. Winfield limestone. Finley limestone. ^b ?Marshfield sandstone.
		Roubidoux formation.	70-225+	Second sandstone. Moreau sandstone. St. Elizabeth formation and Bolin Creek sandstone member. ?Marshfield sandstone. ?Bolivar sandstone.
		Gasconade limestone.	450-650	Third and Fourth Magnesian limestones and Third sandstones. Includes Osage limestone; Cole Camp sandstone of Winslow; also Gasconade limestone, Gunter sandstone, and Proctor limestone of Ball and Smith. Lesueur limestone.
Cambrian.	Potosi or Yellville group.	Elvins formation.	0-120	Basal part of the Potosi limestone and the "Potosi slates and conglomerates" of Nason.
		Acadian.		?Fourth Magnesian limestone (in part). Decaturville limestone.
	True Saratogan.			Second sandstone of Shumard (in part).
Archean.		Granites and porphyries.		

^a The names "Folley limestone," "Cap-au-Grès sandstone," and "Winfield limestone," together with a number of other new names, were published by Keyes in Some geological formations of the Cap-au-Grès uplift: Proc. Iowa Acad. Sci., vol. 5, 1898, pp. 58-63.

^b The names "Finley limestone," "Marshfield sandstone," and "Decaturville limestone," appear in a provisional table of geologic formations in Missouri, by Shepard, E. M., Bull. Bradley Geol. Field Sta., 1904, p. 42.

Ulrich remarks:

As has already been stated, none of the classifications and subdivisions of the Ozark series of rocks, briefly discussed in the foregoing pages, has proved wholly satisfactory. An arrangement that would be above criticism is perhaps impossible. Some of the beds vary so greatly

from place to place that it is difficult to follow them over any considerable area. The difficulties are greatly enhanced by the apparent scarcity and imperfect preservation of the fossils and by the general similarity in lithologic character exhibited by widely separated beds in the series. The occurrence of beds of sandstone at intervals in the mass of magnesian limestones was early seized upon as affording a ready means for dividing the series into formations; but experience gradually taught that most of the sandstones were mere lenses, irregularly developed at unequal intervals and occurring locally as many successive beds or with only two or three. In the northern and central parts of the Ozark Plateau the sandstone beds seem to be more regularly developed than elsewhere, and here they are of considerable use in working out the stratigraphy. Along the southern border, however, only the First or St. Peter sandstone seems to have been so well developed as to mark a definite horizon. Along the eastern border, especially in Ste. Genevieve County, the upper half of the series is thicker than usual. It here contains so many beds of sandstone that it is very difficult to establish the boundary line between the Gasconade and Roubidoux formations and between the latter and the overlying Jefferson City limestone.

A careful study of the cherts has yielded perhaps the most reliable of the lithologic criteria employed in discriminating the three formations of the Potosi group. As this group covers by far the greatest part of the Ozark area, the opportunities for studying and testing the value of certain varieties of chert as indices of particular horizons are unusual. Having checked the results in many instances by evidence afforded by fossils, which really are much commoner in these rocks than is generally believed, we have gradually become convinced that the story as told by the cherts is rarely at fault. The mere presence of considerable quantities of chert is at once reliably indicative of the Potosi group, the underlying limestones being practically free from it, as is true also of the Joachim limestone at the top of the series. It is to be remembered, however, that the proportion of chert in a given bed may vary greatly in near-by exposures. This is shown often very strikingly in opposite faces of a hill, the one side of which forms a bluff, the other a gentle, soil-covered slope. In cases of bluff exposure, where side erosion is active and takes place under conditions very different from those prevailing on gentle slopes, the limestone beds may often seem to be almost entirely without chert, but on the other side of the hill the surface may be thickly strewn with it.

The classification presented in tabular form on page 104 is based upon more or less extended investigations in all parts of the field. The formations are discriminated chiefly by lithologic differences and limited in most cases by at least local stratigraphic discordances. As the formations are intended to express as much as possible lithologic units deemed worthy of being mapped separately, the evidence of the fossils found in them was accorded secondary rank. However, in the determination of the age of the deposit the faunas were depended upon almost exclusively.

It will be observed that the division between the Ordovician and Cambrian is drawn as a dotted line opposite the Roubidoux member of the Potosi. This seeming indecision concerning the point at which the line should be drawn is not due to the absence of a fauna, for we have succeeded in collecting a large one, but because of the conflicting elements contained in it. The trilobites from the Gasconade and the lower part of the Roubidoux are, so far as observed, nearly all of types that hitherto have been regarded as strictly indicative of the Upper Cambrian. On the other hand, the numerous gastropods and fewer brachiopods found in the same beds are nearly all of Lower Ordovician types.

Ulrich ^{52a} also gives detailed descriptions of the formations.

The latest classification of the rocks of this series is that made by Buckley, ¹⁰⁶ who in 1909 published a paper in which several new names were introduced for the rocks lying between the Roubidoux and the Bonneterre.

K 12. IDAHO AND UTAH.

Walcott^{859a} has recently classified the Cambrian of northeastern Utah and southern Idaho. The localities lie in the vicinity of Logan, between Great Salt Lake and Bear Lake. The classification below is taken from his paper:

Cambrian formations in northeastern Utah and southern Idaho.

Formation.	Character.	Thickness (feet).	
		Blacksmith Fork.	West of Liberty.
<i>Upper Cambrian.</i>			
St. Charles formation.....	Bluish to gray arenaceous limestones, with some cherty and concretionary layers, passing at the base into thin-bedded gray to brown sandstones.	1,225	1,197
<i>Middle Cambrian.</i>			
Nounan formation.....	Light-gray to dark lead-colored arenaceous limestones.....	1,041	814
Bloomington formation.....	Bluish-gray, more or less thin-bedded limestones and argillaceous shales. Small rounded nodules of calcite occur scattered irregularly through many of the layers of limestone.	1,320	1,162
Blacksmith formation.....	Gray arenaceous limestone in massive layers.....	570	23
Ute formation.....	Blue to bluish-gray thin-bedded fine-grained limestones and shales, with some oolitic, concretionary, and intraformational conglomerate layers.	759	731
Spence shale.....	Argillaceous shales.....	30	30
Langston formation.....	Massive-bedded bluish-gray limestone with many round concretions.	107	30
Brigham formation.....	Massive quartzitic sandstones.....	1,250+	1,000+

In a recent paper Blackwelder^{84b} writes as follows regarding the Cambrian of northeastern Utah:

Just below the fossiliferous Cambrian shales and limestones there is a quartzite 1,000 to 1,500 feet thick. This quartzite rests now on the eroded surface of the Algonkian quartzite and slate, and now on the much older gneiss and schist which are generally referred to the Archean. Walcott has named it the Brigham quartzite, but it may be seen most clearly at places such as Ogden and Willard, rather than at Brigham. The oldest fossils found in the shales are referred by Walcott to the Lower Cambrian. The Brigham quartzite may therefore be assigned also to the early Cambrian and the quartzites and slates beneath the unconformity to the Algonkian. There is, however, an alternative view, advocated by Daly and others, that the oldest Cambrian faunas in the Rocky Mountains are Middle Cambrian and that the thin Brigham quartzite is the same in age; that the unconformity represents a brief time interval and that the great quartzite slate series is not Algonkian, but simply early Cambrian. Critical studies over a wide area are a necessary preliminary to the settlement of this question. It is to be remembered that the unconformity seems to imply the complete removal of the great quartzite series during the erosion interval and over wide areas. The time involved should therefore be more than a brief interruption.

The House Range, which lies near the western boundary of Utah, between the 39th and 40th parallels, comprises a section which according to Walcott, "extends from well down in the Lower Cambrian to the base of the Ordovician, and is the best and most complete of the Basin Range sections so far studied."

Walcott's published section ^{859b} (condensed) is as follows:

Section of Cambrian rocks in House Range, Utah.

Formation.	Character.	Thickness (feet).
<i>Upper Cambrian.</i>		
Notch Peak formation.....	Gray arenaceous limestone in more or less massive layers.....	1,890
Orr formation.....	Gray slightly arenaceous limestones and shales.....	1,825
<i>Middle Cambrian.</i>		
Weeks formation.....	Thin-bedded shaly limestones, with a few bands of oolitic and arenaceous limestones.	1,390
Marjum formation.....	Gray to dark, more or less thin-bedded arenaceous limestone.....	1,092
Wheeler formation.....	Alternating bands of thin shaly limestone and calcareous shale.....	570
Swasey formation.....	Bluish-gray oolitic and arenaceous limestone, with some calcareous and argillaceous shales.	238
Dome formation.....	Massive-bedded gray siliceous limestone.....	355
Howell formation.....	Dark, more or less massive limestone and pinkish argillaceous shales..	640
<i>Lower Cambrian.</i>		
Pioche formation.....	Arenaceous and argillaceous shaly layers with some thin layers and bands of limestone more or less irregularly interbedded and limited in horizontal distribution.	125
Prospect Mountain formation....	Gray to brown quartzitic sandstones.....	1,200+

Regarding the Pioche shale, Walcott ^{859c} states:

Thickness.—At Pioche, Nev., 210 feet. On the west face of the Highland Range, 18 miles west of Pioche, this formation is 170 feet thick. In the Eureka district of Nevada, 135 miles northwest of Pioche, this formation lies between the Prospect Mountain quartzitic sandstone and the great limestone series and is about 200 feet in thickness. In the House Range section, 105 miles north-northeast of Pioche, the formation is 125 feet thick. In the Big Cottonwood section of the Wasatch Range, about 125 miles northeast of the House Range, near the old shore line, the Pioche formation is represented by the lower portion of the arenaceous shales which are here 250 feet in thickness. The Pioche formation horizon is next met with to the north where the line of the Canadian Pacific Railroad crosses the Continental Divide. At this place the formation is called the Mount Whyte formation.

K 18. PENNSYLVANIA.

The results reached by Stose in the study of the Chambersburg quadrangle, Pennsylvania, comprising part of South Mountain and the valley about Chambersburg, may be taken as representative for southeastern Pennsylvania. The following statement ⁸⁰⁰ is taken from an article in the *Journal of Geology*:

The rocks in this area are largely concealed by the sandstone débris which covers the mountain tops as well as the valleys and slopes. Their character, thickness, and relation are therefore not readily determined. The structure is also complicated by schistosity and jointing which exist in all these rocks. The mountains are composed of Georgian (Lower Cambrian) quartzites, sandstones, and shales and older igneous rocks; the adjacent portions of the valley of Cambrian and Ordovician limestones and shales.

Old volcanics.—The basement rocks exposed in the area are ancient volcanic rocks, greenstone and altered rhyolite, which underlie the basal Cambrian unconformably. They occupy the plateau-like tract overlooked by higher peaks in the center of the mountain area shown on the map and in the extreme southeast corner and are extensively developed to the eastward.

The volcanic origin of these ancient rocks is clearly shown by flow banding, amygdaloidal structure, and spherulites, as described by Williams and Bascom. The greenstones are sheared dense rock, veined with asbestos and chlorite. The original structure is seldom preserved, but the rock is apparently an altered basalt. The rhyolitic rocks are of purple and red tints, often porphyritic and frequently banded by flow structure or spherulitic streaks. The rhyolitic rocks predominate in this area and apparently overlie the greenstone, for the basal Cambrian sediments are composed largely of rhyolitic fragments and not of basaltic detritus, as would be the case if the greenstone were younger and had been eroded from most of the area.

Basal sandstones.—Overlying these softer rocks are about 4,500 feet of sandstone, quartzite, and shale of Georgian (Lower Cambrian) age. The basal beds, forming the higher and more rugged portions of the mountains, are composed of coarse purple and yellowish banded sandstones, fine conglomerate, and arkose, with white feldspathic and vitreous sandstones above. The purplish conglomerate bed is composed of small pebbles and grains of quartz, feldspar, and purplish slate or tuff, the flat slaty fragments often having a diameter of 2 inches. This grades almost imperceptibly through soft purplish arkose into the reddish rhyolitic eruptives below, demonstrating their derivation largely from similar volcanic rocks exposed along the near-by shore of the Georgian sea. In Maryland, and also at Mount Holly, at the north end of South Mountain, basal conglomerates contain numerous large quartz pebbles, probably in part derived from the granitic basement complex of the Piedmont.

This basal sandstone, on account of its hardness, forms high, rugged ridges in the heart of the range, such as Rocky Mountain and Snowy Mountain. It is continuous with the Weverton sandstone of the Catoctin and South mountains, Maryland, as mapped by Keith, and the name is therefore used here. The underlying Loudoun formation, which is described by Keith as variable in composition and thickness in Maryland, was not recognized as a distinct formation in this area but may be represented in the soft arkose at the very base of the sedimentary series.

Upper shales and sandstones.—Above the Weverton sandstone there are about 3,200 feet of shale and soft sandstone in which are two horizons of hard, ridge-making sandstone. The softer beds are poorly exposed, being everywhere covered by the débris from the adjacent sandstones. Their presence is inferred from the fact that their outcrop is always occupied by valleys and depressions. Their character is indicated in part by occasional fragments of thin shaly sandstone and black banded slate or red ferruginous shale. The hard sandstone beds form the ridges along the mountain front and cap the high, flat-tipped Sandy Ridge, as well as Big Flat Ridge north of Fayetteville. The lower of the two sandstones is the more massive and is composed of a hard quartzitic stratum, usually of dark-gray color and veined with quartz, and a softer, granular, white layer containing long, slender scolithus tubes. The upper hard bed at the top of the shale is a milk-white or slightly pinkish granular calcareous sandstone, frequently disintegrating by the removal of the soluble cement to yellowish quartz sand, which is quarried for building purposes. This bed also contains numerous *Scolithus linearis* borings, and in places *Camarrella minor* and fragments of *Olenellus* have been found, by which its age has been determined to be Georgian (Lower Cambrian).

In the Catoctin and South mountains of Maryland Keith has mapped above the Weverton sandstone 800 to 1,200 feet of shale (Harpers) and 500 to 700 of sandstone (Antietam). The Harpers shale is typically exposed at Harpers Ferry, on the Potomac River, and, as described by Keith, consists of a bluish-gray shale with a few thin sandstone beds. Northward these sandstone beds are said to thicken, some attaining 50 feet, but do not have an appreciable effect on the topography. On the road from Monterey to Waynesboro, in the southeast corner of the area shown on the map, this series is fairly well exposed, but, according to Keith, the structure is complicated by folding and faulting. Above the Weverton sandstone in this section, as seen by the writer, are shales or slates, in part dark-banded, containing a conspicuous white scolithus-bearing sandstone 20 to 30 feet thick, all of which is mapped by Keith as Harpers shale. Above the shale is the scolithus sandstone in which Walcott found *Olenellus* and *Camarrella minor*, as noted above, and which is mapped by Keith as Antietam sandstone.

North of Little Antietam Creek there are two ridge-making sandstones above the Weverton sandstone, one composing Sandy Ridge and the other Curve Mountain, and between them is black-banded slate with thin ferruginous sandstones. The upper bed forming Curve Mountain is undoubtedly the Antietam sandstone, and it is apparent that one of the sandstone beds in the Harpers shale of Maryland increases in prominence northward, so that in Pennsylvania it reaches such dimensions that it forms a distinct ridge. The Harpers formation in this area therefore consists of shales and soft sandstones, with a quartzitic member near the middle which is here named the Montalto quartzite, from Montalto Mountain. Northward the shale gradually thins, and the sandstone continues to expand until at the northern border of the area it occupies almost the whole interval of the formation, indicating a gradual change from a fine mud deposit in the south to coarser siliceous sediments in the north. Similar conditions may have continued into Antietam time and have affected the deposition of the Antietam sandstone. The patchy occurrence of the Antietam in the Maryland area, as mapped and described by Keith, may be due to its irregular deposition in that area, instead of to infolding in the Harpers shale and to faulting, as previously supposed. Irregularity of Antietam sedimentation in the Pennsylvania area also is indicated by the absence of ridge-making character east and southeast of Montalto, where the bed is thin, disintegrated, and inconspicuous.

In the columnar section of the Mercersburg-Chambersburg folio these older strata are given the following thicknesses by Stose:⁸⁰²

Shenandoah limestone.	Feet.
Antietam sandstone.....	500-800
Harpers schist and Montalto quartzite member (20-850).....	2,750
Weverton sandstone.....	1,250
Old volcanics.	

In an article on the Cambrian and Ordovician limestones of the Appalachian Valley, Stose^{801a} says:

The limestones of the Appalachian Valley, which in the South are separated into many formations, have generally been treated as a unit in the North under the name Shenandoah, or other local terms, such as Valley, Lancaster, Kittatinny, and York. These rocks include all the strata between the Cambrian quartzites of Georgian age and the Martinsburg ("Hudson") shale of Ordovician age.

In a paper on the sedimentary rocks of South Mountain the author briefly described the formations comprising the Shenandoah group in southern Pennsylvania. Later studies of these rocks in the Cumberland Valley of Pennsylvania have furnished data for a more complete description of the group, including the faunal content and correlation, based on determinations by E. O. Ulrich.

The formations comprising the Shenandoah group in southern Pennsylvania are as follows:

	Martinsburg formation	{ Eden. Utica. Upper Trenton. Lower Trenton. Black River. Lowville. Upper Chazy.	} Ordovician.
Shenandoah group.	Chambersburg limestone, 100-600 feet.....	{	
	Stones River limestone, 800-1,000 feet.....	Lower and middle Chazy.	
	Beekmantown limestone, 2,250-2,300 feet [including Stonehenge limestone member at the base, 500 feet].....	Beekmantown.	
	Conococheague limestone, 1,635 ± feet	Saratogan.	
	Elbrook formation, 3,000 ± feet	} Acadian.	
	Waynesboro formation, 1,250 ± feet		
	Tomstown limestone, 1,000 ± feet		
Antietam sandstone.....	Georgian.	} Cambrian.	

The Tomstown limestone * * * is composed largely of limestone, both massive and thin bedded, in part cherty, with some shale interbedded near the base. * * * [The more characteristic fossils which it has yielded are *Salterella* sp. undet., *Kutorgina* n. sp., and fragments of *Olenellus*. These definitely determine its age as Georgian (Lower Cambrian).—G. W. S.]

In central Virginia a formation 1,600 to 1,800 feet thick, occupying about the same interval but apparently including beds which in the Chambersburg area are calcareous sandstones and are mapped with the overlying Waynesboro formation, has been named Sherwood limestone by H. D. Campbell. * * *

The Waynesboro formation is a series of sandstones, purple shales, and limestones overlying the Tomstown formation. At the base are very siliceous gray limestones that weather to slabby porous sandstone, large round masses of rugose chert, and white vein quartz. In the middle of the formation are dark-blue to white subcrystalline limestones and dolomites, which become siliceous upward and merge into mottled slabby sandstone and dark-purple siliceous shale at the top. * * * A few poorly preserved shells, two of which are identified as *Obolus* (*Lingulella*) sp. undet., obtained from sandy shale at the very top of the formation, suggest Acadian (Middle Cambrian) age but are not conclusive.

In central Virginia the Buena Vista shale, described by H. D. Campbell, is at this general horizon, but, as previously stated, apparently has a different lower limit. It is described as bright variegated shale, 600 to 900 feet thick, with mottled limestone and shale in the lower part. Mr. Walcott found in it a species of *Ptychoparia* related to Acadian (Middle Cambrian) species of Tennessee.

The Elbrook formation is the thick series of gray to light-blue shaly limestone and calcareous shale that overlies the purple Waynesboro formation. The formation is decidedly shaly, most of the included limestones being minutely laminated and weather readily into calcareous shaly plates. * * * Near the middle are massive beds of dolomite and very siliceous or quartzitic limestone that weathers to porous slabby sandstone and frequently forms knobs and ridges. The formation is limited above by limestone conglomerates containing rounded vitreous quartz grains and others containing tabular fragments of limestone, which characterize the base of the overlying formation. * * * The only fossils found in this formation were fragments of trilobites, which suggest Acadian.

The Conococheague limestone is characterized by beds containing thin sandy laminæ and quartz grains that weather into hard shale fragments and thin slabby sandstones which generally give rise to rocky hills and rugged topography.

The base of the formation is usually easily determined because it is marked by siliceous beds and conglomerates that produce a ridge. The conglomerates are of two kinds; one is composed of rounded limestone pebbles, 1 inch or more in size, in a matrix containing numerous round coarse grains of vitreous quartz; the other is composed of long slender fragments of limestone in a calcareous matrix, which, because the fragments are tilted at various angles, is called "edgewise" bed. Interbedded with the conglomerates are oolites and dark shaly limestones with red clay partings.

The body of the formation is a closely banded dark blue limestone, the bands varying from one-half inch in width to minute laminæ. The banding is inconspicuous in the fresh rock but is brought out in weathering as yellowish sandy streaks across a light-blue or gray surface. Toward the top these partings become more numerous and sandy, and weather into hard sandy plates and sheets. Chert is not an important constituent of the formation in the Chambersburg and Mercersburg quadrangles. * * * The fossils found in this formation comprise *Dikelocephalus hartii* Walcott; *D.* sp. undet.; and *Billingsella* like *B. desmopleura*. The trilobites place this part of the formation definitely in the Saratogan (Upper Cambrian). In the basal conglomeratic beds a species of *Cryptozoon*, probably *C. proliferum* Hall, characterized by a mammiferous surface, the elevations one-half to 1 inch in diameter, is rather generally present.

The Beekmantown is a rather pure limestone lying between the siliceous Conococheague below and the very pure Stones River above. A minutely laminated appearance on weathered surfaces of many of the beds, due to their impurities, and pink to white fine-grained limestone or marble are characteristic features of the formation. Near the base are siliceous banded beds and large "edgewise" conglomerate, closely resembling the Conococheague formation. These have been separated as a transition phase under the name Stonehenge member of the Beekmantown.

Although sparingly fossiliferous as a whole, the Beekmantown has yielded a large variety of forms, which are listed in Stose's paper and in accordance with which the Pennsylvania occurrence is correlated by Ulrich with the New York formation of the same name.

For descriptions of the overlying later Ordovician limestones see Chapter IV (pp. 176-179).

The Cambrian and Ordovician limestones are exposed in Center County, Pa., on the Nittany anticline, where Ulrich has distinguished several subdivisions of the Beekmantown.

In eastern Pennsylvania, in the vicinity of Philadelphia, the early Paleozoic rocks are highly metamorphosed. The Wissahickon mica gneiss, which has been considered to be of Cambrian or Ordovician age, is now regarded as pre-Cambrian. Its relations to the Paleozoic are clearly described by Bascom.^{58a} The Cambrian is represented by the Chickies quartzite and part of the Shenandoah limestone. The upper part of the Shenandoah is of Lower Ordovician age, probably Beekmantown. The middle and possibly later Ordovician are represented by the Octoraro schist, in some part at least. (See pp. 177-178.)

Regarding the Cambrian and Lower Ordovician (Chickies quartzite and Shenandoah limestone), Bascom says:

The Chickies quartzite usually shows a conglomeratic lower member, which is largely composed of elongated pebbles of the blue quartz that characterizes the pegmatites and some facies of the Baltimore gneiss. This lower member of the quartzite is not often exposed. * * * The conglomerate passes upward into a gray, compact, crystalline quartzite, which, in turn, grades into a siliceous slate or a sericitic quartz schist, or is altogether supplanted by the quartz schist. * * *

Thirty miles west of the Philadelphia district a section through the Chickies quartzite shows a considerable thickness of micaceous feldspathic material interbedded with the quartzite. Such beds occur as the uppermost member of the series, separating typical quartzite from the overlying limestone, and also as a lower member. Toward the east these micaceous beds become very thin and are altogether absent from the Philadelphia district. * * *

The thickness of the formation varies; it never exceeds and is often less than 1,300 feet, although the isoclinal folding in some localities gives the appearance of greater thickness. An overturned synclinorium with stratification and cleavage dips to the southeast is the prevailing structure. * * *

The name of the formation is taken from the locality of its finest exposure and greatest thickness, on Susquehanna River north of Columbia. At this locality the quartzite shows abundant traces of *Scolithus linearis*, as is the case also in the North Valley Hills, and underlies quartzite in which *Olenellus* fragments have been found by Walcott, thus establishing its age as Georgian ("Lower Cambrian"). The quartzite of the Philadelphia district deposited farther to the east than this typical exposure of Georgian quartzite on Susquehanna River may have been laid down in an encroaching sea and thus belong to a later stage in the Cambrian than the Georgian. No forms of life save *Scolithus linearis* have been found in it, hence it can not posi-

tively be stated to be of Georgian age. It can, however, be safely affirmed to be Cambrian and is to be correlated with the Cheshire quartzite of New England, the Poughquag quartzite of New York, the Hardyston quartzite of New Jersey and provisionally with the Setters quartzite of Maryland. It is the Primal sandstone of H. D. Rogers and the Formation No. 1, Chickies sandstone of the Second Geological Survey of Pennsylvania. * * *

The Shenandoah ("Chester Valley") limestone is a heavily bedded crystalline white or blue magnesian limestone. Its surface exposure in the Philadelphia district is confined, with a few scattered outcrops along the Huntingdon and Cream Valley faults, to Chester Valley, where it covers an area 20 miles long and 2 to 2½ miles wide. * * * The limestone is highly siliceous and magnesian. The analyses show great variation in the percentages of SiO₂ and MgO, but no analysis gives a sufficiently high content of MgO to warrant calling the formation a dolomite. It is everywhere crystalline, and increasingly so from west to east. Associated with increasing crystallinity is a lighter color, though blue and white limestone may occur in the same quarry.

It is in places quite micaceous, and always so in the neighborhood of the overlying mica schist. The beds immediately underlying the mica schist are siliceous, micaceous, and schistose and are to be characterized as calcareous schist. The limestone is abundantly traversed by calcite and quartz veins. Quartz, feldspar, phlogopite, graphite, pyrite, and siderite are accessory constituents, disseminated in minute grains and crystals. Limonitic iron ore occurs in pockets in the limestone.

Intercalated with the limestone are beds of siliceous or micaceous schists. These intercalations, which are lenticular in character, are conspicuous in the limestone west of the Philadelphia district but occur infrequently in that portion of the limestone confined to Chester Valley. Near Pomeroy, 25 miles west of the Philadelphia district, an intraformational calcareous conglomerate shows near the top of the formation. * * *

If the interpretation of the structure given above is correct the thickness of the formation must be much less than the width of its outcrop. It is not determinable exactly, but probably is not greater than 1,000 feet.

Fossils of Chazy, Beekmantown, and Trenton ages have been found in the limestone occurring to the west of Chester Valley and stratigraphically continuous with the limestone of Chester Valley. Fossils have also been found in Chester Valley in somewhat ambiguous material. This material is a drusy, geodiferous rock which seems to have originated through the replacement of calcareous material by silica. A mass of the rock is exposed just south of Bridgeport, near the Trenton branch of the Philadelphia Railroad. Elsewhere it is found only in scattered fragments which rest on the limestone and accompany more or less persistently the contact of limestone and Octoraro schist. It thus seems to mark a definite horizon whose persistence between the schist and the limestone precludes the possibility of a faulted or an unconformable contact.

The material has not proved fossiliferous except at one locality, near Henderson station, where fragments resting on the surface of the ground have been found to contain gastropod and cephalopod forms.

The following determinations were made by E. O. Ulrich, of the United States Geological Survey: *Raphistoma*, two species, *Maclurea*, *Lituites*, *Cyrtoceras*. These are Ordovician forms and indicate a horizon in the lower half, probably Beekmantown. The limestone overlies conformably Georgian ("Lower Cambrian") quartzite and is therefore Cambro-Ordovician in age. It is correlated with the Stockbridge limestone of New England and New York, doubtfully with the Cockeysville marble of Maryland, and with the Shenandoah limestone of Virginia. It is the most easterly representative of the great belt of limestone, the Auroral limestone of H. D. Rogers and Formation No. II of the Second Geological Survey of Pennsylvania. Aside from a few scattered and very minor exposures, the limestone of the Philadelphia district is confined to and controls the form of Chester Valley, a conspicuous topographic feature of the district. For this reason it has long been locally known as the "Chester Valley limestone."

It is here called the Shenandoah because it has the same limits and stratigraphic associations as the extensive and well-known limestone of that name.

That calcareous sedimentation, which began in Cambrian time, continued into Ordovician time is shown by the presence of Lower Ordovician fossils in an upper member of the Shenandoah limestone.

Further sedimentation in Ordovician time is represented by the Octoraro. This is the best-known Paleozoic deposit in this region and, like the preceding Paleozoic sediments, is dynamically metamorphosed and free from igneous intrusions.

K 18. NEW JERSEY.

The Cambrian and Lower Ordovician strata of New Jersey have been described recently by Weller^{880a} and Kümmel⁵¹³ on the basis of earlier reports and recent field work. From Kümmel's paper we take the following general description:

The Hardyston quartzite is the lowest formation of the Cambrian system, and is probably to be correlated with the Poughquag quartzite of Dutchess County, N. Y., and the Chickies quartzite of Pennsylvania. It is unconformable on the pre-Cambrian complex and is the oldest fossiliferous rock in New Jersey. It varies considerably in composition and thickness. Typically it is a quartzite, at many places conglomeratic and containing pebbles of quartz, feldspar, granite, gneiss, and slate. Locally the formation is a calcareous sandstone. It is usually but not invariably feldspathic. In some localities its arkose character is so marked that it is not readily distinguishable from a coarse granite. Beds of slate occur in its upper portion.

Its thickness ranges from a few feet to 200 or more, and it passes into the overlying sandstone through slaty or shaly layers, several of which are in places interbedded with limestone layers, so that its upper limits are indefinite. Since it contains a species of *Olenellus*, it is regarded as of Georgian (Lower Cambrian) age.

The Hardyston quartzite grades upward into the thick magnesian Kittatinny limestone of the Kittatinny Valley. Above, it is limited by an unconformity at the base of the Jacksonburg (Trenton) limestone. The presence of thin shales and scattered seams of sandstone in the great mass of limestone shows an influx of land sediments at recurrent intervals during its formation.

The known fauna of the Kittatinny is not extensive and is found at but few localities, but it suffices to establish the Cambrian age of the greater part of the formation. No Middle Cambrian fossils have been found, but as the *Olenellus* fauna of the Hardyston quartzite is considered to be of Lower Cambrian age, and as no evidence of a break in sedimentation has been observed, a Middle Cambrian fauna would naturally be expected between the *Olenellus* fauna below and the *Dikelocephalus* fauna above. In one locality a fauna of Ordovician (Beekmantown) age has been found in beds near the top of the Kittatinny limestone. This formation, therefore, where complete, represents a period extending from the middle or upper part of the Lower Cambrian to the lower part of the Ordovician, inclusive.

From a discussion of the fossils found in the Kittatinny limestone, probably mostly from its upper portion, Weller^{880a} concludes:

The position of these various fossiliferous beds of the Kittatinny limestone in the formation as a whole can not be determined with certainty, but it may probably be stated, with a degree of safety, that all of these fossiliferous localities, with the exception of that near Carpentersville, are in the upper portion of the formation. The Carpentersville locality is probably somewhere in the lower third of the entire series. So far as the fossils afford any definite evidence, the age of all is upper Cambrian. No middle Cambrian faunas have been recognized, although the *Olenellus* fauna of the Hardyston quartzite is usually considered to be of lower Cambrian age, and a middle Cambrian fauna would naturally be expected to occur somewhere in the formation.

K 18. SLATE BELT, EASTERN NEW YORK AND WESTERN NEW ENGLAND.

The stratigraphy and structure of eastern New York and adjacent New England were worked out by Walcott in 1886 and 1887, and the results were published in part in a paper entitled "The Taconic system of Emmons."⁸⁴⁹ Dale^{207a} subsequently studied the "slate belt," of which the Taconic Range is a central feature, and incorporated Walcott's manuscript material and other data in a report from which the following extract is taken. (See also references to Cambrian and Lower Ordovician in Chapter IV, pp. 183-192.)

The formations shown [on the geologic map] are but two—Lower Cambrian and Lower Silurian (Ordovician). The larger part is Cambrian. This includes the "sea-green," the "unfading green," the purple, and the mottled slates, while the "red" slates, with the accompanying "bright-green" slates, are in the Ordovician. An area of about 8 square miles in Benson containing black roofing slates is of uncertain age—certainly Cambrian or Ordovician, quite possibly Ordovician. The Ordovician areas are very irregular—in some places isolated lenticular masses, compound synclinal in structure, surrounded by and overlying the Cambrian. Some very small isolated Ordovician areas—as near Hillsdale, west of Middle Granville, and west of Lake St. Catherine, near the Wells and Poultney line—probably represent single and overturned synclines. The Ordovician also surrounds lenticular masses of Cambrian, probably compound anticlinal in structure, which protrude through the Ordovician. The central belt of Ordovician sends out long, narrow spurs into the Cambrian area, which alternate with tapering, baylike recesses of Cambrian, the formations being thus dovetailed into one another. On the eastern side the Cambrian slate series comes into contact with the Ordovician schist mass of the Taconic Range; but north of Rupert and east of West Pawlet, Vt., for a space of 6 miles there appears to be a transition from the Ordovician slate into the Ordovician schist. The central Ordovician belt, with all its complex ramifications, thus appears to be merely a continuation of the mass of the Taconic Range itself, and 40 miles south, in Petersburg, Rensselaer County, N. Y., a continuation of the same Ordovician area again merges into the schists of the Taconic Range. Hudson graptolites also occur quite close to the schist mass in Pawlet. * * *

Owing to excessive and minute folding, as well as cleavage and the friable character of some of the shales, it has been found very difficult to construct an entirely satisfactory columnar section of the strata. The relative position of some of them is doubtful, owing to their intermittent character and the possibility of their merging along the strike into other members of the series. The thickness of several of them is uncertain, owing to scarcity of measurable sections. As the lower limit of the Cambrian is nowhere reached within the slate belt the section starts with an uncertainty, and the prevalence of shales in the Ordovician makes the top of the column indefinite.

Dale gives a table showing the probable equivalence of the various divisions recognized in the great sequence of Cambrian and Ordovician shales.

For an account of the Cambrian and Ordovician of Mount Greylock and adjacent areas in western Massachusetts, see Chapter IV (pp. 192-194).

K 19. EASTERN MASSACHUSETTS.

The Cambrian rocks of the Boston Basin were thus described by Crosby:¹⁸¹

The oldest rocks which we have found are the Primordial slates and quartzites; and the age of these is certainly and definitely known only at the Paradoxides quarry, in Braintree. We appear to be justified, however, in regarding them, provisionally at least, as all of about the same age, partly on account of a general lithologic resemblance, but mainly because their relations to the different classes of eruptive rocks are everywhere the same. In Weymouth and

Braintree, where we first met these rocks, they are either typical clay slates or slightly calcareous; but along the northern base of the Blue Hills occasional layers are distinctly siliceous. They probably underlie a large part of the Boston Basin, being covered by the conglomerate and the newer slate; and north of the basin they occur in isolated areas among the eruptive rocks. In some of these areas, especially in the Middlesex Fells and Melrose, and in Woburn, clay slate similar to that in Quincy and Braintree is repeatedly interstratified with quartzite; while toward the southwest, in Natick, and also in Reading and Lynnfield, there are extensive developments of quartzite with little or no slate. It is very clear that the quartzite north and west of the Boston Basin is the source of the quartzite pebbles which play such a prominent part in the composition of the conglomerate, especially in the central and northwestern sections of the basin. In general, the quartzite is more and the slate less abundant northwestward, indicating that the ancient shore line along which these strata were deposited lay in that direction; and originally the Primordial strata were probably spread continuously over all the region to the southeast of that line.

Crosby¹⁸⁰ in his earlier work included in the Cambrian the Roxbury conglomerate, which he¹⁸² and others now assign to the Carboniferous.

The fossiliferous slates of Braintree are referred to in the literature on the geology of eastern Massachusetts since 1818. Fossils were described by W. B. Rogers, who stated:⁶⁷⁵

The rock in which these fossils occur is a compact, dense, rather fine-grained silico-argillaceous slate or slaty sandstone, containing little or no carbonate of lime. * * * One of the most curious facts relating to the trilobite of the Quincy and Braintree belt is its seeming identity with *Paradoxides harlani*, described by Green in his monograph of North American trilobites.

Recent finds of fossils belonging to the Braintree slate are reported by Shimer,⁷³⁹ who says:

Some time ago while having a driveway excavated at his home on Quincy Avenue, in East Braintree, Mass., Mr. Thomas A. Watson found a rather angular slate boulder, about 2 feet in diameter. He kindly turned it over to the Massachusetts Institute of Technology.

The slate is quite similar in appearance to that of the celebrated *Paradoxides* quarry on Hayward Creek; it is similarly metamorphosed but is lighter gray in color and lacks the peculiar purplish tinge of the Hayward Creek slate.

In it the following fauna was found:

Name.	Abundance. ^a	Previous occurrence.	Age.
<i>Acrothere gamagei</i> (Hobbs).....	r	Hayward Creek.....	Middle Cambrian.
<i>Hyalithes shaleri</i> Walcott.....	r	Hayward Creek.....	Middle Cambrian.
<i>Paradoxides harlani</i> Green.....	C	Hayward Creek.....	Middle Cambrian.
<i>Strenuella strenua</i> (Billings).....	R	North Attleboro, North Weymouth, and Nahant.	Lower Cambrian.
? <i>Strenuella strenua</i> (Billings).....	R		
<i>Olenellus</i> (<i>Holmia</i>) <i>bröggeri</i> Walcott.....	R	North Weymouth.....	Lower Cambrian.
<i>Ptychoparia rogersi</i> Walcott.....	r	Hayward Creek.....	Middle Cambrian.
<i>Agraulos quadrangularis</i> (Whitfield).....	C	Hayward Creek.....	Middle Cambrian.

^a C=very common; c=common; r=rare; R=very rare.

This fauna includes five species of the Middle Cambrian, two of which are very abundant, and two of the Lower Cambrian. There is thus a great predominance of the Middle Cambrian element, though it indicates a persistence of the Lower Cambrian element into Middle Cambrian times. So while we have here a transition fauna, the rock must be assigned to the Middle

Cambrian period. This very interesting transition fauna is the first recorded from this region to show in any way a passage from the Lower to the Middle Cambrian.

Shaler and Foerste^{732a} found other localities of occurrence of Cambrian strata at North Attleboro, Mass. The fossils belong to the *Olenellus* zone and occur in red shales and limestone. At the several separate localities the following forms have been collected:

Locality 1, *Hyalolithes princeps?*, *Hyalolithes micans*, *H. billingsi*, *Stenothecha rugosa* var. *pauper*, *Salterella curvata*, *Pleurotomaria (Raphistoma) attleboroensis*, *Fordilla troyensis*. In red shale near by occurred *Agraulus strenuus*.

At locality 2 were found: *Obolella atlantica* Walcott, *Obolella crassa* Hall, *Scenella reticulata* Billings, *Stenothecha curvirostra* S. & F., *Stenothecha rugosa* var. *abrupta* S. & F., *Platyceras primævum* Billings, *Hyalolithes americanus*, *Hyalolithes communis* var. *emmonsi* Ford, *Hyalolithes quadricostatus* S. & F., *Microdiscus bellimarginatus* S. & F., *M. lobatus* Hall, *Olenellus walcotti* S. & F. (probably a young form of some known species), *Ptychoparia attleboroensis* S. & F. (probably the young form of some species of trilobite), *Agraulus strenuus?* Billings.

K-L 12-13. WYOMING.

Cambrian strata which outcrop around the crystalline rocks of the Bighorn Mountains constitute the Deadwood formation. They consist of sandstones, shales, and limestones from 850 to 1,050 feet in thickness.

Darton^{239a} gives many details of local variation in character. The following is a representative section:

Section of Deadwood formation in Wolf Creek canyon, west of Sheridan, Wyo.

White massive sandstone at base of Bighorn limestone.	Feet.
Thin-bedded limestone, gray, greenish, and pinkish tints, with flat-pebble limestone conglomerate and glauconite.....	300
Gray and greenish shale with thin limestones and sandstones.....	300
Brown to buff massive sandstone; many fossils.....	50
Thin-bedded brown and gray sandstones.....	50
Gray sandstones and shales.....	35
Hard brown cross-bedded sandstone.....	6
Brown sandstone and sandy shale.....	30
Dirty-buff to brown and reddish soft cross-bedded sandstone; much glauconite; many fossils...	20
Soft greenish-gray sandstone.....	12
Buff sandstone with fossils.....	8
Dark-gray and greenish shales with thin sandstone beds above.....	200
Coarse-grained cross-bedded buff to brown, massive sandstone.....	30

The distribution of the Deadwood formation in central Wyoming has recently been described by Darton^{244a} as follows:

General relations.—The sandstone of the Deadwood formation is at the base of the sedimentary series in northern and central Wyoming. It thins out to the southeast and apparently ceases at no great distance east of longitude 107°, so that in Converse, Albany, and Laramie counties the Carboniferous rocks lie directly on pre-Cambrian granites and schists. In the Shirley Hills a hard, massive sandstone and conglomerate underlying Madison limestone may be Deadwood. On the West Fork of Troublesome Creek, 9 miles northwest of Difficulty post office and about Leo, this sandstone, 30 feet or more thick, is hard and in part conglomeratic. Near North Platte River, north of the mouth of the Medicine Bow, it is about 100 feet thick. Whether in these areas it is a shore deposit of Madison age or the Deadwood formation was not ascertained. In the basal sandstone in the gorge of North Platte River, 3 miles northeast of Pathfinder, Mr. Walcott found a few fragmentary fossils which he regards as Cambrian.

The hard sandstone at the base of the sedimentary series in the Casper Range and in the ridges to the southeast appears to be a shore deposit of the Casper formation.

Rattlesnake Mountains.—The Deadwood formation outcrops along a portion of the crest of Rattlesnake Mountains west of Oil City. It is about 800 feet thick. At the base and near the middle are 25 to 40 feet of brown to buff fossiliferous sandstone and the basal beds are somewhat quartzitic. Sandy gray shale with thin gray sandstone layers constitute the greater part of the formation, but there is a small amount of impure slabby limestone and reddish shale near the top. Glauconite is a conspicuous ingredient in most beds.

Wind River Mountains.—On the northeast slope of Wind River Mountains the Deadwood formation is about 750 feet thick, and it presents all the features which are characteristic in the Bighorn and other ranges northeastward. Its presence was recognized by Comstock and its distribution was shown in part on maps of the Hayden Survey.

The basal member, which lies on granite, is about 100 feet thick and is the usual hard brownish sandstone. Next are sandy shales and slabby limestone, the latter including more or less of the typical flat-pebble conglomerate of gray limestone pebbles covered with glauconite. The top layer of this limestone contains many trilobites. At the top of the formation is a hard, coarse, fossiliferous sandstone.

Owl Creek Mountains.—Extensive exposures of the Deadwood formation extend along the upper slopes of Owl Creek Mountains and in the canyon of Bighorn River. It also appears along Crow Creek northeast of Circle and in Owl Creek canyon. The thickness is 900 feet and the succession of rocks is similar to that in the Bighorn and Wind River mountains. At the base is hard coarse-grained reddish-brown sandstone, locally conglomeratic below and lying on a remarkably smooth plain of the pre-Cambrian rocks. It varies from 50 to 100 feet in thickness and is succeeded by 200 to 300 feet of sandy shales and thin-bedded sandstones, with a prominent bed of sandstone in their lower portion. In Bighorn Canyon this bed is 50 to 60 feet thick and of bright reddish brown color. The medial member is 400 feet or more of soft greenish-gray shale with a conspicuous gray to buff limestone in its lower part. This limestone, usually 50 feet thick, consists partly of flat pebble limestone conglomerate. Southwest of Embar it is 30 feet thick and 300 feet above the base of the formation. At the head of Muddy Creek it is 40 feet thick and underlain by a somewhat thicker mass of sediments. The top member of the formation is slabby light colored limestone over 100 feet thick at most localities, but apparently either very thin or absent in Owl Creek canyon. It contains frequent layers and masses of the characteristic intraformational conglomerate of flat limestone pebbles more or less intermingled with thin, twisted, and broken layers of limestone in a matrix of shale and fine limestone sand. Many of the pebbles are so thickly covered with grains of glauconite that they appear to be green, but inside they are gray or pinkish, similar to the associated beds.

Fossils.—Fossils at various horizons in the Deadwood formation are of middle Cambrian age, and *Dicelamus politus* and *Ptychoparia oweni* are the principal forms. The former is a small oval shell, which occurs in great abundance in the middle sandstones and in the limestone layers in the shales, as well as in the upper limestone series. The *Ptychoparia* is a trilobite which often abounds in the basal sandstone. In the middle sandstone of the formation, a short distance west of Garfield Peak of Rattlesnake Mountains, the fossils included a new species, which Mr. Walcott has designated *Obolus (Westonia) dartoni*. In the top sandstone west of Lander, *Orthis (Plectorthis) [Eoorthis] wichitaensis* was found.

Blackwelder, in an unpublished manuscript (1910), says:

The Deadwood formation of central Wyoming expands westward without suffering much change in lithologic character. Near the south end of the Teton Range the basal sandstone is still only 160 feet thick, but it is overlain by fossiliferous shales and striped limestones, which are locally conglomeratic and oolitic, to a thickness of 1,000 to 1,100 feet. The supposed Cambrian beds are not sharply separated from the overlying massive limestones which contain Ordovician and Silurian fossils.

K-L 13. BLACK HILLS, SOUTH DAKOTA.

The Cambrian Deadwood formation of the Black Hills is described by Darton ^{232a} in detail in his paper on the geology of the hills. A convenient summary of the facts is given in a later paper, ^{237a} as follows:

Deadwood formation.—The outcrop of this formation encircles the Black Hills, appearing usually in the base of the great infacing limestone escarpment. It lies on a relatively smooth surface of Algonkian rocks, although there are many local irregularities of shore lines and beach phenomena. The rocks are mostly sandstones and sandy shales, with frequent occurrences of basal conglomerate. In the southern hills the thickness varies from 4 feet to 50 feet in greater part, and the principal material is a coarse dark-brown massive sandstone. To the northward the formation gradually thickens, apparently by the addition of higher beds comprising dark-gray shales, mostly sandy, and beds of sandstone. In the region about Deadwood, where the formation attains its greatest thickness of over 400 feet, it comprises about 30 feet of basal conglomerate overlain by 30 feet of coarse dark-brown sandstone; 200 to 400 feet of gray shales, with layers of flaggy limestone, limestone conglomerate, and sandstone; a conspicuous member of hard massive sandstone 5 to 12 feet thick; and at the top 20 to 45 feet of green shales. The limestone conglomerate is a very characteristic rock, consisting of flat pebbles and flakes of limestone more or less thickly sprinkled with glauconite grains, and is of the intraformational type.

Throughout its course the formation contains fossils of which the following middle Cambrian forms have been reported by C. D. Walcott: *Obolus*, *Hyalolithes*, *Dicellomus*, *Asaphiscus*, *Olenoides*, *Ptychoparia*, and *Acrotreta*.

K-L 15-16. MINNESOTA, WISCONSIN, AND MICHIGAN.

Sardeson ⁷⁰⁰ suggests that the "New Ulm" quartzite of southern Minnesota may be of Cambrian age, as it contains pebbles of "quartzite conglomerate like the rock (Huronian?) which is in situ at Redstone." The well records, ³⁹⁴ however, which have been carried across southern Minnesota, from the type region of the Sioux quartzite (Algonkian) to and beyond New Ulm, have served to correlate this quartzite with the Algonkian Sioux quartzite.

The Cambrian and lower Ordovician strata of the upper Mississippi Valley have been divided by recent writers into the following formations, all of which are well established in the literature of several States:

Ordovician:

- St. Peter sandstone.
- Prairie du Chien group (formerly called "Lower Magnesian limestone"):
 - Shakopee dolomite.
 - New Richmond sandstone.
 - Oneota dolomite.

Cambrian:

- Jordan sandstone.
- St. Lawrence formation
- Dresbach sandstone.
- Shales and sandstones.

The Cambrian strata in southern Wisconsin were described as the "Potsdam sandstone" by Chamberlin, ¹³³ who stated the synopsis of characters thus in part:

Rocks mainly light-colored sandstone in central and southern Wisconsin and red sandstone in the Lake Superior region, but embrace some beds of limestone and shale. Maximum known thickness about 1,000 feet.

Following this synopsis is an account of the conditions of deposition of the sandstone and of the life of the epoch, from which the following is taken:

On the southern side of the Archean island the lower part of the formation usually consists of coarse quartzose sand, of an exceeding open, porous nature, with but little aluminous or ferruginous and almost no calcareous matter. Higher in the series the sandstone becomes finer grained and the accessory substances named more abundant. Somewhat above the middle of the series a stratum of shale occurs, attaining a known thickness of 80 feet. This is not everywhere present and seems to be mainly developed at some distance from the ancient shore line. It appears to indicate that for a time there was a deepening of the waters, admitting of the accumulation of fine sediment, except near the shore, where the deposit of sand continued. Above the shale, sandstone reaching a thickness of 150 feet is again found. This is medium or coarse grained and slightly calcareous. It in turn is overlain by a deposit of associated shale and limestone (the Mendota limestone), which attains a thickness of 35 feet in the vicinity of the lake from which it derives its name. These beds indicate a modification of the conditions of deposition, such as to permit not only the settling of fine sediment but the accumulation of calcareous mud as well. The latter was doubtless derived from the calcareous remains of life, since the sea then swarmed with living organisms whose shells and skeletons are found entombed in the strata. The frequency of broken and worn fragments implies that the greater portion were ground to powder, forming the calcareous flour that subsequently hardened into limestone. These beds appear to point quite surely to a moderate deepening of the waters.

Overlying this impure limestone is a third and thinner bed of sandstone (the Madison) with which the Potsdam series closes. This, on the whole, is finer grained than that below and is bound more firmly together by cementing material, which is mainly a calcareous and ferruginous infiltration. The thickness of this bed is about 30 feet.

The "Lower Magnesian limestone" (Prairie du Chien group), which overlies the Cambrian strata, is described by Chamberlin as the equivalent of the "Calciferosus" (Beekmantown) of New York, and as a "cherty magnesian limestone, from 65 to 250 feet thick," which "contains but few fossils." Chamberlin^{133a} says further:

During the previous epoch the accumulation of sandstone gave place for a time to the formation of limestone (the Mendota). At the close of the epoch, without any very marked disturbance of existing conditions, the formation of limestone was resumed and progressed, with some interruption, till a thickness varying from 65 feet to 250 feet was attained. This variation in thickness is mainly due to irregularities of the upper surface of the formation, which is undulatory and, indeed, in some localities may appropriately be termed billowy, the surface rising and falling like the swells of a subsiding sea. In the localities where these phenomena are best developed, these petrous billows vary in height from a gentle swell to elliptical domes rising a hundred feet above their bases, while their length ranges from a few rods to a quarter of a mile or more, and their width from one-third to one-half their length. The symmetry of outline here indicated is frequent and typical, though not universal. It finds its best-observed expression in Green Lake and Winnebago counties, where the axes of the domes lie in an east-westerly direction much more commonly than otherwise, or, in other words, are at right angles to the trend of the formation. While not equally conspicuous everywhere, this undulatory surface is prevalent throughout the State and beyond.

The internal structure of these rock billows is interesting. In the more typical ones at least, and perhaps universally, the superficial strata dip in every direction from the center, most rapidly at the sides (the dip sometimes reaching 30°), and less so at the extremities; or, in other terms, the beds are generally concentric with the surface. The rock of this superficial portion is as homogeneous and even grained a dolomitic limestone as is common to the formation and presents no unusual evidence of fracture or disturbance. Indeed, the rock gives the impression of having been laid down as a mantle of calcareous sediment over an irregular surface.

Where erosion has exposed the interior, however, a very different structure is exhibited. The core of the dome appears to be composed of a brecciated mass formed of limestone fragments bound together by calcareous material that seems to have been a mud derived from the wear of the rocks themselves. Although the base of the formation has never been seen immediately beneath one of these prominences, yet from all that can be ascertained from the study of the lower beds in the vicinity, it is probable that the basal strata are homogeneous and horizontal, and unaffected by the peculiarities that lie above.

* * * * * * * * *

In addition to the foregoing peculiarities of stratification, the unity of the formation in eastern Wisconsin is interrupted by a shaly stratum in its subcentral portion, and in northwestern Wisconsin by a sandstone layer of very irregular thickness, sometimes merely consisting of a layer of lenticular or pocket-like deposits. Locally there are seams of sand and shale intercalated in the series, particularly in the basal portion.

The bedding of the rock is usually uneven and heavy, and its texture is coarse, rough, and irregular, though exceptionally it becomes uniform in bedding and grain, forming a beautiful and serviceable rock.

In composition it is, in the main, a magnesian limestone, or, more technically, a dolomite. But it contains in addition much siliceous material, most commonly in the form of flint or chert nodules but sometimes in disseminated sand grains and not infrequently as an oolite, in which the center of the spherules is a grain of sand, about which concentric layers of calcareous material are gathered. Silica also often constitutes a crystalline lining of cavities, forming beautiful little geodes lined with variously colored quartz. A varying amount of aluminous impurity is also present throughout the rock.

A notable feature of the formation is the occurrence, at various heights, of brecciated layers interstratified with others more homogeneous. These are composed of fragments of limestone in a matrix of finer material, derived from the same source. They seem to indicate that the formation, during its deposition, suffered successive variations of conditions, from comparative quiet to forcible wave action, probably due to slight oscillations of level. The comparative absence of fossils under such circumstances is not surprising. There seems little doubt, however, that the material of the formation was derived mainly from the calcareous remains of life.

Chamberlin and later writers have described the St. Peter sandstone, which overlies the Prairie du Chien group ("Lower Magnesian limestone") as Ordovician. (See p. 180.) Walcott^{854b} quotes the descriptions of the Cambrian strata by Irving, Strong, Wooster, and Winchell, in addition to the account by Chamberlin. The descriptions of Chamberlin have been supplemented in later work by more extended investigation and correlation of the faunas by Sardeson⁶⁹⁹ and by Ulrich.⁸²¹

K-L 18. ADIRONDACK REGION, NEW YORK.

The Potsdam sandstone of the Adirondack region has been recently studied by Cushing,^{203a} from whose detailed account the following passages are taken:

Lying unconformably on the old and much eroded pre-Cambrian surface, a great sandstone formation appears, on the north and east and on the eastern half of the southern border of the Adirondack region. This is a water-deposited formation and, so far at least as its upper portion is concerned, a marine formation. It is thickest on the northeast, thinning out to disappearance both to the south and west. As, furthermore, it appears to be the upper beds which persist and the lower ones which disappear in these directions, it seems certain that, so far as the immediate region is concerned, the marine invasion came on it from the northeast and extended progressively southward and westward.

In Clinton County, where the formation is thickest, the basal portion is rather sharply differentiated from the rest in character, and this portion has considerable thickness, though

how much and how large a part of the whole thickness it constitutes, is wholly uncertain. The writer was the first to show this, and it has lately been reaffirmed by Van Ingen. This portion consists in part of coarse basal conglomerates, in part of poorly indurated sand beds of small durability, and in smaller part of thoroughly indurated sandstones. It is nearly everywhere characterized by a considerable feldspar content, in addition to the quartz, and this feldspar is for the most part fresh. Considerable magnetite also appears in places, along with grains of garnet and occasional zircons. The rock has therefore an arkose character in this portion, while above it is prevailing of pure quartz sand. Red is the predominant color of the base, and there is but little white sandstone in it, while above the latter is the prevailing color. As a general proposition, a feldspar content and a prevalence of red beds go together and are certain signs of the basal portion.

Basal conglomerates are a prominent feature in Clinton County wherever the proper horizon is exposed. For the most part these are not extra coarse, the larger pebbles seldom exceeding an inch in diameter. The pebbles are prevailing or exclusively of quartz, derived from the quartz veins of the pre-Cambrian rocks, and are embedded in a coarse sand matrix in which there is a large feldspar and considerable magnetite content. Along most of the northern border the general lack of pebbles of the underlying rocks, which are mostly Saranac gneisses, is indicative of quite prolonged wear of the material, so that only the extra-resistant pebbles of vein-quartz origin were sufficiently durable to persist as pebbles. The undecayed character of the feldspar grains of the sands in these conglomerates indicates that all soil and largely weathered rock had already been removed and carried offshore to be deposited and that the waves were working on tolerably fresh rock, whose grinding to sand had to be performed by water action alone, unaided by any special weakness due to previous weathering.

In some few localities conglomerates indicative of much less vigorous wave action are found. These contain numerous pebbles of the underlying gneisses, often of large size and showing great variation in size, and quartz pebbles are much less conspicuous or lacking. These seem to be purely local deposits laid down in sheltered hollows in the pre-Cambrian floor, whose presence is likely due to uneven depth of weathering of the floor rocks. It is in rocks such as these that the pebbles of diabase and syenite porphyry which demonstrate the pre-Potsdam age of these dikes are found. Such conglomerates are much less resistant rocks than the commoner quartz-pebble conglomerates, and present exposures usually show them in much disintegrated condition.

* * * * *

Very abundant also in the basal portion of the formation are beds of rapidly disintegrating, very red coarse arkose sandstones, made up mainly of quartz and feldspar grains and the whole much permeated with red hematite.

* * * * *

Well-indurated red sandstones, such as those from the type locality at Potsdam, are not infrequent in the basal portion of the formation and are numerous exposed at various localities on the north border of the Adirondacks in such situation as to indicate clearly their horizon. At Potsdam itself the section is complicated by faulting, and the horizon of the red sandstone there can not be demonstrated, though inferentially it is low in the formation. Along with the red there is much hard glassy brown sandstone, also containing fresh feldspars but lacking the hematite coloration of the red beds. Above, the reds become striped and mottled with white, forming a species of passage beds to the middle division.

Van Ingen is the only observer who has undertaken to differentiate between the middle and upper portions of the Potsdam. He says:

“The middle portion of the sandstone is made up of well-sorted materials, of finer grain, compactly cemented, and of white, steel-gray, or yellowish color, with very little or no feldspathic content. The grains of sand are both angular and rounded, with the former predominating. The layers are more regular, though their surfaces are ripple-marked, and in section they are seen to be almost universally cross-bedded. Pebbles are found on the surfaces of some layers of the middle portion, but unlike those of the upper portion they seem to have been

of soft mud derived by erosion of contemporaneous sediments, cast on the beach at times of rough water and flattened and squeezed out by the subsequent pressure and consolidation of the superimposed sand deposits.

“The upper portion of the formation has frequent beds of irregular laminated sandstone, with partings of greenish arenaceous shale. The shale surfaces are covered with fucoids and worm trails. Pebbles of shale and dolomite, which were hardened before the time of their entombment, are found embedded in the sandstone layers, and their disintegration causes cavities to form in the layers containing them. The dolomite pebbles become more abundant toward the upper horizons. In the upper levels frequent beds are composed of nicely rounded grains of clear quartz with a little cement that crumble to a sugary powder under the hammer. Rounded grains of quartz of a slightly larger size occasionally cover the upper surface of a layer of finer-grained sandstone, and, being without cement, they stand out in relief above the surface with an appearance of having been sprinkled from a pepper pot.”

* * * * *

The thickness of the Potsdam in Clinton County is unknown. The thickest measured section is that in the Ausable Chasm, but the section there is complicated by faulting and is by no means complete, all the basal portion being lacking. Walcott's measurement gives 350 feet, and Van Ingen's "at least 455 feet" as the thickness here. In the Morrisonville well, with the drill resting at 1,250 feet in the Potsdam sandstone, at least 750 feet of the formation had been drilled through, and the bottom samples were of clear, glassy quartz sand, with no trace of the feldspars which characterize the basal portion, indicating that it had not been reached. From this record alone it seems perfectly safe to say that the formation has a thickness considerably in excess of that amount in Clinton County. The writer's estimate, based on the broad belt of outcrop in the northern part of the county, assigns a minimum thickness of at least 1,000 feet to the formation, with a likelihood that it is considerably in excess of that amount.

* * * * *

The paleontologic and stratigraphic work of Walcott and Van Ingen has shown that the upper portion of the formation, through a thickness of some 350 feet, carries a sparse Upper Cambric fauna. With the exception of a few supposed tracks, of uncertain nature, no fossils have so far been found in all the remainder of the formation, and there is therefore an utter lack of paleontologic evidence as to its age, and the possibility that the lower portion may be older than the Upper Cambric must be conceded. But it seems to the writer that, fossil evidence being lacking, the formation as it occurs in New York is not susceptible of subdivision. The basal rocks grade into those of the middle division, as do those into the upper, and there is no marked structural break at any horizon which would warrant the assumption of any great difference in age between base and summit, or any marked pause in sedimentation. Prof. N. H. Winchell has long held and has recently reiterated the view that the typical Potsdam at Potsdam is much older than the upper, white, less-indurated beds, and he classes it in the middle Cambric and correlates it with a portion of the Keweenawan of the upper lake region. As above indicated, the writer's judgment is that any present attempt to divide the formation on the basis of age is premature and has but slender basis of fact, considering the lack of all evidence from fossils.

As has been shown by many observers, the transition from Potsdam to Beekmantown sedimentation is not a sharp one but through a series of passage beds. Near the summit of the former, thin beds of gray dolomite make their appearance, interbanded with the soft white sandstones which prevail there, increase in frequency till they constitute half the mass of the rock, and finally prevail and cut out the sandstones altogether. The sandstone layers are characteristically Potsdam in appearance, and the dolomites as characteristically Beekmantown. There is no mixing of materials but rather a rapid alternation of two contrasted sets of deposition conditions. Walcott has measured a thickness of 25 feet of such passage beds along the Chateaugay River and 70 feet near Whitehall. In the writer's judgment, the latter is much

nearer the usual figure than the former. These beds are exposed at many localities along the northern border of the region, but seldom suitably for measurement of thickness. They seem usually of considerable bulk.

Cushing's account of the Potsdam is followed in the report cited by a description of the overlying Beekmantown. In his latest studies, however, he distinguishes under the name "Theresa dolomite" the dolomitic beds which immediately succeed the Potsdam west of the Adirondacks and which he no longer regards as equivalent to the Beekmantown. Cushing^{204b} says:

Theresa dolomite.—The Potsdam grades upward into a formation which consists of sandy dolomite layers and beds of weak brown sandstone which are mostly near the base and are quite like the upper beds of the Potsdam. The line between the two formations is drawn at the base of the first dolomite layer, but in all probability this is not a constant horizon over the district. The name given to the formation is mainly intended for local use and the necessity for its introduction arises from present doubt as to the exact equivalent of the formation elsewhere in the region.

When fresh the dolomite is a hard and tough bluish-gray rock, which, however, quickly weathers to iron-stained sandy crusts. All the beds are somewhat sandy. The most characteristic lithologic feature of the rock is the glittering calcite cleavages which appear on the freshly fractured surface. These cleavages run up to an inch in length, have a somewhat satiny luster, owing to the included sand grains, and are produced by the deposit of the calcite cement around the sand grains with similar crystallographic orientation—in other words, producing true sand crystals on a small scale. This same lithologic peculiarity is a feature of the so-called Potsdam-Beekmantown passage beds farther to the eastward, and, so far as my observation goes, is confined to that horizon, not appearing in the Beekmantown above.

In the lower portion of the formation the large *Lingula* previously mentioned is abundant, a gastropod which has not yet been determined occurs at all horizons, occasional cystid plates and traces of other fossils are found, and fucoidal markings are frequent on the surfaces of some layers.

The general thickness of the formation over the quadrangle is from 60 to 70 feet. Like the Potsdam beneath, it thins to the west and apparently also to the south, though widespread sand deposits hide the decisive proof of the latter. In addition to this thinning because of overlap, it has also suffered erosion at its summit, owing to uplift (apparently slight) and wear during a lengthy time interval. For instance, it has a thickness of but 20 feet near the north end of Perch Lake, though recovering its normal thickness of 60 feet within a mile on each side, and the diminution in thickness is by the wearing away of the upper beds. Coincidentally with this local thinning, the overlying formation thickens, showing basal beds which are lacking on each side and plainly owing their existence to the surface depression.

For the description of the overlying Pamela and higher formations, see Chapter IV (p. 185).

The Potsdam sandstone and possibly the "Theresa dolomite" belong to the Saratogan or Upper Cambrian, formerly called the "Potsdam series." Walcott introduced the term "Potsdam series" in the large sense in 1891, but in 1903 he withdrew it in order to avoid confusion, and introduced Saratogan instead. After giving the reasons for the change he says:⁸⁵⁸

The type locality of the Saratogan is north and west of Saratoga Springs, N. Y. The section has, at the base, about 200 feet of evenly bedded, compact grayish to yellowish colored sandstone, that rests unconformably against or upon spurs or ridges of pre-Cambrian gneiss. At a locality 3 miles north of Saratoga Springs the sandstone is about 40 feet in thickness; it is

overlain by an oolitic limestone, 30 feet, and a dark-gray, evenly bedded limestone 50 feet in thickness. In this latter limestone the following fauna occurs:

Cryptozoa proliferum.	Billingsia saratogensis.
Obolus (<i>Lingulepis</i>) acuminatus.	Matthevia variabilis.
Platyceras minutissimum.	Dikelocephalus hartii.
Platyceras hoyti.	Dikelocephalus speciosus.
Metoptoma cornutiforme.	Ptychoparia calcifera.
Metoptoma simplex.	(A.) saratogensis.

The Calciferous formation of the New York section rests conformably on the Upper Cambrian limestone.

The formations now referred to the Saratogian are as follows:

Type.—Sandstones and limestones of the south side of the Adirondacks, Saratoga County, N. Y., containing the Upper Cambrian fauna.

Correlated.—Upper part of Cambrian limestones of Dutchess County, N. Y., and an unknown portion of the limestones of the "marble belt" of western Vermont.

Upper part of shales of Tennessee (Knox), State of Georgia, and Alabama (Conasauga), and the lower part of the Knox dolomite.

Upper part of the sandstones of the upper Mississippi Valley (St. Croix), Upper Cambrian limestones of South Dakota, Wyoming, Montana, and Colorado.

Upper calcareous beds of the Cambrian of northern Arizona (Tonto) and central Texas (Katemcy).

Upper Cambrian limestones and shales of Nevada (Hamburg), Idaho, and Montana (Galatin).

Black shales of the upper portion of the New Brunswick and Cape Breton Island Cambrian sections.

Upper Cambrian shales and sandstones of Conception Bay, Newfoundland (Belle Isle).

Recent contributions to the classification and interpretation of the Cambrian and Lower Ordovician of the New York province have been made by Grabau,³⁸³ and also by Ulrich and Cushing.⁸²² (See p. 184.)

The general relations of the Cambrian of the Adirondacks in eastern New York and Vermont, and thence southward, were thus stated by Walcott:⁸⁵⁴

The strata referred to the Cambrian, on the western side of the Sutton Mountain anticlinal or the belt extending southwesterly from Quebec to the Vermont boundary, consist of more or less of the Sillery series, as found in the vicinity of Quebec, and, according to Drs. Selwyn and Ells, of a subjacent series of hard quartzite rocks interstratified with mica schist and black slate. The volcanic series, referred to the Cambrian in this region, indicates that during earlier Cambrian time the volcanic products were deposited contemporaneously with the included sandstones and slates, thus giving a phase of sedimentation not known elsewhere in the Cambrian of the Appalachian province. For this reason and from the fact that there is not any paleontologic evidence of the age of this volcanic series, I am inclined to think that it may belong to some pre-Cambrian terrane.

Entering the northern end of the valley, between the Green Mountains and the Adirondacks, a sudden change occurs in the sedimentation. At the base the *Olenellus* fauna ranges through 1,000 feet of magnesian limestone, and for 250 feet higher up in arenaceo-argillaceous shales. More or less arenaceous matter is associated with the limestones, and, about 2,000 feet above, a great lenticular mass of limestone occurs in the argillaceous shales, in which a fauna of Upper Cambrian aspect is found. At other localities this fauna occurs in the shales themselves and in a brecciated limestone at the same relative horizon. As far as known the upper portion of the Cambrian is formed of the shales. Proceeding southward and nearer the old coast line in Addison County, Vt., the limestone series is found to graduate into the Granular quartzite or the beach sand. From this point this shore deposit is traced without interruption to the Massachusetts boundary; and then, with more or less interruption, to the Hudson River below

Poughkeepsie, N. Y. It is taken up again in New Jersey, and thence may be followed, with some interruption, across Pennsylvania to Maryland, whence it extends as an almost continuous formation across Virginia into eastern Tennessee and thence, with some interruption, into Georgia and Alabama. On all this long line it forms the basal member of the Cambrian; and wherever fossils have been found in it they belong to the *Olenellus* or Lower Cambrian fauna.

The offshore or deeper-water deposits are represented by finer-grained sandstones, shales, slates, and limestones. In southern Vermont they form the roofing-slate belt that passes into New York, where the section comprises some 12,000 feet of shales, slates, and interbedded sandstones, with more or less calcareous matter, either as brecciated conglomerate or as thin-bedded, intercalated limestones. These extend, with some change in their character and regularity of exposure, to the Hudson River in Dutchess County. Near Stissingville, in this county, the basal sandstone rests upon the pre-Cambrian and contains the *Olenellus* fauna. A few remains of the latter have also been found in the immediate superjacent limestone. The Middle Cambrian and Upper Cambrian faunas occur in bedded limestones. As the quartzite exposed on the eastern side of the limestones of the "marble belt" represents but a very small portion of the great series of shales, slates, etc., of the Cambrian on the western side of the "marble belt," it is probable that the lower portion of the limestone is of Cambrian age, the same as in Dutchess County. This observation also applies to the basal limestone in New Jersey and Pennsylvania, where there is very little thickness of shales between the basal quartzites and the limestone.

The Beekmantown ("Calciferous") of the Champlain district was studied in detail by Brainard and Seely,⁹⁵ whose paper contains maps and local structure sections. They say:

The term Calciferous was used by the older geologists of New York and Vermont to designate the strata between the Potsdam sandstone and the Chazy limestone. The lower boundary is well defined, as the Potsdam sandstone has been long recognized and carries a peculiar fauna. The upper boundary, the base of the Chazy, is less definite; but we consider it to be certain strata of sandstone, from 30 to 40 feet in thickness, described in the "Geology of Canada," 1863 (p. 123), and found in the Champlain region in several localities below all other beds containing characteristic Chazy fossils.

In our study of the rocks of the Champlain Valley we have been surprised at the development of the Calciferous formation—at its vast thickness, its variety of rock, and its abundant fauna. That the earlier geologists, who made explorations on this ground, Profs. Emmons, Adams, and Hitchcock, should have made such brief mention of this grand subdivision must be attributed to the fact that they had wide areas to examine and but brief time allotted them. The Calciferous is, moreover, a most difficult formation to decipher, because of its great thickness, the absence of fossils in most exposures, and the resemblance to each other of its various beds of magnesian limestone.

In our study of these rocks every important exposure has been visited on the Vermont side of Lake Champlain from Philipsburgh to Benson, and most of those on the New York side. Instead of a thickness of 300 feet for the Calciferous, as estimated in the Vermont report, we find a thickness of 1,800 feet; instead of the four or five species of fossils there mentioned we find over a hundred species, many of which are as yet undescribed.

There are two localities in which the entire sequence of Calciferous strata can be seen. One of these is in eastern Shoreham, and was first discovered by Rev. Augustus Wing and referred to by him as "the Bascom ledge." (See *Am. Jour. Sci.*, 3d ser., vol. 13, p. 343.) It is a great monocline 2 miles in width and 3 to 5 miles in length, in which all the Lower Silurian rocks are seen overlying at least 200 feet of Potsdam sandstone. The strike is somewhat sinuous and the dip varies from 9° E. to 38° E., but there are no abrupt changes in either except at the northern or western borders. Much of the rock is covered with soil, but exposures on hillsides, along watercourses, and in escarpments of cliffs are sufficient to reveal the character and thickness of all the members of the Calciferous formation. * * *

The strata of the Calciferous seen at various exposures in this monocline are as follows, in ascending order:

Division A.	Feet.
Dark iron-gray magnesian limestone, usually in beds 1 or 2 feet in thickness, more or less siliceous, in some beds even approaching a sandstone. Nodules of white quartz are frequently seen in the upper layers, and near the top large irregular masses of impure black chert, which, when the calcareous matter is dissolved out by long exposure, often appears fibrous or scoriaceous.	
Thickness.....	310
Division B.	
Dove-colored limestone, intermingled with light-gray dolomite, in massive beds; sometimes for a thickness of 12 or 15 feet no planes of stratification are discernible. In the lower beds and in those just above the middle the dolomite predominates; the middle and upper beds are nearly pure limestone; other beds show on their weathered surfaces raised reticulating lines of gray dolomite. Thickness.....	295
Division C.	
1. Gray, thin-bedded, fine-grained calciferous sandstone, on the edges often weathering in fine lines, 40 or 50 to the inch, and resembling close-grained wood. Weathered fragments are frequently riddled with small holes, called <i>Scolithus minutus</i> by Mr. Wing.....	60
2. Magnesian limestone in thick beds, weathering drab.....	100
3. Sandstones, sometimes pure and firm, but usually calciferous or dolomitic.....	70
4. Magnesian limestone like No. 2, frequently containing patches of black chert.....	120
Thickness of C.....	350

Division C is followed in ascending order by division D, which Whitfield assigned to the Chazy. (See p. 187, Chapter IV.) Ulrich, however, regards division D as the most typical part of the Beekmantown. As observed by Brainard and Seely, whose section Cushing^{203b} reprints with approval, division D is made up as follows:

	Feet.
Blue limestone in beds 1 or 2 feet thick, breaking with a flinty fracture, often with considerable dolomitic matter intermixed, giving the weathered surface a rough curdled appearance; becoming more and more interstratified with calciferous sandstone in thin layers, which frequently weathers to a friable, ocherous rotten stone.....	80
Drab and brown magnesian limestone, containing also toward the middle several beds of tough sandstone.....	75
Sandy limestone in thin beds, weathering on the edges in horizontal ridges 1 or 2 inches apart, giving to the escarpments a peculiar banded appearance. A few thin beds of pure limestone are interstratified with the siliceous limestone.....	120
Blue limestone in thin beds, separated from each other by very thin rough slaty layers, which protrude on the weathered edges in undulating lines. The limestone often appears to be a conglomerate, the small inclosed pebbles being somewhat angular and arenaceous.....	100
Thickness of D.....	375
E. Fine-grained magnesian limestone in beds 1 to 2 feet in thickness, weathering drab, yellowish, or brown. Occasionally pure limestone layers occur, which are fossiliferous, and rarely thin layers of slate. Thickness.....	470

Cushing continues:

Cassin formation.—In the upper part of division D and in division E are numerous fossiliferous horizons carrying a rather abundant fauna. These beds are confined to the Champlain Valley, so far as the immediate region is concerned, and have therefore the same restricted distribution as the following Chazy. In discussing Brainard and Seely's paper, Prof. Whitfield recognizes and emphasizes this point and the considerable differences between these upper beds and the ordinary sparingly fossiliferous character of the normal Beekmantown. He urges the similarity of the fauna to that of the Quebec group of Canada, argues that these beds have more natural affinity with the Chazy than with the Beekmantown, and that they should either be placed with that formation or else considered as distinct from either and given a separate

name, "as Fort Cassin, or Philipsburg formation, or any other appropriate name." ^a This seems to the writer not only as eminently proper but really a necessary procedure. The thickness and importance of this group, consisting of the upper 220 feet of division D and the whole of E, is such as definitely to warrant its separate mapping in the Champlain region, and the writer proposes the name "Cassin formation" for it, to make Whitfield's suggestion more precise and definite.

L 12. SOUTHWESTERN MONTANA.

Peale originally described the Cambrian of the Gallatin section in southern Montana and furnished details to Walcott, ^{854a} who writes as follows:

The Gallatin section of the Cambrian includes 1,250 feet of strata, of which 835 feet are limestone, resting upon 415 feet of sandstone. Conformably subjacent to the latter, there are 5,000 feet of alternations of conglomeratic micaceous sandstones, with bands of siliceous limestones and indurated clay shales, referred to the Algonkian by Dr. A. C. Peale. ^b

A more detailed manuscript section, that Dr. Peale kindly prepared at my request, is as follows:

Gallatin limestones, 835 feet:

Pebbly limestones, 145 feet. Fossils, *Leptaena melita*, *Ophileta* sp.?, *Triplesia calcifera*, *Ptychoparia* sp.?, *Ptychoparia* (E.) affinis.

Dry Creek shales, 30 feet.

Mottled limestones, 160 feet. Fossils, *Ptychoparia* sp.?, *Hyalithes* sp.?

Obolella shales, 280 feet. Fossils, *Obolella* sp.?

Trilobite limestones, 120 feet. Fossils, *Lingulella* sp., *Acrotreta gemma*, *Kutorgina sculptilis*, *Agnostus bidens*, *Hyalithes gregaria*, *Olenoides serratus*, *Ptychoparia gallatinenses*, *Bathyriscus? haydeni*.

Gallatin sandstones, 415 feet:

Gallatin shales, 290 feet. Fossils, *Lingulella* sp.?, *Hyalithes* sp.?, *Ptychoparia* sp.?

Gallatin quartzite, 125 feet.

In the report just quoted Walcott expressed the view that the 5,000 feet of strata beneath the "Gallatin sandstones," which Peale assigned to the Algonkian, might be Cambrian and equivalent to the Bow River group of Canada. But in 1909 he found that only the upper part of the Bow River is Cambrian, and it is separated from the major part by an unconformity. Most of the Bow River is therefore pre-Cambrian, and the equivalent in Montana is the same.

The Gallatin sandstones of Peale in the above section were later called by him Flathead formation, but the name Flathead is now restricted to the basal quartzite, and the overlying shales have been named Wolsey shale. The latter two formations and the overlying limestone were measured in detail on Crowfoot Ridge in the Yellowstone Park by Iddings and Weed ³⁹³ and the result is given in their monograph on the park.

In the same volume Walcott ^{393b} describes the Cambrian faunas from these formations. He finds that—

The Cambrian fauna of the park includes 10 species that are referred to the upper division and 21 that are referred to the middle and lower divisions of the Middle Cambrian fauna.

The Middle Cambrian fauna * * * is more intimately related to that of the Black Hills and the upper Mississippi Valley in Wisconsin and Minnesota than to the Middle Cambrian fauna of Nevada or British Columbia. There are no indications of the Lower Cambrian or Olenellus fauna. The upper-division fauna is also strongly related in its Brachiopoda to the Mississippi Basin fauna.

^a Whitfield, R. P., Observations on the fauna of the rocks at Fort Cassin, Vt., with descriptions of a few new species: Bull. Am. Mus. Nat. Hist., vol. 3, 1890, pp. 27-28.

^b Tenth Ann. Rept. U. S. Geol. Survey, pt. 1, 1890, p. 131.

The Middle Cambrian series is well developed and somewhat diversified around the Little Belt Mountains. Weed⁸⁶⁹ distinguished the following:

Middle Cambrian:	Feet.
Yogo limestone.....	70
Dry Creek shale.....	40
Pilgrim limestone.....	80
Park shale.....	800
Meagher limestone.....	60
Wolsey shale.....	150
Flathead sandstone.....	60

With reference to the above statements, Ulrich comments (personal note):

The series of rocks in Montana and Wyoming from the base of the Flathead quartzite to the top of the Gallatin limestone seems essentially equivalent to the Cambrian sections in central Texas, Oklahoma, Missouri, and Iowa. In each case we have a good Upper Cambrian sandstone followed, except in the far Northwest, by younger sandstone and dolomites. As to the base of the Cambrian, it is a question if at any of these localities any Middle Cambrian (like that in the Great Basin or like the Acadian of the East) is present.

The following description of the Cambrian formations in the Philipsburg quadrangle, Montana, and the discussion of their correlation are condensed from the description in an unpublished paper on the geology and ore deposits of that quadrangle, by F. C. Calkins, and from the unpublished folio on the quadrangle, by the same author.

The Flathead quartzite is composed of more or less vitreous quartzite with an average thickness of about 200 feet. It lies unconformably upon pre-Cambrian red shales and sandstones equivalent to the Spokane shale of the typical Belt section. The evidence of this unconformity, whose importance was long ago established by Walcott, is especially clear in the Philipsburg district. Near the head of Rock Creek, in the Anaconda Range, a cliff exposure shows the base of the Flathead resting on the Spokane with an angular discordance of about 30°. On a branch of Lost Creek, about 8 miles northwest of Anaconda, a slighter discordance is displayed, and here the base of the Flathead is locally a coarse conglomerate of well-rounded pebbles of a quartzitic sandstone identical with that which forms the immediately underlying Spokane beds. Due probably to beveling in the erosion interval preceding the deposition of the Flathead are the great and rapid variations in the thickness of the Spokane formation. This is at least 5,000 feet thick in the gorge north of Georgetown Lake, while at the head of Mill Creek, 13 miles southeast, the Flathead is separated from the Newland limestone by only a few scores of feet of the Spokane formation. There is likewise a great diminution in the thickness of the Spokane between the northwest corner of the quadrangle and the center of its northern margin. The uplift that initiated the beveling seems therefore to have been relatively greater to the eastward.

There is some evidence that a shore line of the Flathead sea traversed the southeast part of the quadrangle. In the locality near the head of Mill Creek where the Spokane is thinnest, the Flathead quartzite is irregular in thickness, much thinner on the whole than in most other places, and at one point was seen to taper to a knife-edge, leaving the superjacent Silver Hill formation in direct contact with the Spokane. The locality is, however, one of complex folding and thrust faulting, and the possibility of the thinning out of the quartzite by faulting nearly parallel to stratification planes is not absolutely excluded.

The Silver Hill formation is here on the average about 400 feet thick. A maximum thickness of 700 feet was observed near the head of Rock Creek, in the Anaconda Range, but this dwindles to about 150 feet within 10 miles eastward. Its lower part consists mainly of dark-greenish, rather siliceous shales, the upper part of calcareous shales and thin-bedded limestones. It shows rapid gradation into the Flathead quartzite below and the dolomites above.

In the vicinity of Silver Hill, about 12 miles west of Anaconda, where the best exposures occur, a threefold subdivision of the formation can be made; it here comprises in descending order:

	Feet.
Shales, calcareous, strongly banded in brown, white, and green, interbedded with laminated limestone.....	90
Limestone with thin brown siliceous laminæ about 1 inch apart.....	120
Shale, dark green, not noticeably calcareous, with a 3-foot intrusive sheet of dark igneous rock near the base.....	120
	330

In places, as near Princeton, these rocks are very poorly exposed and here not even a two-fold subdivision can be actually made on the ground. The middle and uppermost divisions can rarely be separated. The thin-bedded rocks between the Flathead and the Hasmark therefore constitute a convenient stratigraphic unit.

The Paleozoic rocks above the Silver Hill formation consist preponderantly of thick limestone strata, which are separated by relatively thin shales. The first two of the calcareous strata, with the shale that parts them, are mapped as the Hasmark formation. It comprises a basal member chiefly of blue-gray dolomite, a medial member of dark shales, and a top member of white fine-grained dolomite. The highly magnesian character of the highest and lowest members is apparently not shared by the supposedly equivalent Pilgrim limestone. The lower dolomite is about 600 feet thick; the upper about 350 feet. The thickness of the medial shale member varies widely. Its maximum, attained in the southern part of the quadrangle, is about 150 feet; at Philipsburg it is virtually absent, although a few fragments of shaly rock are locally found at the horizon separating the gray from the white dolomite. On Boulder Creek, also, near the northern boundary of the quadrangle, this horizon is marked by only a few feet of shaly limestone. The shale has yielded a few imperfect shells like *Obolus*.

The upper and main part of the Red Lion formation has a very peculiar lithologic character, not shown by the corresponding beds farther east. It consists of gray, drab, and white, rather thickly stratified limestones, whose bedding is marked by closely spaced laminæ of siliceous or argillaceous material, about one-fourth of an inch in average thickness, which project in relief on the weathered surface. These are invariably wavy or crinkly, and locally, where they constitute the greater part of the rock, they anastomose so that the limestone forms little isolated lenses flattened parallel to the bedding planes.^a

The lowest part of this peculiar limestone is the most siliceous and shaly, and it may roughly be said to grade downward into the lower member, consisting of black shale and thin-bedded magnesian limestone, without the cherty banding. This member has a thickness of only about 15 feet on the west side of Cable Mountain, but although it is rarely well exposed, it is apparently two or three times as thick in some other sections.

Fossils were collected from the upper part of the Red Lion formation by Mr. Kindle in 1907 and submitted to Secretary Walcott, of the Smithsonian Institution. In a lot from Rock Creek, in the western part of the Anaconda Range, he found *Billingsella coloradoensis* Shumard and *Anomocare* sp.; in a lot from the vicinity of Princeton, the same forms together with *Cyrtolites* sp. and *Agraulos* sp. All the specimens, according to Dr. Walcott,^b "are of Upper Cambrian age and therefore correspond to the Yogo limestone."

Correlation of Cambrian formations.—The ascription of the series above described as a whole to the Cambrian depends on (1) the unconformity at the base of the lowest quartzitic member which can reasonably be correlated only with the widespread unconformity at the base of the Flathead, the lowest Cambrian formation of the known Montana sections, and (2) the presence of Upper Cambrian fossils in the limestone of the Red Lion formation. Thus

^a The structure of this rock is very similar to that of the Abrigo limestone, illustrated in "Geology and ore deposits of the Bisbee quadrangle," by F. L. Ransome (Prof. Paper U. S. Geol. Survey No. 21, 1904, Pl. VI, B).

^b Letter to F. C. Calkins, June 3, 1908.

the identity of the Flathead is clear, and the limestone of the Red Lion is probably equivalent to the Yogo, the highest Cambrian formation of the central Montana sections.

The age of the intermediate members of the series is more obscure, but tentative correlation may be based on the following considerations: There is in the Philipsburg Cambrian and in that of the Little Belt Mountains and the Livingston region a basal sandstone or quartzite, overlain by alternating shales and limestones that constitute more or less definite stratigraphic units. It is a reasonable supposition that considering only relatively thick and homogeneous strata, the lowest shale in the Philipsburg section corresponds to the lowest shale in the Livingston section, the lowest limestone in the one to the lowest limestone in the other, and so on. On this assumption, the most probable correlation seems to be the following:

Tentative correlation of Cambrian formations.

Philipsburg quadrangle.		Little Belt Mountains.	
Red Lion formation.....	{	Upper member.....	Yogo limestone.
		Lower member.....	Dry Creek shale.
Hasmark formation.....			Pilgrim limestone.
	{	Shale and laminated limestone.....	Park shale.
Silver Hill formation.....		Laminated limestone.....	Meagher limestone.
		Green shale.....	Wolsey shale.
Flathead quartzite.....			Flathead quartzite.

There is not, however, a sufficiently detailed resemblance between the Philipsburg section and those farther east to make a correlation so largely lithologic wholly safe. The Pilgrim limestone, for example, has not been described as magnesian and had it been as obviously so as the Hasmark, the fact would hardly have escaped notice; the few specimens in the National Museum do not appear magnesian. The peculiar laminated limestone of the Red Lion formation, again, does not seem to resemble the Yogo. A real correlation between the Philipsburg and other sections is hardly possible before more Cambrian fossils have been found about Philipsburg, and strata actually traced from one region to another. There is reason to believe that when both these things have been accomplished, formations equivalent in the usual senses may prove to be not quite contemporaneous. The highest limestone in the Philipsburg quadrangle has a fauna of younger facies than that in the Little Belt Mountains, and the Flathead quartzite contains older fossils in the more easterly parts of Montana than in the more westerly parts. It may be that for each or for several of the epochs of the Cambrian period the controlling conditions of deposition were initiated at the east and gradually invaded more and more westerly areas—that there were, in fact, successive westward transgressions.

L 18-19. ST. LAWRENCE VALLEY.

In the valley of the St. Lawrence it is necessary to distinguish the formations of the Ottawa Basin and its northeastern extension to Quebec from those of the region lying farther southeast. The two are separated by the St. Lawrence-Champlain thrust and the stratigraphic sequences are unlike, as are the facies of the formations and faunas. (See Chapter IV, pp. 196-206.)

In the Ottawa Basin and thence past Montreal the Cambrian is represented only by the overlapping littoral deposit of the Potsdam (Upper Cambrian) sandstone. The Lower Ordovician Beekmantown or "Calciferous" succeeds. The characteristics of these formations and the enumeration of their fossils are given according to Ami in the tables quoted in Chapter IV (pp. 200 and 201).

Logan's original descriptions⁵⁴⁴ remain the most satisfactory concerning the details of character and occurrence in Canada. In so far as they relate to the stratigraphy of the formations in New York, they are replaced by Cushing's recent work. (See pp. 120-123.)

The later reports of the Canadian Survey, particularly those by Ells, contain many statements and descriptions relating to the Potsdam and "Calciferosus."^{618a}

The Cambrian terranes of the region southeast of the St. Lawrence-Champlain fault were described by Logan as part of the "Quebec group." They are now comprised under the terms Levis and Sillery. Their typical character in the vicinity of Quebec is summarized by Ami in the table quoted on pages 202-203.

The "Quebec group" was established by Logan,^{54g} who described the strata in the vicinity of Quebec and gave a detailed section, which is here included as an account of the rocks, though no longer accepted as a correct interpretation of the succession:

At the upper end of the island of Orleans, on the northwest side, between high and low water marks, there are exposed about 500 feet of black graptolitic shales, such as belong to the Utica and Hudson River formations, dipping southeast 50°; resting upon which is a series of different strata, dipping in the same direction, and at the same angle with them; the contact between the two being visible. After a short distance across the measures, undulations occur. The effect of these on the distribution of the beds has been partially ascertained, round the upper end, to the southeast front of the island, and for several miles along it. The following is the sequence of the strata; the beds are, however, in some places so corrugated and broken that the measurements here given can only be taken as rude approximations to the truth.

	Feet.
1. Green calcareo-magnesian shale, weathering to a yellowish or reddish brown, interstratified with thin bands of purplish-gray argillaceous shale. Some of the magnesian shales are nearly grass-green, and the surfaces of most of the green beds are marked with fucoid-like forms of purplish gray; the green shales hold about 20 per cent of dolomite. The mass is strong and offers considerable resistance to weathering influences.....	100
2. Gray argillaceous shale, much softer than the magnesian shale.....	100
3. Gray limestone conglomerate; the rounded masses are chiefly of gray limestone; the matrix in many parts weathers to a brownish color and is probably dolomitic. Fossils occur, some of them replaced by silica, but those as yet obtained in this locality are too obscure to be determined; the band in some parts appears to break into lenticular patches.....	10
4. Green yellow-weathering calcareo-magnesian shale with gray argillaceous bands of the same character as No. 1.....	100
5. Gray soft argillaceous shale.....	200
6. Yellowish-gray dolomite, weathering orange-brown. It holds occasional masses of ash-gray limestone and in some parts of its thickness a multitude of pebbles of quartz as large as peas, and becomes toward the top a dolomitic sandstone.....	70
7. Gray fine soft argillaceous shale, with compound graptolites (<i>Phyllograptus typus</i>) about 30 feet from the summit.....	170
8. Gray limestone conglomerate; the matrix in some parts weathers to a reddish brown, being dolomitic, and contains large concretions of carbonate of lime in concentric fibrous layers like travertine. The band holds fossils in some places.....	35
9. Gray fine soft shale, with occasional bands of sandstone weathering brownish, none of them over 6 inches; the bands of sandstone increase in number toward the top.....	500
10. Olive-green argillaceous shale, striped with purplish-gray bands.....	700
11. Olive-green arenaceous shale, with disseminated soft grains of a green mineral, resembling glauconite and approaching it in composition. In the upper part of the deposit the shale contains so much grit as to become almost a sandstone; and within about 100 feet of the top it assumes a red color, in one or two bands.....	400
12. Yellowish-white limestone conglomerate; the matrix assumes a dolomitic aspect in some parts; the rounded masses or bowlders are occasionally 1 or 2 feet in diameter, and some parts of the bed hold fossils.....	10
13. Gray, drab-weathering sandstones, in general slightly calcareous, interstratified with gray argillaceous shales; some of the sandstone beds toward the bottom are 3 or 4 feet thick and hold occasional calcareous pebbles. The sandstones become thinner ascending, and then the shales prevail; but these become by degrees more and more arenaceous, and a band or two about 200 feet from the top assumes a red color.....	400

14. Gray limestone conglomerate; the matrix, weathering to a brown in some parts, is probably dolomitic.....	30
15. Gray, drab-weathering sandstones and shales, the sandstones slightly calcareous.....	300
16. Dark-gray and green shales, with thin bands of gray quartzite and occasional thicker beds of drab-weathering sandstone, some of them being lenticular masses; the dark shales appear in some parts to pass into black.....	900
17. Red and green shales, the red prevailing, interstratified with occasional thin layers of gray hard sandstone or quartzite, and a few of gray hard limestone; some of the bands of shale are of a deeper red than the general mass, approaching a maroon color. Toward the top of the equivalents of these shales, at Cape Rouge, there occur a small <i>Lingula</i> and <i>Obolella pretiosa</i> ; the thickness of the deposit is from 1,500 feet to	1,000
	5,025

The strata from 1 to 17 are in ascending order, provided they are not inverted, of which we have no evidence unless it be the occurrence of an *Obolella* [not *Obolella* Walcott] in the red shales. Several species of this genus occur in the Potsdam group, and one in what is considered the equivalent of the Calciferous portion of the Quebec group, at Troy, in New York. The genus being only recently established, it is not yet certain of what value it may be in determining the horizon. For the purposes of generalization, in describing the Quebec group, the series will be considered an ascending one; not so much, however, with the view of asserting the order of the strata as to render more intelligible the facts connected with their geographical distribution.

It has since been shown that the sequence is inverted and also that errors in correlation arose from the failure to distinguish between fossils collected from the pebbles of the limestone conglomerates and those from the matrix. The extension of the term "Quebec group" to strata of widely differing ages led to its abandonment. The long controversy which led to this result and the detailed facts as finally ascertained are given in the report by Ells.³¹¹ Walcott⁸⁵⁰ reviewed the evidence with Ells in the field and discussed Ells's report, adding thereto his own observations. He says:

When first reading the description of the Point Levis rocks in 1874, I was puzzled by the mixing of the faunas in the lists published by Mr. Billings and the statement made by Sir William E. Logan, that the fossils were from the matrix. On reaching Quebec, in August, 1889, I took the first opportunity to examine the lowest bed of limestone conglomerate back of St. Joseph de Levis and northwest of the Catholic Cemetery. Dr. Ells accompanied me. As we crossed the ridge I picked up a loose boulder full of Potsdam or Upper Cambrian fossils. A second boulder was found embedded in the matrix and then several more; some of which were 3 feet in diameter. The matrix is a hard gray impure limestone that occurs at this point in a solid band, that we traced 500 feet or more. In the matrix I found the Calciferous fauna was represented by *Obolella* sp.?, *Orthis* sp.?, *Camerella calcifera* Billings, *Ecculiomphalus canadensis* Billings, *Ecculiomphalus intortus* Billings, *Ophileta complanata* Vanuxem, *Pleurotomaria canadensis* Billings, *Pleurotomaria* sp.?, *Orthoceras*, 4 sp. undet., *Ceraurus?* *apollo* Billings, *Ceraurus eryx* Billings, *Bathyurus bituberculatus* Billings, *Bathyurus quadratus* Billings.

In a bed of limestone 50 feet higher in the section I found, in addition to the preceding, the following: *Bathyurus cordia* Billings, *Bathyurus oblongus* Billings, *Amphion caleyi* Billings. In the succeeding band of limestone conglomerate *Orthis porambonites* Pander occurs.

A large number of specimens were obtained from the boulders embedded in the limestone containing the fossils of Calciferous age, among which I have identified *Camerella calcifera* Billings(?), *Agnostus americanus* Billings, *Dicelocephalus magnificus* Billings, *D. oweni* Billings, *D. belli* Billings, *Arionellus subclavatus* Billings, *Menocephalus?* *sedgwicki* Billings, and *Illænenurus illænooides* Billings (sp.). Other species occur, but the preceding list is sufficient to indicate the fauna of the Upper Cambrian or Potsdam zone.

Dr. Eells accepted the view that the Calciferous fauna occurred in situ in the matrix of the conglomerate, and that the bowlders containing the Potsdam fauna were derived from pre-existing strata. In the next band of conglomerate, above that which forms the ridge on the north side of the cemetery, the matrix also carries Calciferous fossils, and they are also abundant in the bowlders. In a search of two days I failed to find a Potsdam fossil at this horizon. From Dr. Eells I learned that nearly all the fossils described by Mr. Billings came from the lower zone, and we found traces of extensive collecting. With these exact data I was enabled, at once, to correlate the lower belt of limestone and conglomerate with the central band of the Phillipsburgh section, where an identical fauna occurs 1,000 to 1,100 feet above the recognized Potsdam sandstone.

This zone is 600 feet beneath the zone of "*Maclurea ponderosa*," where Mr. Billings placed the Levis conglomerates. The long period of uncertainty regarding the true mode of occurrence of the faunas in the Levis calcareous rocks is now terminated, and a fixed datum point secured for comparison with the known section on the shores of Lake Champlain.

Dr. Eells quotes the greater part of the conclusions contained in Prof. Charles Lapworth's instructive paper on the graptolites of the "Quebec group."^a In this the graptolitic zone of the Levis shales is correlated with the typical Arenig of Great Britain and the Phyllograptus beds of Scandinavia. The graptolites of the Citadel Hill or Quebec City strata are correlated with the middle Llandeilo zone of Great Britain.

The stratigraphic succession, as determined by Dr. Eells, is as follows:

1. Black, green, and gray shales, with thick bands of grayish and sometimes yellowish-white quartzose sandstone and occasional thin bands of limestone conglomerate.
2. Greenish, grayish, and blackish and occasional bands of reddish or purple shales, with thin layers of gray sandstone. Annelid trails (fucoidal markings of Eells) are numerous on the greenish shales. On the south shore of the St. Lawrence below Levis, and also on the south shore of the Island of Orleans, beds of conglomerate occur at about this horizon, in which the Lower Cambrian fauna occurs.
3. Bright-red shales, with thin bands of greenish and gray shale.
4. Red, greenish-gray, and black shales, with interstratified Sillery sandstones. *Obolella pretiosa* in the upper part, near Sillery, and on the south side of the river *Obolella pretiosa*, *Protospongia fenestrata*, *Phyllograptus typus*, *Tetragraptus serra*, and *Lingula quebecensis*.
5. Levis shales and conglomerates of Point Levis.
6. Black and grayish-striped or banded shales, with the black and graphitic shales and limestone of the Athabaska and Somerset synclinal, the latter not appearing in the Quebec and Point Levis sections.
7. The black or brownish bituminous shales and limestones of the city of Quebec and northwest side of the Island of Orleans. The contained fauna is of Trenton-Utica age.

From the Cape Rouge section and the strata on the south side of the St. Lawrence, Dr. Eells concludes that the evidence afforded by the stratigraphy and the graptolites, determined by Prof. Lapworth, is sufficient to refer the Sillery rocks of 1, 2, 3, and 4 of the section to the Cambrian system, and the Levis beds (5) to the Lower Ordovician.

The thicknesses of the Sillery and Levis rocks are not given; but Dr. Eells told me that the measurements given by Logan were as nearly correct as could be determined. These were 2,000 feet for the Levis shales and 5,000 to 6,000 feet for the Sillery series as now known.^b

The *Obolella pretiosa* ranges through from 1,500 to 2,000 feet of the Upper Sillery, and the lower conglomerate, of 2, occurs in the lower portion of this series. The Cape Rosier *Dictyonema sociale* zone is regarded as the lowest of the graptolitic zones, and to indicate the horizon of the Tremadoc terrane of Great Britain. The Cape Rosier beds are referred to the Upper Cambrian by Prof. Lapworth and Dr. Eells, but with our present knowledge of the Cambrian in America, I would refer them to the Lower Ordovician or to the Lower Calciferous. The occurrence of the typical Calciferous fauna within 100 feet of the base of the Levis series, at St. Joseph de Levis, points very strongly to considering the graptolitic fauna of the Upper Sillery to be of Calciferous age, if a comparison is made with the Phillipsburgh section.

^a Lapworth, Charles, Report on some graptolites from lower Paleozoic rocks: Trans. Roy. Soc. Canada, 1886, pp. 167-184.

^b This transfers to the Sillery a considerable portion of the strata originally referred to the Levis.

Dr. Ells refers the Sillery series to the Cambrian and in this I mainly agree with him, except that the upper portion is evidently a passage series between the Cambrian and Ordovician. On lithologic and stratigraphic evidence the line would be drawn at the summit of the red shales. On paleontologic evidence, as furnished by the graptolites, I would include the upper portion of the Sillery red and green beds in the Ordovician, as I think they are above the typical Potsdam zone of America.

It will be recalled that Dr. Ells stated that the Sillery beds rested unconformably upon the slates, quartzites, etc., which he refers to the Lower Cambrian. He mentions that, in this lower series, beds of gray subcrystalline limestone occur. It may be that we here have the source from which the limestone conglomerate of the Sillery was derived, which contains the *Olenellus* fauna. This would be in accordance with the mode of occurrence of the *Olenellus* or Lower Cambrian fauna to the southward, in Vermont and eastern New York.

In this quotation Walcott states that he would refer the Cape Rosier beds to the "Calciferous" (Beekmantown) rather than to the Upper Cambrian as was done by Lapworth and Ells.^{47, 311c}

The limestones near Phillipsburg, which in the preceding quotation are assigned to the "Calciferous" (Beekmantown), were thus described by Logan:^{544w}

	Feet.
A.	
1. Dark-gray and yellowish-white dolomites, weathering gray and yellowish brown.....	400
2. White and dove-gray pure compact limestones.....	100
3. Reddish-gray, brown-weathering dolomites and black dolomites with some thin-bedded black* limestones.....	200
	700
B.	
1. White and dove-gray pure limestones, with some yellow-weathering magnesian bands.....	120
2. Dark-gray and black limestones, some of the beds magnesian.....	120
3. Dark bluish-gray thin-bedded nodular limestones, with thin layers of bluish-gray slate, probably magnesian; the surfaces of some of the beds weathering into a red or yellow ochereous arenaceous earth.....	150
4. Black slaty thin-bedded nodular limestones, with two or three thick beds of purer limestone toward the base.....	300
5. Black limestones, some of them massive, weathering bluish gray; interstratified toward the bottom with black and dark-gray, yellow-weathering magnesian beds.....	350
	1,040

The remainder of this section comprising divisions C and D is given on pages 845-846 of Logan's report.

The faunas of the Potsdam and "Calciferous" of the Eastern Townships of Quebec and of the Phillipsburg formation are listed by Ami.^{14a}

L 19. MAINE.

Certain shaly, calcareous, and quartzitic strata, which are highly altered, occur on the shores and islands of Penobscot Bay, where they have been studied in detail and provisionally assigned to the Cambrian by Smith, Bastin, and Brown,^{760a} who say:

The oldest rock of the Penobscot Bay region is the Ellsworth schist, which represents sediments probably of Cambrian or even pre-Cambrian age. The deposition of these arenaceous sediments was followed by dynamic action sufficient at least to inaugurate the changes of impure sand into a crystalline schist. This metamorphism is believed to have begun before the deposition of the next younger formation, inasmuch as the Ellsworth schist exhibits a much greater degree of alteration than any other rock in the quadrangle.

The next epoch probably began in Cambrian time with the deposition upon the ocean bottom of muds and impure sands that are now represented by the Islesboro slate, with which the Calderwood slate is possibly to be correlated. This deposition presumably took place in moderately shallow water and not far from shore, but the position of the land masses which furnished the sediments is wholly conjectural. Gradually conditions became favorable for the deposition of the beds now represented by the Coombs limestone. The considerable amount of argillaceous material associated with the limestone, as well as the great variations in the purity of the limestone from place to place, may be taken as indicating shallow water and somewhat shifting currents.

The changes which closed the period of limestone deposition were more rapid and of greater magnitude than those at its beginning and resulted in the deposition above the limestone of sands and gravels of considerable purity which are now consolidated to form the Battie quartzite. The conglomerate beds of this quartzite show a somewhat impure quartzitic matrix in which are embedded pebbles of very pure quartzite. The fact that most of these pebbles are well rounded indicates that the rock from which they were derived was itself a well-indurated sandstone or possibly a quartzite. The massive quartzites have a composition about like that of the matrix in the conglomerates. Presumably these rocks represent shallow water or beach deposits which were subject to the sorting action of waves and currents. No quartzite beds which could have served as the source for such deposits are known in this part of the State, though they may occur buried beneath later formations.

The parent formation need not have been wholly or even largely of quartzite, for the assorting and disintegrating action of waves and currents would suffice to separate more resistant quartzitic portions from less resistant shaly or calcareous materials. Certain beds, however, must have been very pure quartzite in order to furnish the clean, pure pebbles characteristic of the conglomerate.

After the deposition of the Battie sands and gravels conditions for the deposition of muds were again restored and very extensive deposits were laid down, which are now represented by the Penobscot slate, the most widely outcropping and the thickest formation of the region. The change is probably indicative of slight but long-continued subsidence. Within the adjoining Rockland quadrangle these muds were succeeded conformably by thick deposits of limestone, which is now thoroughly crystalline and of great economic importance in the production of lime. The presence of beds of limestone conglomerate at various horizons within this limestone formation indicates a shallow-water origin.

Detailed descriptions of the formations are given in the Penobscot Bay folio.

L 19. CARLETON AND YORK COUNTIES, NEW BRUNSWICK.

The "slate belt" of southwestern New Brunswick comprises "Cambro-Silurian" (that is, Cambrian and Ordovician) and Silurian ("Upper Silurian") strata, which are separated by a marked unconformity and are intruded by granite. Bailey^{44a} states the conditions and exact localities of the observations made in 1900 and concludes in part as follows:

The general tendency of these observations has been to confirm the view * * * that while a Silurian age must be assigned to certain tracts, such as that in which fossils were found by Mr. Wilson, of the Geological Survey staff, 6 miles north of Canterbury, and that discovered by the writer in the settlement of Waterville, in the parish of Southampton, yet the great bulk of the strata in the counties under consideration is, as previously supposed, of greater antiquity, being at least Cambro-Silurian or Ordovician (the age to which they had previously been assigned), if not even older. In seeking for evidence on this question a careful resurvey was made along the line where the supposed Cambro-Silurian or older rocks are met and overlapped by the fossiliferous Silurian rocks to the north, with the result that incontestible

evidence of discordance is found along the whole length of that line. A new and well-marked instance of this was seen near the head of Eel River, in South Richmond, Carleton County, where heavy beds of bright-red slates, associated with amygdaloidal diorites, have afforded large fragments to the overlying Silurian beds.

An effort was then made to determine the limits of the fossiliferous Silurian rocks previously discovered by Mr. Wilson. Fossils similar to those obtained by that gentleman, but occurring very sparsely, were collected at several points on Eel River, and strata exhibiting similar associations were followed for 6 or 8 miles in the direction of the St. John River. Here, however, approaching the great granite belt, they not only failed to yield fossils but became so greatly altered as to be recognizable only with difficulty. In connection with this work the fossiliferous slates were found to be associated throughout with heavy beds of slaty conglomerates, the composition of which, though somewhat different from that of the South Richmond conglomerates, equally indicates their derivation from the supposed Cambro-Silurian and Cambrian strata. The course of these conglomerates is therefore provisionally regarded as marking, upon one side at least, the line of separation of the two systems in the parish of Canterbury. The southern side, owing to progressive metamorphism, can not be definitely assigned.

So far, the conclusions reached * * * were based upon stratigraphical and lithological grounds only. But near the end of the season * * * new and most important evidence, tending to confirm the views already reached, was brought to light. This consisted in the discovery near the village of Benton, in Carleton County, of a band of very black, more or less graphitic slates, associated with gray and white quartzites and containing a few layers charged with large numbers of graptolites of the genus *Dictyonema*. Among these were some of large size ($2\frac{1}{2}$ by 3 inches), showing both in their outlines and in the dimensions and structure of the polypary a very close resemblance to the form *D. sociale* or *D. flabelliforme* Eichwald, occurring in rocks of Cambrian age on Navy Island, in the harbor of St. John, as well as at Matane, in the Province of Quebec. They are regarded as identical by Dr. H. M. Ami, after careful studies and comparisons, and Dr. G. F. Matthew (by whom the Navy Island form has been figured and described) is also disposed to adopt the same view. It would seem, therefore, that although the occurrence of a single fossil species is in itself very insufficient evidence upon which to determine and represent the horizon of a great group of strata, yet, when this is taken in connection with the stratigraphy of the region, pointing as it does in the same direction, a strong presumption is established in favor of the Cambrian age of the beds yielding these forms.^a

L 20-22. NEW BRUNSWICK, CAPE BRETON, AND NEWFOUNDLAND.

In 1900 Matthew contributed to a paper by Ami¹⁶ the following statement of the succession of formations within a radius of 20 miles of St. John, New Brunswick:

^a For further details see Repts. Geol. Survey Canada, new ser., vol. 16, 1904, pp. 279-282A.

Pre-Silurian rocks within 20 miles of St. John, New Brunswick.

System.	Terrane.	Condition.	Characteristic strata.	Characteristic fossils.	Thickness (feet).	Locality.
Lower Ordovician.	Division 3, "Bretonian."	Mud rocks with slaty cleavage and plant remains.	Gray sandstone.	5? <i>Leptobolus grandis</i> .	700	"Falls" at St. John. Navy Island, St. John. King Street, St. John. Germain Street, St. John. King Street E, St. John. Wright Street, St. John.

Arenicolites, worm trails. No fossils.	1, 200	{ Caton's Island, King's County. Loch Lomond, St. John County.
Huronian ?	Coldbrook group, etc.	Partly crystalline.	Ash rocks, felsites. Diabase, diorite.	No fossils.	10, 000?	Carleton Heights. Loch Lomond Hills.
Grenvillian.	Upper series of the Laurentian area. (Part of "Portland group.")	Partly crystalline.	Clay slates and diorites. Limestones and quartzites. Mica schist, etc.	{ Eozoonal fragments. Archaeozoon, sponges. No fossils.	1, 200?	Howe's Road. Green Head. Douglas Avenue. Green Head.
Laurentian.	Crystalline schist. (Part of "Portland group.")	Crystalline.	Feldspathic gneiss. Chloritic gneiss. Quartz diorite (intrusive).	No fossils.	(?)	Indiantown. Fairville, etc.

N. B.—A double transverse line indicates a marked discordance of stratification; a single transverse line indicates a discordance that is not so obvious. (This remark does not apply to the lines separating the subdivisions of the groups in the second column.) It will be seen that the terranes or formations do not always agree with those of Europe—that is, the physical and paleontological breaks are not synchronous.

Laurentian.—In the column of geological systems, beginning with the oldest or Laurentian, Dr. Matthew has assigned certain crystalline schists of Indiantown and Fairville to this horizon. These form a part of the Portland group (lower) of the reports bearing upon the geology, whereas the upper part of this group he classifies as Grenvillian, consisting of clay slates, norites, limestones, quartzites, underlain by mica schists.

Huronian.—The Laurentian Archean rocks are succeeded upwards, as Dr. Matthew points out, by rocks of doubtful Huronian age, consisting of ash-rocks, felsites, diabase, diorite, such as are met with at Carleton Heights and Loch Lomond Hills, all grouped under the designation "Coldbrook group." Both above and below this Coldbrook group, as well as between the Laurentian of Indiantown and the Grenvillian limestones, slates, etc., of Green Head, Douglas Avenue, etc., a marked discordance of stratification occurs, which apparently indicates long lapses or intervals of time between them.

Cambrian.—Above the Coldbrook group, and beneath the Cambrian or St. John group, Dr. Matthew describes and classifies certain purplish and green shales, purplish-red sandstones, and coarse red conglomerates, which are exposed on Caton's Island, in King's County, and at Loch Lomond, St. John County, under the term "Etcheminian."

Between this Etcheminian and the St. John group the discordance of stratification is not as obvious as in the case of the preceding system with the Etcheminian. The fauna of the Etcheminian, however, is essentially a Cambrian fauna according to the writer.

The Acadian, Johannian, and Bretonian constitute the three divisions which Dr. Matthew has established in the St. John group. The strata which they represent are 1,650 feet in thickness and consist of mudstones, with slaty cleavage, also sandstones and flags with conglomerate. The uppermost or Bretonian division of the St. John group, which is to be seen in the black graptolitic shales and sandstones of Navy Island and at the falls on the St. John River, near the suspension bridge, are by him referred to the Lower Ordovician. Many of the species which occur here are eminently characteristic of the Levis division of the Québec group, in the St. Lawrence Valley. These strata correspond to the Skiddaw and Arenig formations of England and Wales and to similar horizons in Scandinavia, France, and elsewhere.

It is from the Cambrian or lower and most important portion of the St. John group of rocks that Dr. Matthew has obtained material from which he described and illustrated the very extensive extinct fauna and flora of these old Paleozoic sediments.

In 1904 Matthew⁵⁸² described the Cambrian as follows:

Confining our attention to the areas where Cambrian fossils have actually been found, we note throughout this North Atlantic region the prevalence of volcanic deposits, or of red and green mud beds, in the initial period of Cambrian time. If the former are not actual lava flows, or the cores of old volcanic cones and ridges, they are the compacted ashes, mud, and stones from such a source.

Resting on these volcanic deposits, though sometimes intercalated with them, are beds of sand and mud that easily show their relation to such a source as the volcano, by the fact that this sand consists largely of feldspathic particles, while the mud beds are pale-green or red accumulations of volcanic dust that have fallen into or been swept into the sea. Hence it would appear that while the first volcanic eruptions occurred over land surfaces, the land soon sank, and the later ones were thrown into the sea. It is in the levigated material thus thrown into the sea, or swept into it by rivers, that we meet with the earliest organic remains of the Cambrian time. These levigated deposits are chiefly in the Etcheminian terrane and contain a very ancient group of Cambrian organisms. They also exhibit a cycle of deposits corresponding to that of the St. John terrane above them, for they have in the middle coarse sandy sediments, that separate two groups consisting largely of mud beds; of these the lower has conglomerates and sandstones intercalated, while the upper are found to contain flaggy sandstones.

The principal sandstones, however, are in the middle member, which is comparatively barren of fossils but contains much diffused hematite, giving the rock a markedly red color. These beds also, like those of the corresponding stage of the St. John terrane, frequently show

ripple-marked layers replete with worm burrows, worm trails, and other marks of a shallow-water origin. * * *

In the outer areas of the Cambrian rocks of the Atlantic coast the Etcheminian terrane is easily traced by the prevailing red color, as well as by its fossils. In this outer zone fine slates prevail and there are beds of limestone, as may be seen in the Massachusetts and Newfoundland areas. In the inner zone (New Brunswick and Cape Breton) the sediments are coarser and limestones are wanting; it is in this inner zone that a middle member of sandstones and flags is most distinctly marked.

The organic remains of this middle member are similar to those of the lower sediments, so that the Etcheminian rocks have only two faunas, an upper and a lower. The volcanic rocks beneath them have yielded a scanty fauna, which may not be more than a subfauna of the Lower Etcheminian. More material is required to determine the importance of this fauna.

So far as the St. John terrane is concerned, it is clear that the basins we have now are but fragments of deposits that have been spread over large areas of the Atlantic coast, and there may be extensive tracts occupied by slates and flags so far metamorphosed that Cambrian fossils can not be recognized. The materials which make up the flags and slates of the Johannian division glisten with water-borne particles of mica, the sands are of uniform texture, and there are no traces of shore lines, though shallow-water beds abound.

Also the Bretonian division, with its fine-grained dark-gray mud beds holding graptolites and the perfect preservation of its delicate organisms, indicates the presence of a water cushion of considerable depth above its muds, when these were being deposited, a cushion which we can hardly think less than 1,000 feet deep. But a sea of this depth would have covered a wide area along the Atlantic coast, and we therefore infer that the known basins of Cambrian rock are but small fragments of the widespread mantle of sediments that covered this region at the beginning of Ordovician time.

The group of organic remains of the outer zone of the Etcheminian rocks appears to differ widely from that of the inner. This may be because they do not come from the same time horizon; but it seems more likely to be due to some physical cause, either difference in the depth of the sea in the two zones, or paucity or abundance of sediment in the waters, or difference of temperature of the sea water in the two zones. Whatever the cause, olenelloid trilobites have not been recognized in the strata of the inner zone, while they are characteristic of the faunas of the outer zone.

The Etcheminian, St. John, and Bretonian terranes are divided by Matthew into "assises" or faunal zones, and the faunas comprising 380 species are listed accordingly in the paper cited above.

In earlier papers relating to the Cambrian and pre-Cambrian, Matthew had included the Etcheminian in the latter, as a formation underlying the "Lower Cambrian" (Olenellus zone).

Walcott^{857b} studied the sections both in New Brunswick and Newfoundland and reached conclusions differing from those of Matthew, which the latter subsequently accepted, namely:

(a) The "Etcheminian" terrane of Matthew is of Lower Cambrian age.

(b) The Olenellus fauna is older than the Paradoxides and Protolenus faunas of the Middle Cambrian.

(c) The Cambrian section of the Atlantic province of North America includes the Lower, Middle, and Upper Cambrian divisions as defined by me in 1891.

Walcott's conclusions are based on the following sections in part, and others to be found in his paper:^{857a}

Smith Sound section.—On the northern shore of Smith Sound, east and west of Smith Point, the Cambrian rocks are well exposed along the shore. At Broad Cove, west of the point,

the transition beds between the Upper Cambrian (Olenian) and the Middle Cambrian (Paradoxidian) are concealed by the drift at the head of the cove. West of the cove the fissile and arenaceous shales of the Upper Cambrian are well exposed and contain *Olenus*. On the eastern side of Broad Cove the Middle Cambrian is exposed. The measured section begins with the dark argillaceous shales and is as follows:

Middle Cambrian, downward:		Feet.
1a.	Dark argillaceous shales, with fragments of Paradoxides in the upper portion. At 45 feet down the Paradoxides are abundant; also <i>Acrothele</i> , <i>Obolus (L.) ferrugineus</i> , <i>Ptychoparia</i> , etc. At 110 feet down a 4-inch band of pinkish limestone carrying fragments of trilobites occurs. A roll in the strata comes in at this point and continues for a considerable distance along the shore. It starts between the two east wharves at Broad Cove and extends some distance east of the eastern point of Broad Cove.....	110
1b.	Below the limestone greenish shale extends downward to a layer of reddish argillaceous shale 20 feet in thickness. No recognizable fossils were found in this bed.....	80
1c.	Pinkish nodular limestone in several layers, interbedded in reddish shale. Fossils: Paradoxides (undet.), <i>Ptychoparia</i>	4
1d.	Reddish-purple argillaceous shales with interbedded greenish-colored bands..... This band of shales corresponds stratigraphically to the <i>Protolenus</i> zone of the Hanford Brook section of New Brunswick. A basalt dike cuts through the shales a few feet above their base. On the weathered surface it has the appearance of a massive sandstone. It is 3 feet 4 inches in thickness, is vertical, and the dip of its cleavage planes is almost coincident with the dip of the shales.	135
1e.	Nodular limestones. A pinkish layer 4 inches thick contains at base numerous fragments of trilobites and appears to be made up of a conglomerate formed of fragments of pinkish-colored limestone and purple shale, and dark iron- or manganese-stained nodules resembling a stromatoporoid-like growth, and a few small quartz pebbles....	3
The entire stratum is as follows:		
	Inches.	
	Dark nodular limestone.....	25
	Purplish-colored shale.....	2
	Pinkish limestone.....	2
	Brick-red shale.....	3
	Pinkish conglomerate (?) limestone.....	4
At the point of exposure on the shore this band is faulted down 15 feet to the west. It is exposed near the top of the bank on the eastern side of the fault, where its dip is lower than on the western side.		
The stratum 1e is taken as the base of the Middle Cambrian (Paradoxidian). It is the horizon indicated by Mr. Matthew in his diagrammatic section as the base of the Cambrian, and corresponds in stratigraphic position to the St. John quartzite of the New Brunswick Cambrian.		
One observes no difference, in either strike or dip, between the shales beneath this band of nodular limestone and conglomerate and the shales above it until one passes to the east of the fault line that cuts through and breaks the band a few feet above the water's edge.		
Lower Cambrian (Etcheminian of Matthew):		
2a.	Reddish-purple argillaceous shale with greenish shales in bands at irregular intervals and a massive band of greenish shale near the base. Dip near base 20° to 23° W.....	284
At 110 feet from the summit fragments of a large undetermined trilobite were noted. On the south side of Smith Sound, at Britannia Cove, <i>Olenellus (H.) bröggeri</i> occurs at a horizon corresponding to 140 feet below the summit of the stratum.		
Near the base of 2a the following fossils were found:		
	<i>Obolella atlantica</i> .	
	<i>Hyalithes</i> sp.	
	<i>Orthotheca</i> sp.	
	<i>Microdiscus</i> sp. undet.	
	<i>Olenellus (Holmia) bröggeri</i> .	
	<i>Solenopleura? bombifrons?</i> .	
2b.	Greenish-colored arenaceous limestone, passing into an intraformational conglomerate formed of nodules of pinkish limestone mixed with fine sand and carrying numbers of fragments of trilobites.....	1½
	Pinkish-colored nodular limestones.....	¾
Fossils: Fragments of trilobites and a small brachiopod.		

Lower Cambrian (Etcheminian of Matthew)—Continued.	Feet.
2c. Reddish-purple to brick-red argillaceous shale	56
The following fossils occur in the central and lower portions of this band:	
<i>Obolella atlantica</i> .	
<i>Microdiscus bellimarginatus</i> S. & F.	
<i>Microdiscus</i> n. sp.	
<i>Olenellus</i> (<i>Hölmia</i>) <i>bröggeri</i> .	
<i>Zacanthoides</i> sp. undet.	
<i>Agraulos</i> sp.	
<i>Micmacca walcotti</i> .	
2d. Brick-red and pinkish nodular limestone in layers varying from 3 feet to 6 inches in thickness.....	27
This is one of the most important horizons in the Lower Cambrian of Newfoundland (Smith Point limestone). It is very persistent about Trinity Bay, and it occurs, although much thinner, at various exposures in Conception, St. Marys, and Placentia bays. The upper 24 feet at Smith Point is practically solid limestone layers. The lower layer of limestone, 1 foot in thickness, is separated by 2 feet of reddish shale in which 3 inches of limestone occurs.	
Fossils: In the upper 6 inches of the top layer of limestone numerous fragments of <i>Olenellus</i> (<i>H.</i>) <i>bröggeri</i> and <i>Solenopleura</i> ? occur. About 3 feet below this, in the next bed of limestone, immense numbers of <i>Hyolithes princeps</i> are found in association with the fauna that marks this limestone band wherever it is found. The following species were collected in a few hours:	
<i>Iphidea labradorica</i> (<i>Kutorgina granulata</i> M.).	
<i>Fordilla troyensis</i> .	
<i>Scenella reticulata</i> ?	
<i>Randomia auroræ</i> .	
<i>Helenia bella</i> .	
<i>Orthotheca pugeo</i> .	
<i>Hyolithes princeps</i> .	
<i>Coleoloides typicalis</i> .	
<i>Hyolithellus micans</i> ?	
2e. Green argillaceous shale.....	23
2f. Massive stratum of nodular limestone, divided into 18 inches of a pinkish limestone and 3 feet of purple to a pink mixed with purple argillaceous shale. Fossils: <i>Coleoloides typicalis</i>	4½
2g. Green argillaceous shale in massive bands, with numerous small pinkish limestone nodules scattered irregularly on the line of bedding. At 51 feet from the base the limestone nodules increase in number and size and form the greater part of a layer 2 feet in thickness. Above this the reddish-purple and green shales occur in bands varying in thickness.....	62
Fossils:	
<i>Hyolithes rugosus</i> Matt.?	
<i>Coleoloides</i> .	
<i>Urotheca pervetus</i> Matt.	
Crustacean, n. g., n. sp.	
2h. Reddish-purple argillaceous shales, with irregularly distributed bands of nodular limestone of varying thickness. A layer of nodular limestone 42 feet from the summit has 12 inches of pinkish and reddish-purple limestone above, with 10 inches of greenish limestone below. In both layers numerous tubes of <i>Coleolides</i> occur. At 66 feet below the summit a second band of nodular limestone 20 inches in thickness occurs. Thin layers of nodular limestone occur both above and below the two thicker bands mentioned	136
2i. Green argillaceous shale, with a few thin layers of purple shale, also scattered layers of pinkish-colored nodular limestone. Fossils: Annelid trails are abundant in some portions of the greenish-colored shales.....	30½
2j. Reddish-purple shale, with layers of greenish and pinkish-colored limestone nodules scattered irregularly on the line of bedding. The nodular limestones are usually from 2 to 4 inches in thickness, but at 60 feet from the top a layer 12 inches thick occurs.....	185
The section is here cut off by the drift coming down to the water's edge.	

The nodular limestones of the Smith Point section are one of the most noticeable features of the lower portion of the section. * * * The only fossils found in the lower part of the section except annelid trails occur in the nodules. The bedding planes of the shale in the slate quarries on Smith Sound are clearly indicated, at nearly right angles to the cleavage, by the lines of scars left by the nodules.

Base of Cambrian in Smith and Random sounds.—The base of the Cambrian is exposed at the slate quarries east of Tilton Head, on the north side of Smith Sound, in the synclinal basin formed of the Avalon and subjacent Cambrian rocks. The section, however, is not here complete. On the south side of Smith Sound, near Britannia Cove, the Smith Point limestone, carrying *Hyalithes*, etc., is well exposed, and 220 feet above it, in the green shales, *Olenellus (H.) bröggeri* was found. Below, the limestone beds are much broken. Crossing Random Island from Britannia Cove to the north shore of Random Sound, one finds a much more complete section, east of Hickmans Harbor Point. At Hickmans Harbor Point the Signal Hill conglomerate of the Avalon series is well exposed, and above, to the eastward, the Random terrane. The summit of the latter is very beautifully shown at the slate quarries about half a mile east of Hickmans Point, where the strike of the upper bed of the Random sandstone is N. 50° E., dip 70° SE. Immediately on this band of reddish-tinted sandstone there is a thin layer of conglomeratic limestone that forms the basal bed of the Cambrian.

Random Sound section, upward:	Ft. in.
1a. Conglomerate formed of small pebbles of the subjacent Random rocks, and small quartz grains and pebbles, all cemented together by a fine calcareous sandy matrix. Often there is scarcely a trace of calcareous matter.....	6
Fossils: Slender tubes of <i>Coleoloides</i> and fragments suggest <i>Archæocyathus</i> .	
1b. Reddish-purple sandstones capped by coarse-grained grayish-purple sandstone 6 inches thick.....	3
1c. Pinkish-colored limestone with <i>Coleoloides</i>	6
1d. Reddish-purple argillaceous shale.....	10
1e. Purple to pink, hard, irregular arenaceous limestone.....	1½
Fossils: <i>Coleoloides</i> and sections of what appears to be a small <i>Obolella</i> -like shell.	
1f. Green and reddish-purple argillaceous shale in broad bands. At 140 feet up nodular limestone appears, and at 170 feet a band of pinkish-colored limestone 6 inches thick with <i>Coleoloides</i>	171
A change of dip and overturn occurs here, which breaks the section and cuts out probably 100 feet or more of the shales. Estimated.....	
	100
1g. Green argillaceous shale.....	42
1h. Reddish-purple argillaceous shale.....	98
1i. Greenish argillaceous shale.....	84
1j. Pinkish-colored, massive-bedded nodular limestone.....	6
Fossils: <i>Hyalithes princeps</i> , <i>Coleoloides typicalis</i> , also numerous fragments of small <i>Hyalithes</i> , of which, owing to the cleavage of the limestone, it was impossible to get good specimens.	
1k. Reddish-purple and green argillaceous slates, cleaned so as to make a good roofing slate at Bryant's quarries, about 1 mile east of Hickmans Point. The estimated thickness of this slate in the syncline is over 200 feet.....	200+
The total thickness of the section up to the <i>Hyalithes</i> limestone is over 500 feet, which, with the 369 feet above the limestone at Smith Point, gives a total thickness of fully 900 feet for the Lower Cambrian on the western side of Trinity Bay.	

In the city of St. John [New Brunswick] the examination of the outcrops led me to the conclusion (a) that the Lower Cambrian strata beneath the St. John quartzite had been deposited on and against an irregular, uneven shore line; (b) that the sands of the St. John quartzite had been spread conformably over the beds of the Lower Cambrian ("Etcheminian"); (c) that where the pre-Cambrian (Algonkian) rocks projected above the Cambrian beds, or formed the shore lines, the St. John quartzite conformably overlapped the reddish-purple and greenish-colored arenaceous micaceous shales and thin-bedded sandstones of the Lower Cambrian ("Etcheminian") and came in unconformable contact with the Algonkian rocks. * * *

Seely Street section.—The section exposed at the head of Seely Street, beside the Park Road, is as follows. The pre-Cambrian Algonkian rocks have an uneven surface where the basal beds of the Cambrian rest against them.

Lower Cambrian, upward:	Feet.
1a. Dark reddish-brown fine conglomerate and sandstone, with reddish and green, hard arenaceous shale. The conglomerate contains small quartz pebbles and bits of the subjacent Algonkian siliceous beds. Strike N. 40° [E.] mag., dip 70° SE.....	12
1b. Space concealed. From the abundant débris in the soil as exposed in a cutting beside the road the section here is formed of reddish-purple and green sandy shales.....	85
1c. Reddish-purple and greenish arenaceo-micaceous shales and thin-bedded sandstone..	52
Middle Cambrian:	
2a. Light-gray fine-grained quartzitic sandstone in thick layers. The grains of sand become coarser in the upper part of section and a layer of white quartz-pebble conglomerate occurs near the summit. Strike at base N. 55° E. mag., dip 70° SE.....	40-45
2b. Arenaceous and argillaceous greenish-colored shales and thin-bedded sandstones, passing above into dark argillaceous shales. About 25 feet above the base the <i>Paradoxides</i> fauna appears in great abundance. For further details of the section of the St. John Cambrian rocks see Mr. Matthew's papers.	

It will be noted that the strike of the basal Lower Cambrian bed 1a is N. 40°, while that of the St. John quartzite is N. 55° E. This does not indicate an unconformity as the change of strike occurs in the beds below; the shales just beneath the quartzite are conformable to the quartzite.

Hanford Brook section, St. John County, New Brunswick.—The Middle Cambrian portion of the Hanford Brook section as exposed at McAfee's sawmill on the south bank of the brook below the mill is as follows:

Middle Cambrian downward:	Feet.
1a. Greenish-colored argillaceous shales with abundant remains of <i>Paradoxides</i> and other forms of the <i>Paradoxides</i> fauna.....	30+
1b. Massive calcareo-argillaceous layer carrying the <i>Paradoxides lamellatus</i> fauna. Strike E. and W., dip 45° N.....	3
2a. Gray sandstone and greenish arenaceous and argillaceous shale..... Very few traces of fossils were found in this bed. It is the horizon of fauna b4 and b5 of Matthew.	34
2b. Greenish argillaceous shale with a layer of sandstone 8 inches thick, and a little below, another layer of sandstone 4 feet in thickness. The sandstones are very hard, fine grained, and with fossiliferous phosphatic nodules near the bottom..... Fossils: This horizon carries the <i>Protolenus</i> fauna, fauna b3 of Matthew.	10
2c. Fine-grained dark-gray arenaceous argillites in layers 10 to 20 inches in thickness, that break up on exposure into irregular shaly layers. Strike E. and W., dip 25° N..... Fossils: <i>Protolenus</i> fauna, b2 of Matthew. About midway of the subdivision there is a layer of greenish-gray fine-grained sandstone 14 inches in thickness, in which numerous small phosphatic nodules occur in the lower 3 inches, with many fragments of fossils.	16
2d. Dark-green to grayish-green fine-grained compact, hard sandstone..... Fossils: Fauna b1 of Matthew.	18
3. Light-gray to white quartzitic sandstone in massive layers, the upper portion passing into greenish-tinted quartzitic sandstone.....	30+

The section from the quartzite downward for a distance of nearly 300 feet on the surface is entirely concealed. The highest beds of the subjacent Lower Cambrian are exposed at the upper end of the mill pond, where they have a strike of N. 60° E., dip 20° NW.

Lower Cambrian downward:	Feet.
1a. Estimated thickness concealed beneath the "St. John quartzite".....	136
1b. Massive-bedded dark purplish-colored arenaceous shales and sandstones. Toward the lower portion a few calcareous nodules appear in the shales..... Strike in upper beds, N. 60° E., dip 20° NW. In beds 215 feet below summit, strike N. 70° E., dip averaging 20°-25° NW.	320

Lower Cambrian downward—Continued.		Feet.
1c. Reddish and greenish arenaceous and argillaceous shales and thin-bedded sandstones, with a few thin interbedded calcareous sandstones. Strike N. 65° E., dip 35° to 40° NW.....		30
Fossils: In a thin reddish-brown, slightly calcareous sandstone occur great numbers of a slender species of Hyolithes that resemble <i>H. communis</i> . Just below it I noted, in a hard, very fine grained, compact sandstone, specimens of Coleoloides like <i>C. typicalis</i> and a large <i>Iphidea labradorica?</i> This appears to be the horizon of the Hyolithes limestone fauna of the Smith Sound section of Newfoundland. Unfortunately the sediments are of a type in which fossils are rarely found well preserved.		
2. Reddish-purple conglomerate in fine sandstone matrix. White quartz and reddish and greenish siliceous pebbles occur, some of which are from 2 to 6 inches in diameter. Strike N. 65° E., dip 40° NW.....		31
3. Reddish-purple to grayish-purple fine-grained sandstones, passing into flaggy gray and greenish-gray micaceous sandstone, interbedded with thick layers of sandstone.....		395
About 120 feet down a few layers of white quartz pebbles appear in the dark sandstone, and at 175 feet down broad annelid trails were seen on the smooth surface of a thick layer of sandstone.		
The dip decreases from 40° at the top to 30°, and then 25° at the base, where the strike is N. 55° E.		
At this point the upper beds of the basal conglomerate outcrop on the south side of the brook, but they are cut off a few feet down by a fault that brings up some of the beds of No. 3 of the section, and possibly No. 1c. On the north side of the brook a syncline and fault expose a considerable portion of No. 3 of the section. Up the brook the basal quartzite appears again beneath the sandstone of No. 3, from which it extends nearly to the contact with dark pyroclastic andesitic rocks of the Algonkian.		
4. Rather coarse siliceous, massive-bedded conglomerate, formed of white quartz, jaspery reddish and greenish-colored pebbles. The upper 8 feet has a light-gray color that passes below to a purplish tint.....		128
Total of Lower Cambrian.....		1,040

The contact with the Algonkian rocks is not seen, the base of the conglomerate being considered as near the last angular boulders of the conglomerate seen in the bank, a little distance below the outcrop of Algonkian rocks.

In connection with the discussion of the Etcheminian, Walcott⁸⁵⁷ published the following general classification of Cambrian formations:

Classification of the Cambrian formations.

		Lower Calciferous.	Lower portion of the Calciferous sandrock of New York and Canada; Lower Magnesian limestone of Wisconsin, Missouri, etc.
Cambrian.	Upper Cambrian.	"Potsdam" [Saratogan].	<p style="text-align: center;"><i>Type.</i></p> <p>Sandstones of the north and east sides of the Adirondack Mountains of New York and adjoining parts of Canada.</p> <p style="text-align: center;"><i>Correlated.</i></p> <p>Limestones of the south side of the Adirondacks and Dutchess County, New York, and an unknown portion of the limestones of the "marble belt" of western Vermont. Shales of Tennessee (Knox), Georgia, and Alabama (Conasauga). Sandstones of the upper Mississippi Valley (St. Croix), South Dakota, Wyoming, Montana, and Colorado. Sandstones and calcareous beds of northern Arizona (Tonto) and central Texas (Katemcy). Limestones and shales of Nevada (Hamburg), Idaho, and Montana (Gallatin). Black shales of the upper portion of the New Brunswick and Cape Breton Island sections. Shales and sandstones of Conception Bay, Newfoundland (Belleisle).</p>
	Middle Cambrian.	Acadian.	<p style="text-align: center;"><i>Type.</i></p> <p>Shales and slates of eastern Massachusetts (Braintree), New Brunswick (St. John), and eastern Newfoundland (Avalon).</p> <p style="text-align: center;"><i>Correlated.</i></p> <p>Limestones of Dutchess County, N. Y. (Stissing), and central portions of Tennessee and Alabama sections (Coosa). Limestones of central Nevada and British Columbia (Mount Stephen).</p>
	Lower Cambrian.	Georgian.	<p style="text-align: center;"><i>Type.</i></p> <p>Shales and limestones of western Vermont (Georgia) and Red sandrock.</p> <p style="text-align: center;"><i>Correlated.</i></p> <p>Quartzite of western slope of Green Mountains ("Granular quartz") and Appalachian Range of Pennsylvania, Virginia, Tennessee (Chilhowee), Georgia, and Alabama. Shales with interbedded limestones and roofing slates of southern Vermont, New York, and south to Alabama. Limestone, sandstone, and shales of Straits of Belleisle (Labrador), northwest coast of Newfoundland, and peninsula of Avalon (Placentia). Basal series of Hanford Brook section, Caton's Island, etc., New Brunswick (Hanford). Shales and limestones of eastern and southeastern Massachusetts (Attleboro). Lower portion of Eureka and Highland ranges, Nevada (Prospect). Portion of Wasatch Cambrian section (Cottonwood). Base of Castle Mountain limestone, British Columbia (Castle Mountain).</p>

In 1904 Matthew⁵⁸¹ published the results of his studies of the Cambrian of Cape Breton. He gives detailed sections and diagrams and presents a revised classification with the following comments:

In consequence of the finding of trilobites, brachiopods, etc., of Cambrian genera in the Etcheminian strata, and for reasons given below, the writer proposes to revert to the classification of 1889, wherein these deposits are called the Basal series (of the Cambrian system).

It has been found that slates with fossils of Cambrian genera are included in the important group of volcanic rocks which lie at the base of the Etcheminian, and that where the dip of the

volcanics can be found, as is not infrequently the case, it agrees with that of the Etcheminian. It is thought therefore that those volcanics (the Coldbrook group) should be included in the Basal Cambrian.

Both in New Brunswick and in Cape Breton the Coldbrook group begins with lavas showing deposition free of pressure, as they are amygdaloidal; or with agglomerates devoid of evidence of marked aqueous wear. The deposition therefore did not begin in deep water, or on exposed sea coasts, or under heavy pressure. The foundation upon which the volcanics rest shows in several places marks of deep subaerial decay at the line of contact. Calcareous bands are dissolved, leaving the siliceous portion of the strata. The feldspar of the granitic rocks is kaolinized and the magnesian silicates are hydrated, impure graphite beds are changed to a black amorphous crumbling shale, and a depression or narrow valley is usually found at the contact of the two terranes. These conditions appear to indicate that the pre-Cambrian complex had long been above the sea level in these districts when the first Cambrian effusives were thrown out upon it.

Another point worthy of note in this connection is the large amount of feldspathic material in the Etcheminian beds; the very sands are often composed of feldspathic grains, and these largely of nonkaolinized feldspar, as though they had not been exposed to subaerial decay. Feldspar in this condition is found in two kinds of deposits, those that are the result of glacial wear and those found around volcanic vents, where particles of rock have been torn from the walls and blown out upon the surface of the earth. These if dropped into the sea would soon be covered up by fine mud and preserved in their original crystalline condition. The Etcheminian appears to represent largely the submarine condition of such effusive rocks. On the other hand, the Coldbrook series, as has been intimated above, represents the preceding subaerial phase of the eruptives. It is true that we find in many places conglomerates at the contact of these two series of rocks, thus diverse in appearance; but elsewhere there are no beds of rolled fragments at the contact, and the passage is direct from ash beds or diabases to the slates and sandstones. In reports of the Canadian Geological Survey of 1870-71, pages 57-59, etc., relating to the province of New Brunswick, both these groups of rocks have been included in the Huronian system. They may be equivalent in age to the upper part of that series, but unfortunately the absence of fossils in the original Huronian leaves this matter in doubt.

As we contemplate the physical conditions of the initial epochs of Cambrian time in the Maritime Provinces, we seem to see a region long elevated above the sea, now subjected to depression nearly to the sea level, the depression being accompanied with extrusion of lavas and volcanic mud and the ejection of stones and ashes. These at first were cast upon a land surface, but, as the crust of the earth continued to sink, it was covered by the sounds and bays of a shallow sea, diversified with pre-Cambrian ridges and islands, of greater or less extent.

For the above reasons, as well as because the stratified rocks of the underlying complex are markedly unconformable to the Cambrian, the volcanics are thought to belong to the latter, and to give the natural base of this system.

The accompanying table will then show the classification of the Cambrian system, as seen in the Maritime Provinces of Canada.

Base of the Paleozoic rocks in the Maritime Provinces of Canada.

Groups and kind of rocks in Cape Breton.	Canadian reports.	European writers.	Maritime Provinces.	Leading genera of the several groups.	English equivalent.
3. Dark-gray and black carbonaceous shales, often changed to slates; a few thin seams and lentils of dark limestone, and some thin flags.	St. John group of Canadian geological reports.	Primordial (Cambrian).	Lower Silurian.	e. Harpes, Trinucleus, in northwestern New Brunswick. d. Cyclognathus, Paraholinella, Tetragraptus, Didymograptus, in southern New Brunswick.	Llandeilo.
2. Micaceous gray slates, flagstones, and quartzites. Iron bearing in Mira Valley, Cape Breton.			Ordovician.	c. Asaphellus, Parabolina, Triarthrus, Bellerophon.	Arenig.
1. Dark-gray slates or shales with calcareous lentils. Gray sandstones. Internoded conglomerates at and near base.			3. Bretonian division.	c. Dictyonema, Monoholina, Schizambon, Acrotreta. b. Peltura, Sphaerophthalmus, Leptoplastus, Ctenopyge. a. Parabolina, Agnostus, Anomocare, Orthis, in southern New Brunswick.	Tremadoc.
1. Dark-gray slates or shales with calcareous lentils. Gray sandstones. Internoded conglomerates at and near base.	St. John group of Canadian geological reports.	Cambrian.	2. Johannian.	c. Agnostus, Lingulella. (Place of Olenus.)	Ffestiniog and Maentwrog.
3. Fine greenish-gray argillites, some reddish gray. Horizon of roofing slates in Cape Breton and Newfoundland.			1. Acadian.	b. Paradoxides, Beyrichia, Lingulepis. a. Obolus, Lingulella, Lingulepis. d, e. Paradoxides, Solenopleura, Ptychoparia, Microdiscus. c. Paradoxides, Conocoryphe, Liostracus, Agnostus. a-b. Protolenus, Ellipsocephalus, Beyrichona, Trematobolus, in southern New Brunswick.	Menevian.
2. Red sandstone and red and gray argillite. Lower iron-bearing horizon of Cape Breton Cambrian.			3. Upper.	Solenopleura?, Ostracoda, 4 genera. Acrothele, Lingulella, Obolus, Acrothyra, Hyolithes.	Solva.
2. Red sandstone and red and gray argillite. Lower iron-bearing horizon of Cape Breton Cambrian.	Huronian of New Brunswick in part.	Sparagmite formation, Norway.	Etcheminian.	2 and 1. Lower.	Caerfai.
1. Gray shale or slate with some quartzite and conglomerate, the latter especially at the base.			3. Upper.	Holasaphus, paradoxidoid trilobite, Ostracoda, Billingsella, Lingulella, Acrothyra, Obolus, Hyolithes. Lingulepis, Leptobolus, Obolus, Lingulella, Acrothyra, Acrotreta, Hyolithes.	
Co. Dolerites, breccias, and amygdaloidal ash rocks. Some gray shales about middle.	Huronian of New Brunswick in part.	Basal Cambrian (mihi).	Coldbrookian.	Obolus, Lingulella, Lingulepis, Acrothyra, Acrotreta, Leptobolus, 2 Ostracoda.	Pebidian.

L-Q 10-21. CANADIAN SHIELD.

Throughout the region covered by the Canadian Survey there occur areas of unfossiliferous clastic, usually sandy formations (the Athabaska-Nastopoka series), which rest unconformably on the metamorphosed or disturbed pre-Cambrian rocks and are themselves but little disturbed. They have been described as "Cambrian" by the Canadian Survey, but are now believed to be older than the *Olenellus* fauna, and consequently to belong to the late pre-Cambrian, according to the classification in this paper.

M 19-20. GASPE PENINSULA.

The Cambrian ("Quebec group") is poorly exposed on the Gaspé Peninsula but is described by Logan^{544k} as follows:

Below the Magdalen, the breadth of the formation has been ascertained by transverse sections in two places only; one of them being at the Great Pond River, where it is about 2 miles, and the other at Griffin Cove, where it is less. Approaching Cape Rosier the breadth gradually diminishes; and the Hudson River strata finally disappear under the waters of the Gulf, at Anse a la Tierce. The remainder of the distance to Cape Rosier is occupied by the gray calcareous sandstones, red shales, and limestone conglomerates of the Quebec group.

In the Great Pond section also the rocks which succeed to the Hudson River strata belong to the Quebec group, and they prevail for a breadth of about 11 miles, before becoming covered up by the Upper Silurian limestones. Two miles in the middle of this section are occupied by sandstones of the Sillery series, with the red shales which usually accompany them. The dips on both sides of the area occupied by these sandstones are to the southward; the inclination on the north side being 51° and that on the south side 64°. It is probable, however, that the strata are arranged in a synclinal form, and that those on the south side are inverted; the general synclinal probably contains several subordinate undulations of a similar character. The rocks on each side of the sandstone appear to belong to the Levis formation; some of the masses on the south side resemble the magnesian conglomerate bands of Point Levis. * * *

On the section from Griffin Cove, at the distance of 2 miles southwestward from the coast, about one-eighth of a mile is covered with large angular fragments of greenish sandstone, some of which are fine conglomerates, with quartz pebbles as large as peas. None of this rock has been seen in place; but the abundance and angularity of the fragments leave little doubt that the beds can not be far removed. The position of the fragments may therefore be assumed as that of the Sillery sandstones, particularly as they occur in what would be a continuation of the axis of the Sillery synclinal on the Great Pond section. Between the position of these sandstones and the Hudson River strata on the coast there would be room for the rocks of the Levis formation, but none of them have been there observed. * * *

Between Cape Rosier and the base of the Gaspé limestones a sudden turn in the coast gives a natural section, nearly at right angles to the strike, of 2¼ miles in length. The coast is low and shelving, and the violence of southeastern storms has heaped upon it a great mass of gray limestone shingle, which covers nearly the whole of it, with the exception of three points. One of these is Cape Rosier itself, where a breadth of 450 yards of the strata, including what are seen between high and low water marks, is exposed. The strata consist of gray limestones, in beds varying from 6 inches to a foot in thickness, with two thicker conglomerate beds, made up of gray limestone pebbles in a calcareous matrix, very much resembling the conglomerates of Ste. Anne des Monts, the whole interstratified with black and gray shales. Separated from the strata of the cape by an interval of 1,000 yards, covered by limestone shingle, there occur, at the next point exposed, gray, yellow-weathering limestones, probably magnesian, interstratified with jet-black and gray shales, with a band of conglomerate or brecciated limestone on the northeast side. The distance across the strata is about 800 yards; but there are intervals of concealment in it, making up 300 yards of the amount, and, though the dip is pretty uniform in direction to the southwest, there are variations in the inclination, which ranges from 44° to 60°. Another interval of concealment occurs, of about 1,000 yards across the measures; but a

partial exposure at the end of the distance shows a continuation of the same alternation of shales, limestones, and sandstones. Red, purple, black, and olive-green shales succeed, associated with gray sandstones; some beds fine grained and close in texture and others coarse, with transparent quartz, silvery mica, white feldspar, and very minute bright green grains, probably of glauconite. A few thin layers of black bituminous limestone are interstratified among the shales. Several corrugations are visible in a low cliff, in which these beds are exposed; but the measurement across the shales is about 350 yards, and the dip, which is southwestward, varies in inclination from 26° to 90°.

Between these beds and the base of the Gaspé limestones there is a distance of about 800 yards across the shales, but the strata are only obscurely seen at intervals at the beginning and end of the measurement. The strike appears to be uniform, being N. 62° W.; but only the extreme edges of the beds are anywhere seen, and the dip is sometimes to the one side and sometimes to the other, at inclinations varying from 50° to 90°. The strata consist of black shales and thin limestones, which become somewhat arenaceous toward the south side; and the last beds, seen immediately in contact with the overlying Gaspé limestones, are of jet-black shale, yielding a black powder.

M 21. NORTHERN NEWFOUNDLAND.

Logan^{544y} described the lower Paleozoic strata of northern Newfoundland under the headings "Potsdam group" and "Quebec group." He first recognized sixteen divisions and later reclassified them under letters. He says:

In the ascending section of the Labrador and Newfoundland rocks the divisions were arranged under the numerals 1 to 16. Some of these divisions have since been remeasured in greater detail than before; while with respect to others, the examination of their equivalents in other localities has shown that these divisions include additional strata. In giving these farther results, it will be convenient to designate the divisions by letters, and to indicate the subordinate parts of each by numerals. To facilitate a comparison of the present results with those stated in the previous chapter, a summary of the section already referred to is here given, with the former numerals, but having the letters now to be used, prefixed. The thickness formerly assigned to these divisions, and the localities in which they were observed, are also appended.

The preceding summary represents Logan's conclusions in assembling the results of his observations. The measured sections are given by him in detail and may be abstracted as follows:

Between 1 and 2 miles inland from the northeast side of the East Arm of Bonne Bay [northern Newfoundland] there arises a range of hills of Laurentian gneiss, 2,000 or 3,000 feet in height, on the flank of which is exposed the following measured section:

	Feet.
A.	
1. Blackish-blue fine-grained slate. Of this slate only 105 feet of the upper part are seen; the lower part is concealed in the space between the upper portion and the gneiss and may comprise a thickness of about 230 feet.....	335
2. Blackish-blue slate interstratified with gray quartzites, in beds of from 6 inches to 3 and 4 feet. In the 80 feet at the bottom the quartzites greatly predominate, and they constitute 15 feet at the top, while the intermediate 175 feet consist chiefly of slate.	270
	605
	605

B.	
1. Light-gray, yellow-weathering limestone, in beds of from 1 to 3 inches thick, interstratified with blackish-blue, slightly calcareous slate, both containing small specks of silver-white mica, which are more abundant in the limestone than in the slate. The limestones hold in abundance fragments of trilobites, chiefly belonging to three or four species. Among them is <i>Paradoxides (Olenellus) vermontana</i> , a new species of Bathyrurus, and the pygidium of a species so closely resembling <i>B. extans</i> of the Birdseye and Black River formation that it can scarcely be distinguished from it and may possibly be the same.....	80
2. Grayish-green micaceo-arenaceous shale, interstratified with a few beds of grayish quartzite weathering slightly yellow.....	80
3. Strata concealed.....	30
4. Reddish granular quartzite in thick beds.....	105
5. Gray and grayish-green micaceo-arenaceous shale in beds from a quarter of an inch to an inch thick, interstratified with a few beds of gray, very ferruginous sandy dolomite and fewer of gray quartzite.....	127
6. Reddish quartzite, in beds of from 1 to 2 feet thick.....	34
7. Gray arenaceous dolomite, weathering yellowish brown, interstratified with reddish quartzite, in beds of from 1 inch to 1 foot thick, and with reddish and grayish micaceo-arenaceous shale, predominating toward the top. The beds of dolomite and shale contain fossils, among which are <i>Obolella chromaticea?</i> , <i>Obolus labradoricus</i> , <i>Paradoxides vermontana</i> , <i>Conocephalites</i> , a new species of Bathyrurus, and one or more undetermined species of <i>Salterella</i>	27
	483
	483

C.	
1. Whitish quartzite in beds of from 6 inches to 2 feet, interstratified with light-gray micaceo-arenaceous shale, in layers of from 6 inches to 1 foot, which occur at intervals of from 5 to 10 feet.....	150
2. White and reddish quartzite, in beds of from 1 to 3 feet thick, interstratified toward the bottom with a gray arenaceous dolomite, weathering yellowish brown.....	160
3. White and reddish quartzite, in beds of from 1 to 3 feet thick, interstratified with greenish micaceo-arenaceous shale, constituting about one-half the amount.....	90
4. Gray pure limestone, in beds of from 1 to 3 feet thick, marked with a few reticulating strings of yellowish-weathering dolomite. The rock is a mass of comminuted organic remains, among which are <i>Paradoxides vermontana</i> and undetermined species of Bathyrurus and <i>Salterella</i> , as before.....	20
5. Blackish-blue soft shale, interstratified with gray, yellow-weathering limestone, probably magnesian, in beds of 1 or 2 inches thick. The quantities of shale and limestone are about equal, and the whole is intersected by reticulating strings of calc spar.....	35

	Feet.
6. Gray pure limestone, composed of comminuted organic remains, belonging to Paradoxides, Bathyrurus, and Salterella, as before.....	27
7. Bluish-black soft shale, interstratified with gray, yellow-weathering dolomitic bands, as before.....	60
8. Gray pure limestone, probably composed of comminuted organic remains as before; underlaid by bluish-black shale inclosing nodules of blue compact limestone; some of which weather yellowish-brown, and are probably magnesian.....	13
9. Bluish-black soft shale of the same character as before, interstratified with a few beds of quartzite.....	68
	623
	1,711

The summit of the above section occurs on the east side of Deer Brook Bay, on the East Arm of Bonne Bay, and its base about 6 or 7 miles up the East Arm from the mouth of Deer Brook. All of the beds can be seen coming to the coast in succession, with a westward dip, and an inclination of from 20° to 60°. Where the beds of the base were observed, the measures appear to fold over an anticlinal axis, and for about 100 yards they dip to the eastward. For 2 miles beyond this, along the east side of East Bay, the greatest confusion prevails, and nothing reliable in regard to the sequence can be obtained from the exposures. East Bay and West Bay are two deep southward parallel indentations of the coast, which form the extremity of the East Arm. The area between them is from 1 to 2 miles wide, and the strata in it appear to lie in the form of a synclinal. The axis of this synclinal would run about north and south, and in the former direction it would strike to the eastward of the anticlinal just mentioned as occurring on the north side of the East Arm, while the axis of this anticlinal would strike into West Bay. The distance across the East Arm, on the axis of the synclinal, from the position where the lowest beds of the section above given would come upon it to the position where it would be crossed by the lowest beds between East and West bays would be about the same as that occupied by the whole section between the Laurentian gneiss and the coast of Deer Brook Bay. On the west side of this bay there occur some limestones of a peculiar color and character, whose stratigraphical place would be a few hundred feet above the highest beds in the section just given. About the same distance above the base of the strata between East and West bays similar limestones occur; and there is therefore not much doubt that the strata between these bays come in immediate or proximate sequence to those already given in section C. These additional strata are as follows:

C—Continued.

	Feet.
10. White quartzite, in beds of from 2 to 3 feet thick, interstratified with striped olive-drab and black compact arenaceous magnesian brown-weathering limestone, which constitutes one-fourth of the mass and holds small disseminated masses of iron pyrites.....	58
11. Strata concealed.....	150
12. Blackish-gray limestone; it is divided into beds of from 2 to 8 inches, and under the influence of the weather breaks up into thin scales.....	54
13. Smoke-gray compact pure limestone, striped with ochre-yellow arenaceo-ferruginous limestone, passing into brick-red. The gray and yellow alternate in lenticular layers, varying in thickness from a quarter to half an inch, and the rock presents a very peculiar and striking aspect. The yellow and red colors may be the effect of weathering, but in breaking up the rock the same alternation of these with the gray limestone was apparent in the interior. Rock of the same character occurs on the west side of Deer Brook Bay.....	30
14. Olive-gray, brown-weathering ferruginous sandy dolomite, containing thin lenticular patches and thin beds of pure smoke-gray limestone, with disseminated cubes and small masses of iron pyrites.....	17
	309
	309

D.

1. Greenish-white and yellowish-white magnesian limestone, in massive beds, some of which are ferruginous and weather buff, while others remain unchanged in color. They are interstratified with beds of ash-gray limestone, weathering yellowish, and near the middle with two bands of gray calcareo-arenaceous shale, one of 2 and the other of 3 feet thick. These massive limestones terminate in a 4-foot bed of smoke-gray pure limestone in thin layers, interstratified with thin layers of probably magnesian limestone, weathering ocher-yellow. The bed, for the thickness of a foot, is arranged on the strike in a series of curves or arches, which span from 2 to 3 feet, separated by straight intervals, varying from 1 to 2 feet. The curved portions appear to hold a greater number of the yellow-weathering layers than the straight parts, and these layers have in general a lenticular form. The top and bottom of the bed are arranged in even layers, which fill up the inequalities of the intermediate part.....

Feet.

174

483

The surface between East and West bays rises into a mountain of 500 or 600 feet in height, in which the strata dip in directions conforming to their synclinal arrangement, at angles varying from 12° to 25°. Proceeding southward along the east side of West Bay, they are seen to accumulate above one another to the amount of 1,400 feet, in addition to the preceding section. These higher strata consist almost entirely of limestone of various shades of gray, with two or three bands of black, the latter usually thin bedded. Of the lowest 200 feet, about two-fifths weather to various shades of yellow and brown; of the succeeding 300 feet the proportion of yellow-weathering beds is about one-sixth, and in the remaining 900 feet they are but few. If these yellow-weathering beds are, like the similar ones in the detailed section just given, magnesian, it would appear that the proportion of magnesia gradually diminishes in ascending this portion of the series. In the whole of these 1,400 feet, which are supposed to represent the divisions E, F, G, the only strata in which fossils were observed occur at about 400 feet from the top; where the surfaces of various beds, in a thickness of between 10 and 20 feet, are marked by the weathered-out forms of silicified fossils, consisting of undetermined species of *Pleurotomaria* and *Ophileta*.

From West Bay the strata strike, in a general way, along the coast to the westward; they are much contorted and it is difficult to make out any true continuous succession of the beds. At the west horn of the bay, however, the whitish massive magnesian limestones of division D occur; and in the contorted strata for a couple of miles beyond the peculiarly striped smoke-gray and ocher-yellow thin-bedded limestones of C 13 are occasionally seen. At the promontory which faces the west horn of Deer Brook Bay the strata become vertical, or nearly so, but somewhat more regular; and the absence of any beds weathering yellow or brown appears to indicate a proximity to the horizon of the silicified fossils above mentioned. About 800 feet of dark-gray limestones are here exposed, at the summit of which there occurs a bed holding *Maclurea*, *Orthoceras piscator*, and *Leperditia*. Of the genus *Maclurea* the opercula were the only parts observed and these are silicified; but the bed is supposed to be higher in the series than the band with silicified fossils between East and West bays, inasmuch as it is immediately followed, not by the dark-gray limestones, but by about 200 feet of light-gray limestone; a good deal of which, although it does not weather yellow, is magnesian. The summit of these 200 feet is fossiliferous and contains undetermined or undescribed species of *Orthis*, *Ophileta*, *Maclurea*, *Nautilus*, *Amphion*, *Asaphus*, and *Leperditia*: The 800 feet are probably comprised in the divisions F and G, while the 200 feet may constitute a part of H.

The divisions M and N of the Newfoundland rocks have been, in a general way, described from exposures occurring at Table Head. The total thickness was here estimated from measurements by pacing, but few details were ascertained; and the fossils collected having been lost, from the necessity of abandoning them on the coast through stress of weather, it was considered expedient to reexamine the locality. The following detailed ascending section is the result. It commences between 600 and 700 feet lower than the strata comprised in the

division 'M, or 12, as previously given, and the lowest part of these additional strata are considered equivalent to some of those at Point Rich.

H.

	Feet.
1. Bluish-gray limestone in beds of from 1 to 2 inches, interstratified with gray subcrystalline yellow-weathering magnesian limestone in beds of from 3 to 6 inches thick. The beds are fossiliferous, containing the genera <i>Orthis</i> , <i>Ophileta</i> , <i>Maclurea</i> , <i>Pleurotomaria</i> , <i>Murchisonia</i> , <i>Orthoceras</i> , and <i>Bathyurus</i> . The described species are <i>Orthis electra?</i> , <i>Maclurea matutina?</i> , and <i>Orthoceras piscator</i>	100
2. Strata concealed.....	165
	265

Division I of Logan's classification was placed by Billings in the Chazy, with some doubt, and is described in Chapter IV, together with divisions K to P inclusive. (See pp. 211-217.)

Billings⁸¹ classified the faunas and arranged them in a catalogue. Commenting on their distribution and relations, he states:

POTSDAM GROUP.

In this group consisting of divisions A, B, and C, we have 19 species, none of which are found in the Potsdam sandstone in Canada. But in that part of the group, which is usually known, in the State of Vermont, under the designations of the Red sandrock and the Georgia slates, the following occur: *Scolithus linearis*, *Palæophycus incipiens*, *Obolus labradoricus*, *Obolella (Kutorgina) cingulata*, *Olenellus thompsoni*, *O. vermontana*, *Conocephalites adamsi*, and *C. teucer*. As these are the most abundant species in the formation, both in Vermont and Newfoundland, there can be little doubt but that the rocks in which they occur, in these two widely separated localities, are of the same age. * * * In the next overlying strata, division D, *Lingula acuminata* was found at Bay St. Barbes. I have compared the specimens from this locality with those that occur so abundantly in the upper part of the Potsdam in the township of Beverly, in Canada West, and believe them to be perfectly identical.

CALCIFEROUS FORMATION.

The Calciferous formation is represented in Newfoundland by all the divisions from D to H inclusive. In this series of strata there are 63 species, of which the following 14 are found in Canada and New York: *Stenopora fibrosa*, *Stromatopora rugosa?*, *Lingula acuminata*, *Euchasma blumenbachia*, *Pleurotomaria calphurnia*, *P. calcifera*, *P. laurentina*, *Murchisonia anna*, *Ecciliomphalus atlanticus*, *Orthoceras lamarcki*, *Piloceras canadensis*, *Bathyurus cordai*, *Asaphus canalis*, and *Leperditia turgida*. Excepting *S. fibrosa* and *B. cordai*, all of these occur in the true Calciferous in Canada. *B. cordai* abounds in the same formation in New York. *S. rugosa* is doubtfully determined and is probably distinct from the Black River species of that name. The beds in which *L. acuminata* occurs in Canada are placed in the top of the Potsdam; but as *Pleurotomaria canadensis* and an orthoceratite are associated with it, perhaps these particular strata should be more properly referred to the base of the Calciferous, and they would then correspond to division D. Most of the species are found in divisions G and H, the upper part of the formation in Newfoundland. Two of the species (*S. fibrosa* and *A. canalis*) range upward into the Chazy, the former continuing to the Upper Silurian. The general aspect of the fauna is peculiarly that of the Calciferous, the most striking features being the great numbers of small *Maclurea* and species of *Piloceras*, the latter a genus which seems to have culminated in this particular period.

M-N 11. ROCKY MOUNTAINS OF CANADA.

The stratigraphy of the Canadian Rockies was originally described by McConnell,^{559e} who distinguished the Bow River and Castle Mountain groups. Walcott⁸⁵⁹ has recently studied these rocks and divided them into several formations. He says:

Mr. McConnell proposed the name "Castle Mountain group" for the great series of limestones and shales between the quartzitic sandstones and siliceous shales of the "Bow River group" below and the superjacent Ordovician graptolitic shales on the west and Banff limestone on the east. This includes the upper portion of the Lower Cambrian fauna at the base and the lower portion of the Ordovician fauna at the summit. The term "Castle Mountain" is useful for the series, but I think that local names can be applied with advantage to several of the formations of the "Castle Mountain group" as originally defined. The following table^a gives the relative positions and thicknesses of the new formation names herein proposed and defined for the Canadian Rocky Mountain section:

Cambrian formations of the Canadian Rocky Mountains.

Formation.	Character.	Thickness (feet).		
		Mount Stephen.	Mount Bosworth.	Castle Mountain.
<i>Upper Cambrian.</i>				
Sherbrooke formation.....	Bluish-gray arenaceous, dolomitic, massive, and thin-bedded to shaly limestones, with a few oolitic layers and cherty inclusions.	0	1,360	0
Paget formation.....	Bluish-gray oolitic limestones, usually thin-bedded.	0	360	0
Bosworth formation.....	Arenaceous dolomitic limestones, massive, thin bedded, and shaly, with bands of purple and gray siliceous shales.	Not measured..	1,855	0
<i>Middle Cambrian.</i>				
Eldon formation.....	Massive arenaceous, dolomitic limestones, with a few bands of purer bluish-gray limestone.	Not measured..	2,733	2,195
Stephen formation.....	Limestones and shales, calcareous and siliceous.	562	640	366
Cathedral formation.....	Massive arenaceous and dolomitic limestone....	1,600-1,800	1,595	987
<i>Lower Cambrian.</i>				
Mount Whyte formation [a].....	Alternating bands of limestone and siliceous and calcareous shale.	315	390	248
St. Piran formation [b].....	Mainly gray quartzitic sandstones, with a few bands of siliceous shale.	300	300+	500+
Lake Louise formation.....	Siliceous shales.....
Fairview formation.....	Gray quartzitic sandstones.....

[^a In the book cited, through a typographical error, the Mount Whyte formation was placed in the Middle Cambrian in the table on page 2, but the fauna was recognized by Walcott as Lower Cambrian, and is so termed on page 4.]

[^b The St. Piran and the two underlying formations compose the upper part of the Bow River group. In 1910 Walcott found a conglomerate at the base of the "Fairview formation," recently renamed by him the Fort Mountain sandstone (Mon. U. S. Geol. Survey, vol. 51, 1912, p. 131), that marks an unconformity between it and the underlying part of the Bow River group, which is very much the thicker portion. He therefore regards the Bow River group as chiefly pre-Cambrian. (Personal communication.)]

^a The table as here printed is not an exact quotation but is made up from Walcott's paper.—B. W.

The following notes on the occurrence of Cambrian and Ordovician strata are quoted from Schei:^{550c}

At Cape Camperdown, on Bache Peninsula, is found granite overlain by an arkose-like conglomerate sandstone, in flat strata, the dip being north-northwest. Its thickness here probably does not exceed 500 feet, though the contour swells to considerably greater magnitude by reason of intrusions of diabase, occasioning an additional thickness of perhaps 300 feet. At its upper part this sandstone merges gradually, by interstratification, into a series of gray sandy and marl-like schists and limestone conglomerates. From a few inches up to a couple of yards in thickness these conglomerates and schists, continuously interstratified, build up a series 600 to 900 feet in thickness, interrupted by two compact beds of yellowish-gray dolomitic limestone about 150 feet in thickness. These again are overlain by a series similar to the underlying one, excepting that here the limestone conglomerates exceed the schists.

In a detached block, in all probability originating from one of the two 150-foot beds, were traces of fossils, of which one, *Leptoplastus* sp., can be identified. In another detached block, whose mother rock is not known, was found *Anomocare* sp. It may be said with certainty after the finding of these fossils that this series contains deposits of the Cambrian age.

The second series of conglomerates is overlain by a light grayish-white limestone in a bed some 300 feet in thickness, observed in the midst of the section of Cape Victoria Head. Indistinct *Orthoceras*, *Lichas*, and *Symphysurus* assign this limestone to the Lower Silurian period.

Above the *Orthoceras*-bearing light-colored limestone bed are some less extensive strata of alternating limestone and quartz sandstone, and finally a 100-foot bed of close brown limestone of which certain layers are fossiliferous and gave an *Asaphus*, traces of other trilobites, and some gastropods.

Following the direction of the dip to the north side of Princess Marie Bay we find it again, though seemingly somewhat abrupt, in the limestone beds of Norman Lockyer Island. A fauna with *Halysites* sp., *Zaphrentis* sp., *Orthisina* sp., *Rhynchonella* sp., *Leperditia* sp., *Illænus* sp., etc., assigns this limestone to Lower Silurian. It is again found with its fauna at the base of Cape Harrison; in this case with a thick superincumbent bed of marly sandstone, quartz sandstone, and finally extensive limestone conglomerate.

CHAPTER IV.

MIDDLE AND UPPER ORDOVICIAN.

Color, light bluish purple.

Symbol, 17.

Distribution: General throughout the continent. In the Arctic mapped with the Silurian; in the Rocky Mountains of the United States included in narrow bands of Cambrian and lower Ordovician.

Content: Early to uppermost Ordovician (Chazy to Richmond, inclusive).

Middle and upper Ordovician areas.

FIGURE 6.—Sketch map showing the distribution of middle and upper Ordovician rocks represented on the geologic map of North America and the key to references in the text.

H 13. TEXAS. * 1

In the Caballos Mountains, southern Texas, is exposed an area of Paleozoic rocks from which Udden⁸¹⁹ procured Ordovician fossils. Other Paleozoic formations are probably represented.

With reference to the Upper and Middle Ordovician in the district north and east of El Paso, Richardson^{668a} states:

The Montoya limestone also has been recognized by its stratigraphic position and fossils in both of the quadrangles [El Paso and Van Horn]. This limestone contains two distinct Ordovician faunas, the Richmond and Galena, and on paleontologic grounds it is desirable to separate the two, but the small thickness of the formation, only about 250 feet, and the scale of the maps will not admit of it.

Fossils characteristic of the Galena occur in the lower part of the Montoya limestone, the zone being commonly marked in the El Paso quadrangle by massive dark-colored limestone containing little or no chert. The upper part of the limestone is prevailing gray, but some of the beds are almost white while others are dark, and the two parts of the formation can not always be distinguished lithologically. The zone which carries the most abundant Richmond fossils in places is seamed with conspicuous bands of chert a few inches in thickness. In the Van Horn quadrangle the base of the Montoya limestone is commonly marked by the presence of thin-bedded earthy yellow and reddish limestone, but otherwise in both quadrangles the contact is apparently conformable. Like the El Paso limestone, the Montoya is characteristically magnesian. Mr. Ulrich has identified the following fossils from the Montoya limestone:

Fossils from the Galena beds.

Receptaculites oweni.
Maclurina manitobensis.
Maclurina acuminata.

Hormotoma major.
Ormoceras sp. undet.

Fossils from the Richmond beds.

Streptelasma rusticum.
Hemiphragma imperfectum
Monotryprella quadrata.
Strophomena flexuosa.
Leptaena unicostata.
Dinorthis subquadrata.

Dinorthis proavita.
Platistrophia acutilerata.
Rhynchotrema capax.
Orthis whitfieldi.
Parastrophia divergens.

In southwestern United States outside of the areas here considered few Ordovician rocks are known. The system apparently is not represented by sediments in either the Grand Canyon or Bisbee districts. The Longfellow formation in the Clifton quadrangle, Arizona, probably should be correlated with the El Paso limestone as well as a part of the Ordovician limestone in the central Texas region. Recently several small areas of Ordovician rocks have been reported in central New Mexico by Gordon and Graton.^a Mr. Ulrich reports that the Beekmantown fauna of the El Paso limestone is of the type prevailing in the Wichita Mountains, Oklahoma, in the upper 1,000 feet or so of the Arbuckle limestone; and that the Galena and Richmond faunas of trans-Pecos Texas are similar to those in the Mississippi Valley, Oklahoma, the Black Hills, the Bighorn Mountains, and elsewhere.

I 12-13. ARIZONA AND NEW MEXICO.

The interval corresponding to the Ordovician appears to be represented throughout most of Arizona only by a parting between two limestones containing Middle Cambrian fossils.^{657, 658a} These relations resemble those of the Grand Canyon section.

^a Am. Jour. Sci., 4th ser., vol. 21, 1906, p. 190.

Near the eastern boundary of Arizona, in the Clifton district,^{541a} the Longfellow limestone represents the early Ordovician ("Calciferous," Ulrich) and possibly some Upper Cambrian, but the later Ordovician is lacking.

The Ordovician of New Mexico is described by Gordon and Graton³⁷² as comprising the equivalent of the lower Ordovician and also limestones which carry a distinct Richmond (uppermost Ordovician) fauna. Fuller descriptions are given by Lindgren.⁵⁴²

I 14. OKLAHOMA.

In the Arbuckle Mountains of Oklahoma Ordovician strata are represented by the Arbuckle limestone (Upper Cambrian and early Ordovician; see pp. 82-83, Chapter III), the Simpson formation (of Chazy or Stones River age), and the Viola limestone (of Black River to Richmond age). Taff and Ulrich^{808a} give the following account of the stratigraphy and correlation:

After the Arbuckle limestone was deposited there was a general change in the nature of the sediments. The top of the limestone seems to have been slightly eroded locally and upon the surface were deposited beds of pure sand. At other places the Arbuckle limestone is overlain by shaly and impure lime—the basal beds of the Simpson formation. On these local sandy beds at the base there were deposited greenish shales and thin crystalline and shelly limestones interstratified with a number of beds of sandstone, making a total thickness ranging from about 1,200 to 2,000 feet.

A generalized section measured on the south side of the Arbuckle uplift gives the following beds:

	Feet.
Thin limestone and shale.....	890
Sandstone.....	100-200
Thin-bedded limestone and shale, with some sandstone.....	1,250

The sandstone separates the formation into two divisions, regarding which Taff and Ulrich say:

The fauna of the lower division of the Simpson formation is decidedly similar to that of the Chazy of New York and Canada and of the Pogonip formation of Nevada. Considering these east and west connections, it is surprising to note that the lower Simpson fauna, so far as known, contains none of the prolific fauna of the lower division (Murfreeseboro limestone) of the Stones River group in middle Tennessee, which is believed to be of equivalent age. As a whole, the fauna of the upper part of the Simpson is closely related to the upper division of the Stones River group in Tennessee and Kentucky and the equivalent beds in the upper part of the Mississippi Valley.

The description of the Viola limestone follows and comprises the items quoted below:

There is a gradual transition from the top of the Simpson formation up into the basal part of the Viola formation. The top layers of the Simpson are usually argillaceous, are thinner, darker, and more evenly stratified than those at the base of the Viola, and in places contain partings and beds of clay. The rocks at the contact on each side, however, vary somewhat in different parts of the field.

The Viola formation is a continuous but slightly variable deposit of limestone 500 to 700 feet thick, which usually appears massive on very fresh exposures. Upon weathering, however, the bedding is pronounced, showing layers rarely more than a foot in thickness. In the lower and middle parts especially there are occasional bands and nodular masses of chert.

The Viola limestone is divisible into three members, distinguished by variations in bedding, in texture, and to a less extent in the color of the limestone. The upper and middle members

are approximately 300 feet thick. The lowest member is somewhat thinner and more variable than the others. The lowest member consists of light-colored, coarse-textured, and usually roughly bedded limestone. It probably will not exceed 100 feet in thickness anywhere, and in places is much less.

The middle member consists of white to light-blue and generally even- and thin-bedded limestone. On account of the abundance of fossil trilobites of the genus *Trinucleus* in certain layers it might be known as the *Trinucleus* member. It is characterized by white surface where weathered and even bedding. * * *

An investigation of the fossils by Mr. Ulrich, who collected and studied the rock section, shows that there are three faunal divisions, which correspond to the three lithologic members above described. The most fossiliferous development of the basal member was noted at the extreme northern occurrence, in the region at the base of Double Mound, 6 miles northeast of Roff. A preliminary study of the fossils collected shows [a large number of species, nearly all of which] occur in *Phylloporina* and *Clitambonites* beds of the Ordovician section in Minnesota. These beds are correlated with latest Black River and earliest Trenton. Many of the species occupy these horizons in New York and Canada and what are regarded as equivalent positions in middle Tennessee and Kentucky.

As a whole the middle member or *Trinucleus* bed of the *Viola* limestone is not abundantly fossiliferous. The organic remains occur chiefly in three horizons, one near the base, another above the middle, and the third near the top. The first and second contain an abundance of graptolites. Next to the *Trinucleus* the graptolites are the most characteristic and commonest fossils of the middle member. The fossils indicate that the *Trinucleus* beds were deposited during the latter half of the Trenton age.

The upper member of the *Viola* limestone is approximately 300 feet in thickness, but only in the upper 25 feet is it abundantly fossiliferous. The lower 50 feet yielded no fossils. In the middle portion the fossils are not only rare but poorly preserved. The fossils are all species characterizing the upper divisions of the Richmond age in Minnesota, Wisconsin, Illinois, Indiana, and Ohio. In northern Arkansas the same fauna occurs in the Polk Bayou limestone and in middle Tennessee in the Fernvale formation.

I 15. ARKANSAS.

Purdue⁶⁵⁵ has recently published the results of studies of the stratigraphy of the Ouachita Mountains, in Arkansas, as worked out by himself and Ulrich:

	Feet.
Carboniferous: Stanley shale.....	6,000
Unconformity.....	
Age unknown:	
Fork Mountain slate.....	100
Arkansas novaculite.....	800
Missouri Mountain slate.....	300
Probable unconformity.....	
Ordovician:	
Blaylock sandstone.....	1,500
Polk Creek shale.....	100
Bigfork chert.....	700
Stringtown shale.....	100
Unconformity.....	
Ouachita shale.....	900
Crystal Mountain sandstone.....	700
Probable unconformity.....	
Age unknown: Collier shale (observed thickness).....	200
	11,400

The Collier shale was considered by the Geological Survey of Arkansas as of Lower Silurian (Ordovician) age.^a Some of the older rocks above this shale are certainly of Ordovician age, as

^a Geol. Survey Arkansas, vol. 3, 1890.

is shown by the fossils they contain; and the Crystal Mountain sandstone, the formation immediately above, is considered Ordovician on lithologic grounds. But careful search has failed to reveal any fossils in the Collier shale, nor has it any lithologic characters that would give it claim to an age classification with the overlying rocks. On the other hand, it is quite different from the rocks above, and at its top there is at least locally a conglomerate which future study may determine to be widespread. For these reasons, it is thought best not to even provisionally place this with the Ordovician. It may be Cambrian. If so, these are the oldest outcropping rocks in the State. * * *

It is a dark, soft, graphitic clay shale, containing widely separated thin beds of dense black and intensely fractured chert. As a result of the severe squeezing and shearing it has undergone practically all traces of bedding have disappeared. It is intensely crumpled and is full of glossy, slickensided surfaces. In places slaty cleavage may be observed. The upper 100 feet or more is quite calcareous, limestone occurring in dark-colored crystalline lenses and layers one-half inch or more in thickness, distributed through the shale. In other parts the limestone is several feet in thickness and occurs in much contorted layers from a few inches to more than 2 feet thick, interbedded with thin seams of graphitic shale. In such cases the limestone is dark and compact, is much jointed, and on long exposure weathers in very uneven surfaces. * * *

The rocks of known Ordovician age within the Ouachita Range include five formations, which are here known as the Crystal Mountain sandstone, the Ouachita shale, the Stringtown shale, the Bigfork chert, the Polk Creek shale, and the Blaylock sandstone.

The Crystal Mountain sandstone consists of two parts—a lower massive one composed wholly of sandstone, 300 feet thick, and an upper part consisting of rather massive layers of sandstone interbedded with black to gray shale, 400 feet thick. The shale is in places altered to ribboned slate, like the lower part of the Ouachita shale. The lower part is the main rock of the Crystal Mountains, which owe their existence to this massive, slow-weathering formation. It is a coarse-grained white sandstone, composed of well-rounded grains, and commonly weathers to the color of brown sugar. In many parts it is thickly set with a network of quartz veins from the thickness of a knife blade to several inches. In other parts there are fissures from several inches to several feet in width, the walls of which are lined with magnificent clusters of quartz crystals. * * *

This formation has not to the present time produced any fossils, and it is considered of Ordovician age wholly on lithologic grounds. The sandstone passes gradually into the Ouachita shale above, and the close resemblance of the included shale beds to the Ouachita shale seems to the observer in the field conclusive evidence that the two are of the same age.

The Ouachita shale is the next formation above the Crystal Mountain sandstone, into which it passes by gradual increase of sandy layers. * * * The formation is intensely crumpled, and for that reason its thickness has not definitely been made out, but it probably is not less than 900 feet.

For the most part this is a dark-colored clay shale, but not uncommonly the dark layers alternate with green ones. In many places slaty cleavage is developed, when the alternating layers of dark and green produce ribboned slate. Somewhere in the lower portion there are thin layers of limestone, interbedded with the shale. Quartz veins and thin layers of hard flinty material are common, and fragments of quartz frequently occur on the ground where this is the surface rock. The shale is frequently dissected by straight, well-defined joints. Graptolites, while not so common as in the shales above, are frequently to be found.

The Stringtown shale in Arkansas rests unconformably upon the Ouachita shale and is from 75 to 150 feet thick. It consists of two parts, a lower calcareous part and an upper shaly part. The lower part of the formation contains lenses of bluish compact brittle limestone, usually thickly set with calcite veins. The basal portion of this is sometimes conglomeratic, the pebbles ranging from the size of peas to 2 inches in diameter and subangular. They consist of shale, very fine grained brown sandstone, and limestone. * * *

The maximum observed thickness of the limestone lenses is about 75 feet. They are made up of layers from a few inches to 2 feet in thickness and they may thin down to a few feet or entirely disappear, within very short distances. The rapid thickening and thinning of the limestone, its sporadic occurrence, the conglomerate it contains, and the lithologic difference between the shale of the formation and that beneath led to the conclusion in the field that there is an unconformity between the two formations, which afterward was confirmed on paleontologic evidence by Mr. E. O. Ulrich. The irregular occurrence of the limestone is due to its having been put down in the valleys of the old land surface, and the pebbles of the conglomerate at the base of the limestone doubtless were carried in by the streams flowing over that surface.

The upper or shale portion of the formation usually is from 50 to 75 feet thick. It is a very black shale and is soft enough to soil the fingers in handling, qualities due to the presence of a large per cent of finely disseminated graphite. In places the graphite is conspicuous and occurs in thin, wavy sheets. While most of this part of the formation is shale, there sometimes occur in it, especially near the top, thin beds of dark-colored chert, very similar to the Bigfork chert, next to be described, as well as thin layers of limestone. Some of the shale layers are quite calcareous, and when the lime is dissolved out from these, there remains a gray to pink colored porous, spongy shale, fragments of which are frequent on the slopes. Fossil graptolites abound in the shale of this formation and occur sparingly in the limestone.

The Bigfork chert is a very close textured, even-bedded siliceous rock, in layers from 1 to 18 inches thick, but the most common thickness is from 3 to 6 inches. * * * The color varies from a slate to a dark gray, the former being most common. It is very brittle and under the blows of the hammer flies into small pieces. The fracture is angular, in some of the layers approaching conchoidal. In places it is thickly set with a network of fine quartz veins. It is along these veins that the stone breaks when struck with a hammer, and so numerous are they that it often is difficult to secure a hand specimen with fresh surfaces. Straight joints several inches in length with remarkably smooth surfaces are common. Weathered portions have the appearance of fine-grained gray weathered sandstone. Usually the layers are crumpled to an astonishing degree, and it probably was the strain accompanying this intense folding that caused the network of thin joints, which subsequently were filled with quartz, forming the veins above described. Its thickness is about 700 feet.

This formation is mapped by the Geological Survey of Arkansas ^a as novaculite, but it differs materially from the true novaculite of the area in being of a coarser texture, darker color, thinner bedded, not translucent, older, and in having a much more complex structure.

The Polk Creek shale overlies the Bigfork chert, with which it is conformable, and outcrops along the bases of many of the ridges in the Ouachita Range. In color, hardness, and texture this shale is much like the Ouachita shale. It resembles that also in containing a large number of quartz veins and locally in having slaty cleavage well developed. In this, as in the Ouachita shale, graptolites abound. It differs from that shale in containing no sandy or calcareous layers and in being only about 100 feet thick. In places it appears to be absent.

The Blaylock sandstone is well exposed at the eastern end of the mountain, where the Little Missouri River cuts across the exposed edges. Like the other formations described, it is extremely crumpled. The repetition of beds resulting from the crumpling renders its thickness difficult to determine, but this is thought to be about 1,500 feet in the thickest part. Apparently it is conformable with the Polk Creek shale beneath. In parts, through a hundred feet or more, it consists almost wholly of sandstone, while in other parts it is made up of alternating beds of sandstone and shale. The sandstone is in layers that usually are from 1 to 6 inches thick, and the bedding is very even. Some of the layers are quite quartzitic and contain numerous thin quartz veins. Others of the thin layers closely resemble chert. It is fine grained to medium grained, and varies from dove-colored to dark gray or green. Graptolites occur in it rather sparingly. The interbedded shale is dark colored, often black, and fissile. In places it contains large numbers of graptolites.

^a Geol. Survey Arkansas, vol. 3, 1890.

The exact stratigraphic relations of this formation are not at present understood. The only area in which it has been carefully studied is in the southern part of Montgomery and Polk counties, where it outcrops over an east-west belt about 3 miles wide, and from which it thins northward until it is only a few inches to a few feet thick where it outcrops on the north slope of Caddo Mountain. That the formation is absent north of Caddo Mountain is known, for the horizon at which it occurs is widely exposed. Whether the sudden appearance and rapid thickening as we pass southward is due to its having been put down in a trough, or to an erosion interval during which that part to the north was removed, will require further field work to determine; but its much contorted condition and its relations to the overlying formation, later to be described, impress one with the strong conviction that probably it is due to an erosion interval. * * *

From recent work it appears that the age of the Missouri Mountain slate, the Arkansas novaculite, and the Fork Mountain slate can not yet be determined, for no fossils have been found in them^a by recent workers in the area. They may be of Ordovician age, they may be Silurian, and they may be Carboniferous. Their lithologic character is so very different from the nearest rocks of Devonian age (coarse-grained sandstones and black shales), which occur in northern Arkansas, that the possibility of their being of that age is scarcely entertained. On the other hand, their siliceous character might easily permit them to be considered contemporaneous with either the Ordovician limestones of the Ozark region, which contain a great deal of chert, or with the Boone formation (Mississippian) of that region, which is largely and in parts entirely chert. The representative of the Silurian in northern Arkansas is the St. Clair limestone, which contains no chert. * * *

The Missouri Mountain slate, where the Blaylock sandstone is present, rests upon that formation; where that is absent, it rests upon the Polk Creek shale at all points where contacts were observed. While it partakes of the large and comparatively gentle folds of the area, it appears not to enter into the minute crumpling of the Blaylock sandstone and lower formations, but on the contrary to rest upon their upturned and what seem to be eroded edges. Whether it does or not has thus far eluded all efforts to determine, on account of the great amount of débris nearly always present on the slopes where the contact between the two formations would otherwise be exposed.

This formation varies from 50 feet and less to 300 feet in thickness, the thinnest part being, so far as observed, along the southern border of the Ouachita Range. The formation is a clay slate. A few feet of the basal portion usually is green. Locally this lower portion is somewhat sandy and such parts contain small crystals of iron sulphide. The remainder, above the basal portion, varies from a blood-red to a dark red, containing patches and streaks of green. The green at the base may be the original color, but that above is secondary. * * *

The Arkansas novaculite is the principal formation of the Ouachita Range. Owing to an unconformity at the top, its thickness is quite variable, but the maximum observed is about 800 feet. The character of the formation varies from the base to the top, as well as in different parts of the same horizon. In a general way it may be described as consisting of a lower, heavy-bedded siliceous part that is wholly novaculite and an upper, thin-bedded part of the same material, interpolated with thin layers of black soft shale. In places there is an intervening portion containing sandstone.

The lower portion is about 300 feet thick and consists of massive beds from 2 to 10 feet thick, with large ripple marks showing along the bedding planes. This part of the formation furnishes the abrasives that are known in the markets as the Ouachita and Arkansas stone. It is a very close textured rock, the grains being of microscopic size. The common color is a very light gray, but bluish tints and pink, black, and dove-colored spots are quite common in the lower 50 to 75 feet. The fracture is uneven to conchoidal, and it is very brittle. In

^a Prof. L. S. Griswold, in the report of the Geological Survey of Arkansas, vol. 3, 1890, pp. 404-407, names several localities in which graptolites were supposedly obtained from above the novaculites. Several of these localities were visited by Mr. H. D. Miser, who reports that in each case the graptolites occur above the Bigfork chert instead of above the novaculite.

luster it is often waxy, and thin edges frequently are translucent. The bedding is quite irregular, small lenses between the beds being very common. * * *

The upper portion, in those parts where it is all present, is much thicker than the lower. It consists of layers of novaculite the most common thickness of which is from 1 to 6 inches, interpolated by layers of shale that is very black and soft when unaltered. When weathered, this shale is brown to green in color, producing a banded effect. The novaculite layers usually are dark to black but lithologically are not otherwise very different from the massive novaculite beds of the lower part of the formation. This part of the formation is frequently and sometimes wholly removed, as a result of an unconformity between it and the Carboniferous rocks that rest upon it.

The Fork Mountain slate, when present, lies at the top of the Arkansas novaculite, and is about 125 feet thick. On account of the unconformity above mentioned, it is only locally present, having in many places been removed by erosion. * * *

This formation consists of gray to greenish and chocolate-colored slates, containing thin layers of quartzite in the lower part.

I 16. ALABAMA, GEORGIA, AND SOUTHEASTERN TENNESSEE.

The classification and synonymy of the Ordovician worked out by Hayes ⁴¹⁷ in the southern Appalachian region is:

Ordovician rocks in southern Appalachian region.

Period.	Formation names used in report.	Names hitherto applied to the same rocks.		
		Smith, Geology of valley region adjacent to Cahaba coal field, 1890.	Smith, Outline of the geology of Alabama, 1878.	Safford, Geology of Tennessee, 1869.
Silurian [Ordovician].	Rockmart slate.....	Cincinnati or Nashville.	Nashville.
	Chickamauga limestone.	Trenton or Pelham limestone.	Trenton, Chazy or Maclurea.	Trenton or Lebanon Maclurea limestone.
	Knox dolomite.....	Knox dolomite.....	Quebec or Knox dolomite.	Knox dolomite.

The stratigraphic relations and distribution of the formations are described in the Stevenson, Gadsden, and Chattanooga folios of the Geologic Atlas of the United States, according to the divisions which have been carefully worked out as lithologic units. Recent paleontologic studies by Ulrich and Bassler, not yet published, appear to lead to the discrimination of several paleontologic facies and to correlation with the Stones River and other established horizons of the Mississippi Valley and New York sections.

A recent study of the Birmingham district ^{107a} has resulted in the following lithologic distinctions:

Silurian: Clinton (Rockwood) formation.....	Feet. 250-500
Unconformity.	
Ordovician: Chickamauga (Pelham) limestone.....	200-1,000
Unconformity.	
Cambro-Ordovician: Knox dolomite (includes at base Ketona dolomite member, 600 feet) ..	3,300
Cambrian:	
Conasauga (Coosa) limestone.....	1,000
Rome (Montevallo) formation (great thickness).	

In these systems there are included the Rome (Montevallo) formation and the Conasauga (Coosa) limestone, both of known Cambrian age; the overlying Knox dolomite, the lower part of which is regarded as Cambrian and the upper part Ordovician, though the plane of division between the Cambrian and Ordovician is unknown; and the Chickamauga (Pelham) limestone, of known Ordovician age.

The lowest Cambrian rocks exposed in this area are limestone and shale, possibly 1,000 to 1,500 feet thick, so far as can be judged from the width of outcrop in Opossum Valley. These rocks have been designated the Conasauga limestone by the United States Geological Survey and the Flatwoods or Coosa formation by the Alabama Geological Survey. They consist of thin-bedded blue limestone interbedded with shale, which in some sections, as in the vicinity of Bessemer, carries considerable chert in thin layers. This limestone is underlain by a mass of shale of great thickness, which to the east is known as the Rome formation. Locally it has been called the Montevallo shale. In this report it is called the Rome formation.

The Knox dolomite includes the rocks between the Conasauga and the Chickamauga (Pelham) limestone. In the Birmingham region and other parts of Alabama the lower part of the formation is almost free from chert, and on account of both this lithologic difference and its economic importance it has been separated out as a member from the mass of the Knox and named the Ketona dolomite member. The name Ketona is chosen because of the extensive quarry in this member at Ketona. The Ketona dolomite overlies the Conasauga (Coosa) limestone with apparent conformity and is 500 to 600 feet thick along Opossum Valley east of Birmingham. It is a nearly pure dolomite, with but little chert. It is thick bedded, crystalline in texture, and of prevailing light gray color. From it is drawn most of the fluxing rock used in the Birmingham furnaces. * * *

The rest of the Knox dolomite, 2,700 to 2,800 feet thick, overlies the Ketona dolomite member conformably. It is composed of dolomite with chert layers, which in places reach a thickness of 10 feet or more. Possibly one-fourth of the formation is chert.

Overlying the Knox dolomite unconformably is the Chickamauga limestone, of Ordovician age. It is the same as the Trenton or Pelham limestone of the Alabama Geological Survey. In Birmingham Valley this is a thin-bedded bluish to dove-colored limestone ranging generally from 200 to 500 feet thick. It has been used for flux to some extent.

I-J 16-17. OHIO, KENTUCKY, AND TENNESSEE.

The well-known areas of Ordovician strata exposed on the Cincinnati and Nashville domes in Ohio, Kentucky, and Tennessee are mapped from the respective State geologic maps. The terranes comprise the oldest sediments exposed, namely, Middle Ordovician limestones of the Stones River group and others of Trenton age and the overlying Cincinnati series (Upper Ordovician), consisting of strata of Utica, Lorraine, and Richmond age. They are thin limestones and shales, which are inconstant in thickness and faunal content.

In Ohio Orton ⁶²⁰ distinguished the following beds:

<i>Cincinnati group of southwestern Ohio.</i>		Feet.
Lebanon beds.....	293
Cincinnati beds proper:		
Hill Quarry beds.....	125
Eden shales.....	250
River Quarry beds.....	50
		— 425
Point Pleasant beds.....	50

The Point Pleasant formation was subsequently, by Winchell and Ulrich, ^{944a} shown to be of Trenton age and to be "terminated above with a heavy current-formed crinoidal layer, which includes large pebbles and disturbed masses of the

underlying limestone layers and exhibits other evidences of unconformity by erosion" with the overlying shales. In the report just cited the authors state:

The strata of the Cincinnati period as exposed in Ohio, Indiana, and Kentucky are divisible into three groups, having about the same geological value as the Chazy, Stones River, Black River, and Trenton groups of the Trenton period and the Medina, Clinton and Niagara groups of the Niagara period. These three divisions correspond very nearly with the Lower, Middle, and Upper Hudson of the Kentucky geologists, and the Eden shales, Hill Quarry beds, and Lebanon beds of Prof. Edward Orton in volume 1, *Geology of Ohio*.

At Cincinnati we begin the period with the Utica group, which here consists of over 250 feet of grayish and blue calcareous shales and marls, in which many layers of more or less crystalline limestone, from 1 to 20 inches thick, are included. The lower 14 or 20 feet of this division are of a darker color than the succeeding shales, being greenish gray or drab rather than light blue.

It is this portion that agrees best in all respects with the Utica of New York and Canada, and it was so determined by Prof. James Hall as early as 1842. The gray shales contain more or less abundantly such widely distributed and characteristic Utica fossils as *Triarthrus becki*, *Primitiella unicornis*, *Leptobolus insignis*, *Lingula daphne*, *Dicranograptus ramosus*, *Diplograptus spinulosus*, *D. putillus*, *Dendrograptus simplex*, and *D. tenuiramosus*. Of these, the last three, as well as many other species, continue into the main body of the shaly strata of the group. Throughout, fossils, Bryozoa especially, occur in greater abundance, variety, and perfection than at any other known locality for the Utica. At the top the shales pass rather gradually into the "Hill Quarry beds."

The latter, for which we propose to use the name Lorraine group, are clearly equivalent to the greater part of the New York strata which Emmons included under that name.^a At the base of the division, which at Cincinnati comprises about 200 feet of strata, there are some arenaceous layers that on weathering frequently preserve the fossils as casts. Above these there are numerous layers of crystalline limestone, 3 to 10 inches in thickness, separated by relatively thin bands of shale. In the upper 60 or 70 feet the bedding is more irregular and the limestone layers thinner and generally argillaceous, unfitting them for building purposes. Fossils are well preserved and exceedingly plentiful and among them may be recognized nearly every species that has been described from the equivalent beds in New York. Perhaps 300 species of fossils are known from the Cincinnati exposure of the Lorraine group and of these at least two-thirds are limited to the group, which is, considering the very similar lithological characters of the preceding and succeeding beds, a surprisingly large percentage.

Resting on the Lorraine there is a series of alternating thin-bedded shales and limestones and in some localities finally a sandstone, in all quite 350 feet thick in southwestern Ohio and southeastern Indiana. Almost the entire series is excellently exposed at Richmond, Ind., so that the name Richmond group which we propose to apply to the series is eminently appropriate. East and southeast of Oxford in Ohio the whole group consists of thin-bedded limestones and shales, but at Richmond the upper part shows an increase of arenaceous matter while the uppermost layers of shale have become harder and include one or two heavy beds of impure limestone. Southward from this locality in Ripley and Jefferson counties, Ind., the heavy layers are increased. In the last county their texture is very compact and the color a drab or dove, reminding one in both respects very greatly of some beds of the Trenton period. In Indiana and Ohio this upper part of the group is, as a rule, not very fossiliferous, but when the bed is traced over into Kentucky it becomes a veritable coral reef reaching from Jefferson County, Ky., to and beyond Marion County. The rock in this distance has changed some, being in the last county of a yellowish color and finely arenaceous texture, the whole giving way very readily under the weather so that the surface is sometimes thickly strewn with masses of *Columnaria*, *Tetradium*, *Labechia*, and *Beatricea*.

^a We refer particularly to Emmons's Lorraine sandstone, the greater part, if not all, of his Lorraine shales, which Walcott in 1879 referred to the Utica, being probably equivalent to the upper part of the Utica at Cincinnati.

Foerste ³³⁹ gives the history of the classification of the Cincinnatian series and describes its representatives in the Tennessee Valley and thence south to the central basin of Tennessee. He concludes with the following list of local formations:

According to the preceding observations, the Ordovician exposures in the valleys of the Tennessee River, the Buffalo River, Swan Creek, and South Harpeth Creek suggest the following lithologic succession, in descending order:

Cincinnati group:

Richmond:

Mannie shale.

Leipers creek limestone.

Lorraine:

Warren limestone; clay rock at Newsom.

Swan Creek limestone. Richly fossiliferous Lorraine limestone in the eastern part of the area studied, containing *Platystrophia lynx*.

Utica: Saltillo limestone.

The Lorraine appears to become thinner west of the Cincinnati anticline, so as to be represented by thinner sections or so as to be entirely absent along the Mississippi in Missouri and adjacent Illinois, in the Wells Creek basin in northern Tennessee, and along the Tennessee River in southern Tennessee. The Richmond also appears to become thinner west of the northern half of the Cincinnati anticline. It becomes thinner also southward along the flanks of the anticline. In some parts of Tennessee it is entirely absent along the western flank of the anticline. West of the southern half of the anticline, in Tennessee, the thickness of the Richmond appears to vary irregularly.

Details of the distribution of the Ordovician strata, with numerous graphic sections, are given by Foerste ^{338, 340} in subsequent articles.

The Ordovician strata of the central basin of Tennessee have been minutely mapped and described by Hayes and Ulrich,^{431a} who give the following classification and correlation with Safford's nomenclature:

Generalized time scale for central North America.	Mappable lithologic equivalents in the Columbia quadrangle.	Safford and Killebrew, Elements of the geology of Tennessee, 1900. Middle Tennessee.		Safford, Geology of Tennessee, 1869. Middle Tennessee.		
Ordovician.	Richmond.	Fernvale formation.	Hudson (College Hill; Cincinnati). Includes Hudson phosphate.		Upper Nashville.	
		(Wanting.)				
	Lorraine.	Leipers formation.				
	Frankfort.	(Wanting.)				
	Utica.	(Wanting.)				
	Trenton.	Catheys limestone.	(f) (g) <i>Cyrtodonta</i> and <i>Stromatopora</i> beds.	Nashville (Trenton).	Lower Nashville (Orthis bed.)	
		Bigby limestone.	(d) (e) <i>Dove</i> and <i>Ward</i> limestones.			
		Hermitage formation.	(c) Capital limestone or Mount Pleasant phosphate.			
	Black River.	(Wanting.)	(b) <i>Orthis</i> bed.		Carters Creek limestone.	
	Stones River.	Carters limestone.	(Not classified.)	(a) Carters limestone.		
		Lebanon limestone.	Lebanon limestone.	Lebanon limestone.		Glade limestone.
		(Not exposed.)	Ridley limestone.	Ridley limestone.		Ridley limestone.
			Pierce limestone.	Pierce limestone.	Pierce limestone.	
	Murfreesboro limestone.	Murfreesboro limestone.	Stones River (Chazy).	Central limestone.		

J 11-12. GREAT BASIN, NEVADA AND UTAH.

A zone containing Trenton fossils is distinguished at Eureka, Nev., in the base of the Lone Mountain limestone, which is unconformable to the Eureka quartzite below. The limestone is 1,800 feet thick and is all of Ordovician age. Fossils found in the upper part were assigned to the "Upper Silurian" by Hague,³⁹¹ but they are now regarded by Ulrich^a as of Richmond age (uppermost Ordovician). The distribution of the Lone Mountain limestone is not well known. The limestone or its

^a Personal note.

equivalent may occur in any of the ranges where the Cambrian and Ordovician are mapped together or where the Silurian is shown, throughout Nevada and western Utah.

Ulrich ^a regards part of the Lone Mountain limestone as much older than the Bighorn dolomite and Whitewood limestone of Wyoming or the Harding sandstone and Fremont limestone of Colorado. According to Kindle ⁴⁹⁸ the beds which have been classed as Silurian, on account of containing *Halysites catenulatus*, may in general be regarded as possibly Ordovician, and Ulrich states that *Halysites* occurs generally in the West in faunas which are regarded as of Richmond age but is also known in faunas which are correlated with late Black River horizons.

J 13. SOUTHERN COLORADO AND NEW MEXICO.

Throughout much of southern Colorado, New Mexico, and Arizona Ordovician rocks are generally lacking and the hiatus corresponding with the period also comprises earlier and later epochs, down to the pre-Cambrian and up to the Carboniferous, over extensive areas. Ordovician deposits along the shores of the Colorado land constitute the Harding sandstone and related formations. At Canon City, the type locality, the sandstone rests on Algonkian strata, is 86 feet thick, and is overlain by the Fremont limestone, 200 feet thick. The sandstone contains the oldest known fish remains^{855a} and the limestone an invertebrate fauna containing Trenton and Richmond fossils.^a The Fremont limestone is overlain by Carboniferous limestone, Silurian and Devonian strata being absent, yet, as stated by Crosby,¹⁸³ the line of demarcation "is not strongly defined, though it represents a long period of nondeposition and a great time break."

J 15. NORTHERN ARKANSAS.

The Ordovician section of northern Arkansas is very incomplete. There are unconformities at several horizons and the formations are irregular in thickness to the extent of being entirely lacking in some sections though present elsewhere. Ulrich ⁸²⁰ states that the equivalents of the upper Stones River, Black River, Trenton, and Utica are absent. The lower Stones River and the Joachim dolomite of Missouri are represented by the Iward limestone, the lower Richmond by the Polk Bayou limestone, and the upper Richmond by the Cason shale. Beneath the Iward limestone there is in many places a representative of the St. Peter sandstone.

J 15-16. MISSOURI AND SOUTHERN ILLINOIS.

The lower Ordovician of Missouri and southern Illinois comprises the later formations of the "Magnesian Limestone series" or "Ozark series." The latest published classification is given in Chapter III (p. 104), according to Ulrich.

The strata placed in middle and later Ordovician comprise the Trenton, Hudson, and Cape Girardeau of Keyes's section.^{491a} More recent discussions bearing on the correlation of the "Magnesian Limestone series" and the St. Peter sandstone have been published by Hall and Sardeson ³⁹⁵ jointly and by Berkey.⁷¹ The strata to which Keyes applied the name Trenton are now known as Plattin limestone (at the

^a Ulrich, E. O., personal note.

base) and Kimmswick limestone, and Keyes's Hudson is now called Thebes formation. The formation overlying the Thebes is known as Girardeau limestone. According to Ulrich ^a the Thebes formation includes more than the Maquoketa shale, recognized farther north in Missouri and elsewhere.

Keyes described the three higher Ordovician formations as follows:

Trenton limestone.—In southeastern Missouri the Trenton limestone as now understood embraces, besides the Trenton as comprehended in earlier reports of the State, the Black River and Birdseye limestones of Shumard. The latter probably more properly represents the lower and less fossiliferous portion of the Trenton of the region and nowhere can be separated faunally or lithologically from the upper part containing the typical Trenton fauna.

The lower Trenton ("Black River" and "Birdseye" limestone) is a compact, heavily bedded limerock, often not unlike certain lithographic stones in texture.

The upper Trenton, or Trenton proper, is well exposed in all the counties along the Mississippi River from Marion to Cape Girardeau. In its northern extension it is chiefly a buff-colored or yellowish-gray limestone with occasional shale partings. Fossils are abundant in places, though often in the form of casts. Southward the limestone becomes compact, bluish-drab, with abundant fossils.

Hudson shales.—Everywhere on the eastern border of Missouri, wherever the Trenton limestone is exposed, blue calcareous shales are found to overlie it. These shales rapidly disintegrate, upon exposure to the weather, into a soft plastic clay. Numerous thin seams of impure limestone are intercalated and often form beds of considerable thickness. Fossils are abundant and well preserved. They are all very characteristic of the fauna occurring at Cincinnati, Richmond (Indiana), and in northeastern Iowa.

Upon lithological and faunal grounds, Swallow and Shumard early correlated these shales with the Hudson River shales of New York and Ohio. In 1868 Worthen called these beds the "Thebes" shales, from the village of that name in southern Illinois, on the Mississippi River below Cape Girardeau. As defined by the Illinois geologist, the Thebes shales and sandstone form the lowest member of the Cincinnati group, the upper section embracing practically the same beds as the Girardeau limestone of Shumard but placed by the last author in the Upper Silurian. In the same region Shumard had previously (though through delays not published until several years later) divided those shales into—

	Feet.
Upper Hudson shales.....	45
Cape Girardeau sandstone.....	35
Lower Hudson shales.....	50

At Thebes the whole formation is well exposed in a sharp anticline, bringing up centrally the Trenton limestone above the water level of the Mississippi River, and successively, on either side, all the beds of the Hudson shales.

North of the Missouri River, in Pike, Ralls, and Marion counties, the lithological characters and fossils are essentially the same as in the southern part of the State.

Girardeau limestone.—This rather well marked division of the lower Silurian in southeastern Missouri was first differentiated by Shumard in 1885 and provisionally called by him the Cape Girardeau limestone but was regarded as a member of the Upper instead of the Lower Silurian.

Lithologically the limestone is bluish, very compact, and resembles somewhat the stones used in lithographing. It is rather thinly bedded, with numerous vertical fractures or joints. Fossils of peculiar types abound. Its thickness is over 60 feet.

Worthen also recognized this formation as a distinct horizon but made it the upper member of the Cincinnati group, the superior part of the Lower Silurian of the region.

^a Personal communication.

Ulrich states that the Upper Hudson shales, the Cape Girardeau sandstone, and the Lower Hudson shales of Keyes are now all regarded as of Richmond age.

From Missouri these Ordovician strata cross the Mississippi into southern Illinois, where they have very recently been critically studied by Savage,⁷⁰³ who distinguishes "Galena-Trenton" light-colored crystalline nonmagnesian limestone, 68 to 80 feet; "Richmond-Maquoketa," 91 feet, consisting of a lower member of sandstone or sandy shale (Thebes sandstone) and an upper one of bluish shale; and Alexandrian, consisting of the Cape Girardeau limestone and certain overlying beds, 41 feet. Savage proposed the new term "Alexandrian," from Alexander County, Ill., to designate a terrane which bridges "the lost interval between the Cincinnati and the Clinton." This terrane, previously distinguished by Ulrich in the Mississippi Valley, appears to constitute a transition from Ordovician to Silurian. Its correlation with Brazilian strata is discussed by Schuchert.⁷¹⁵

J 16. INDIANA.

The strata and faunas of the Cincinnati series in Indiana have been described in great detail by Cumings,¹⁹⁶ who has reclassified the sequence of limestone and shale beds according to formations and faunal zones. The divisions do not possess very distinctive lithologic characters, all being limestone, shaly limestone, or shale, and they do not maintain a uniform character over any large area, as a rule. The following is Cumings's classification,^{196a} as tabulated by him in comparison with those that preceded:

Tabulation of the various classifications of the Cincinnati group.

Early authors.	Orton, Ohio Survey, 1873.	Winchell and Ulrich, 1897.	Nickles, 1902.	Nickles and Foerste, 1905.	Ulrich, 1906 (Bassler).	Present report.

						Rafinesquina alternata zone. Dalmanella zone. {Dekayia ulrichi zone. Callopora onealli zone.}

J 17-18. MARYLAND, VIRGINIA, AND EAST TENNESSEE.

The middle and later Ordovician of the Appalachian Valley south of Pennsylvania are represented by the strata which lie between the Knox dolomite below and the Clinton ("Rockwood") formation above. In many places, especially along the east side of the Appalachian Valley, there is a distinct unconformity between these strata and the Knox dolomite. The formations are calcareous, generally limestone in the western sections but shaly or sandy in the eastern. They have been described by Hayes,^{419-426, 428} Campbell,^{121, 123-125} and Keith^{475-479, 481} as Chickamauga limestone, Athens shale, Tellico sandstone, Sevier shale, Holston marble, and Moccasin limestone; by Safford⁶⁸⁹ as Lenoir limestone and Nashville or Sevier shale; and by Smith⁷⁴⁸ as Chickamauga. Darton^{221a} applied the name Shenandoah limestone to the full thickness of limestone occurring between the Lower Cambrian quartzite and the Upper Ordovician shales (Martinsburg shale), especially in Virginia.

Local descriptions follow, in order from southwest to northeast.

In central eastern Tennessee (Knoxville quadrangle) the sequence and thickness of lithologic formations of the Ordovician differ somewhat in the northwestern and southeastern areas. Keith^{475a} gives the two following sections:

Generalized section northwest of Bays Mountain.

Period.	Formation name.	Thickness (feet).	Character of rocks.
Silurian [Ordovician].	Sevier shale.	1,000-1,200	Light-blue sandy and calcareous shales, with beds of limestone and argillaceous marble.
	Tellico sandstone.	250-500	Bluish-gray calcareous sandstone.
	Chickamauga limestone.	200-400 500-700	Variegated marble, red, brown, gray, and white. Blue limestones and gray argillaceous limestones.
Cambrian.	Knox dolomite.	3,500	Magnesian limestone, white, gray, light and dark blue, with nodules of chert.

Generalized section southeast of Bays Mountain.

Period.	Formation name.	Thickness (feet).	Character of rocks.
Silurian [Ordovician].	Sevier shale.	500-600 200-400 500-600 500-650 500-750	Light-blue calcareous shale. Bluish-gray and red calcareous sandstones and shales. Light-blue calcareous slates. Bluish-gray and gray calcareous sandstones and shales. Light-blue calcareous shale.
	Tellico sandstone.	800-900	Bluish-gray and gray calcareous sandstones and shales.
	Athens shale.	1,000-1,200	Light-blue calcareous shale. Black calcareous shale.
	Chickamauga limestone.	0-50	Gray argillaceous limestone.
Cambrian.	Knox dolomite.	3,500	Magnesian limestone; white, gray, light and dark blue, with nodules of chert.

In northeastern Tennessee Keith ^{481a} distinguishes the following formations:

Generalized section of the sedimentary rocks in the Great Valley, Greeneville quadrangle.

System.	Formation name.	Thickness (feet).	Character of rocks.
Ordovician.	Sevier shale.	1,300-1,800	Calcareous sandstones and shales. Bluish-gray and yellow calcareous shale and shaly limestone.
	Tellico sandstone.	2-200	Red and gray calcareous sandstone.
	Athens shale.	1,000±	Black and bluish-black calcareous shale.
	Moccasin limestone.	450-500	Red, blue, gray, and drab massive and shaly limestone.
	Chickamauga limestone.	0-450	Blue and gray limestone, shaly in part, and variegated marble.
—?— Cambrian.	Knox dolomite.	3,000-3,500	Magnesian limestone, light and dark blue, white, and gray, with nodules and layers of chert and a few beds of calcareous sandstone.

In southern Virginia M. R. Campbell ^{121a, 125a} has mapped the lithologic divisions named below:

Generalized section for portion of Bristol quadrangle north of Clinch Mountain.

Period.	Formation name.	Thickness (feet).	Character of rocks.
Silurian [Ordovician].	Sevier shale.	1,100-1,300	Sandy shale. Blue calcareous shale which generally weathers yellow upon exposure. Occasional beds of impure limestone near the base.
	Moccasin limestone.	400-500	Red argillaceous limestone.
	Chickamauga limestone.	900-1,000	Blue limestone with occasional small lentils of red and gray marble.
Cambrian.	Knox dolomite.	2,300-2,800	Limestone conglomerate with pebbles of chert or beds of red earthy limestone. Gray or white magnesian limestone with nodular cherts occurring at intervals throughout the formation.

The Shenandoah limestone, the comprehensive series of Cambrian and Ordovician limestones of the valley of Virginia, formerly known as the "Valley limestones," is briefly described by Darton,²²¹ who recognized a lower division of dark magnesian limestones, grading upward into lighter-colored cherty strata, and followed by purer, more thickly bedded, highly fossiliferous limestone. Variations in the character of these formations are noted in the reports by W. B. Rogers^{676a} and J. L. Campbell,¹²⁰ but the distinctions made have no systematic value. For central Virginia H. D. Campbell¹¹⁹ has introduced the following classification:

Section of the Valley limestones near Lexington, Va.

Ordovician:	Feet.
Liberty Hall limestone	1,000±
Murat limestone.....	100-150
Natural Bridge limestone.....	3,500+

The correlation of these divisions with those recognized both north and south depends on detailed studies, in progress, from which it appears that the limestone formations present differences of sequence and facies not previously suspected. Bassler⁶⁰ states:

The name Shenandoah limestone proposed by Darton for the Valley limestone of early geologists was made to include all the limestones in the Valley of Virginia occupying the interval between the Cambrian quartzites and the Upper Ordovician shales. The lower portion of the great limestone series had been found by Mr. Walcott to include Lower, Middle, and Upper Cambrian rocks, but the Ordovician portion had been determined only to the extent that Trenton strata were supposed to occur at the top. The work of the writer in Virginia brought out the fact that the geologic succession of the Ordovician division was quite different in various parts of the valley. In northwestern Virginia a great thickness of Beekmantown is overlain by 1,000 feet of Stones River, and this in turn by 400 feet of Black River, while the strata bearing Trenton fossils form the lowest division of the overlying shales. In central western Virginia the Black River alone rests upon the Beekmantown, but in southwestern Virginia two distinct arrangements were noted. Along the western edge of the valley the Beekmantown is followed by 1,000 or more feet of Stones River but no Black River, while along the eastern side only the Black River occupies the interval between the overlying shales and the Beekmantown. In each case the Trenton does not form the upper part of the limestone, but is the basal member of the overlying shales.

The Shenandoah limestone, therefore, is a broad term, embracing strata of Cambrian and Ordovician age, the geologic succession of the latter varying in different parts of even the type area.

The classification of the Ordovician limestones of southern Pennsylvania as worked out by Stose and Ulrich is given in Chapter III (pp. 107-111). There is no reason to look for any marked difference in the section where the belt crosses Maryland, but the divisions have not been traced.

K 10. TAYLORSVILLE DISTRICT, CALIFORNIA.

The Grizzly formation, which occupies the summit of Grizzly Peak, in the Lassen Peak quadrangle, California, is an unfossiliferous formation, 400 feet thick, which underlies the Montgomery limestone. As the latter is considered by Walcott^{271b, 272} to be of Niagara age, it is possible that the Grizzly formation is of Ordovician age.

K 12. WASATCH AND UINTA RANGES, UTAH.

The quartzite of the Wasatch and Uinta ranges, distinguished by the Fortieth Parallel Survey as Ogden quartzite and mapped as Devonian, is correlated by Weeks⁸⁷³ and Ulrich as Ordovician. In the Wasatch section it rests upon limestone of Cambrian and Ordovician age, is 800 to 1,200 feet thick, and is overlain by Silurian limestone, at least in Cache Valley. Along the south side of the Uinta Range it lies upon the Lodore shale (Cambrian) and is immediately followed by limestone of lower Mississippian age. No equivalent is known on the north side of the Uinta Range.

Blackwelder ^{84c} showed that the quartzite in Ogden Canyon is a Cambrian quartzite which owes its apparent stratigraphic position to an overthrust. There is therefore no Ordovician quartzite in Ogden Canyon and the name is inappropriate. But an Ordovician quartzite does occur in Cache Valley and also south of Ogden. In green shales at the base of this quartzite have been found abundant fossils, which, on preliminary examination, E. O. Ulrich ^{84d} pronounces to be of the age of the Beekmantown fauna of the Eastern States.

K 13. BLACK HILLS.

In the northern Black Hills occurs a formation similar to the massive Bighorn dolomite, known as the Whitewood limestone, which is of Trenton age. It is 80 feet thick near Deadwood, but thins out toward the south.^{241a, 471}

In the Front. ranges of Colorado north of Colorado Springs the Ordovician, like other pre-Carboniferous Paleozoic systems, is lacking.

K 16. SOUTHEASTERN WISCONSIN AND NORTHEASTERN ILLINOIS.

The St. Peter sandstone, Trenton limestone (as defined by the Wisconsin Geological and Natural History Survey), Galena dolomite, and "Cincinnati" shale constitute the Ordovician of Wisconsin and northeastern Illinois above the "Lower Magnesian" ("Calciferous") limestone. The St. Peter⁷¹ is a friable white or yellow sandstone, which varies in thickness from a thin edge to 212 feet and lies unconformably on the "Lower Magnesian." The overlying Trenton is in part a simple, in part a magnesian limestone with clayey partings, about 115 feet thick, in which several distinct subdivisions are recognized. Next higher is the Galena, a coarse-grained thick-bedded dolomite, about 250 feet thick, which becomes more argillaceous toward the northeast and northwest. The highest formation of the Ordovician section is the "Cincinnati" shale, bluish or greenish, with intercalated limestones, which reaches a thickness of 200 feet or more.^{133e} A period of nondeposition and erosion followed in Wisconsin and elsewhere in the central western United States⁸⁸⁵ covering late Ordovician time. This period of nondeposition corresponds to the interval between the "Cincinnati" shale and the Galena dolomite. The so-called "Cincinnati" shale is of Richmond age. In southwestern Wisconsin and northwestern Illinois the Ordovician shale outcrops and is there known as Maquoketa shale.

The formations in northern Illinois constitute the southward extension of those described by Chamberlin for Wisconsin. Bain⁵¹ has recently described the limestones and associated strata of northwestern Illinois. Above the earlier Ordovician rocks he recognizes the St. Peter sandstone, Platteville ("Trenton") limestone, Galena limestone, and Maquoketa shale.

K 17-18. PENNSYLVANIA AND NEW JERSEY.

The limestones of southeastern Pennsylvania have been described by Stose.⁸⁰¹ The quotations regarding the Cambrian and early Ordovician formations given in Chapter III (pp. 107-113) are here continued for the later Ordovician.

The Stones River limestone is composed in general of three divisions—a middle band of massive pure granular limestone containing the large gastropod *Maclurea*

magna and thin beds of black chert that weather into small rectangular blocks; an upper series of thin-bedded pure limestone; and a lower series of interbedded massive pure beds and magnesian layers. From the middle division 22 species of fossils have been obtained, among which there are eight which occur in the middle Chazy of the Champlain Valley. As a whole, the fossils as well as the lithologic character of the formation are practically the same as those of the Stones River group of Tennessee.

The Chambersburg limestone is the uppermost division of the Shenandoah limestone. It is characterized throughout the area by fossiliferous thin-bedded limestones with argillaceous partings. It varies in thickness across the strike from a maximum of 600 feet in the Chambersburg belt to about 100 feet in the McConnellsburg Cove.

Its most typical development is in the Chambersburg belt, throughout which fossils are abundant. The following section in the railroad cut $1\frac{1}{2}$ miles west of Kauffman is the most complete continuous section in this belt:

Black shale (Martinsburg).	
Largely concealed, but probably chiefly shale (near the top are black carbonaceous limestone with conchoidal fracture, shaly dark crystalline limestone, thin sandstone, and 10 feet of coarse crystalline limestone containing <i>Lingulas</i>).....	150
Calcareous shale and limestone.....	100
Nodular clayey limestone.....	50
Dark platy limestone.....	94
Compact dark limestone, very fossiliferous.....	108
Cobbly limestone containing numerous <i>nidulites</i> , <i>Bryozoa</i> , and a layer of <i>cystid heads</i>	105

607

The "cobbly" character of the weathered outcrop of certain of the beds, due to a wavy lamination or clay parting that crosses the bedding at a high angle and, on weathering, gives rise to rounded lenticular masses resembling rough cobbles, is one of the noticeable features of this formation. The upper 200 feet of the formation is composed largely of shale with interbedded thin fossiliferous limestones.

* * * * *

Nearly everywhere this formation yields on careful search an abundance and great variety of fossils, and those from the Chambersburg quadrangle differ from those obtained in the Mercersburg quadrangle. In the Chambersburg belt the formation may be divided into four faunal zones.

* * * * *

In the Mercersburg quadrangle four faunal zones are also distinguished, but they do not correspond with those of the Chambersburg belt.

In southeastern Pennsylvania and Maryland the Ordovician strata are overthrust by pre-Cambrian schist and metamorphosed to phyllite and schist. The complex relations have been worked out by Bascom^{57, 58} and Mathews,⁵⁷⁹ who distinguish the established divisions of the section in adjacent fossiliferous districts.

The Cambrian and Lower Ordovician formations of the Philadelphia district (*Chickies quartzite* and *Shenandoah limestone*) are described in Chapter III (pp. 111-113). Bascom^{58b} continues the description of the Ordovician formations as follows:

Further sedimentation in Ordovician time is represented by the *Octoraro*. This is the last known Paleozoic deposit in this region and, like the preceding Paleozoic sediments, is dynamically metamorphosed and free from igneous intrusions.

The *Octoraro schist* is largely confined to the South Valley Hills, pinching out to the northeast and expanding to the southwest. Outliers of the mica schist occur north of *Berwyn* and of

Paoli and on Henderson and Bridgeport hills. The Henderson and Bridgeport outliers, while lithologically similar to the main mass of mica schist, can not be positively correlated with the formation. Their relation to limestone of Chazy age, as seen in the Schuylkill River cut, is such as to admit interpretation either as an interbedded structure or as the overlying synclinal structure which the Octoraro schist must possess.

The mica schist is characterized by a pronounced lamination of a slaty rather than a schistose type. The laminæ exhibit lustrous silvery surfaces and a blue-gray or green-gray color, which under the action of weathering alters to reddish yellow.

The chief constituents of this mica schist are quartz, muscovite, orthoclase, and chlorite. Quartz occurs in interlocking grains which show undulatory extinction and other pressure effects in their form and arrangement. Orthoclase occurs sporadically in considerable areas, but it is not an important or characteristic constituent. Chlorite is uniformly distributed through the rock, interspersed with wavy lamellæ of muscovite. Plagioclase, biotite, magnetite, ilmenite, tourmaline, apatite, and pyrite are accessory constituents.

The constituents of the schist do not possess clearly defined outlines and the crystalline texture is neither so coarse nor so sharply defined as in the Wissahickon gneiss.

In the hand specimen quartz is completely overlain by minute plates of mica, which alone show on the cleavage surface, while eyelets of quartz may show on the edges of the laminæ. Cubes of pyrite more or less altered to limonite are characteristic. Considerable oxide of iron is present in this formation, which is evidently the source of the limonite ore that occurs sporadically in pockets between the limestone and the schist.

The analyses of the mica schist, with the relatively high alumina and low silica and absence of lime, fairly indicate a sedimentary origin for the formation.

* * * * * * * * *

The lower beds of this formation are more calcareous, more siliceous, finer, and darker colored than the upper beds. The outlying areas at Bridgeport and Henderson are of this character. In some places there appears interbedded with the mica schist a quartz schist or a quartzite similar to the Cambrian quartzite. Fragments of such a quartz schist show 1 mile north of Paoli on the northwestern boundary of the mica schist, and 2 miles north of Wayne such a siliceous member furnishes sand for local use.

The mica schist of the South Valley Hills appears to overlie the Shenandoah limestone without faulting or unconformity. This is indicated by the lithologic gradation between the limestone and schist which may be seen at the northwest base of the South Valley Hills and by the persistence of the same geodiferous quartzose beds along the contact of the two formations and is confirmed by the fact that the outcrops show that deformation was by folding and flowage and not by faulting.

The structure of the hills is evidently synclinal, though cleavage and fissility are so pronounced as to obscure the stratification. On the limbs of the syncline cleavage and bedding are approximately parallel, while cross structures prevail in the trough of the syncline.

* * * * * * * * *

The structure of the formation in the South Valley Hills indicates a thickness probably not exceeding 1,000 feet. It is not known, however, whether the full thickness of the formation is present here.

* * * * * * * * *

The formation is held to be Ordovician in age on the ground of its normal stratigraphic position on the Cambro-Ordovician limestone. It is correlated with the Berkshire schist of the New England section, the Hudson schist of New York, and doubtfully with the phyllites of Maryland. It is the Primal upper slate of the First Geological Survey of Pennsylvania, and the Cambrian phyllite of the Second Geological Survey.

Ranging southwestward from Orange County, N. Y., the Cambrian and Ordovician strata pass into New Jersey with the facies described as the Hardyston

quartzite, the Kittatinny limestone, the Jacksonburg limestone, and the Martinsburg shale. The formations have been described by Kümmel,^{512, 513a} from whose recent account the following notes on the Ordovician are taken. The description of the Cambrian formations has been given in Chapter III (p. 113).

In northern New Jersey, as elsewhere in the great Appalachian Valley, there is no sharp line of demarcation between the rocks of the Cambrian and those of the Ordovician system. The base of the Ordovician lies somewhere below the top of the Kittatinny limestone, as stated above, but the exact position of this division line can not readily be determined.

Above the Kittatinny limestone, and separated from it by a break in sedimentation indicated by a calcareous basal conglomerate, is a dark-blue or black fossiliferous limestone, correlated with the Lowville, Black River, and lower Trenton limestone of the New York section and hitherto classed as "Trenton," some layers of which contain as much as 95 per cent or more of calcium carbonate. Calcareous shales occur interbedded with these limestones and above them to the top of the formation. The sequence of conglomerate, limestone, and shale is a variable one, but, so far as observed, the transition to the overlying formation is always through a series of calcareous shales which become less and less limy.

The thickness of the Jacksonburg formation varies from 135 to 300 feet or more. It contains an abundant fauna, 98 forms having been described by Weller. At the type locality the lower strata for a thickness of 58 feet carry a Lowville-Black River fauna, and the higher beds have a lower Trenton fauna.

The Jacksonburg limestone passes upward through the calcareous shales mentioned above into a great thickness of shale, slate, and sandstone, which has heretofore been known as the "Hudson River slate" but which is now correlated with the Martinsburg shale of West Virginia and takes that name.

The formation ranges from the finest-grained shale and slate to fine sandstone. The former beds on the whole are black and more abundant in the lower part, whereas the sandstone beds are dark bluish gray, many of them calcareous, and occur more commonly higher in the formation. The fine-grained rocks exceed the gritty beds.

* * * The whole formation is so crumpled and cleaved that no accurate estimate of its thickness can be made, but it is probably at least 3,000 feet, and it may be more.

Four species of graptolites of the Normanskill fauna of New York have been found in the lower portion of the Martinsburg shale, so that the beds in which they occur are equivalent in age to the middle portion of the typical Trenton limestone of central New York. A few miles north of the New Jersey State line *Schizocrania* and graptolites characteristic of the Utica shale of the Mohawk Valley have been found in beds close to the overlying Shawangunk conglomerate.

Detailed descriptions of the fauna are given by Weller.^{769, 878, 880.}

K-L 12-13. WYOMING AND NORTHERN COLORADO.

The Ordovician of this region is a relatively thin deposit of limestone, attaining a maximum thickness of 300 feet, lacking in many sections, and locally underlain by a sandstone which carries remains of fish.⁸⁵⁵ Darton^{241, 244} has recently summed up the known facts in a comprehensive manner.

In the Bighorn Mountains the Ordovician strata constitute the Bighorn dolomite, which in the north averages about 300 feet in thickness, including a basal white sandstone, a massive magnesian limestone, and about 100 feet of softer thinner-bedded limestone at the top. The strata range in age from Black River at the base to late Richmond at the top and are said to be divided by a hiatus equivalent to later Trenton, Utica, Eden, and Lorraine, of which, however, the evidence is mainly paleontologic.

In the Owl Creek and Wind River mountains of central and western Wyoming the Bighorn dolomite occurs with much of the character which it has in the type locality of the northern part of the Bighorn Range.

K-L 15. MINNESOTA, NORTHEASTERN IOWA, SOUTHWESTERN WISCONSIN, AND NORTHWESTERN ILLINOIS.

The Ordovician exposed on both sides of Mississippi River comprises the following formations, in descending order:

- Maquoketa shale.
- Galena dolomite.
- Decorah shale ("Green shales" of Minnesota reports).
- Platteville limestone.
- St. Peter sandstone.
- Prairie du Chien group (of Beekmantown or Lower Ordovician age):
 - Shakopee dolomite.
 - New Richmond sandstone.
 - Oneota dolomite.

The Prairie du Chien group is discussed in Chapter III (pp. 119-120). The classification of the Ordovician into the formations enumerated above is based on the work of Calvin¹¹⁸ and of Grant, Burchard, and Ulrich.³⁸⁶ In the folio by the three authors last cited the middle and upper Ordovician rocks are described in detail and lists of fossils are given. The following is an abstract of their description:

Unconformably upon the Prairie du Chien formation lies a comparatively thin sandstone long known as the St. Peter from the fact that it occurs along the lower course of St. Peters (now known as Minnesota) River. The thickness of this sandstone varies considerably, averaging in this district perhaps 70 feet but ranging from 35 to 175 feet. * * * The variation in the thickness of the St. Peter sandstone is due, at least in the main, to irregularities in the surface of the underlying formation—the Prairie du Chien—which suffered considerable erosion before the sandstone was deposited. The top of the sandstone likewise may have been somewhat eroded prior to the deposition of the succeeding Platteville limestone, although this is not evident from discordance of stratification.

* * * Nearly everywhere at the base of the formation there is a foot or two of bluish-green sandy clay shale. Above this basal shale the St. Peter is practically pure quartz sandstone, the percentage of silica in its composition being very high and at some places exceeding 99 per cent. * * *

The grains are well waterworn and of medium fineness, the greater part passing a sieve having 40 meshes to 1 inch.

* * * * *

The transition from the St. Peter sandstone to the overlying Platteville limestone is marked by a bed of blue sandy shale which ranges in thickness from a few inches to 5 feet or more. This shale is not commonly sharply separated from the sandstone, but grades into it. On the other hand, the upper edge of the shale is sharply delimited by the overlying massive beds of the lower part of the limestone. The sand grains in the shale do not usually extend to its upper surface, and very rarely are these grains found in the lower beds of the Platteville. * * *

The St. Peter can be regarded as a practically nonfossiliferous formation, though a few casts, mainly of pelecypods or bivalve shells, have been reported from it. This scarcity of fossils seems to be due as much to the fact that in so porous a rock solution would destroy calcareous shells as to the fact that few animal remains were entombed in it originally. The St. Peter is a wide-reaching formation in the upper Mississippi Valley, and in the Ozark region it is represented by the sandstone which immediately underlies the Joachim limestone and which has frequently been termed the "First Saccharoidal" sandstone.

The Platteville limestone is noticeably different from the other calcareous members of the Paleozoic section in these quadrangles in that it is largely a pure limestone, or a magnesian limestone, rather than a dolomite. In earlier reports on this district this formation was called the Trenton limestone, but the name Platteville has recently been applied to it, as it is possible that these beds do not represent the exact equivalent of the Trenton in its type locality. * * *

The Platteville averages 55 feet in thickness and maintains this average over a considerable part of the area.

Generalized section of Platteville limestone.

4. Limestone, principally in thin beds, and shale	10-15
3. Thin-bedded brittle fine-grained limestone	15-25
2. Thick-bedded magnesian limestone or dolomite.....	15-25
1. Blue shale, at some places sandy.....	1- 5
* * * * *	

It is at some places difficult to draw the boundary between the Platteville and the Galena on purely lithologic criteria. The contact, however, is probably unconformable, despite its obscurity and the fact that it apparently occurs in the midst of a shaly unit. A close study of the fossils rarely fails to locate the contact within very narrow bounds, and then the actual physical break between the two formations may in places be determined. At many places the first few inches of the Galena consist of a shale or clay containing more or less clear evidence that it is a deposit which has been reworked by water. At some places it contains fragments of fossils, more perfect forms of which occur in the bed just below. At some localities this lowest bed of the Galena consists of a yellow to white clay, called "pipe clay," underlain by an inch or two of dark carbonaceous clay.

* * * * *

The Platteville is commonly highly fossiliferous, more so than any other formation within the area except possibly the Maquoketa shale. Although practically all the beds of the formation except the basal shale contain fossils in greater or less abundance, certain beds are literally packed with organic remains. The dolomitic second member contains relatively few fossil remains, and at some places this bed may appear almost barren. A few species range through nearly all the beds, notably *Leperditia fabulites* Conrad, which is the most characteristic fossil of the formation. Many other species, however, being more restricted in range, may occur in only one or two of the beds.

* * * * *

The Platteville is regarded as the equivalent of the Stones River group of Tennessee and Kentucky, a group that lies lower than the Black River and Lowville (Birdseye) limestones of New York.

* * * * *

Lithologically the Galena is a dolomite—a granular, crystalline, coarse-grained porous rock, which weathers into exceedingly rough, pitted, and irregular forms. * * * The formation exhibits the same lithologic character everywhere except in its extreme upper and lower parts. As a whole it is massive in appearance; the average thickness of the beds is from 1 to 4 feet. Near the bottom and near the top, however, thinner beds occur. Chert nodules are common in the middle part. At many places very thin seams or partings of clayey material, a little darker in color than the main mass of the dolomite, separate the formation into irregular layers. * * *

The thickness of the formation within this area averages about 235 feet.

The upper portion of the Galena is thin bedded, earthy, and noncrystalline. Shale occurs as partings, and in the uppermost strata, where the Galena passes into the Maquoketa, it forms the rock and the limestone becomes nodular. Near the bottom of the Galena occurs a so-called oil rock, a finely laminated brown to black

shale, which is made up largely of microscopic unicellular algæ and which contains as much as 20 per cent of heavy oil.

Some beds of the Galena contain abundant organic remains, but the main body of the dolomite carries few recognizable fossils. Locally, however, where the basal limestone and shale were deposited, as shown in the first two sections of the Platteville limestone given in the description of that formation, they are highly fossiliferous.

* * * * *

The Galena and Platteville form a thick dolomite-limestone series, which is of much importance in the upper Mississippi Valley. The lithologic features of the two formations here described are those which are common to the lead and zinc district. Outside of this district the characteristics vary somewhat, and toward the west the Galena becomes less dolomitized, especially in its lower part.

In the lead and zinc district the Platteville, commonly known as "Trenton" in the reports on this district, is essentially a nondolomitic formation, while the Galena is a dolomite. If this lithologic distinction should be used as a means of separating these formations in areas lying farther west the thickness of the Platteville would be there greatly increased. Recent work, however, has shown that the Platteville is a well-defined formation of comparatively uniform thickness, possessing distinctive faunal characteristics; that, at least locally, it is separated from the Galena by a period of nondeposition; and that in certain localities, especially at places west of the Mississippi, the Galena is in considerable part nondolomitic.

* * * * *

Upon the Galena dolomite lies a shale formation, which has been described in reports of the Iowa Geological Survey under the term Maquoketa, a name derived from Little Maquoketa River, on which it is typically exposed. The same formation is known in the Wisconsin State reports as the Cincinnati shale. * * *

The shale ranges in thickness from 160 to 200 feet and in the region south of this area is more than 200 feet thick.

* * * * *

The Maquoketa shale in this area can be arranged roughly into the three characteristic divisions described below:

General divisions of Maquoketa shale.

	Feet.
3. Argillaceous and calcareous shale, in beds becoming thicker and possibly dolomitic toward the top, about.....	35
2. Plastic blue and green shale and clay, with some indurated fossiliferous bands near the top, about.....	100
1. Drab and blue thin fissile shale, interbedded with thin layers of fossiliferous argillaceous limestone; near base is a thin, hard conglomerate of fine chert and phosphatic pebbles in a ferruginous matrix.....	60
* * * * *	

The Maquoketa shale in general throughout the upper Mississippi Valley forms a markedly fossiliferous horizon. There is at the very base of the formation a thickness of 2 to 5 feet of shale which contains rather abundant fossils. * * * At the top of the formation there is another horizon, more frequently exposed, that affords fossils, at some places in great abundance. * * * This association of species indicates that the beds are of Richmond age.

* * * Definite evidences of stratigraphic unconformity or of an erosion interval at the base of the Maquoketa have not been observed during the survey of this area. The change from the dolomite beds of the Galena to the shale is fairly abrupt, and mention has been made of a small conglomerate that occurs locally in the basal shale, but the sedimentation planes on the two sides of the contact line are parallel, as far as seen. The evidence, so far as it goes, does not indicate any marked physical break between the formations, although the fossils would indicate a period of nondeposition.

Upon the Maquoketa lies a heavy magnesian limestone of the Niagara, whose basal layers apparently rest concordantly on the magnesian upper Maquoketa beds where these are present. Here the lithologic change is less abrupt than at the bottom of the formation; nevertheless, the evidence furnished by fossils indicates a hiatus. There is also some evidence that the topmost fossiliferous Maquoketa beds are not everywhere present, this fact suggesting that erosion has actually occurred.

The Ordovician formations which traverse northeastern Iowa range northward into Minnesota in the apparent embayment of the sea which lies between the Isle Wisconsin^{133b} on the east and the Peninsula of Minnesota, which terminates in the Sioux quartzite area, on the west. The strata have been made the object of an elaborate correlative study by Ulrich.⁹⁴⁴

K-L 17-18. ONTARIO AND NEW YORK.

North of Lake Ontario is a wide belt of Ordovician strata which extends south-eastward around the Adirondack crystalline rocks into the Mohawk and Hudson valleys, New York. In Ontario the section as described by Ami^{20a} comprises limestones and shales from the Potsdam to the Lorraine inclusive. The sandstones are local basal shallow-water deposits resting unconformably on the pre-Cambrian.

The distribution and character of these strata from Kingston, on the St. Lawrence, to Georgian Bay are described by Logan^{544d} with detailed local sections and lists of fossils. His general statement runs as follows:

From the province line, where it crosses Lake Champlain in eastern Canada, the Birdseye, Black River, and Trenton formations, striking through the valley of this lake and the valleys of the Mohawk and Black rivers, reach the waters of the St. Lawrence and cross over into western Canada. On the United States side of the St. Lawrence they occupy a breadth extending from the Thousand Islands to Sandy Creek, and on the Canadian side from the neighborhood of Kingston to the outside of the Prince Edward peninsula.

It has already been stated that between the Potsdam formation and the strata characterized by the fossils of the Birdseye and Black River formations, to the westward of the Laurentian ridge of the Thousand Islands, there are about 80 feet of strata the age of which is not very clear. These appear in two succeeding escarpments and are traceable for a considerable distance.

Logan then gives a minutely divided section of strata outcropping at Vanluvin's mills, Storrington, which are assigned to the Chazy by Ami. Around Kingston these basal beds are Pamela, but near Georgian Bay they are Lowville. In either case they are lithologically nearly the same.

Logan's descriptions of the Black River and Trenton limestones are characterized by that degree of detail which marks his work and makes it a standard of reference that can not be adequately summarized.

In New York the Ordovician strata range south of the Adirondack area through Jefferson, Lewis, Oneida, Herkimer, Montgomery, Schenectady, and Saratoga counties to the Hudson. North of the Adirondacks they extend through St. Lawrence, Franklin, and Clinton counties to Lake Champlain. Their distribution as shown on the map of North America is taken from the New York State map of 1901.⁵⁹²

The district west, south, and east of the Adirondacks includes the local sections that were established as the standard New York section, which became the basis of North American correlation.

Dana ²²⁰ distinguished "Calciferous epoch, Chazy epoch, Trenton epoch, Utica and Hudson epochs" and described the strata which characterize each epoch in this and other districts. The New York State Survey publishes the following classification, ¹⁵⁵ which shows also the distribution of the several divisions and brings out the fact that they are not uniform throughout the State.

Extent of unit formations along their strike from west to east in the State of New York. [a]

^a Revised in accordance with letters from John M. Clarke, Jan. 13 and 19, 1910.—B. W.

^b The Frankfort begins well down in the Trenton and extends upward to some undetermined age. Possibly it corresponds to the Martinsburg shale.—E. O. Ulrich, comment on manuscript.

Grabau ³⁸³ published a discussion of the Ordovician in 1909 and suggested a revised classification.

It appears from the investigations of recent years that the Ordovician limestones west and south of the Adirondacks, like those of the upper St. Lawrence Valley, differ from the formations of corresponding age that occur east of the Hudson-Champlain trough. The western strata were spread over the margin of the continent in embayments that extended north and south of the Adirondack island or peninsula. They are neither uniform in distribution nor continuous in sequence.

Cushing ^{204a} has recently worked in Lewis and Jefferson counties west of the Adirondacks, in the original locality of the Lowville (or "Birdseye"), Black River, and Trenton limestones, to which Logan refers as quoted above (p. 183). He there determined the following section:

- | | |
|--|--------|
| 7. Trenton limestone: Thin-bedded black, somewhat shaly limestones, with lenses of gray crystalline limestone. | Feet. |
| 6. Black River limestone: Massive black limestone, lower portion full of black chert nodules. | 15-20 |
| 5. Lowville limestone: Blue or dove-colored fine-grained limestone, with beds of thin shaly limestones, which constitute nearly one-third of the formation. | 75-85 |
| 4. Pamela limestone: Blue and dove limestone, with intercalated magnesian limestones and, in the upper half of the formation, much whitish impure limestone and some yellow water lime. A thin basal sandstone and overlying shales. | 40-130 |
| [Unconformity.] | |
| 3. Theresa formation: Somewhat calcareous, sandy dolomites, weathering to rotten stone, with interbedded weak sandstones, especially near the base. | 20-60 |
| 2. Potsdam sandstone: White, yellow, and red quartzose sandstone, brown spotted and weakly cemented toward the summit. | 0-80 |
| 1. Pre-Cambrian. | |

Referring to Chapter III (p. 123) for the description of the Potsdam and "Theresa" formations, we may quote Cushing^{204c} on the Pamela and Lowville of the Watertown district (west of the Adirondacks) as follows:

The Pamela limestone is the most interesting formation in the section, since it represents the thinned edge of a formation which, while widespread elsewhere, has not heretofore been recognized in New York and is probably in existence in the State as a surface formation only in this immediate district. Because of its wide separation from other areas where the formation appears and because it represents only a small portion of the entire formation, the giving of a local name seems justified, and in Pamela Township the entire thickness and both contacts are exposed.

The formation consists essentially of limestone, though the bulk of it is not pure limestone. At its base is found a thickness of from 10 to 20 feet of sandstone and greenish shale, the sandstone being coarse but weak, owing to calcareous cement, and somewhat pebbly at the base, while the overlying green shales are both sandy and calcareous. * * *

The formation has a thickness of from 125 to 150 feet along the western margin of the Theresa quadrangle and somewhat less than half that thickness on the eastern border. * * * Above the sandy base the lower portion of the formation, 50 to 60 feet in thickness, is composed of alternating beds of blue-black limestone, dove limestone, and gray magnesian limestone. The beds usually run from 1 to 3 feet in thickness, though the black limestones may reach a thickness of 10 to 15 feet. The upper half of the formation lacks the black limestone and consists of alternations of dove limestone, gray magnesian limestone, light-gray to white thin-bedded impure limestone, and yellow water lime. About midway of this upper half is a horizon where the rocks have a pronounced pink tinge through a thickness of from 10 to 20 feet. Outside of the dove limestone beds, most of the material of this upper division is thin bedded, and the abundance of light-colored layers sharply distinguishes it from the lower division. Near the summit certain layers contain abundant nodules of coarsely crystalline calcite and sometimes celestite as well. At the extreme summit are 10 to 15 feet of more massive beds of gray limestone overlain by a thickness of a few feet of white impure beds which are somewhat sandy, and these uppermost white beds are regarded as forming the base of the overlying Lowville formation. From base to summit the formation carries an abundant ostracod fauna. In addition, the black limestones of the lower division carry a considerable additional fauna of gastropods, cephalopods, corals, and trilobites. There is some evidence that, as the formation thins to the east, owing to overlap, these black fossiliferous limestones occur at higher and higher horizons, in fashion similar to the rise of the basal sandstone in the same direction.

Many of the beds of dove limestone have mud-cracked surfaces. In connection with the ostracod fauna and the presence of water limes, this seems to indicate shallow-water and closed-basin conditions, similar to those which characterized the deposition of the water lime of the Upper Silurian in the State; but the fossiliferous limestones of the lower portion of the formation indicate that a period of open water, permitting the incoming of a marine fauna, preceded the closed basin conditions.

* * * [The Lowville] is a quite pure limestone formation, with a thickness of some 75 feet. The upper 20 feet are of pure limestone of blue or dove color and are exceedingly fossiliferous. Beneath follow 10 to 15 feet of thinner, more shaly limestones, with occasional fossils, after which through 30 feet thickness appear alternations of these thin layers with thicker beds of blue or dove limestone, with a basement of 10 feet of massive blue limestone, and then the white shaly beds already noted as forming the base of the formation. * * * The lower part of the Lowville formation carries mainly an ostracod fauna, other forms being scarce, though they do appear. "But the lower Lowville Ostracoda include species of *Leperditia* and *Isochilina* of much larger size than any so far observed in the underlying Pamela."^a

This local section is placed by Cushing^{204d} in comparison with those of the Mohawk and Champlain valleys.

^a E. O. Ulrich, letter of March 25, 1908.

Comparison with the Champlain and Mohawk sections.

Champlain Valley.	Mohawk Valley.	Watertown district.
Black River and Lowville, 40 to 60 feet.	{ Black River, 0 to 15 feet. Lowville, 0 to 25 feet.	Black River, 20 feet. Lowville, 60 to 75 feet.
Chazy. { Upper, 200 feet. Middle, 350 feet. Lower, 340 feet.	Absent. Absent. Absent.	Absent. Pamelia, 40 to 140 feet. Absent. Absent.
Beekmantown. { Division E, 470 feet. Division D, 375 feet. Division C, 350 feet. Division B, 295 feet.	} Absent.	Absent.
Beekmantown, A, 310 feet. Passage beds, 30 to 75 feet.	} Little Falls dolomite, 500 (?) feet.	Unconformity Theresa, 20 to 60 feet.
Potsdam.	Absent.	Potsdam.

Cushing ^{204e} concludes:

It has been shown that four formations—the Lowville, Pamelia, Theresa, and Potsdam—are present underneath the Black River limestone in the Watertown region, and that there is a great unconformity, both by erosion and by overlap, between the Theresa and Pamelia formations. The Pamelia formation is of upper Stones River age, and [is] thus a formation hitherto unrecognized in the New York section. It is thought that the unconformity mentioned can be traced down the St. Lawrence Valley to the Champlain meridian and represents the expanded western representative of the break discovered by Ulrich in the Champlain Valley between divisions A and B of the Beekmantown. It is also thought that it represents the proper line of division for northern New York between the Cambrian and Lower Silurian systems, thus relegating to the Cambrian nearly 400 feet of strata which have hitherto been classed as Beekmantown.

Prior to the recognition of the "Theresa" and Pamelia formations, described above, the terms Beekmantown ("Calciferous"), Chazy, Lowville ("Birdseye"), Black River, Trenton, and Utica were used. Their general distribution and relations all about the Adirondacks have been stated by Cushing.²⁰³

In 1910 Ulrich and Cushing ^{822a} published a detailed study of the Little Falls dolomite of the Mohawk Valley, in course of which they developed the relations between the Little Falls dolomite and overlying strata. They class the dolomite as the uppermost Saratogan and separate it from the Beekmantown, with which it has hitherto been placed. They describe an unconformity at the top of the dolomite and take the plane of that unconformity as the basis of classification. They say:

Our comparative study of the region has, we think, made clear the correlation of the Calciferous of the Champlain and Mohawk valleys and seems to us also to show that the Little Falls dolomite (division A and the lower part of B) does not properly belong with the Beekmantown, either structurally or faunally, and has been heretofore classed with it simply on the basis of supposed lithologic resemblance; that it is separated from the remainder of, or rather the true

Beekmantown, by an unconformity, while it invariably grades into the Potsdam beneath through a series of passage beds; and that faunally also its association is with the Potsdam, the Hoyt limestone of the Saratogan region being merely a more calcareous and more fossiliferous phase of its lower portion, of very local character, rather than a phase of the Potsdam.

Local sections of the Ordovician in the Mohawk Valley have been described with great detail and faunal lists are given in publications by Cumings,¹⁹⁵ Cushing,²⁰² Prosser,^{647, 652} Walcott,⁸⁴⁵ and White.^{908, 909, 910}

The Champlain-Hudson Valley is here mapped according to the authorities cited by Merrill^{592a} for Clinton, Washington, Rensselaer, Columbia, Dutchess, Ulster, and Orange counties. The Ordovician of this region comprises, above the Beekmantown, the Chazy, Trenton, and "Hudson River." The Chazy is restricted to the northeastern section.⁸²³ Near Albany the "Hudson River shales" are now recognized as representing, in ascending order, the Normans Kill, middle Trenton, Utica, and Lorraine. The Normans Kill shale is a clastic representative of the lower Trenton limestone of the western part of the State.

It is convenient to take up the discussion at the north in Clinton County and to proceed southward. Cushing's general statement of the relations of the several Ordovician formations around the Adirondacks is quoted on page 186. The Chazy is thus described by Cushing:²⁰¹

Brainard and Seely have recognized three subdivisions of the Chazy rocks. * * * The lower subdivision is largely constituted of quite crystalline limestones of gray color, often full of crinoidal fragments and with *Orthis costalis* the most abundant fossil; the middle division is of blue-black fine-grained limestone and contains *Maclurea magna* at nearly all horizons; the upper division is quite variable in character but is largely composed of somewhat impure blue limestones, carrying *Rhynchonella plena* abundantly.

The aggregate thickness of the Chazy limestone at Chazy village is 740 feet, with the base not shown. On Valcour Island, Brainard and Seely give it a thickness of 890 feet, and there it seems to reach its maximum.^a

Brainard's section at Valcour Island⁹⁴ reads, in ascending order:

Group A (Lower Chazy).

1. Gray or drab-colored sandstone, interstratified with thin (or sometimes thick) layers of slate, and with occasional thin layers of limestone at the base, containing <i>Camerella (?) costata</i> Bill.....	Feet. 56
The slaty sandstone gradually passes into—	
2. Massive beds, made up of thin alternating layers of tough slate and of nodular limestone, containing undetermined species of <i>Orthis</i> and <i>Orthoceras</i>	82
3. Dark bluish-gray, somewhat impure limestone, in beds of variable thickness; often packed with <i>Orthis costalis</i> Hall, which occurs with more or less frequency through the whole mass. Other fossils are <i>Lingula huronensis</i> Bill., <i>Harpes antiquatus</i> Bill., <i>Harpes otawaensis</i> Bill. (?), <i>Illænus arcturus</i> Hall (= <i>bayfieldii</i> Bill.), <i>Lituities</i> sp. (?).....	110
4. Gray, tolerably pure limestone in beds 8 to 20 inches thick, separated by earthy seams, the bedding being uneven. Many layers consist of crinoidal fragments, largely of <i>Palæocystites tenuiradiatus</i> Hall. Near the middle of the mass, for a thickness of 10 feet, some of the fragments and small ovoid masses (<i>Bolboporites americanus</i> Bill.) are of a bright-red color, and these beds on the west side of Bluff Point are extensively quarried and furnish a fine marble for indoor use.....	90
Total thickness of A.....	338

^a Ulrich regards this as a mistake, for in his judgment it robs the Beekmantown of its most essential part, namely, division D.—B. W.

Group B (*Middle Chazy*).

	Feet.
1. Impure nodular limestone, containing <i>Maclurea magna</i> Lesueur	25
2. Gray massive pure limestone, abounding in crinoidal fragments	20
3. Bluish-black thick-bedded limestone, usually weathering so as to show pure nodular masses enveloped in a somewhat impure lighter-colored matrix; everywhere characterized by <i>Maclurea magna</i> . Near the middle of this mass, for a thickness of about 30 feet, the fossils are silicified and of jet-black color. The more important, besides <i>Maclurea</i> , are species of <i>Strophomena</i> , <i>Orthis</i> , and <i>Orthoceras</i>	210
4. Dark compact fine-grained limestone, with obscure bedding, weathering to a light gray. This rock resists erosion and is the upper stratum at Bluff Point, sloping upward from the lake at an angle of 5° to a height of 170 feet. In one exposure the basal portion is densely oolitic. Fossils are infrequent, but at a single locality there were collected <i>Orthis perveta</i> Con., <i>Orthis platys</i> Bill., <i>Leptaena fasciata</i> Hall, <i>Asaphus canalis</i> Con., <i>Cheirurus polydorus</i> Bill., <i>Harpes</i> sp. und., <i>Illænus incertus</i> Bill., <i>Lichas minganensis</i> Bill., <i>Sphærezochus parvus</i> Bill., and several undescribed species	20
5. Bluish-black limestone like No. 3, but less pure, containing <i>Maclurea magna</i> Lesueur, <i>Orthis perveta</i> Con., <i>Strophomena incrassata</i> Hall, <i>Orthis borealis</i> Bill. (?), <i>Orthis disparilis</i> Con., or <i>O. porcia</i> Bill.	75
Total thickness of B	350

Group C (*Upper Chazy*).

1. Dove-colored compact limestone, in massive beds, containing a large species of <i>Orthoceras</i> , <i>Placoparia</i> (<i>Calymene</i>) <i>multicosta</i> Hall, <i>Solenopora compacta</i> , and a large <i>Bucania</i>	60
2. Dark impure limestone, in thin beds, abounding in <i>Rhynchonella plena</i> ; at the base a bed 4 or 5 feet thick is filled with various forms of <i>Monticulipora</i> or <i>Stenopora</i>	125
3. Tough arenaceous magnesian limestone, passing into fine-grained sandstone	17
Total thickness of C	202
Aggregate thickness of the Chazy on Valcour Island	890

Raymond^{660, 661} gives a classification of the faunal divisions of the Chazy (*Herbertella exfoliata* division, *Maclurites magna* division, and *Camartæchia plena* division) and distinguishes a number of faunal zones. He also discusses the distribution and correlation of the formation so far as it has been identified in Canada and the United States.

The belt east of the Hudson has been mapped by Dale^{207, 208} from Lake Champlain south to the Kinderhook (latitude 42° 30'). The rocks are chiefly slate, range in age from Lower Cambrian to Lorraine, and are but sparsely fossiliferous. The areal distribution of distinct formations is not worked out and the divisions mapped by Dale are broad and indefinite.

The post-Beekmantown Ordovician is included under the term "Hudson" and the stratigraphy is summed up as follows:^{208a}

Table showing the Hudson formation as exposed in Rensselaer County and the northeastern part of Columbia County, N. Y.

Description of strata.	Fauna.	Estimated thickness in feet.	Age.	Metamorphic equivalent.	
				[Description.]	Estimated thickness in feet.
Black shale with arenaceous limestone, etc. ^a Black and gray shale with interbedded grit. ^c Similar shale with limestone and limestone conglomerate. Black siliceous white-weathering, "cherty-looking" shale. ^e Reddish, purplish, greenish shale, with small quartzite beds. ^e	Diplograptus amplexicaulis. ^b Normans Kill graptolite fauna. Trenton fauna in limestone and cement of conglomerate. ^d	1,200-2,500?	Trenton..	{Sericite schist, black, green, or purple, in places with greenish quartzite up to 20 feet thick.	1,000-2,000

^a See Ruedemann, Rudolf, Bull. New York State Mus. No. 42, 1901, pp. 535-537, stations 24, 25, 26.

^b See Ruedemann, op. cit., for other fossils.

^c Rarely with small beds of quartzite.

^d The pebbles of this conglomerate contain Trenton, Chazy, and Lower Cambrian fossils. See Ruedemann, Rudolf, Bull. New York State Mus. No 49, 1901, and Ford, S. W., Am. Jour. Sci., 3d ser., vol. 23, 1884, pp. 206-208. [Regard this zone as overlying the true Normans Kill.]

^e The vertical relations of the colored shale and the black siliceous shale to each other and to the black and gray shale with Normans Kill graptolite fauna are not clear. They are all intimately associated. The greenish shale sometimes includes small limestone beds.

The presence of strata of Chazy, Trenton, and Lorraine age constituting the upper part of the Stockbridge dolomite in the compressed syncline near Rutland, Vt., was shown by the discovery of fossils by Wing in 1877.²¹⁶ and has been confirmed by Wolff⁹⁴⁵ and by Dale.²⁰⁵

The faunal horizons of the "Hudson shales" in the vicinity of Albany have been worked out by Ruedemann,⁶⁷⁸ who sums up his results as follows:

This paper purports to demonstrate the presence of four zones of shales in the "Hudson River shales" of the Hudson Valley region about Albany. These zones, which extend from north-northeast to south-southwest, consist, going from west to east, of shales containing the Lorraine, Utica, middle Trenton and Normans Kill graptolite faunas. The shales last named include lower Trenton conglomerate and rest on lower Trenton limestone. This succession of zones places the Normans Kill graptolite beds, which form the mass of the "Hudson River shales" in the Hudson River valley, between the middle and lower Trenton and determine, together with other facts, the lower Trenton age of these shales.

The beds lie conformably inverted, on account of their being the remnant of the underturned wing of an overturned fold of Appalachian type. This fold has turned into an overthrust fault, which brought the Cambrian beds as the next succeeding terrane above the Normans Kill shales.

On account of the fact that the mass of beds hitherto called Hudson River shales and correlated with the Lorraine beds of central New York is composed of terranes ranging from the Lorraine to the lower Trenton, and on account of the lack of a fully representative fauna and of a complete section of the Lorraine portion of these terranes, it is proposed to drop the term "Hudson River shales" for the uppermost part of the Lower Silurian and the term "Hudson River group" for the Utica and Lorraine beds and to employ the term Normans Kill shales for the classic facies of a part of the lower Trenton which is characterized by the graptolite fauna at the Normans Kill.

The limestone conglomerate referred to in the above quotation was made the subject of refined study by Ruedemann,⁶⁷⁹ with reference to the faunas of matrix and pebbles, origin of materials, and conditions of deposition. From this paper the following summary is taken:

1. The investigation of the lower Siluric shales of the neighborhood of Albany has led to the observation of a conglomerate bed embedded in these shales and outcropping on Rysedorph Hill near Rensselaer, on the Moordener Kill near Castleton, and at Schodack Landing.

2. The most interesting feature of this conglomerate is the fauna which the component pebbles and the matrix contain. To describe these and to obtain from them conclusive data as to the age of the inclosing Normans Kill shales is the principal purpose of this paper.

3. The conglomerate contains a great variety of pebbles. In the southern outcrops, at Schodack Landing, nonfossiliferous sandstone pebbles prevail; going northward, fossiliferous limestone pebbles increase, and on Rysedorph Hill they are the principal components.

4. The limestone pebbles are shown by their faunas to be derived, in very small number, from Cambric and Chazy rocks; more frequently from the Lowville limestone; and prevailingly from extremely fossiliferous black and gray limestone beds which are of lower or lowest Trenton age.

5. A specially interesting feature of the fauna of these Trenton pebbles was found in the considerable number of new forms, largely brachiopods, trilobites, and ostracods. Some of these belong to genera new to the American Trenton but well represented by very similar forms in equivalent north European beds. These, as well as several other forms which also occur in the Rysedorph Hill conglomerate and are restricted to the eastern Trenton, support the conclusion derived from the distribution of the Normans Kill graptolite shales, viz, that in lower Trenton time the eastern Trenton sea had attained connection with the Atlantic.

6. As the fauna of the Trenton pebbles is in marked features different from that of the beds known in the Mohawk and Hudson valleys, it is supposed that the material was derived from the regions to the east and northeast, where the Trenton beds have now become metamorphosed and the fossils obliterated.

7. The occurrence of the lower Trenton limestone pebbles in this region is taken to indicate that at the beginning of the Trenton period the quiet limestone-depositing Trenton sea extended also over this region; while the presence of Normans Kill shale of lower Trenton age proves that this favorable condition soon came to an end, and a radical change in the physical conditions took place.

8. The conglomerate itself is intraformational. It is embedded in shale of the same age, and the fauna of the matrix of the conglomerate is of lower Trenton age. The conglomerate, therefore, evidently does not mark any important change in the physical condition of the region but is probably due to a temporary elevation of a low Appalachian ridge into the sphere of wave action.

This conglomerate closely resembles the conglomerate of the Quebec formation of Citadel Hill, Quebec, in its constitution, associated shales, and faunas.

The full statement of Ruedemann's studies of the graptolites is contained in two memoirs, to which reference should be made for adequate appreciation. The first of these⁶⁸⁰ deals chiefly with horizons discussed in Chapter II of this work; from the second⁶⁸¹ the following table is quoted:

Correlation table of the graptolite zones of New York.^a

System.	Stage.	Graptolite zones in New York.	Distribution in North America.	Corresponding zones in Great Britain and Scandinavia.	Extra-American distribution.
Siluric	Clinton beds	Zone of <i>Monograptus clintonensis</i> and <i>Retiolites gemitzianus</i> var. <i>venosus</i> .		Zone of <i>Cyrtograptus murichsoni</i> .	Great Britain, France, Belgium, Scandinavia, Bohemia.
	Richmond beds (?)		Zone of <i>Dicellograptus complanatus</i> in Indian Territory, Wisconsin, Minnesota, Ohio, Canada.	Zone of <i>Dicellograptus complanatus</i> .	Great Britain, Scandinavia.
	Lorraine beds	Zone of <i>Diplograptus peosta</i> and <i>D. foliaceus</i> mut. <i>vespertinus</i> .	Canada, Vermont, Pennsylvania, Ohio, Wisconsin, and Minnesota (Maquoketa shale and part of Galena?).	Zone of <i>Pleurograptus linearis</i> .	Great Britain, Scandinavia.
	Frankfort shale	Zone of <i>Glossograptus quadrimacronatus</i> and <i>Climacograptus typicalis</i> .	Canada (Magog, Cove Fields, etc.), Canada, New Jersey, Alabama, Arkansas, Indian Territory, Nevada, British Columbia.	Zone of <i>Dicranograptus cingani</i> .	Great Britain, Scandinavia.
	Utica shale	Subzone of <i>Climacograptus caudatus</i> and <i>Corymoides curtus</i> mut. <i>comma</i> .	Canada (Point Levis zone), Arkansas, Nevada.	Zone of <i>Nemagraptus gracilis</i> .	Great Britain, Scandinavia.
	Upper Trenton	Zone of <i>Diplograptus amplexicaulis</i> (Upper Dicellograptus zone).	Canada (St. Anne zone), Newfoundland.	Zone of <i>Didymograptus geminus</i> .	Great Britain, Scandinavia.
	Middle Trenton	Zone of <i>Nemagraptus gracilis</i> (Normans Kill shale).	Canada (main Point Levis zone).	Zone of <i>Didymograptus bifidus</i> and <i>Phyllograptus typus</i> (Upper Tetragraptus zone).	Great Britain, Scandinavia, France, Bohemia, Victoria.
	Lower Trenton	Zone of <i>Diplograptus dentatus</i> and <i>Cryptograptus antennarius</i> (Third Deepkill zone).		Zone of Tetragraptus (Lower Tetragraptus and Dichograptus zones).	Great Britain, Scandinavia.
	Black River limestone and Lowville limestone.	Subzone (transitional zone) with <i>Didymograptus forcipiformis</i> (Ash Hill quarry).			
	Beekmantown limestone.	Subzone of <i>Didymograptus bifidus</i> and <i>Phyllograptus anna</i> . Zone of Tetragraptus. Subzone b of Goniograptus. Subzone a of Clonograptus.			
(Cambrian ^b)	Schaghticoke shale	Zone of <i>Dictyonema flabelliforme</i> .	Canada (Gaspé, St. John).	Zone of <i>Dictyonema flabelliforme</i> .	Great Britain, Scandinavia, Esthonia, Belgium.

[Ordovician] Champlainic.

^a This in part replaces the correlation table in Memoir 7 (facing p. 490).

^b It is still a mooted question whether the shale of *Dictyonema flabelliforme* constitutes the last horizon of the Cambrian or the first of the Champlainic (Lower Siluric), and several authors have lately inclined to the latter view.

In the southern part of the Hudson Valley the Ordovician divides around the pre-Cambrian of the Highlands. In the eastern area the strata are more or less metamorphosed; they are described with the similar slates and schists of New England (below). The western area extends through Ulster and Orange counties to New Jersey.²²⁵

Ries⁶⁷³ recognized in Orange County the Trenton limestone and the "Hudson River slates." Of the limestone he mentions one occurrence near Newburgh Ferry. The slates are widely distributed.

In the western part of the county the formation is represented by interbedded shales and red and brown or gray sandstones, while in the central part the slates and shales only appear. The sandstone beds again come in toward the northeast. Conglomerates are occasionally seen in the northeastern part of the county. * * * Fossils are rare but have been found at several localities. * * * They show a mixed Hudson River-Trenton fauna. * * * These rocks rest unconformably on the Cambrian limestones and gneisses and underlie younger rocks in the same manner. Their thickness in this county is probably not less than 2,000 feet.

K-L 18-19. VERMONT, NEW HAMPSHIRE, MASSACHUSETTS, AND CONNECTICUT EAST OF THE GREEN MOUNTAINS.

The presence of middle Ordovician strata in Vermont, in continuation of the Canadian occurrences, is probable, but their distribution is not known. They probably lie in synclines, overthrust by Cambrian and below remnants of the Silurian, which here, as in New Brunswick and eastern New York, is probably unconformable to the older strata. The structure is much confused by folding, thrusting, and igneous intrusions. In Canada immediately north of the international boundary Ellis³¹² has traced out the divisions of the "Quebec group" and distinguished the belts of graptolitic slates of the Ordovician. (See pp. 132-134.) The southward extension into New Hampshire and Vermont was described by Hitchcock^{452, 453} as the Calciferous mica schist and the Coos group.

In Massachusetts and Connecticut the upper part of the Stockbridge dolomite is of Beekmantown, Chazy, and Trenton age and the Berkshire schist is assigned to the general position of the "Hudson River"—that is, to Trenton and later Ordovician, the upper limit being indeterminate.

Along the boundary between New York on the west and Vermont, Massachusetts, and Connecticut on the east extends the Taconic Range, the area of the Taconic system of Emmons. Dana published the results of his prolonged study of the structural relations and his conclusions as to the true order of the strata of the Taconic Range in a series of papers in the *American Journal of Science* (1872-1887).^{218, 219} He also summed up the history and facts in the *Quarterly Journal*.²¹⁷

The early discoveries of fossils by Wing (see p. 189) were followed by Walcott's discoveries in the central Taconic area, which proved the Cambrian and Ordovician age of the strata. Walcott⁸⁴⁹ distinguished the rocks of certain areas as "terranes" and concluded that terrane 3, the upper part of the Stockbridge dolomite, was equivalent to the "Calciferous" (Beekmantown), Chazy, and Trenton limestones of the Champlain-Hudson Valley and terranes 4 and 6 were of "Hudson" age.

In Berkshire County, northwestern Massachusetts, lies Mount Greylock, which is composed of the Stockbridge dolomite and overlying strata. Dale²⁰⁶ worked out its structure and gives the following tabulation of the stratigraphy as determined by him, in comparison with other classifications:

General lithologic character, order, and estimated thickness of the strata of Mount Greylock, East Mountain, and Stone Hill.

Formations (natural order).	Lithologic character.	Thickness (feet).	Age.			
			Emmons, 1855.	Hall, 1839-1844.	Dana, 1882-1887.	Walcott, 1888.
Greylock schist...	Muscovite (sericite), chlorite, and quartz schist, with or without biotite, albite, magnetite, tabular crystals or lenticular plates of interleafed ilmenite and chlorite, ottrelite, microscopic rutile, and tourmaline. These schists are rarely calcareous or graphitic.	1,500-2,000	Pre-Potsdam..... Lower Taconic No. 3. "Talcose or magnesian slate."	Trenton (Hudson River).	Lower Silurian....	Trenton (Hudson River).
Bellowspipe limestone.	Limestone, more or less crystalline, generally micaceous or pyritiferous, passing into a calcareous schist, or a feldspathic quartzite, or a fine-grained gneiss with zircon and microcline, or a schist like the Berkshireschist. The more common minerals are graphite, pyrite, albite, and microscopic rutile and tourmaline. More rare, galena, zinc blende, siderite.	600-700	Pre-Potsdam..... Lower Taconic No. 3. Included in "Talcose or magnesian slate."	Trenton (Hudson River).	Lower Silurian....	Trenton (Hudson River).
Berkshire schist...	Muscovite (sericite), chlorite, and quartz schist, with or without biotite, albite, graphite, magnetite; frequently with tabular crystals or lenticular plates of interleafed ilmenite and chlorite. Garnet, ottrelite. Microscopic rutile and tourmaline. These schists are in places calcareous, especially toward the underlying limestone, where they are often graphitic.	1,000-2,000	Pre-Potsdam..... Lower Taconic No. 3. "Talcose or magnesian slate."	Trenton (Hudson River).	Lower Silurian....	Trenton (Hudson River).
Stockbridge limestone.	Limestone, crystalline, coarse or fine; in places a dolomite, sometimes quartzose or micaceous, more rarely feldspathic, very rarely fossiliferous. Galena and zinc blende rare. Irregular masses of iron ore (limonite) associated sometimes with siderite, often with manganese ore (pyrolusite). Some quartzite.	1,200-1,400	Pre-Potsdam..... Lower Taconic No. 2. "Stockbridge limestone."	Lower Silurian (Trenton and lower).	Lower Silurian....	Trenton (Trenton); Canadian (Chazy, Calciferous).
Vermont formation	Quartzite, fine grained, alternating with a thin-bedded micaceous and feldspathic quartzite (the latter with calcite, pyrite, tourmaline). Associated with these quartzites, and probably at the base of this horizon, is a coarse-grained micaceous quartzite (tourmaline), passing in places into a conglomerate and containing blue quartz, feldspar (plagioclase, microcline), and zircon, all of clastic origin. Total thickness: Minimum..... Maximum.....	800-900 5,000 7,200	Pre-Potsdam..... Lower Taconic No. 1. "Granular quartz."	Cambrian (Potsdam).	Lower Cambrian (Olenellus).

In the same monograph Pumpelly⁶⁵⁴ describes the structural and stratigraphic grounds for correlating the Cambrian and Ordovician strata of Mount Greylock with the Hoosac schist on the east. The latter is mapped as Cambrian and Ordovician. (See Chapter III, p. 114.)

In southwestern Massachusetts and adjoining parts of Connecticut and New York lies the Mount Washington mass of the Taconic Range, which has been more particularly studied by Hobbs,⁴⁵⁵ who distinguished four formations apparently equivalent to those recognized by Dale, namely:

Mount Washington, Hobbs.	Mount Greylock, Dale.
Top.	
Everett schist	Greylock schist.
Egremont limestone	Bellowspipe limestone.
Riga schist	Berkshire schist.
Canaan dolomite	Stockbridge limestone.

Ordovician strata, which, though highly metamorphosed by igneous injection, are identified as representatives of the Stockbridge dolomite and "Hudson shale," form part of Manhattan Island, New York.⁵⁹³ They have been traced through eastern New York and western Connecticut to the fossiliferous area of the Taconic Range, first by Dana, and later by Gregory.³⁸⁷

L 12. SOUTHWESTERN MONTANA.

There is no recognized break in the sequence of lower Paleozoic strata which appear around the uplifts of southwestern Montana; and yet no strata which may certainly be referred to the Ordovician are known there. Apparently but slight record of marine or land conditions was made in the region during that long time.

L 16. UPPER PENINSULA OF MICHIGAN.

Rominger^{677a} describes in detail the occurrence of "Chazy and Calciferous, Trenton, and Hudson River" strata in the Upper Peninsula of Michigan. The distribution of the formations as shown on the map of North America is taken from the geologic map of Michigan published by the present Survey, and the following notes are abstracted from a paper by Lane.⁵¹⁷

Lane describes in ascending order St. Peter sandstone, Trenton limestone, Utica shale (Eden of Ohio), and Lorraine or Maysville shale as formations composing the Ordovician between the "Calciferous" and his "Richmond and Medina transition beds."

The St. Peter sandstone does not outcrop in Michigan but is recognized in well drilling as a quartz sand between the "Trenton" limestone above and the "Calciferous" limestone below. Its thickness is very irregular, presumably because it lies on an uneven surface.

The "Trenton" of northern Michigan, according to Lane and Grabau, comprises the equivalents of the Chazy, Black River (Lowville or "Birdseye" and Black River of present usage), and Trenton of Hall's classification in New York, or the Chazy and Mohawkian of the present New York State Survey classification. The base of this limestone is the passage into the St. Peter sandstone, or, where that is

lacking, the contact with the "Calciferos" (lowermost Ordovician) or the pre-Cambrian, upon which it overlaps. The passage from the "Trenton" limestone or dolomite to the overlying shale described by Lane as the Utica is well marked lithologically. Lane states the thickness of the "Trenton" as 250 to 271 feet. It is in places dolomitic. Subdivisions in the Green Bay region are recognized by him as follows:

	Feet.
Galena limestone:	
[Limestone,] crystalline, granular.....	83
Limestone, fossiliferous 55 feet, white 8 feet, dark 9 feet.....	72
Alternating blue and brown, crystalline, granular. With the dark base compare the Wisconsin oil rock.....	225
Sandy limestones, "quartz" 6 feet, limestone 44 feet, quartz 1 foot, limestone 24 feet; compare quartz sandstone at Marinette at 260-275 feet.....	75
Wisconsin Trenton (Platteville?), blue shale and limestone (blue shale 4 feet, black limestone 141 [14?] feet, limestone 19 feet, blue shale 4 feet).....	41

The formation recognized by Lane as the Utica shale is described as a black shale ranging in thickness from 50 feet at the north to about 200 feet at the south. The formation described by him as Lorraine or Maysville is an abundantly fossiliferous blue shale which he correlates with the Maquoketa of Iowa.

Lane groups certain coarser deposits and residual red clays formed from limestone as "Richmond and Medina transition beds." The former he places in the Ordovician, the latter in the Silurian, although he does not doubt that Ulrich is right in placing the Richmond of Indiana in the Silurian. He states, however, that in this region the strata to which he applies the name Richmond are so closely associated with the underlying shales, being included with them in many well drillings, that it is not convenient to separate them from the Ordovician. The strata described by Lane as Richmond and Medina consist of red and green shale, with some limy beds, and vary in thickness from little or nothing to about 142 feet at Cheboygan, thickening toward the south.

Ulrich in commenting on Lane's view states that the Utica and Lorraine do not outcrop in Michigan, but that the "Trenton" is succeeded by the Maquoketa, of Richmond age, with a hiatus between equivalent to the Eden, Utica, and Maysville of the Cincinnati section.

L 17. MANITOULIN ISLANDS.

The east end of Great Manitoulin Island, Ontario, falls within the area mapped on the French River sheet. In reporting on that area Bell⁶⁷ summarized the results of his own work and that of his colleagues in preceding years. The several formations of the later Ordovician—"Chazy?, Trenton, Utica, and Hudson"—are described in some detail. To the Chazy are doubtfully assigned the lowest beds of the Paleozoic in this region, certain chocolate-colored marls, with some fine sandstones, 100 feet thick. Bell obtained no fossils from these strata, but Ami²⁴ states that "Billings notes in a list of fossils from the island farthest south of the group, off Point Pallideau, Lake Huron, the occurrence of *Modiolopsis parviuscula*, *Vanuxemia inconstans*, *Pleurotomaria staminea*, and *Lingula huronensis*, species known to occur in the Chazy of different portions of Ontario, notably in the Montreal-Ottawa-Champlain basin."

The "Trenton group" is represented by gray limestones with shaly and marly beds, approximately 320 feet thick. Locally these strata rest upon the Ste. Marie sandstone^{54a} or directly upon the pre-Cambrian quartzite ledges of the north-eastern islands (Badgely Point, etc.), where they carry Black River fossils. Ami^{24a} cites a number of collections of fossils from these strata.

"Hudson River" strata of the islands are described as bluish-gray and drab marls and shales, interstratified with thin limestone and fine-grained sandstone, altogether 250 to 300 feet thick, including a 30 to 40 foot band of limestone at the top. Ami states:

It is extremely desirable that further collections be obtained from the Ordovician and Silurian succession of the Manitoulin Island district of Lake Huron, inasmuch as the sedimentation of that area is not only quite distinct from that of the Niagara and Toronto districts on the Ontario basin, but bears strong resemblance to the succession known and recorded in Indiana, Ohio, and Kentucky to the south, as well as to that of the Island of Anticosti, in the valley of the St. Lawrence, east.

The beds called Utica shale are described as black and bituminous and 60 feet thick. Some of the collections (Nos. 14-20) contain faunas which appear to indicate the presence of the summit beds of the Ordovician, either Lorraine or Richmond; elsewhere Lorraine (21-22) and Richmond (23-32) have been distinctly recognized. To the Clinton (Medina strata being absent) are assigned drab, buff, and purplish magnesian limestones.

L 17. LAKE NIPISSING, LAKE TEMISCAMING, AND MATTAWA.

Outliers of Ordovician limestone containing Black River and Trenton faunas occur on islands in Lake Nipissing, Lake Temiscaming, and 6 miles below Mattawa, on the Ottawa.⁵⁵ They are too small to be shown on the map but are important, as their correlation, according to Ami,^{15a} shows "that in Ordovician times the marine waters of the Lake Huron Paleozoic basin were directly connected with those of the Nipissing and Mattawa or Upper Ottawa regions."

L 18-19. ST. LAWRENCE VALLEY.

The distribution of the Ordovician, exclusive of the Beekmantown ("Calciferous"), in the St. Lawrence Valley as here mapped is taken from the map sheets of Ontario and Quebec. The line at the base is that between the "Calciferous" and Chazy, and that part of the Ordovician above this line comprises the equivalent of the Chazy, Lowville ("Birdseye"), Black River, Trenton, Utica, and Lorraine of the New York section. The Pamela limestone²⁰⁴ and the underlying but unconformable "Theresa formation" have also been traced in the latest work (1908).^a

The southwestern or upper part of the St. Lawrence Valley is known in Canadian geology as the Ottawa Basin. This basin is bounded on the southwest by the Frontenac axis, the belt of pre-Cambrian rocks which crosses the St. Lawrence and connects with the Adirondack area. On the east a similar area of older rocks, eroded to the Potsdam sandstone, separates the Ordovician of the Ottawa basin from the equivalent Ordovician strata that extend from Montreal to Quebec, down the north side of the St. Lawrence Valley.

^a Ami., H. M., personal communication, Sept., 1908.

The St. Lawrence Valley east of the river between Montreal and Quebec is divided by the St. Lawrence-Champlain thrust fault into two zones, the line of division, according to Logan,^{54h} passing through Quebec and curving thence to Lake Champlain. Strata that occur southeast of this line differ in lithology and faunas from those of probably equivalent age that are found northwest of it. The facies differ across the thrust fault. Those of the northwestern zone (Ottawa, Montreal, Quebec) may be described under the New York names cited above, but those of the southeastern zone ("Eastern Townships") belong to the Sillery, Levis, and Quebec formations (named in ascending order), which constitute the old Quebec group of Logan and Billings. The Sillery (Cambrian) and Levis (Beekmantown or "Cal-ciferous") are described in Chapter III (pp. 131-134). The Quebec formation (restricted) is the equivalent of the upper Chazy and lower Trenton.^{16b, 853}

In Ells's report on the geology of the area shown on the Three Rivers map sheet³¹⁴ occurs the following table, which is based on correlations by Ami:

System.	Formations.		Character of strata, etc.	
	West of fault.	East of fault.	West of fault.	East of fault.
Silurian.....	Medina.....		Red shales and sandstones.	
	Lorraine.....		Grayish shales and sandstones.	
	Utica.....		Black bituminous shales.	
Cambro-Silurian or Ordovician.	Trenton.....	} (Farnham).....	Limestones.....	} Black graptolitic shales and black or dark impure limestones.
	Black River.....		Limestones.....	
	Chazy.....		Chiefly limestone; shale in lower part.	
	Calciferous.....		Magnesian limestones.....	
	Potsdam.....		Sandstones.....	
Cambrian.....		Sillery.....		Red and gray and green slates and greenish-gray sandstones.
Archean.....	Grenville.....		Gneisses and limestones with granites and igneous rocks.	

It is convenient to consider the formations northeast of the St. Lawrence-Champlain fault separately from those southeast of it. We first take up the Ottawa basin.

The Paleozoic rocks of the Ottawa Basin are bounded on the southwest by the Frontenac axis, an outcrop of pre-Cambrian rocks which extends across the St. Lawrence into New York and connects with the Adirondack mass; beyond this axis to the southwest along the upper St. Lawrence and Lake Ontario is another area of Ordovician strata, in which the section differs somewhat from that of the Ottawa Basin. Ami²⁰ contrasts them as follows:

Ordovician east of the Frontenac axis.

- VII. Lorraine: Buff-weathering and dark siliceous shales and mudstones.
- VI. Utica: Dark-brown and black bituminous shales and limestones at the base.
- V. Trenton: Dark-gray impure and semicrystalline fossiliferous limestone.
- IV. Black River: Heavy-bedded and hard compact fine-grained impure limestones, etc.
- III. Chazy: Limestones, shales, sandstones, and grits; shallow water deposit at the base.
- II. Beekmantown (Calciferous): Dark-gray impure magnesian limestone or dolomites, cavernous and fossiliferous.
- I. Potsdam: Light-yellow and rusty-colored sandstones and conglomerates; shore deposits resting on the Archean crystallines.

Ordovician west of the Frontenac axis.

- V. Lorraine: Arenaceous shales and mudstones, at times very fine-grained argillites.
 IV. Utica: Dark-brown and black fossiliferous shales, etc.
 III. Trenton: Gray impure fossiliferous limestones.
 II. Birdseye and Black River [Pamelia, Lowville, and Black River]: Heavy-bedded impure fossiliferous limestones and fine-grained compact lithographic beds at the base.
 I. Rideau [Ste. Marie^a]: Mostly red and yellow (at times green) colored sandstones; shallow-water deposit; false bedding prevalent; a basal series resting unconformably upon the subjacent Archean crystallines [Chazy.—B. W.].

The following tables of the geologic formations which make up the Ordovician near Ottawa, Montreal, and Quebec, northwest of the St. Lawrence-Champlain fault, are taken from a paper by Ami.^{16a}

[Part of] synoptical table of the geological formations about Toronto, Ontario.

System.	Formation.	Character of strata, etc.	Characteristic fossils.	Thickness.
Ordovician.	Lorraine.....	Light yellowish green and gray calcareous and magnesian and arenaceous shales or mudstones, some very fine grained argillites, bluish gray in color.	<i>Diplograptus hudsonicus</i> Nicholson, <i>Monotrypella undulata</i> Nich., <i>Zygospira headi</i> Billings, <i>Platystrophia biforata</i> Schlotheim, v. <i>lynx</i> Eichwald, <i>Drepanodus arcuatus</i> Hinde, <i>Distacodus incurvatus</i> Hinde, <i>Pronodus? politus</i> Hinde, <i>Lyrodesma poststriatum</i> , <i>Liospira subconica</i> Hall, <i>Modiolopsis modiolaris</i> Hall, <i>Byssonychia radiata</i> H., <i>Modiolopsis pholadiformis</i> H., <i>Orthoceras lamellosum</i> H., <i>Ormoceras crebrisepium</i> H., <i>Triarthrus becki</i> Green, <i>Favistella stellata</i> H., <i>T. calycina</i> N., <i>Tetradium minus</i> Safford.	Between 600 and 650 feet. Varies in thickness in different exposures. Thickness depends upon amount of denudation and erosion.
	Utica.....	Dark-brown and black bituminous shales (only reported and observed in drillings from deep wells).	The characteristic fossils of this formation as exposed at Whitby and vicinity east of Toronto are <i>Leptograptus flaccidus</i> Hall, <i>Orthograptus quadrimucronatus</i> H., <i>Leptobolus insignis</i> H., <i>Schizocrania filosa</i> H., <i>Zygospira modesta</i> Say, <i>Lyrodesma pulchellum</i> Emons, <i>Trocholites ammonius</i> , <i>Triarthrus canadensis</i> Smith, <i>T. becki</i> Green.	About 100 feet.
	Trenton.....	Dark and light gray and yellowish-gray impure fossiliferous limestones with shaly partings.	<i>Diplotrypa</i> sp., <i>Dicranopora</i> sp., <i>Plectambonites sericea</i> Sowerby, <i>Orthis (Dalmanella) testudinaria</i> Dalman, <i>Rhynchotrema</i> sp.	About 550 feet in bore holes.
	Birdseye and Black River.	Dark-gray impure, but also and for the most part fine-grained compact yellowish-gray lithographic limestone, with basal beds of a calcareo-arenaceous or arkose nature.	<i>Isoclitina lithographica</i> n. s. . .	About 160 feet in bore holes.
Unconformity.				
Pre-Cambrian.				

^a According to a personal communication from Dr. Ami, the sandstones at Rideau are of Potsdam age. They are not of widespread occurrence in this district. Sandstones which are similar but are of Chazy age locally form the base of the Ordovician succession (Storrington, near Kingston, and island off Pallideau) and were described by Logan (Geology of Canada, 1863, p. 196) as the Ste. Marie sandstone. Hence in Dr. Ami's judgment Rideau in this section must give place to Ste. Marie.—B. W.

[Part of] synoptical table of geological formations about Ottawa, Canada.

System.	Formation.	Character of strata, etc.	Characteristic fossils.	Thickness.
Silurian.	Medina.....	Bright brick-red argillaceous and arenaceous shales or marls, occasionally spotted or mottled green.	No fossil organic remains have as yet been detected in these shales.	About 100 feet in thickness. On one of the outliers examined a 60-foot well was sunk in these shales.
	Lorraine.....	Buff-weathering fine-grained brittle shales and mudstones, at times arenaceous.	<i>Zygospira headi</i> Billings, <i>Byssonychia radiata</i> Hall, <i>Modiolopsis modiolaris</i> Conrad, <i>M. pholadiformis</i> Hall, <i>Liospira subconica</i> Hall, <i>Calymene senaria</i> Conrad, <i>Cyrtolites ornatus</i> Con.	Exact thickness not ascertained, but probably not less than 100 or 150 feet.
Ordovician.	Utica.....	Dark-brown and black bituminous softshales and limestone bands interstratified in the basal portion of this formation.	<i>Leptograptus flaccidus</i> Hall, <i>Orthograptus quadrimicronatus</i> Hall, <i>Schizambon canadensis</i> Ami, <i>Schizocrania filosa</i> Hall, <i>Batostomella erratica</i> Ulrich, <i>Turpilepas canadensis</i> Henry Woodward, <i>Stephanella sancta</i> Hinde, <i>Triarthrus spinosus</i> Billings, <i>Asaphus latimarginatus</i> Hall (= <i>A. canadensis</i> Chapman) <i>Endoceras tenuistriatum</i> Hall.	From 60 to 75 feet.
	Trenton.....	Nodular and evenly bedded, for the most part bluish-gray, light-weathering impure limestones and shales, fossiliferous, marine sediments, in part bituminous, cherty.	<i>Licrophycus ottawaensis</i> Billings, <i>Pasceobus globosus</i> B., <i>Astylospongia parvula</i> Billings, <i>Streptelasma corniculum</i> Hall, <i>Archæocrinus microbasalis</i> Bill., <i>Cleioocrinus magnificus</i> B., <i>Glyptocrinus ramulosus</i> B., <i>Heterocrinus canadensis</i> B., <i>Iocrinus subcrassus</i> M. and W., <i>Reteocrinus stellaris</i> B., <i>Amygdalocystites florealis</i> Bill., <i>Ateleocystites huxleyi</i> B., <i>Comarocystites punctatus</i> B., <i>Pleurocystites filitextus</i> B., <i>Agelacrinites dicksoni</i> B., <i>Monticulipora billingsi</i> Foord, <i>Batostoma ottawaensis</i> Foord, <i>Prasopora selwyni</i> Nicholson, <i>Solenopora compacta</i> B., <i>Orbiculoidea circe</i> B., <i>Skenidium merope</i> B., <i>Rafinesquina alternata</i> Conrad (Emmons), <i>Trematis ottawaensis</i> B., <i>Ambonychia amygdalina</i> B., <i>Pterinea trentonensis</i> Conrad, <i>Conularia trentonensis</i> H., <i>Protowartha cancellata</i> Hall, <i>Eccyliomphalus trentonensis</i> Con., <i>Ophileta ottawaensis</i> B., <i>Trochonema umbilicatum</i> H., <i>Hormotoma bellicincta</i> H., <i>Orthoceras python</i> B., <i>O. ottawaense</i> B., <i>Serpulites dissolutus</i> B., <i>Zygospira recurvirostra</i> H., <i>Isotelus gigas</i> De Kay, <i>Bronteus lunatus</i> B., <i>Harpes ottawaensis</i> B.	From 450 to 500 feet.

[Part of] *synoptical table of geological formations about Ottawa, Canada*—Continued.

System.	Formation.	Character of strata, etc.	Characteristic fossils.	Thickness.
Ordovician.	Birdseye and Black River.	Fine-grained and compact light-gray impure limestones, marine and fossiliferous, some beds massive, others shaly and nodular.	<i>Stromatocerium rogosum</i> Hall, <i>Receptaculites occidentalis</i> Salter, <i>Streptelasma profundum</i> Hall, <i>Tetradium fibratum</i> Safford, <i>Columnaria halli</i> Nicholson, <i>Maclurea logani</i> Salter, <i>Goniceras anceps</i> Hall, <i>Heliocotoma planulata</i> Salter, <i>Orthis tricrenaria</i> Conrad, <i>Strophomena incurvata</i> Shepard, <i>Cyrtodonta subtruncata</i> Billings, <i>Cyrtoceras sinuatum</i> B., <i>Onco-ceras constrictum</i> Hall, <i>Actinoceras bigsbyi</i> Stokes, <i>Orthoceras rapax</i> B., <i>Illæ-nus ovatus</i> B., <i>I. conradi</i> B.	About 150 feet.
	Chazy.....	Light-gray impure fine-grained and concretionary and fossiliferous limestones, cement rock. Yellowish-gray calcareous and arenaceous shales, rusty-weathering, with phosphatic nodules. Arenaceous shales and sandstones and magnesian bands, fine grained and light yellow weathering.	<i>Leperditia canadensis</i> Jones, <i>Isochilina ottawa</i> J., <i>Camartoechia plena</i> Hall, <i>Dinorthis platys</i> Hall, <i>Orthis (Hebertella) borealis</i> , Billings. <i>Lingula belli</i> Billings, <i>Modiolopsis parviuscula</i> B., <i>Ctenodonta</i> n. sp., <i>Cyrtodonta breviscula</i> B., <i>Serpulites</i> sp., <i>Scolithus</i> , n. sp. <i>Orthis imperator</i> Billings, <i>Asaphus canalis</i> Conrad, <i>Lingula tyelli</i> Billings.	About 20 feet..... 30 feet..... 150 feet.....
	Calciferous [Beekmantown].	Magnesian limestones, fine and coarse grained buff-weathering, hard and cherty, at times soft and saccharoidal or arenaceous and holding cavities lined with crystals of quartz, passing down into arenaceous layers or sandstones.	<i>Cryptozoon calciferum</i> Dawson, <i>Ophileta complanata</i> Vanuxem, <i>Hormotoma anna</i> Bill., <i>O. disjuncta</i> B., <i>Orthoceras lamarcki</i> B., <i>Pleurotomaria gregaria</i> B., <i>Ribeiria calcifera</i> B.	250 to 300 feet.
[Cambrian.]	Potsdam.....	Light-yellow or white and light-colored, at times rusty-weathering sandstones with conglomerates at the base.	<i>Ophileta</i> sp. cf. <i>O. complanata</i> Van. <i>Orthoceras</i> sp., <i>Scolithus canadensis</i> Billings, <i>Climactichnites wilsoni</i> Logan, <i>Protichnites septem-notatus</i> Owen.	About 200 feet.
Unconformity.				
Pre-Cambrian.				

200 feet.

[Part of] *synoptical table of geological formations about Montreal, Canada.*

System.	Formation.	Character of strata, etc.	Characteristic fossils.	Thickness.
Post-Devonian. [Unconformity.]	Eruptives.	Nepheline syenite, dolerite, trachyte, breccias, diorites, olivine diabase, dikes, etc.	None.	Forming conspicuous masses coming through the Ordovician plain.
Devonian. [Unconformity.]	Oriskany and Hamilton(?).	Fragments of light-gray impure fossiliferous limestone.	<i>Spirifer mesacostalis</i> Hall (teste Prof. H.S. Williams); <i>Spirifer cumberlandæ</i> , <i>S. pennatus?</i> , <i>S. arenosus?</i> , etc.	Not ascertained. Isolated patches and fragments.

[Part of] synoptical table of geological formations about Montreal, Canada—Continued.

System.	Formation.	Character of strata, etc.	Characteristic fossils.	Thickness.
Silurian.	Lower Helderberg.	Light-gray impure sub-crystalline and altered limestone, as small outliers.	<i>Leptaena rhomboidalis</i> , <i>Strophodonta varistriata</i> , <i>Strophonella punctulifera</i> , <i>Pentamerus (Sieberella) galeatus</i> , <i>Atrypa reticularis</i> , <i>Platystoma depressum</i> .	Only a few feet thick, preserved near some protecting dike of eruptives.
[Unconformity.]	Lorraine.....	Black or dark-brown and buff-weathering shales and arenaceous beds and mudstones; fossiliferous.	<i>Favistella stellata</i> , <i>Orthograptus quadrimucronatus</i> , <i>Zygospira headi</i> , <i>Pterinea demissa</i> , <i>Byssonychia radiata</i> , <i>Clidophorus planulatus</i> , <i>Orthodesma parallelum</i> , <i>Protowarthia cancellata</i> , <i>Cyrtolites ornatus</i> .	From a few feet to 400 or 600 feet, and runs to the south and west.
Ordovician.	Utica.....	Dark-brown and black bituminous shales or pyroschists with impure limestone bands at base; fossiliferous.	<i>Leptograptus flaccidus</i> , <i>Lepidobolus insignis</i> , <i>Schizocrania filosa</i> , <i>Cornulites immaturum</i> , <i>Endoceras proteriforme</i> v. <i>tenuistriatum</i> , <i>Triarthrus becki</i> , <i>Trocholites ammonius</i> .	Between 100 and 450 feet.
	Trenton.....	Dark-gray impure fossiliferous limestones and shales extensively quarried for building purposes; at times semicrystalline.	<i>Glyptocystites logani</i> , <i>Heterocrinus tenuis</i> , <i>Pachydictya acuta</i> , <i>Phylloporina trentonensis</i> , <i>Prasopora selwyni</i> , <i>Plectambonites sericea</i> , <i>Trematis montrealensis</i> , <i>Dalmanella testudinaria</i> , <i>Lingula riciniformis</i> , <i>Parastrophia hemiplicata</i> , <i>Rafinesquina alternata</i> , <i>Platystrophia lynx</i> , <i>Cyclonema montrealense</i> , <i>Trochonema umbilicatum</i> , <i>Conularia trentonensis</i> , <i>Trinucleus concentricus</i> , <i>Isotelus gigas</i> , <i>Calymene senaria</i> .	Between 400 and 500 feet.
	Black River....	Light-gray weathering, dark-gray and black impure fossiliferous limestones; building stone.	<i>Tetradium fibratum</i> , <i>Columnaria halli</i> , <i>Stromatocerium rugosum</i> , <i>Helicotoma planulata</i> , <i>Cyrtodonta huronensis</i> , <i>Bathyurus ectans</i> .	About 75 feet.
	Chazy.....	Light and dark gray semicrystalline impure fossiliferous limestone; useful for building purposes.	<i>Bolboporites americanus</i> , <i>Malocystites purchisoni</i> , <i>Blasitoidocrinus carchariædens</i> , <i>Camarotoechia plena</i> , <i>Hebertella borealis</i> , <i>Dinorthis platys</i> , <i>Bathyurus angelini</i> .	Between 150 and 200 feet.
	Calciferous....	Dark-gray, buff and yellow weathering impure earthy and semicrystalline limestones, for the most part magnesian, and holding numerous crystals filling cavities; lower measures arenaceous.	<i>Orthisina grandæva</i> Billings, <i>Pleurotomaria calcifera</i> B., <i>P. canadensis</i> B., <i>Hormotoma anna</i> B., <i>Metoptoma simplex</i> B., <i>Orthoceras lamarcki</i> B., <i>Amphion salteri</i> B., <i>Bathyurus cybele</i> B., <i>Ribeiria calcifera</i> B., <i>Leperditia anna</i> B.	Between 200 and 250 feet.
	Potsdam.....	Light-yellow and rusty-weathering sandstones and conglomerates occasionally present at the base and along certain divisional planes of stratification.	<i>Scolithus canadensis</i> Bill., <i>Protichnite multinotatus</i> Owen, <i>P. lineatus</i> Owen, <i>P. octonotatus</i> Owen, <i>P. septem-notatus</i> Owen.	Between 200 and 300 feet.
[Unconformity.]				
[Pre-Cambrian.]				

[Part of] synoptical table of the geological formations about Quebec City, Quebec.

System.	Formation.	Character of strata, etc.	Characteristic fossils.	Thickness.
Ordovician.	Lorraine.....	Buff-weathering fine-grained magnesian and arenaceous shales and limestone bands.	<i>Orthograptus quadrimucronatus</i> H., <i>Diplograptus hudsonicus</i> Nicholson, <i>Ambonychia</i> (<i>Byssonychia</i>) <i>radicata</i> H., <i>Orthodesma parallellum</i> Hall, <i>Trinucleus</i> sp., <i>Modiolopsis</i> , and <i>Bellerophon</i> .	Several hundred feet thick. Between 700 and 900 feet (719 feet, Logan).
	Utica.....	For the most part dark-brown and buff-weathering or black bituminous shales and thin bands of limestone.	<i>Leptobolus insignis</i> Hall, <i>Schizocrania filosa</i> Hall, <i>Serpulites dissolutus</i> Bill., <i>Triarthrus becki</i> Green, <i>Asaphus latimarginatus</i> Hall (= <i>A. canadensis</i> Chapman).	Estimated at between 250 and 300 feet (318 feet, Logan).
	Trenton.....	Thin and evenly bedded fine-grained and light-gray compact limestones, with thin shaly bands interstratified. Marine and fossiliferous; used for building purposes.	<i>Prasopora selwyni</i> Nicholson, <i>Discina pelopea</i> Billings, <i>Plectambonites sericea</i> Sowerby, <i>Rafinesquina alternata</i> Conrad (Emmons), <i>R. deltoidea</i> Con., <i>Dalmanella testudinaria</i> Dalman, <i>Protowarthia cancellata</i> Hall, <i>Calymene senaria</i> , Conrad, <i>Trinucleus concentricus</i> Eaton.	About 300 feet to 400 feet. Only a few feet observed in various outcrops overlying the Archean.
	Black River....	Heavier-bedded coarser-grained and in part dark-weathering impure semicrystalline limestones, fossiliferous.	<i>Ambonychia bellistriata</i> Hall, <i>Trochoceras halli</i> Foord, <i>Trochilina amii</i> Jones, <i>Illærus milleri</i> Billings.	About 75 feet exposed.
	Quebec.....	Hard compact cherty and calcareous bands, dark-brown or black, more or less thick beds of bituminous shales, limestone beds, and evenly bedded conglomerates and bands holding arenaceous material. Fossiliferous throughout; much disturbed and faulted, folded, and considerably altered, slickensided, etc.	<i>Diplograptus angustifolius</i> Lapw., <i>Climacograptus bicornis</i> Hall, <i>Dicranograptus ramosus</i> H., <i>Dicellograptus anceps</i> , <i>Paterula amii</i> Schuchert, <i>Corynoides calycularis</i> Nicholson, <i>Shumardia granulosa?</i> Billings, <i>Bathyrurus caudatus</i> B., <i>Aeglina redeviva</i> or n. sp., <i>Remopteurides? schlotheimi</i> B., <i>Primitia logani</i> Jones, <i>Aparchites mundulus</i> Jones.	Several hundred feet in thickness. The precise figures not yet ascertained.
	Levis.....	Dark-gray and brown and black carbonaceous shales with limestone beds and conglomerate bands, also light yellow colored dolomites. Fossiliferous throughout. The light yellowish gray limestone often semicrystalline, much folded and faulted and oftentimes slickensided.	<i>Tetragraptus quadribrachiatum</i> Hall, <i>T. serra</i> Brongniart (= <i>T. bryonoides</i> Hall), <i>T. bigsbyi</i> H., <i>T. approximatus</i> Nicholson, <i>Clonograptus flexilis</i> Hall, <i>Dichograptus octobrachiatus</i> H., <i>Phyllograptus typus</i> Hall, <i>Goniograptus selwyni</i> Ami, <i>Trigonograptus ensiformis</i> H., <i>Diplograptus dentatus</i> Bgt. (= <i>D. pristiniformis</i> H.), <i>Holograptus amii</i> Lapw. (MS.), <i>Dictyograptus dawsoni</i> (= <i>D. delicatula</i> Dn.), <i>Lingula quebecensis</i> Billings, <i>Elkania desiderata</i> Bill., <i>Serpulites westoni</i> n. sp., <i>Shumardia granulosa</i> Billings.	Several hundred feet in thickness. The precise thickness not as yet ascertained (about 1,400 feet).

[Part of] *synoptical table of the geological formations about Quebec City, Quebec*—Continued.

System.	Formation.	Character of strata, etc.	Characteristic fossils.	Thickness.
Cambrian.	Sillery.	Red, green, and black shales, the latter graptolitic at times, also coarse, gritty, evenly bedded sandstones and conglomerates occurring as lenticular masses of different sizes in the shales. Beds for the most part tilted at high angle and folded, faulted, and contorted. Fossil organic remains scarce.	<i>Protospongia tetranema</i> Dawson, <i>Lingula quebecensis</i> Bill. or n. sp., <i>Linnarssonina pretiosa</i> Billings (the typical fossil), <i>Phyllograptus</i> sp.	Probably several thousand feet in its greatest development.
[Unconformity.]				
[Pre-Cambrian.]				

The classic descriptions of these Ordovician terranes by Logan^{544a} will be found in his comprehensive monograph of 1863. An interesting discussion of Logan's views on the stratigraphy and structure of this region is given by J. W. Dawson.²⁶⁴ Selwyn⁷²⁶ in 1884 prepared a general description, in which he stated his understanding of the stratigraphy and structure of the region.

The latest comprehensive and detailed account of the Ordovician of the St. Lawrence Valley away from the great cities is by Ells,^{313d} as follows:

The newest rocks of the Cambro-Silurian found in this area are situated to the west of the great St. Lawrence and Champlain fault, between it and the River St. Lawrence. They are evidently the southwestern extension of the Utica-Lorraine beds which occur along the river on both sides between Quebec and Three Rivers. They are well characterized by fossils, which are found at several places and of which very considerable collections have been made, as at St. Hyacinthe and St. Hughes, on the Yamaska River, Chambly Basin, and St. Jean Baptiste village (the latter on the River Des Hurons, which joins the Richelieu a short distance above Mount St. Hilaire), and at Chambly. Rock exposures are, however, rare throughout this entire area. Farther north, on the lower part of the Becancour, opposite Three Rivers, a small collection of fossils was made in 1888, which showed the presence of the typical Lorraine shale formation at this place and served to indicate the apparently uniform extension of these rocks throughout this area.

The rocks of the Lorraine formation differ somewhat in character from those of Utica. They are more sandy in texture, and are generally of a grayish color or have frequent beds of gray sandy shales, which sometimes pass into sandstone layers. The Utica, on the other hand, is generally characterized by the presence of brown or brownish-black bituminous shales, with occasional hard bands of dolomitic limestone, but gray beds like those of the Lorraine are rarely seen.

* * * * *

The valley of the St. Lawrence, from Lake St. Louis almost to Quebec City and for some miles on either side of the river, is occupied by strata of the Utica and Lorraine formations, between which the line of separation at most points is difficult to ascertain, owing to the great mantle of clay so widely distributed throughout this area. This region was one of the first studied by the Geological Survey. The strata exposed are nearly horizontal, disturbances being few and due to intrusive masses of doleritic matter. The rocks where exposed abound in fossils, and their true horizons can therefore be readily determined. The doleritic rocks which intersect these strata form mountain masses, sometimes of large extent, which present conspicuous features in the otherwise monotonously level landscape.

These rocks, both the fossiliferous sediments and the intrusive masses, have been well described in the earlier reports of the Survey.^a In the first of these, viz, that for 1847, the characters of the rocks visible on the line of section between Montreal and Lake Memphremagog are so clearly stated that but little remains to be said on that subject.

As, however, the relations of certain groups, more particularly the crystalline schists and the red and green slates and sandstones of the Upper Cambrian (Sillery) were not at that time clearly understood, these will call for some remarks on a subsequent page. The general horizontality of the measures, except where this is disturbed by the presence of the intrusive masses or dikes, is maintained almost to the vicinity of the great St. Lawrence and Champlain fault, which, as already described in a former report, extends from the city of Quebec to the foot of the Missisquoi Bay. The fault brings beds of the Trenton formation against the Calciferous and Chazy at Phillipsburg and Stanbridge, and its existence is very evident wherever rock exposures are visible along its line, but as there is a heavy covering of drift over a considerable portion of the country which it traverses, its delineation on the map between exposed points must of necessity be largely conjectural.

This great fault marks one of the important geological features of the district under discussion, but the amount of displacement occasioned thereby is presumably no greater than that caused by other heavy faults which traverse the country in a northeast to southwest direction and which are seen as far east as Lake Memphremagog. Not only is this entire area greatly affected by these faults, but extensive crumplings of strata occurred, which have closely involved the rocks of the older or crystalline-schist area with the most recent sediments of the district. Narrow areas of the Cambro-Silurian are seen, which contain fossils but are apparently interstratified with the schists; while in some places the formations are so completely overturned that the fossiliferous Devonian now underlies the Cambro-Silurian.

The rocks of the Trenton formation, which underlie the Utica and Hudson River [Normanskill horizon—Ami] (Lorraine) just described, have also a wide distribution. In the earlier reports of the Geological Survey^b certain portions of these rocks were included in the Upper Silurian; these comprise both the black graphitic limestones and associated clay slates.

Lists of fossils of these Ordovician terranes are given by Ami in appendices to Ells's reports on the areas covered by the Pembroke,²⁶ Perth,^{23a} Montreal,¹⁴ and Grenville¹⁹ sheets.

In that part of the St. Lawrence Valley which lies east of the St. Lawrence-Champlain fault Ordovician rocks occur on both sides of the Sutton Mountain anticline. Omitting the Sillery and Levis (described in Chapter III, pp. 131–134), we have here to deal with the limestones and shales of Phillipsburg, Franklin, and Bedford, which range along the northwestern base of Sutton Mountain, and the Magog shales, which occur southeast of that anticline in the basin of Lake Memphremagog; also with the Quebec formation of Citadel Hill in the city of Quebec and the Ordovician strata which form islands and points along the south shore of the lower St. Lawrence.

The limestones and shales of Phillipsburg and Bedford occur between the St. Lawrence-Champlain thrust fault and Sutton Mountain. The thrust fault strikes Lake Champlain at its northeastern extremity, Missisquoi Bay, passing through the village of Phillipsburg. East of it occur rocks assigned by Ells^{313g} to the "Calciferous" and Chazy. Logan's section of the "Calciferous" (divisions A and B) has been given in Chapter III (p. 134). The strata are gray to black dolomites and limestones, which according to Ells "shade gradually into the Chazy in the upper part,

^a Logan, W. E., Rept. Progress Geol. Survey Canada, 1847–48, pp. 10–22. Hunt, T. S., *idem*, 1858, pp. 171–178. Logan, W. E., Geology of Canada, 1863, pp. 205–210.

^b Logan, W. E., Geology of Canada, 1863, p. 434.

so that the point at which the exact line of division between the two formations occurs is scarcely indicated." Above division B Logan ^{54x} gives C and D, as quoted below, and according to Ami ^{14b} certain fossils (*Ecculiomphali*) cited from division C suggest the "Calciferous." The line between "Calciferous" and Chazy, which Ells placed in the upper part of division B but found obscure, may thus possibly lie at a higher horizon.

Logan's section of divisions C and D runs as follows, from the base upward:

[Division] C.	Feet.
1. Black and dark-gray compact limestones, weathering lead-gray, with a few bands of dove-gray. The beds are all massive and afford abundance of a few species of Testaceæ, the whole of which appear to have the peculiarities of being large sized and thick shelled and occurring in numerous isolated patches, which vary in diameter from about 3 to 10 feet. The fossils are several undescribed species of <i>Murchisonia</i> and <i>Pleurotomaria</i> , <i>Ecculiomphalus canadensis</i> , <i>E. intortus</i> , <i>E. spiralis</i> , several undescribed species of <i>Ophileta</i> , <i>Maclurea ponderosa</i> , several undescribed species of <i>Orthoceras</i> , and one of <i>Nautilus</i> . Toward the base <i>Maclurea ponderosa</i> seems to be somewhat smaller than in the upper part of the deposit, and toward the top one or two beds appear to be of a partially conglomerate character...	150
2. Black slates, or possibly thin-bedded black limestones, with a few thicker beds toward the top; the mass is altogether very imperfectly seen.....	170
	320

[Division] D.

1. Black limestone conglomerates, composed chiefly of the ruins of the thick-bedded limestones of division C. The inclosed masses vary in size from pieces of an inch in diameter to blocks containing 50 and 60 cubic feet and are cemented together by a calcareo-magnesian paste. Of this, however, from the closeness with which the masses are packed together, there is but a very small quantity. The limestones are generally close grained and black or dark gray in color, but there are mingled with them a few scattered blocks of a light-colored yellow-weathering dolomite, some of them a foot in diameter. Many of the masses of limestone contain fossils, and the species are almost wholly confined to those already stated as characterizing the parent beds C 1. There appear to be at least two principal bands of this conglomerate, each varying in thickness in different parts from about 50 to 100 feet. There is an interval between them of from 100 to 150 feet, occupied by black slates holding rounded masses of limestone, which convert parts of the mass, varying in thickness from 10 to 20 feet, into slaty conglomerates. In some parts either the interval between the main two bands of conglomerate increases considerably or there is a third band with similar slates, intervening between it and the second. The whole is contained in a thickness of from 250 to.....	300
2. Black and greenish argillaceous slates, probably interstratified with occasional thin calcareous bands and thin lenticular patches of limestone conglomerate, as well as more important bands of yellow-weathering dolomitic slates. The whole is terminated by a band of black limestone conglomerate similar in character and thickness (from 50 to 100 feet) to those already mentioned and containing <i>Maclurea ponderosa</i> in one of the few places in which the band has been seen. This whole mass of strata is very imperfectly exposed, and much uncertainty exists as to its true general character. Its thickness may be from 750 to.....	1,000
3. Gray and black striped slates, some parts of which are calcareous and weather slightly brownish. They are interstratified with occasional thin beds of black limestone, weathering lead-gray, as well as many strong and solid beds of brown-weathering magnesian limestone and brown-weathering dolomitic slates. Some of the latter are marked by an abundance of fucoïds resembling <i>Buthotrephis flexuosa</i> of Emmons. Occasional beds of sandstone, from 1 to 3 feet in thickness, are met with. About the middle of the mass there has in one place been observed a bed of limestone conglomerate from 5 to 10 feet thick, and other similar ones may occur in different parts of the vertical thickness.....	1,500
	2,800

In commenting on this section E. O. Ulrich states that division C is probably Beekmantown and division D suggests the Rysedorph conglomerate of the New York State Survey reports, although D 1 is probably older.

Following this description Logan gives a section on the international boundary showing two synclines, modified by thrust faults.

The equivalents of the above-described strata near Phillipsburg when traced south into Vermont are known as the Fort Cassin beds, according to Whitfield.⁹²⁷ (See K-L 18, pp. 126-127.) Their extension northeastward along the northwest side of the Sutton Mountain anticline is minutely discussed by Ells.^{313f} The fossils which have been collected at various times for the Canadian Survey from these rocks are reported by Ami^{14c} under the heading "Phillipsburg series."

Southeast of Sutton Mountain Ordovician strata again occupy a large part of the section at least as far east as the international boundary. Their extent eastward in Maine is obscured by their resemblance to the soft slates of the Silurian, by the featureless drift and forest covered character of the country, and by intrusions of igneous rocks. (See Chapter VII, p. 350.) The strata identified in Canada are known as the Magog shales and classed as probably of Trenton and Utica age. Ulrich believes the Magog to be pre-Utica. They contain graptolites which are described as follows by Lapworth.⁵²² (See also a paper by Gurley.³⁸⁸)

Matrix, soft, thin-bedded and flaking silvery shales, greenish gray in color (originally black), apparently altered and spotted by contact metamorphism.

1. *Dicranograptus ramosus* Hall.
2. *Diplograptus angustifolius* Hall.
3. *Diplograptus foliaceus* Murchison (= *pristis*, Hall).
4. *Diplograptus perexcavatus* Lapworth.
5. *Climacograptus bicornis* Hall.
6. *Climacograptus ccelatus* Lapworth.

The fossils are all in a most miserable state of preservation, but all the forms named above are easily recognizable. These fix the age of the strata as Utica or Marsouin or Normans Kill, but somewhat higher in the series than the typical Normans Kill beds. They may safely be termed Upper Llandeilo or Lower Bala and placed generally above or about the horizon of the Trenton or Utica rocks of the western area.

The Quebec formation,^a distinguished by Ami,^{12a} consists of dark bituminous shales with hard calcareous bands, limestones, and conglomerates, several hundred feet thick. The conglomerate forms Citadel Hill and has been described by Weston,⁸⁸⁷ who quotes Ami as follows:

Alongside and up Mountain Street a bold cliff of conglomerate occurs, containing large boulders, embedded in a shaly and calcareo-argillaceous paste with an admixture of quartz-grains.

According to Ami^{12,13} and Ford³⁴⁵ the fauna by which the Quebec formation is characterized comprises Black River and Trenton types and possibly upper Chazy forms.

Not only in the vicinity of Quebec, but thence along the lower St. Lawrence (Island of Orleans, St. Joseph de Levis, St. Simon, Riviere de Loup, Bic, etc.) there occur Ordovician shales, presumably of several horizons, which locally include fragments, boulders, or pebbles of fossiliferous limestones of earlier Ordovician and Cambrian formations.

Logan^{544f} describes the rocks in his account of the "Quebec group." Many of the occurrences probably represent rather the equivalents of the Sillery and Levis than those of the Quebec formation, as restricted by Ami.

^a See table of formations about Quebec, quoted on pp. 202-203.

L 19. CARLETON AND YORK COUNTIES, NEW BRUNSWICK.

The slate belt that extends from the boundary of Maine northeastward to Chaleur Bay is mapped as Cambrian and Ordovician, without distinction of the middle and later Ordovician, which, however, occur there. The lithology of the belt, according to Bailey,⁴⁴ is monotonous, yet the rocks range in age from Cambrian to upper Silurian. The sequence is not complete, the base of the Silurian being marked by a distinct basal conglomerate containing the older Paleozoic rocks as cobbles, but it is not known how much of Ordovician time is represented by the unconformity. Bailey⁴⁶ names the few localities at which the fossils have been found and Ami²⁵ describes those from Tete a Gauche River which are of Ordovician age. The latter describes "Fossils from the black carbonaceous and graptolitic shales from near the railway bridge on the Tete a Gauche River, near Bathurst, Gloucester County, New Brunswick," and names them as follows:

Diplograptus foliaceus Murchison.
Diplograptus truncatus Lapworth.
 ?*Lasiograptus* sp. indt.
Climacograptus bicornis Hall.
Cryptograptus tricornis Carruthers.
Dicellograptus sextans Hall.
Dicellograptus anceps Nicholson.
Orthograptus quadrimucronatus Hall.
 ?*Didymograptus superstes* Hall.
Leptobolus sp.

The above assemblage of forms suggests at once an Ordovician fauna belonging to one of those zones of graptolites occurring along the St. Lawrence and the Hudson rivers. Similar forms from rocks of presumably the same age have also been found in Penobscot County, Maine.^a

These black and at times pyritiferous shales appear to be synchronous or homotaxial with the shales of Normans Kill, near Albany, N. Y., of the city of Quebec, of the north shore of the Island of Orleans, of the Marsouin River, and of numerous other localities in the Gaspe Peninsula. They find their equivalent in Europe in the Llandeilo rocks of Wales, the Moffatt shales of Scotland, and the County Down shales of Ireland.

M 11. BEAVERFOOT RANGE, CANADIAN ROCKY MOUNTAINS.

Graptolitic shales are described by McConnell^{559d} as occurring between the Castle Mountain group (Cambrian and Ordovician) and the "Halysites beds," into both of which they appear to graduate in sections along the Canadian Pacific Railway, east of Columbia River. They are hard black fissile slates, 1,500 feet thick, which in some sections alternate with thin beds of limestone and here and there, near the top, with quartzites and dolomites. Lapworth, reporting on the graptolites, identified *Didymograptus* sp. nov., allied to *Didymograptus euodus* Lapworth, *Glossograptus ciliatus* Emmons, *G. spinulosus* Hall sp., *Cryptograptus tricornis* Carr sp. = *C. marcidus* Hall sp., *Diplograptus angustifolius* Hall, *D. rugosus* Emmons, *Climatograptus coelatus* Lapworth, and doubtful species of *Phyllograptus* or *Lasiograptus*. These forms are referred to "the age of the Utica slate or at any rate to the Trenton-Utica fauna of the United States and Canada. The association of forms is just such as occurs in the Llandeilo (lower and middle) of Britain, and some forms are common to both sides of the Atlantic."

^a Am. Jour. Sci., 3d ser., vol. 22, 1881, p. 434; vol. 40, 1890, p. 153.

The lithologic and faunal similarities of this terrane to those of Dease River, in latitude 60° north, and of the Alaska Range indicates the persistence of like geographic conditions along the trend of the Cordillera in middle and late Ordovician time. Ulrich says:

The graptolite faunas in the Cordilleran basins west of the Rockies from Nevada to Alaska seem to belong to nearly the same horizon. Its age appears to be intermediate between the Levis-Tetraraptus zone and the Normans Kill of the Atlantic side.

M 19-20. GASPE PENINSULA.

Along the south shore of the St. Lawrence, according to Logan,^{544j} are black shales and gray calcareous sandstones of middle and possibly later Ordovician age. They have been described by Dawson²⁶⁷ as the Marsouin River formation, and the horizon of the graptolitic fauna which they contain is discussed by Lapworth,⁵²¹ who states, under the heading "Griffin Point or Marsouin River zone:"

The most characteristic forms from the zone are—

- Didymograptus sagittarius (Hall non Hisinger).
- Cœnograptus gracilis Hall.
- Dicellograptus sextans Hall.
- Lasiograptus mucronatus Hall.
- Climacograptus antiquus Lapworth.
- Diplograptus whitfieldi Hall.

So far as known, these are peculiar to this zone, and the presence of a single one of these species is sufficient to settle the age of the rock in Great Britain, and in all likelihood in America. With these peculiar forms, however, are associated others which have a much longer vertical range and unite this zone to the one which follows it in order of time. These species of long range are—

- Dicranograptus ramosus Hall.
- Glossograptus ciliatus Emmons.
- Diplograptus putillus Hall.
- Climacograptus scharenbergi Lapworth.

They all pass up into the British zone next above the Cœnograptus zone, together with the following species, which range up through at least three complete zones:

- Diplograptus foliaceus Murchison.
- Climacograptus bicornis Hall.

This special Marsouin zone, now under consideration, has long been recognized by geologists upon the continent of America. Its fossils were described many years ago by Prof. J. Hall, in his "Paleontology of New York," from the dark shales of Normans Kill, near Albany, in the valley of the Hudson River. Hall also referred to the detection of the Normans Kill fossils on Marsouin River by Sir William Logan and the Canadian Survey; but the discovery of the existence of rocks containing the Normans Kill fossils as far down as Griffin Cove and between the Marsouin and Quebec, as demonstrated by the present collection, is wholly due to those officers of the Geological Survey of Canada who have studied the district since the retirement of Sir W. Logan. There can be no question of the general identity of this Griffin Cove rock and the Marsouin Cœnograptus zone with that of the Normans Kill of the Hudson River valley.

Lapworth further divides the fauna, which he calls the Trentonian, Marsouin River, or Normans Kill fauna, into two subfaunas, namely:

Subfauna A, the Cœnograptus zone of Griffin Cove and the Marsouin River, answering to the Middle Llandeilo beds of Great Britain to the Glenkiln beds of Scotland, etc.

Subfauna B, the Cove Fields and Orleans subfauna, apparently destitute of *Cœnograptus gracilis* and answering to the highest Llandeilo or Lowest Caradoc beds of England.

The last of these subfaunas shows evidence of a transition into the Utica-Lorraine graptolitic fauna of the Mohawk Valley, New York, and of Lake St. John, Canada.

Ulrich states that the fauna may be called Trentonian only if that term is used as a synonym of Mohawkian and that the so-called Normans Kill is as old as the Black River.

The stratigraphic succession and structural relations are involved in the overthrusts of the sedimentary strata, and the distribution is probably not so simple as it appears even on the detailed maps. The horizon of the Marsouin River formation is repeatedly referred to by Ells^{310a, 311b, 313e} in tracing the sweep of Ordovician strata through the "Eastern Townships" of Quebec, the similarity of the rocks and graptolites indicating the continuity of the zone of deposition as far as the locality of the Magog shales on Lake Memphremagog. In Vermont and New Hampshire the terrane is probably represented in the metamorphosed Paleozoic rocks.

M 20. MINGAN AND ANTICOSTI ISLANDS.

Ordovician strata are exposed along the north coast of Anticosti Island, dipping gently southward under the Anticosti group (Silurian). The lowest strata seen at the base of the cliffs are assigned by Logan to the "Hudson River" [Richmond] formation. Farther north, across the strait, the Mingan Islands consist of rocks referred to the "Calciferos" (Beekmantown) and Chazy, with possibly part of the "Birdseye" (Lowville) and Black River formations. The closely adjacent coast of Quebec is "Laurentian." Thus it appears that the middle Ordovician strata in this region overlap the earlier Paleozoic (pre-Beekmantown) rocks and extend from the north margin of the Gulf of St. Lawrence southward beneath its waters to Anticosti, where the overlying upper Ordovician and Silurian are exposed.

Regarding the Chazy of the Mingan Islands, Logan^{544b} says:

At the Mingan Islands the Chazy formation bears lithological characters somewhat different from those which have been given above. The lowest part seen of the deposit occurs in the bay above Clear Water Point, and the following is a section of the strata in ascending order:

	Feet.
Reddish cream-colored compact limestone with a conchoidal fracture, weathering pale yellow..	1
Greenish and brownish-black shale.....	1
Reddish cream-colored limestone as before, in beds of from 1 to 2 inches to a foot, interstratified with greenish shale in beds of about the same thickness.....	28
Greenish shale with <i>Rhynchonella orientalis</i> (which is a variety of <i>R. plena</i>) in great abundance..	3
Gray granular limestone with false bedding, holding comminuted fragments of encrinites and other organic remains, including <i>Bolboporites americanus</i> , <i>Rhynchonella orientalis</i> , a few of <i>Camerella longirostrata</i> , and other species.....	13
Gray nodular limestone with <i>Columnaria parva</i> , <i>Stenopora adherens</i> , <i>Fenestella incepta</i> , <i>Orthis piger</i> , <i>Strophomena incrassata</i> , <i>Ctenodonta nasuta</i> , <i>Nautilus jason</i> , <i>Amphion canadensis</i> , <i>Harpes antiquatus</i> , <i>Illænus globosus</i>	20
Gray magnesian limestone, with <i>Murchisonia aspera</i> , <i>Maclurea atlantica</i> , <i>Orthoceras multicameratum</i> , <i>O. bilineatum</i> , <i>O. natator</i> , <i>O. maro</i> , <i>O. antenor</i> , <i>O. minganese</i> , <i>O. shumardi</i> , <i>Illænus bayfieldi</i> , and other fossils.....	12
	78

Apparently above these strata but not in immediate sequence Logan lists gray and yellow limestone and green shale in thin beds to a thickness of 171 feet, almost without fossils, which he, however, regards as Chazy and possibly not including the top of that terrane. Ulrich suggests that these strata may be Lowville. Above

them occurs a yellowish-white pure limestone, 30 feet thick, carrying *Maclurea logani*, which Logan^{54c} refers to the "Birdseye" (Lowville) and Black River.

A detailed section of the strata exposed above the beach at the west end of Anticosti is given by Logan,^{54f} with much refinement of distinction among the successive beds and lists of fossils found in each. Limestones and argillaceous shales in thin layers make up most of the thickness noted (959 feet). Gray limestone, greenish shale, and a few layers of limestone conglomerate alternate in the lower 229 feet; bluish and reddish-gray limestone separated by thin greenish shale partings and conglomerates succeed with slight variations throughout the upper 730 feet.

The Ordovician here passes without notable lithologic change or break into the Silurian, and a number of fossils are common to strata above and below the assumed plane of division, yet numerically the extinction of species is more marked than their persistence. Billings⁸² states the facts as follows:

In the Lower Silurian rocks of Anticosti there have been collected 121 species of fossils, of which the proportionally large number of 85 have been described in this and other publications of the Survey as new forms. The remaining 36 are mostly of the common and widely distributed species of the Lower Silurian of Canada West, New York, and other countries. They are the following:

<i>Stenopora fibrosa.</i>	<i>Subulites richardsoni.</i>
<i>S. mammulata.</i>	<i>Trochonema umnicata.</i>
<i>S. papillata.</i>	<i>Pleurotomaria americana.</i>
<i>S. explanata.</i>	<i>P. helena.</i>
<i>Halysites catenulatus.</i>	<i>P. subconica.</i>
<i>Lingula quadrata.</i>	<i>Murchisonia gracilis.</i>
<i>Trematis ottawaensis.</i>	<i>M. ventricosa.</i>
<i>Strophomena imbrex.</i>	<i>Bellerophon acuta.</i>
<i>S. subtenta.</i>	<i>B. bilobatus.</i>
<i>S. planumbona.</i>	<i>Pterotheca transversa.</i>
<i>S. alternata.</i>	<i>Oncoceras constrictum.</i>
<i>Leptæna sericea.</i>	<i>Asaphus platycephalus.</i>
<i>Orthis testudinaria.</i>	<i>A. megistos.</i>
<i>O. subquadrata.</i>	<i>Dalmanites callicephalus.</i>
<i>O. lynx.</i>	<i>Cheirus pleurexanthemus.</i>
<i>Rhynchonella capax.</i>	<i>Harpes ottawaensis.</i>
<i>R. recurvirostra.</i>	<i>Calymene blumenbachi.</i>
<i>Ambonychia radiata.</i>	<i>Leperditia canadensis.</i>

There are no species which are exclusively Upper Silurian; the aspect of the whole fauna is eminently Lower Silurian. The rocks are very fossiliferous throughout, but on approaching the dividing line between this group and division 1 of the Anticosti group, which immediately succeeds, not less than 80 out of the 121 species suddenly disappear and are seen no more. It is evident, therefore, that there is here a break of considerable importance, probably in some way connected with the great gap that occurs between the Hudson River and Clinton formations in Canada West and New York. Of the 41 species that pass this break, 30 appear to have become extinct during the period of division 1; at least they have not been detected in division 2. Of the remaining 11 species, 7 pass upward into division 3 and 6 into division 4.

Ulrich comments to the effect that according to present understanding of the Anticosti problem, none of the beds in Logan's section is older than Richmond.

M 21. NEWFOUNDLAND, NORTHERN PENINSULA.

In 1863 Logan⁵⁴⁴ stated the observed sections of the strata along the western and northern coasts of the great northern peninsula of Newfoundland and distinguished divisions which he numbered from 1 to 16 or A to Q. Some of the fossils listed by him are grouped in associations which indicate that there was confusion, either because they became mixed in collecting or through the occurrence of fossils in conglomerate pebbles or on account of the presence of thrust faults; but no other systematic discussions than those by Logan and Billings are available. Divisions A to H inclusive have been discussed in Chapter III (pp. 149-153). Divisions I, K, L, and M are possibly equivalent to the upper Chazy, Black River, and Trenton of the epicontinental sea that spread to New York, though many typical species of those faunas are absent and Billings was in doubt. Divisions N, O, and P, described by Logan as higher in the series, are classed by Billings as being faunally related to the Sillery and Levis and apparently belong lower in the Ordovician.

Ulrich says (comments on manuscript):

Respecting the Newfoundland section I fail to see reasons for regarding division I and possibly up to and including division N as above the Beekmantown. Part of this series is almost certainly of Beekmantown age, but other parts seem no less certainly of later age. The Levis graptolites in division N are, I am convinced, of early Beekmantown age. Not to enter into detail, it may suffice to say that an analysis of the faunas suggests ages ranging from early Beekmantown to late Black River. As the oldest of these faunas occurs in the uppermost division (N), the succession of the others is not regular; the evidence indicates misinterpretation of the structure, with overthrusting and overturn instead of the regular and unbroken sequence described by Logan.

Logan's section of divisions I, K, L, and M is as follows:

	Feet.
I.	
1. Light yellowish gray mottled and subcrystalline magnesian limestone, with geodes of calc spar. The limestone is divided into beds of from 6 inches to 1 foot and shows occasional fossils, the only recognizable species being <i>Maclurea matutina</i>	65
2. Light yellowish gray mottled magnesian limestone as before, interstratified with grayish-black limestone in beds of from 3 inches to 1 foot. The magnesian beds contain <i>Maclurea matutina</i>	70
	135
K.	
1. Light-gray, subcrystalline limestone, with grayish-black limestone, both in beds of from 2 to 6 inches, and associated with a few bands of grayish-white dolomite, from 6 to 9 inches thick, the whole interstratified at intervals of from 10 to 20 feet with black and grayish-green shales. The light-gray limestone and whitish dolomite are fossiliferous, containing the genera <i>Orthis</i> , <i>Ctenodonta</i> , <i>Ophileta</i> , <i>Maclurea</i> , <i>Pleurotomaria</i> , <i>Murchisonia</i> , and <i>Orthoceras</i> . The described species are <i>Orthis electra</i> , <i>Maclurea matutina</i> , and <i>Orthoceras piscator</i>	100
L.	
1. Grayish-white dolomite and greenish-gray compact limestone, both in beds of from 2 to 6 inches thick, interstratified with about 3 per cent of black and grayish-green shale, all without observed fossils.....	104
2. Light reddish-gray magnesian limestone, in beds varying from 15 inches to 2 feet in thickness. The rock breaks from the cliff in which it is exposed, in rectangular blocks of several feet long and wide, and would make an excellent building stone. No fossils were observed.	16
3. Brownish-gray hard limestone, in beds of from 6 inches to 2 feet; fossils occur at the base, among which are the genera <i>Stenopora</i> , <i>Orthis</i> , <i>Murchisonia</i> , <i>Asaphus</i> , and <i>Lepeditia</i>	65
4. Reddish-gray magnesian limestone, in beds of from 2 to 6 inches, without observed fossils...	6
	191

M.

- | | Feet. |
|---|-------|
| <p>1. Brownish-gray limestone, in beds varying in thickness from 6 inches to 6 or 7 feet, interstratified at distant intervals with reddish-gray dolomite in beds of from 3 to 9 inches, which constitute 1 or 2 per cent of the whole. Both the limestone and the dolomite are fossiliferous throughout; the organic forms, however, are obscure in the whole, with the exception of about a foot of the limestone at the base and 6 feet at the top, including a bed of the dolomite, in the whole of which the fossils are silicified. The genera at the base are <i>Eospongia</i>, <i>Orthis</i>, <i>Ophileta</i>, <i>Pleurotomaria</i>, <i>Murchisonia</i>, <i>Orthoceras</i>, and <i>Asaphus</i>. At the top the same genera occur, but there is a greater number of species, and it is probable that the fossils of these two parts represent those of the whole mass.....</p> | 350 |
| <p>In the fossiliferous beds of divisions K and L, and in part 1 of M, there are several species of each genus, and the same species seem to range through the whole. The described species are <i>Orthis electra</i>, <i>Maclurea matutina</i>, and <i>Orthoceras piscator</i>; but the chief part of the species of the remaining gastropods and cephalopods are so closely allied to some of the common forms of the Trenton group that it scarcely appears doubtful that they are the same. The most striking resemblances are to <i>Orthoceras bigsbyi</i> and <i>O. allumettense</i> of the Birdseye and Black River, and to <i>Murchisonia gracilis</i>, <i>M. bellicincta</i>, and <i>M. perangulata</i> of the Trenton formation.</p> | |
| <p>2. Bluish-gray limestone, in beds varying from 6 inches to 10 feet in thickness, the thicker beds being made up of layers of 1 or 2 inches, distinguishable in section by slight differences in color but without any tendency to separate. Some of the beds are nodular and crumble under atmospheric influences. Fossils are abundant in all the beds but are not readily separated. They consist chiefly of <i>Stenopora fibrosa</i>, <i>Orthis</i> like <i>O. platys</i>, <i>Rhynchonella</i> allied to <i>R. plena</i>, <i>Camerella varians</i>, new species of <i>Maclurea</i>, and <i>Orthoceras</i>; with <i>O. piscator</i>, <i>O. allumettense?</i>, <i>O. bigsbyi?</i>, <i>Amphion</i>, <i>Ampyx</i>, <i>Asaphus</i>, <i>Illænus</i>, and <i>Leperditia</i>.....</p> | 308 |

 1,349

Commenting on the above section, Ulrich suggests upper Beekmantown for division I and middle Chazy for division M.

Billings^{81a} discusses in the following terms the taxonomic relations of the Ordovician strata of Newfoundland which constitute Logan's divisions I, K, L, and M.:

These four divisions consist of 235 feet of magnesian limestones at the base, above which we have 844 feet of light bluish-gray limestones, making in all a thickness of 1,084 feet. Only 37 species of fossils have been collected in this series of beds; and of these, nine species are found in division H below, while ten of them pass upward into division N next above. Three of the species (*Stromatopora compacta*, *Orthoceras allumettense*, and *Asaphus canalis*) occur in Canada, the first two in the Chazy and Black River and the last in the Calciferous and Chazy. The following are closely allied to Black River and Trenton species:

- Ctenodonta angela*, allied to *C. contracta*, B. R.
- Subulites daphne*, allied to *S. parvulus*, B. R.
- Murchisonia simulatrix*, allied to *M. gracilis*, B. R. and Tr.
- Murchisonia cicelia*, allied to *M. perangulata*, B. R.
- Murchisonia sororcula*, allied to *M. perangulata*, B. R.
- Murchisonia augustina*, allied to *M. bellicincta*, Tr.
- Orthoceras hæsitans*, allied to *O. bigsbyi*, B. R.

The occurrence of great numbers of individuals of these species in a silicified condition and weathered out in bold relief gives to the slabs of limestone an aspect so remarkably like that of the well-known specimens from Pauquettes Rapids that at first sight one might be well led to say, This is surely the Black River limestone. But on careful comparison of perfect specimens it is seen that notwithstanding the resemblance none of the species are strictly identical. All present such differences that after a study of collections from both localities they can be separated if mixed up together without their labels. Even *O. allumettense*, which I have identified, differs by being much larger than any specimens that have been seen in the original localities.

If the succession were the same here as it is in Canada and New York, we ought to have the Chazy formation represented in these four divisions. But no one acquainted with the peculiar and strongly featured fauna of that formation could recognize it in this collection. Three of the species are, indeed, Chazy fossils, but then they are not characteristic forms. The typical and leading species which always go together in great numbers and in one compact army, as it were, in every exposure of the true Chazy, are totally absent.^a

The Lamellibranchiata, Gastropoda, and Cephalopoda of these beds have, so far as the genera Ctenodonta, Subulites, Pleurotomaria, and Orthoceras are concerned, an aspect very like that presented by the same genera in the Black River and Trenton formation. But species similar to most of those above compared have a great range and are found in all the different groups of rocks up to the Devonian. Their occurrence here is not, in my opinion, sufficient to counterbalance the negative fact that (excepting those in question) not a vestige of any one of the species of the vast fauna of the Black River and Trenton has been detected. *Tetradium fibratum*, *Columnaria alveolata*, *Leptæna sericea*, *Strophomera alternata*, *Orthis testudinaria*, *Calymene blumenbachi*, and *Asaphus platycephalus* are sure to be found in every collection of any considerable extent from these two formations. If they occurred here as abundantly and persistently as they do in Canada and New York, it would be difficult to give any reason why these four divisions should not be regarded as the equivalents of the Black River and Trenton. But not one fragment of anything which could by any possibility be referred to any one of these species can be seen in this collection. A piece of red limestone was found at Bay St. Paul which is full of *L. sericea*, but it was a loose and worn fragment, lithologically differed from any of the strata in question. Judging from this specimen I should say that the Trenton may possibly occur somewhere near, but we can not refer, on any paleontological ground, the series of strata constituting divisions I, K, L, M to that formation.

Following Logan's section^{544z} we note in ascending order the divisions N, O, P, and Q, occurring apparently above the divisions I, K, L, and M. The numbers 13, 14, 15, and 16 are those by which he first designated the separate divisions.

[N.]

	Feet.
1. Blackish-gray nodular fossiliferous limestone, in beds of from 1 to 3 inches thick, becoming bituminous toward the top. The fossils are <i>Orthis</i> , <i>Strophomena</i> , <i>Rhynchonella</i> allied to <i>R. plena</i> , a new species of <i>Camerella</i> , <i>Orthoceras piscator</i> , <i>O. allumettense?</i> , <i>Amphion</i> , <i>Asaphus</i> , <i>Holometopus angelini</i> , <i>Illænus</i> , and <i>Leperditia</i>	81
2. Black bituminous limestones, in beds of from 1 to 3 inches thick, interstratified with fine brittle black bituminous shale in layers varying from a quarter of an inch to 3 inches. The prevailing fossils are <i>Stenopora fibrosa</i> , <i>Lingula</i> allied to <i>L. philomela</i> , <i>Orthis</i> , <i>Strophomena</i> , <i>Rhynchonella</i> allied to <i>R. plena</i> , a new species of <i>Camerella</i> , with <i>C. varians</i> , <i>Orthoceras</i> , <i>Agnostus</i> , <i>Amphion</i> , <i>Ampyx</i> , <i>Asaphus</i> , <i>Ændymion meeki</i> , <i>Holometopus angelini</i> , <i>Illænus</i> , <i>Nileus scrutator</i> , and <i>Leperditia</i>	174
3. Black bituminous shale, with <i>Graptolithus</i> , <i>Lingula</i> , <i>Orthoceras</i> , and <i>Paradoxides</i> or <i>Olenellus</i>	22
	277

[O.]

14. Gray calcareous sandstones, generally fine grained; in beds of from 6 inches to 2 feet, interstratified with black and greenish shales, which predominate toward the top. The sandstones are sometimes of a conglomerate character and include pebbles of white quartz and black limestone, varying in diameter from the eighth of an inch to 2 inches, with small fragments of red and black jasper and flat pieces of black and green shale. The sandstones and the shales are aggregated in masses varying from 6 up to 60 feet in thickness. No fossils have been met with in this rock.....	700
--	-----

^a Ulrich takes exception to the statement of Billings in regard to the Chazy and says that he (Billings) "was not well acquainted with the lower and middle Chazy faunas. He knew the upper very well, but this is very different from the two lower faunas. These middle and lower Chazy faunas contain species such as mentioned by Billings, greatly like 'Black River' forms. (See Raymond's papers.)"

[P.]

15. Gray, drab, and whitish limestone conglomerates, interstratified in the lower part, with bands of black and greenish shale from 40 to 100 feet thick; and associated with black limestone holding layers of black chert from 1 to 3 inches thick. Graptolites occur in the black limestones and fragments of trilobites in the chert. In the upper part the conglomerate is more massive, great thicknesses showing no trace of bedding. The inclosed pebbles, bowlders, and fragments of limestone range in weight from 1 ounce to a ton and in color from white through various shades of drab and gray to black. Associated with the masses of limestone are occasionally others of gray calcareous sandstone, specimens of which can not be distinguished from those of the sandstone (14) which is beneath. Some masses, which are of the same character as smaller inclosed blocks, are 200 feet long by 30 feet thick. It is difficult to decide whether these are sediments deposited in the bed or inclosed transported masses, notwithstanding that they are divided into beds with partings of black shale. Some of the conglomerate beds are filled with pebbles of black chert. Near to the top, patches of several hundred yards, in the supposed direction of the strike but without observed bedding, consist of light reddish-gray pure limestone, in part highly crystalline, abounding with convoluted shells and other fossils. The genera found in these conglomerates and their interstratified masses are Graptolithus, Orthis, Rhynchonella, Camerella, Ophileta, Maclurea, Orthoceras, Asaphus, Illæus, Amphion, Bathyrurus, Holometopus, Nileus, Ampyx, Agnostus, Endymion, and several trilobites of undetermined genera. The determined species are *Graptolithus headi*, *Camerella calcifera*, *Maclurea ponderosa*, *Bathyrurus saffordi*, *Holometopus angelini*, *Endymion meeki*, and *Nileus scrutator* 700

[Q.]

16. Greenish sandstones of a chloritic aspect, made up apparently of fine grains of quartz and feldspar, with a few scales of mica, mixed with greenish argillaceous matter. Some beds are of a conglomerate character, the pebbles consisting of white quartz and reddish feldspar, varying from the sixteenth of an inch to an inch in diameter; the quartz pebbles are somewhat larger and much more numerous than those of feldspar. They are accompanied by occasional pebbles of red jasper, and by flat pieces of green shale. In some beds the masses inclosed consist of gray limestone. The finer beds are aggregated in thicknesses of several hundred feet, and the conglomerates are from 10 to 20 feet. These fine and coarse sandstones are interstratified with several bands of red shale from 10 to 20 feet thick; and one of 60 feet consists of red shale interstratified with green layers. The thickness of the whole was not measured, but it is supposed to be not much under 2,000

In his descriptions Logan included division N with divisions I, K, L, and M, in a major group, but Billings^{81b} classed N with O and P and commented on the taxonomic relations as follows:

The rocks of these divisions, in ascending order, consist of 277 feet of black bituminous limestone, with some black shales, very fossiliferous; next 700 feet of sandstones, in which no fossils were collected or observed; and at the summit 700 feet of black shales, holding gray and white limestone conglomerates, abounding in fossils, although there are not a great many species. There appear to be in this series of strata two formations, distinguishable from each other both by lithological and paleontological characters. The first includes the black bituminous limestones and shales, forming the upper 277 feet at Table Head, and those of Pistolet Bay and 4 miles northeast from Portland Creek. The rocks at the latter locality appear to lie above the 700 feet of sandstone constituting division O and are therefore in the foregoing descriptions of species referred to division P. Taking these three localities to be on the same or nearly the same horizon, we have from them, in addition to a few not yet described, the following 48 species:

Lingula nympha.
Lingula iole.
Lingula cyane.
Acrotreta gemma.
Orthis delicatula.

* Strophomena aurora.
Strophomena imbecilis.
Strophomena decipiens (?).
Camerella parva.
Camerella varians.*

Rhynchonella corinthia.	Holometopus angelini.*
Pleurotomaria sponsa.	Harpides atlanticus.
*Murchisonia simulatrix.	Harpides concentricus.
*Murchisonia augustina.	Shumardia glacialis.
*Maclurea crenulata.	Cheirurus polydorus.
*Maclurea acuminata.	Cheirurus perforator.
Ecculiomphalus superbus.	Cheirurus sol.
*Orthoceras piscator.	*Amphion barrandei.*
*Orthoceras allumettense.	Triarthrus fischeri.
*Bathyurus nero.	Telephus americanus.
Bathyurus breviceps.	Encrinurus mirus.
Asaphus huttoni.	Remopleurides panderi.
Asaphus morrisii.	Remopleurides schlotheimi.
Asaphus quadratacaudatus.	Ampyx læviusculus.
Nileus macrops.	Ampyx normalis.
Nileus scrutator.	Ampyx rutilius.
*Illænus fraternus.	Ampyx semicostatus.
*Illænus consimilis.	*Agnostus galba.
Endymionia meeki.	Agnostus fabius.

In the above list those with an asterisk before them are found in some one or more of the divisions below N; those with an asterisk after them occur in the gray and white limestones of division P at Cow Head. *Camerella varians* is a Chazy species. *Orthoceras allumettense* is both Chazy and Black River. *Holometopus angelini*, *Endymionia meeki*, and *Cheirurus sol* occur in the Quebec group of Canada East. We find here, for the first time among American trilobites, the peculiar type of Cheirurus, with a spine upon the glabella—*C. perforator*. Another of the same structure, *C. glaucus*, was discovered in the Quebec group in the township of Stanbridge; and a third, *C. satyrus*, in the Chazy, at Montreal, by T. C. Weston, last year, 1864. This type has been known for several years among the Russian trilobites by *Sphærexochus cephaloceros* (Nieskowski) = *Zethus triplicatus* (Eichwald), which occurs in the Pleta limestone. The genus Triarthrus has not heretofore been found below the Trenton in America. Remopleurides occurs in the Chazy, and Amphion in both Chazy and Calciferous; but neither of these genera has yet been reported as occurring above the Chazy in Canada or New York. The general aspect of the trilobitic fauna of this series of strata seems to me to be more like that of the Pleta limestone of Russia and Angelin's two Swedish groups B C and C, than it is to that of any of the American Lower Silurian formations heretofore illustrated.

The second formation above mentioned consists of the 700 feet of black shales with gray and white limestone conglomerates, at Cow Head. In no other part of Newfoundland do we meet with the remarkable fauna which characterizes the Levis formation. It undoubtedly occurs here in full force. The following list contains the species collected at that locality, and also shows how many of them occur in Canada:

	C. H.	C. E.
Stenopora fibrosa (Chazy to Devonian).....	×	
Graptolithus bryonoides.....	×	×
Graptolithus denticulatus.....	×	×
Graptolithus fruticosus.....	×	×
Graptolithus headi.....	×	×
Phyllograptus typus.....	×	×
Ptilograptus plumosus.....	×	×
Callograptus elegans.....	×	×
Orthis hippolyte.....	×	×
*Camerella varians (Chazy).....	×	
Camerella calcifera (Calciferous).....	×	×
Camerella costata.....	×	×
Lingula quebecensis.....	×	×
Maclurea ponderosa.....	×	×
Ophileta bella.....	×	×
Ecculiomphalus distans.....	×	
Asaphus pelops.....	×	×
Bathyurus cordai (Calciferous).....	×	×
Bathyurus conicus (Calciferous).....	×	

	C. H.	C. E.
Bathyrurus saffordi.....	X	X
Bathyurellus nitidus.....	X	
Bathyurellus formosus.....	X	X
Bathyurellus fraternus.....	X	
Nileus affinis.....	X	X
Illænus tumidifrons.....	X	
Illænus arcuatus.....	X	
Illænus consobrinus.....	X	
* Holometopus angelini.....	X	X
Lichas jukesii.....	X	X
Cheirurus vulcanus.....	X	X
Cheirurus mercurius.....	X	X
Cheirurus prolificus (Chazy).....	X	X
* Amphion barrandei.....	X	
Amphion julius.....	X	

In the above list those found at Cow Head are placed in the column C. H. and those which occur in Canada East (as well as Cow Head) C. E. The seven species of graptolites, with *Lingula quebecensis*, occur only in the black slates; all the others in the gray and white limestones. The three species with an asterisk before them are found in the next group of strata below. No one could compare the collections from Cow Head with those of Point Levis and Phillipsburgh without some feeling of astonishment that in localities nearly a thousand miles distant from each other there should be such a perfect identity not only in the fossils but also in the character of the rock. The specimens, if mixed together without their labels, could never be separated. Only a small collection was made at Cow Head, and there can scarcely be a doubt that further examination will bring to light a greater number of species common to the two countries.

This fauna, although upon the whole specifically distinct from the one next below, consists of the same types of trilobites, with the exception of *Bathyrurus cordai* and *B. conicus*, which are Calciferous species, as is also the brachiopod *Camerella calcifera*. There are two species, *Amphion sol*, and *Endymionia meeki*, which are found in division N, in Newfoundland, and not at Cow Head, but they occur in the limestones of Point Levis, which are of the same age as those of Cow Head. There are thus five common species, instead of three, as would appear by the above list.

From Cow Head, Point Levis, St. Antoine, Stanbridge, Bedford, and Phillipsburgh we have in all 219 described species. Of these, the 51 species of graptolites described by Prof. Hall, and also *Lingula quebecensis*, *L. irene*, *Obolella desiderata*, and *Shumardia granulosa* have been found only in the slates and thin-bedded limestones interstratified in the slates. The other 162 species occur in the white and gray conglomerate limestones. That the slates and these peculiar limestones belong to the same group is proved by their occurring together in widely separated localities, although as yet we are unable to show that any of the species are common to both. At Cow Head *G. headi* was found in a loose piece of gray limestone, but it is not quite certain that the specimen belongs to the conglomerates.

The evidence that the rocks at Cow Head in Newfoundland are of the same age as those of the Levis formation in Canada East amounts to this: (1) They are precisely the same in lithological characters and (2) out of the 34 species collected at Cow Head 23 are perfectly identical with those collected at Point Levis, Bedford, Phillipsburgh, and other typical localities of the formation. There is, however, in Newfoundland an important series of strata, consisting of all the divisions from I to O inclusive, having a thickness of 2,061 feet, lying below the Levis formation and above the Calciferous, which has not been recognized in Canada. It thus appears that the Levis formation not only lies above the Calciferous but more than 2,000 feet above it. Yet it holds a large number of trilobites of the Potsdam type and several species, such as *Lingula mantelli*, *Camerella calcifera*, *Bathyrurus cordai*, *B. conicus*, and *Asaphus canalis*, which certainly do occur in the Calciferous.

In the foregoing general catalogue (ante, pp. 366-370) there are 62 species placed in division P. But if we exclude from that division all the species except those collected at Cow Head, only those on the list on page 375 properly belong to it. The others should be placed in division N.

Ulrich (personal communication) comments as follows on the section:

These Ordovician fossils are in the conglomerate boulders here as at Point Levis. The graptolitic shale itself is the Levis thrust inland over the Chazy. The remainder of the section is in question. It may be in part Chazy or all post-Chazy, with persisting Chazy species, as in the Liberty Hall limestone of Virginia.

M-N 14. LAKE WINNIPEG DISTRICT, MANITOBA.

Dowling²⁹⁰ gives the following table of divisions of the later Ordovician in the Lake Winnipeg region and compares them with the formations known in Minnesota.

Formations in Minnesota.			Formations in Manitoba.	
Hudson River or Cincinnati period.	Richmond group.		Stony Mountain.	Limestones and shales.
	Utica group.			
Trenton period.	Trenton group.	Maclurea beds.	Trenton.	Upper Mottled limestone.
		Fusispira and Nemato-pora beds.		Cat Head limestone.
		Clitambonites beds.		Lower Mottled limestone.
	Black River group.	Black River (?).		Winnipeg sandstone and shales.
	Black River group.	Fucoid and Phylloporina beds. [a]	Trenton period.	
		Ctenodonta beds.		
		Rhinidictya bed.		
	Stones River group.	Stictoporella bed.		
		Vanuxemia bed.		
		"Lower Buff."		
Chazy formation.	St. Peter sandstone.			

^a This is the widely spreading zone so well displayed at Silliman Mountain, Baffin Land. The Winnipeg sandstone of Manitoba is probably at the same horizon but may be in part St. Peter.—Comment by E. O. Ulrich on manuscript.

Dowling describes the several divisions of the Ordovician as follows:

The basal beds of the Cambro-Silurian [Ordovician] of Manitoba consist of a series of soft friable sandstones, shaly in the upper part but generally similar to those found in Minnesota beneath the Trenton limestone. Very few fossils have been obtained, and those from the upper part only, denoting merely lower beds of the Trenton. * * * The fossils give no definite information as to the age of the beds but suggest a passage from Black River to Trenton. * * *

In eastern Canada and New York State the Black River is usually a thick-bedded limestone, but in Minnesota it is composed mainly of greenish shales, so that the shales below the limestone in the borings at Rosenfeld and Selkirk may be taken as the passage beds from the Black River. These are represented on Lake Winnipeg by shaly bands in the upper part of the section. The sandstone below, being in the nature of a shore deposit, though occupying a position nearly

similar to the St. Peter sandstone of Minnesota, can not be regarded as definitely of the same age, since no evidence of Chazy fossils has been found in it.

The thickness of pure sandstone in the Lake Winnipeg basin is apparently much less than to the south. The several sections give varying thicknesses [40-100 feet], owing to the uneven nature of the floor on which it was deposited. * * *

The Lower Mottled limestone is the lowest member of the limestone series and rests directly on the basal sandstones and shales. These limestones form the principal part of the sections at Grindstone Point, Bull Head, and Dog Head, and on the islands north to Berens Island. The combined section given by these several exposures amounts to a thickness of about 70 feet. The lowest beds are those seen at Deer Island and Grindstone Point capping the sandstone. Immediately above are the beds occurring at Dog Head, followed by the upper part of the Black Bear Island exposure. Those on Tamarack and Jack Head islands are evidently higher but belong to the same series and form, together with those mentioned above, the following descending section:

	Feet.
1. Hard mottled limestone, dark yellow, with brownish-yellow spots, breaking up into lumpy fragments not wearing discoidal on the beach but irregular. A few pieces from top beds are not so mottled and break smoothly (probably base of Cat Head limestone).....	15
Exposure on west side of Jack Head Island.	
2. Thin-bedded, mottled buff and grayish-white limestone, weathering ashy-white, in which are many large cephalopods: <i>Orthoceras</i> , <i>Sactoceras</i> , <i>Poterioceras</i> , <i>Oncoceras</i> and <i>Cyrtoceras</i> , while specimens of <i>Maclurea manitobensis</i> and <i>Receptaculites oweni</i> are abundant.....	15
Eleven feet of these beds are exposed on Little Tamarack Island and similar beds are exposed on Little Black Island near Berens Island.	
3. Mottled limestone, buff-colored but weathering lighter, in rather thicker beds than above and not so rich in fossils.....	10
These form the upper part of cliff on Black Bear Island.	
4. Thin beds of similar rock, rich in fossil remains.....	20
This band occupies the lower portion of the exposures on Black Bear Island, on Snake Island, and Dog Head or Whiteway Point and the upper part of the cliffs of Bull Head and intervening exposures.	
5. Darker mottled impure limestone, where not weathered, almost blue on fracture; fractures into thin flags with surfaces covered with fucoidal markings. The lower beds are of very earthy limestone resting on the sandstone of the basal series.....	10
	70
* * * * *	*

The Cat Head limestone, the central portion of the limestone series, is best developed at the prominent point on the west side of Kinwow Bay, called Cat Head. The beds are of a fine-grained, evenly colored yellow dolomitic limestone, with numerous concretions of dark-colored chert, filling cavities apparently left by the decay of corals. These beds are seen in the high cliff at Cat Head and along the shore to Lynx Bay. At the western end of the section, 3 miles west of Cat Head, the cherty concretions attain large dimensions. Several are over a foot in length, and one measured 2 feet by 10 inches. The lower beds are fine grained, resembling lithographic stone, and are very rich in fossil remains. The total thickness as observed on the lake is 68 feet. This includes the top beds of Cat Head and Outer Sturgeon Island, which are similar in color but coarser in texture, becoming finally crystalline. The section is made up as follows:

	Feet.
1. Hard, flinty, coarse-grained limestone (Sturgeon Island).....	10
2. Yellow granular limestone, weathering roughly and slightly honeycombed (Cat Head).....	8
3. Similar coarse-grained, weathering dark-yellow, with fucoid-like markings, and very much honeycombed (Cat Head).....	3
4. Yellow limestone with fucoidal markings similar to No. 2 (Cat Head).....	10
5. Fine-grained yellow rock with numerous ashy-colored spots scattered over the whole face of the exposure, from the weathering of small impure flinty concretions (Cat Head).....	27
6. Fine-grained yellow limestone, rich in fossil remains, with numerous large concretions of dark cherty material (Cat Head, McBeth Point, and Inmost Island).....	10
	68
* * * * *	*

The two lower series—the Cat Head and the Lower Mottled—are not of any great thickness, but are in the district readily distinguished from each other. The dividing line is placed at a bed at which the mottled limestone becomes highly charged with siliceous material in the form of chert nodules, while the limestone above changes from a mottled grayish-white with darker spots to a uniform buff, less crystalline rock. The faunal change is not very marked, but it will be noticed that the numerous large cephalopods that characterize the lower are almost altogether wanting in the middle division.

The “Upper Mottled limestone” is described as varying in different localities and in partial sections from hard mottled dolomite exhibiting rough surfaces marked apparently by fucoids to soft, darker mottled impure earthy limestone which passes into the overlying Stony Mountain formation. The thickness is estimated at 130 feet near Winnipeg.

The Stony Mountain formation is stated to represent the interval between the top of the Trenton and the base of the Silurian (upper). Dowling describes the changes of thickness in strata which occupy this interval to the east and south and says:

Although this formation is supposed to thin out altogether in northern Minnesota, there is found at Rosenfeld, in the southern part of Manitoba, a great thickness of shale beds between limestone formations which are probably Trenton and Silurian. At Stony Mountain the section, although incomplete, in a known thickness below the Silurian of 110 feet, consists of shaly beds in the lower part with thick-bedded limestones above. The fossils from this part are mainly from the shaly beds below the limestone of the top of the section, and probably all these are collected from less than 50 feet below the top of the formation. We might infer from this that the upper part, that of which we have a section and a list of fossils, is referable to the Richmond group of Minnesota, and that the lower beds, mostly shales, are similar to the Utica of the Cincinnati formation. One species only, characteristic of the Utica of Minnesota has been found at Stony Mountain—*Primitiella unicornis* Ulrich. The majority of those common to the two localities are from the upper parts of the sections. It is noted in the Minnesota reports that several forms occurring in the Trenton appear in the Richmond group without any evidence of their presence in the Utica. The same might possibly be asserted of some of the Manitoba forms, as several are found to range from the Trenton to the Stony Mountain formation.

A complete list of fossils identified from these divisions of the Ordovician is given in Dowling's report. The faunas were earlier discussed by Whiteaves.⁹²⁰

Ulrich in commenting on this correlation states:

Dowling's determination of the Manitoba Ordovician formations is based entirely on the Minnesota section of 1896. Much having been learned in the last 14 years concerning the Ordovician of the middle and far West, it is desirable to revise the classification of the rocks in both areas according to the present status of information.

O 9. DEASE RIVER, BRITISH COLUMBIA.

Blackish graptolite-bearing slates occur on lower Dease River near its junction with the Liard, in the belt of unaltered Paleozoic rocks of the eastern Rocky Mountains, near the sixtieth parallel. They were first seen in 1887 by G. M. Dawson,^{258a} who states:

From the second great bend to the mouth of the Dease the underlying rocks [underlying supposed Triassic] consist of gray and black schists, the former generally calc schists and the latter more or less highly carbonaceous. They are interbedded with thin limestones, which often weather brown. The calc schists are frequently glossy and in some places form very thin paper-like layers. Some of these rocks closely resemble those met with at the “Grand

Rapid" on the Stikine. The general strike is northwest by southeast, but the direction and angle of the dip is very varied and the beds are frequently much disturbed and twisted and traversed by veins of quartz and calcite. There are probably frequent repetitions of the same horizon, but the general arrangement may be synclinal, the dark shales and schists occupying the higher position and being most abundant about the middle of this length of the river section. Graptolites were found in the dark shales, particularly at a locality in a north bend of the river, 11 miles westward in a direct line from the mouth, and in appearance the whole series is much like that of the Cambrian calc schists and Cambro-Silurian graptolite shales of the Kicking Horse (Wapta) Valley, west of the summit, on the line of the Canadian Pacific Railway.

With reference to the geologic horizon, Lapworth⁵²³ reports:

The graptolites collected by Dr. Dawson from the Dease River are identical with those examined by me from the rocks of the Kicking Horse Pass some time last year.

The species I notice in the Dease River collection are—

- Diplograptus euglyphus (Lapworth).
- Climacograptus comp. antiquus (Lapworth).
- Cryptograptus tricornis (Carruthers).
- Glossograptus ciliatus (Emmons).
- Didymograptus comp. sagittarius (Hall).
- New form allied to Cænograptus.

The graptolite-bearing rocks are clearly of about middle Ordovician age. They contain forms which I would refer to the second or Black River-Trenton period—that is, they are newer than the Point Levis series and older than the Hudson and Utica groups. The association of forms is such as we find in Britain and western Europe, in the passage beds between the Llandeilo and Caradoc limestones. The rocks in Canada and New York with which these Dease River beds may best be compared are the Marsouin beds of the St. Lawrence Valley and the Normans Kill beds of New York. The Dease River beds, perhaps, may be a little older than these.

These rocks are also apparently very similar to the graptolite-bearing slates of the Alaska Range.

O 15. SOUTHWEST COAST OF HUDSON BAY.

An isolated occurrence of limestone containing Trenton fossils near Fort Churchill is described by Tyrrell.⁸¹⁸ The rocks had previously been observed by Bell on Churchill and Nelson rivers and assigned to the Galena-Trenton horizon of the Wisconsin Geological and Natural History Survey by Whiteaves,⁹¹² who also recognized some probable upper Silurian or Devonian forms.

In 1880 Bell⁶⁶ wrote:

Geologically the basin of Hudsons Bay, excluding the western or Winnipeg division, lies within the great Laurentian area of the Dominion. Cambro-Silurian rocks, resting almost horizontally upon these, form an irregular border along the southwestern side of the bay, and in the valleys of some of the rivers they extend inland from 100 to 200 miles. To the south and west of James Bay the Cambro-Silurian [Ordovician] is overlain by Devonian rocks, which here occupy a considerable area.

Among the notes of a preliminary report on the region between Lake Winnipeg and Hudson Bay, Low⁵⁴⁹ includes the following:

The limestones of the Severn and Fawn rivers, as roughly determined from the fossils collected, are not older than the Galena and may be as new as the Niagara; more investigation is, however, required to fix their precise horizon.

The rock is a coarse yellowish-white dolomitic limestone, closely resembling that of Lake Winnipeg. It lies almost flat, being broken only by long, low anticlines and synclines. At the Limestone Rapids of the Severn, where it is more contorted than usual, it rises in a number of low domes, closely resembling a sheet of letter paper when dampened. The total thickness of the beds exposed does not exceed 100 feet.

References to these limestones occur in subsequent reports, but on account of the isolation and small areas of the outcrops there is no complete section nor any definite knowledge of the area of strata of Trenton age or of higher strata. Brock^a states:

With reference to the southwestern coast of Hudson Bay our information is not definite. There are very few exposures and only isolated fossils have been brought down, some possibly from loose boulders. From Tyrrell's fossils and Bell's it is evident that there is at least a band of Trenton, and from other fossils it is certain that Silurian is present, but where the boundary lies between them we do not know.

P-Q 3-7. ALASKA.

Ordovician strata in Alaska are in general not distinguished on the map of North America, the areas in which they occur being classed as Paleozoic undivided. Their presence is known, however, through the discovery by Brooks and Prindle¹⁰⁴ of Ordovician graptolites on the western slope of the Alaska Range, in carbonaceous strata which are intimately associated with phyllites, limestones, and cherts and which have been called the Terra Cotta "series." These strata are probably represented in the metamorphic rocks of the upper Tanana region, formerly known as the "Tanana" schist^{101b} but recently correlated with the Birch Creek schist.¹⁰⁴ Ordovician fossils have also been found on the Porcupine in bluish-gray nonmagnesian limestone 600 feet thick.¹⁰²

Thus the presence of the Ordovician is shown on fossil evidence in the central eastern portion of the Alaska Peninsula. Similar fossiliferous beds are known at several points in British Columbia. Strata which have as yet yielded no fossils, the Wales "series," lie beneath and are older than upper Silurian in southeastern Alaska. On the other hand, toward the north and northwest from the Yukon region the more or less metamorphic schists of the Endicott Mountains and Seward Peninsula include early Paleozoic sediments, possibly Ordovician, and there are similar schists in southern Alaska about Prince William Sound and the Wrangell Range.¹⁰¹

P-Q 17-19. SOUTHAMPTON ISLAND, FOX LAND, AND UNGAVA BAY.

The central portion of Fox or Baffin Land is mapped as Silurian, as are also the islands in the north of Hudson Bay. The presence of Ordovician strata is established in Frobisher Bay, and is probable throughout the areas in this region shown with the Silurian color. (See pages immediately preceding.)

Akpatok Island, in the northern part of Ungava Bay, is described by Bell⁶⁸ as presenting a wall of gray limestone 400 to 500 feet high all along the coast from the north end to the middle of the east side. The strata are horizontal and the total thickness exposed in the heights of the island is estimated at 900 feet, to which

^a Brock, R. W., Acting Director Geol. Survey Canada, letter May 27, 1908.

may be added an unknown thickness beneath the sea. Low⁵⁵⁰ states that the strata range in age from "Galena-Trenton to Lower Helderberg."

Q 3-4. SEWARD PENINSULA.

Kindle has contributed the following note on the Silurian and Ordovician of Seward Peninsula:

The Port Clarence limestone furnished fossils which were determined as Silurian and Ordovician. Recent collections from this limestone show the presence of both Cambrian and Ordovician faunas and indicate that the fauna previously considered Silurian is of late Ordovician age.

R-T 10-20. ARCTIC ARCHIPELAGO.

Large areas in the Arctic Archipelago are colored as Silurian (upper Silurian or Gothlandian) in accordance with the dominant character of the fossils collected by several expeditions. Detailed references and descriptions are given in Chapter V (pp. 265-266). These Silurian strata, however, are in certain localities and probably as a rule underlain by Ordovician. Dawson^{257a} summarizes:

In a paper printed in the report of the British Association for 1855 J. W. Salter states that the Silurian fossils obtained up to that time showed a uniform horizon of Upper Silurian limestone stretching from near the entrance to Barrow Strait to Melville Island and far to the south along Prince Regent Inlet and argues therefrom a wide extent of circumpolar land in lower Silurian (Cambro-Silurian) times. In this he was followed, two years later, by Sir R. Murchison,^a who writes: "I am led to believe that the oldest fossiliferous rock of the Arctic regions is the Upper Silurian." Though the Upper Silurian beds undoubtedly occupy a great part of the American polar region, characterizing the "South of North Devon and nearly all the islands south of Melville and Lancaster sounds, including the south of Banks Land, Prince of Wales Land, King William Land, North Somerset, Boothia, Felix, etc.,"^b the occurrence of Lower Silurian (Utica) fossils in Frobisher Bay, as shown by Hall's collections, on the shores of Kennedy Channel, as determined by Etheridge, and the occasional discovery of Lower Silurian forms in the regions above referred in a general way to the Upper Silurian prove that the generalization made by Salter and Murchison, on the evidence of less complete collections, can not now be admitted and that the limestones of the Arctic represent probably the whole of the Silurian [Lower and Upper], and possibly part of the Devonian.^b Heer^c enumerates the following places, besides those above particularly referred to, as yielding Lower Silurian types: North Devon, Cornwallis Island, Griffith Island, west coast of King William Land, Boothia.

Dawson's inference was verified in 1900 by Schuchert,⁷¹² who studied new collections from Sillimans Mount, at the head of Frobisher Bay, and extended the basis of correlation with other areas in the Arctic Archipelago. After enumerating localities, Schuchert says:

From the foregoing description of localities, it appears that middle Lower Silurian horizons are very extensive in eastern Arctic America. Such are known in places on either side of Hudson Strait, Frobisher Bay, the interior of Baffin Land, and to the north of this land at various localities between latitudes 79° and 80° north. As far as known, these strata unconformably overlie very ancient crystalline rocks and are in turn overlain by Upper Silurian beds of Niagara or Wenlock age. Lower Cambrian rocks are found in southern Labrador, but in the region of

^a Appendix to McClure's voyage, p. 402; Siluria, p. 440.

^b Fielden and De Rance, Quart. Jour. Geol. Soc., vol. 34.

^c Flora Fossilis Arctica, vol. 1, p. 24.

Baffin Land such are not known to be present. Here, then, there seems to be a complete break from the Laurentian to the Trenton, followed by another break paleontologically, in the absence of the Cincinnati beds and probably the lower horizons of the Upper Silurian. The Lower Silurian fossils of this area indicate nothing older than the typical Trenton of New York and the Galena of Wisconsin and Minnesota,^a and nothing younger than the Utica stage of the United States. The thickness of these beds is not less than 900 feet and probably exceeds this.

Schuchert cites lists of fossils collected by Hall and described by Stevens⁷⁹² and Emerson³¹⁸ and gives a new list of 72 species from Silliman's Fossil Mount and their distribution according to horizons (Lowville, Black River, Trenton, and Cincinnati) and according to regions (Minnesota-Manitoba, New York-Ottawa). He concludes:^{712a}

From Mr. Porter's description, it will be seen that the fossils recently collected at Silliman's Fossil Mount are from various horizons, and yet there is nothing to indicate the presence of more than one fauna. The foregoing list shows that at present there are 72 species known from this locality, and of these 28 are restricted to it. There are, therefore, 54 species which are common to other localities, a goodly number with which to make safe correlations. Of these 54 species, 41, or 57 per cent of the known fauna, are also found in the region of Minnesota, Wisconsin, and Iowa, while 17 are known to occur in New York and Ottawa.

On comparing the 54 widely distributed species with those from definite stages in Minnesota, it is seen that 10 are also found in Birdseye (Lowville), 17 in the Black River, 38, or about 70 per cent, in the Galena, the direct equivalent of the New York Trenton, and 11 in the Cincinnati group.

From these figures it is evident that the stage of Silliman's Fossil Mount belongs in the Galena, and that the fauna is more intimately related to that of the Minnesota region than to the Trenton of New York. When the New York Trenton fauna is restudied in the light of recent researches in Minnesota,^b however, it will be shown that the two faunas have more in common than now appears. On the other hand, the lithological similarities of the Minnesota Galena and Silliman's Fossil Mount, light-colored shales predominating in both areas, may explain in large measure the close identity of these widely separated faunas.

Schuchert^{712b} closes his paper with the following summary of the information available on the Arctic Ordovician:

The only Lower Silurian horizons known in northeastern Arctic America are of Trenton and Utica age. The latter zone appears only on the north shore of Frobisher Bay, but the Trenton is found in various places from the north shore of Hudson Strait to latitude 81° north. The Lower Silurian is thickest on Akpatok Island, where it is from 400 to 500 feet in depth. Dr. Bell, however, estimates the entire thickness of these strata in this region to be not less than 900 feet.

In Baffin Land and apparently elsewhere in Arctic America the Lower Silurian strata rest unconformably on old crystalline rocks [except where Cambrian is present in the far north; see p. 155]. To the north of Baffin Land the former are overlain by beds of Niagara or Wenlock age.

The Trenton faunas, occurring in various places around the insular Archean nucleus of North America, have much in common, and this indicates that the conditions at that time were very similar, while the sea was in communication throughout. As yet, however, the distribution of the strata, together with their faunas, are well known only to the south and southeast of the Archean nucleus, yet that of the west (Manitoba) and of the northeast (Baffin Land) show direct communication.

^a See Cambrian of Bache Peninsula, Chapter III, p. 155.

^b Paleontology of the Lower Silurian fossils of Minnesota: Geology of Minnesota, vol. 3, pts. 1 and 2, Geol. Nat. Hist. Survey Minnesota, N. H. Winchell, State geologist.

The Baffin Land fauna had an early introduction of Upper Silurian genera in the corals *Halysites*, *Lyellia*, and *Plasmopora*. In Manitoba similar conditions occur in the presence of *Halysites*, *Favosites*, and *Diphyphyllum*. Other Upper Silurian types do not appear to be present.

The Trenton fauna of Silliman's Fossil Mount, at the head of Frobisher Bay, has 72 species, of which 28 are restricted to it. This fauna shows an intimate relationship with that of the Galena of Minnesota, Iowa, and Wisconsin. Fifty-seven per cent of the species of Baffin Land also occur in the Galena of the regions just mentioned.

S 27. EASTERN COAST OF GREENLAND.

The Ordovician and possibly Cambrian of northeastern Greenland are described by Nathorst,^{609c} who says:

East from the Archean follows a formation of sedimentary rocks which are without doubt older than Devonian and at least in part must be considered of Silurian [Ordovician] age, since there were found at Cape Weber, besides others, *Orthoceratites*, together with small *Orthis* or a closely related brachiopod and small gastropods. Although these fossils in consequence of pressure and the poor condition of preservation resulting therefrom can not be specifically determined, a Silurian [Ordovician] age is nevertheless indicated, since the *Orthoceratites* are younger than Cambrian; still it is not impossible that in the lower formations there may be Cambrian strata.

The strata of which the formation is composed are very variable and consist of white, yellowish, gray, and black limestone or dolomite; red, green, chocolate-colored, and dark slates; and red sandstone, together with perhaps in the lower portions yellowish sandstone.

The Ordovician strata of this region are much folded and conformably overlain by the Devonian.

CHAPTER V.

SILURIAN.

Color, violet.

Symbol, 16.

Distribution: General throughout northern and eastern North America, east of the Great Plains; represented by the Devonian color (15) in the Appalachian zone south of latitude 38°; known to be present in the Cordillera and Alaska but not generally distinguished by separate color, except in Mexico, Nevada, and British Columbia.

Content: In the Appalachians in general includes Medina to Cayuga; in the southern Appalachians is mapped with Devonian; in eastern Canada and New York Helderberg is included on the map; in the interior, includes strata of Niagara age; in the Arctic the Silurian color covers areas of the limestone series known to include Ordovician and Silurian.

Silurian areas.

FIGURE 7.—Sketch map showing the distribution of Silurian rocks represented on the geologic map of North America and the key to references in the text.

G-H 12. SONORA, MEXICO.

Aguilera⁹ in 1906 mentioned certain strata as "doubtful Silurian" in describing under that head "Quartzites and fossiliferous semicrystalline limestones, of gray color and siliceous character, with *Encrinites cyathophyllum* and *Heliolites*; these overlie compact gray and yellowish limestones which occur above a series of breccias and limestones." Aguilera does not name localities at which these rocks occur.

The areas mapped as Silurian in Sonora are so assigned on authority of a manuscript map furnished by Robert T. Hill, and the strata may be similar to those described by Udden and Richardson as occurring in southwestern Texas.

H 13. WESTERN TEXAS.

Describing a region near Marathon, Tex., J. A. Udden^{819a} says:

There must be several thousand feet of sediments exposed in this area. They have been folded and faulted and dip, usually at high angles, either to the southeast or to the northwest. * * * In the south part of the area they consist largely of dark shales and limestones. These contain heavy ledges of cherty quartz, which rise in long ridges running from the northeast to the southwest. The chert is usually interbedded with ledges of dark limestone, which now and then contain round and loaf-like concretions of chert. The prevailing color of the chert is white, but it is sometimes black, green, bluish, or of a brown or a pinkish color. With some of the limestones there are thin seams of sandstones and conglomerates. The latter usually consist of well-worn pebbles, mostly of limestone, but also of hard quartzite. In some shales, which are associated with chert and limestones in a ridge on the south side of Edwards Creek, about 10 miles northeast of Santiago Peak, there is one stratum which contains large concretionary aggregates of crystals of barite. Some of these aggregates are a foot in diameter and consist of columnar crystals radiating from the center of the concretions. The mineral was seen to follow a stratum about 3 feet in thickness, and the concretions in one place appeared to be present in large quantity. The limestones themselves are frequently bituminous. Some ledges consist of small worn organic fragments. From one of these some fossil fragments were taken which Dr. Charles Schuchert has identified as the outer portions of the glabella of a *Trinucleus*. Associated with this there were also a *Plectambonites (sericeus?)*, a *Rafinesquina*, and possibly a *Zygospira*. A gastropod of the genus *Cyclora* was found in another ledge, and in still another limestone a *Nodosaria* was noted. All of these fossils were collected along the wagon road near Ridge spring and at different points south from this place for a distance of 10 miles. The same kind of rocks continue north from this spring as far as to Peña Colorado, 4 miles south of Marathon. North from Peña Colorado we find shales, limestones, and thin conglomerates, but no chert beds. An *Athyris*, a *Fistulipora(?)*, a *Dentalium*, and joints of crinoid stems were observed in the vicinity of Marathon, where the dip of these rocks is quite generally to the northwest. Evidently these sediments are younger than the formation which contains the chert south of Peña Colorado.

The thickness of the ancient sediments, which are seen on these plains around Marathon, is no doubt several thousand feet, and they very likely contain formations of more than one age. For 25 miles the road from the Chisos runs over the edges of beds tilted at high angles. The fossils associated with the chert show that some of these strata belong to the Ordovician, and Dr. Schuchert infers that these are of the Trenton period. In his "Physical geography of the Texas region" Prof. R. T. Hill expresses it as his opinion that the limestones, shales, etc., of these plains may be of Lower Helderberg age,^a and there is no good reason to doubt that the Silurian rocks are represented in this extensive complex of folded strata.

^a Folio 3, Top. Atlas U. S., U. S. Geol. Survey, 1900, p. 4.

H 13. TRANS-PECOS TEXAS.

With reference to the Silurian in the district lying north and east of El Paso Richardson ^{668b} states:

The Silurian system in trans-Pecos Texas is represented in the El Paso region [by] the Fusselman limestone in the Franklin and Hueco mountains. This is a massive whitish magnesian limestone approximately 1,000 feet thick. It overlies the Montoya limestone apparently conformably, although in one locality fragments of the underlying limestone included in the Fusselman give evidence of an unconformity. Throughout the greater part of the formation fossils are scarce, but at a few horizons they are very abundant. The commonest form is a species of radially plicated pentameroid shell which, with *Amplexus* and *Favosites*, determined by Mr. Ulrich, proves that the upper Niagaran stage of the Silurian is here represented. Gordon and Graton ^a have recently found Silurian fossils in the Silver City region and at Lake Valley, N. Mex.; and Taff's Hunton formation in Oklahoma ^b also contains a Silurian fauna.

I 12. ARIZONA.

Reagan ⁶⁶³ states in regard to the Silurian:

The Upper Silurian.—Immediately overlying the Tonto at its outer edge and possibly conformable with it are red to brown fossiliferous coarse-grained lime rocks having a thickness of about 70 feet. They form only a narrow band but are continuously exposed from the Tonto basin to Nantan Mountains, where not covered with talus or lava. The best exposures observed by the writer are on the trail to the Salt springs, some 10 miles southwest of the farmer's residence on Cibicu, and on the John Dazen trail near the Oak Creek break about a half mile southeast of Oak Creek cliff houses. This formation is Silurian; at least the fossils obtained, *Orthis davidsoni*, *Strombodes pentagonus*, etc., seem to bear out this conclusion.

I 13. NEW MEXICO.

Lindgren ^{542b} gives the following account of the Silurian of New Mexico:

The Silurian is recognized at Silver City, at Lake Valley, and probably also at Hillsboro as thin beds of limestone and quartzite, but does not seem to be present everywhere between these places. It lies conformably above the Ordovician and at Silver City can not be differentiated from it. In the Franklin Range of Texas Richardson measured 1,000 feet of Silurian limestone.

I 14. OKLAHOMA.

The Arbuckle Mountains of Oklahoma comprise Silurian and Devonian strata which were separated by Taff into two mapped formations. The lower formation, the Sylvan shale, is of Silurian age, and the upper, the "Hunton limestone," is of Silurian and Devonian age. The Sylvan overlies the highest known fauna of the Ordovician, yet its fauna is related to the Utica of the New York Ordovician. The "Hunton" contains strata carrying in succession Niagara, Helderberg, and Oriskany faunas. The following is the stratigraphy and paleontology according to Taff and Ulrich: ^{808b}

The Sylvan shale and the succeeding Hunton limestone are comparatively thin formations. * * * The nearly pure lime deposits laid down at the close of Viola [upper Richmond, latest Ordovician] time were succeeded by dark-blue to black and green clay in apparently conformable succession. The deposition of the greenish Sylvan shale continued without interruption until it reached a thickness of from 60 to 300 feet. * * *

^a Am. Jour. Sci., 4th ser., vol. 21, 1906.

^b Tishomingo folio (No. 98), Geol. Atlas U. S., U. S. Geol. Survey, 1903.

A preliminary study of the fossils occurring in the dark basal shale shows the following forms:

Diplograptus sp. undetermined.
 Climacograptus sp. near typicalis.
 Leptograptus sp. undetermined.
 Lingula; short, obtuse form.
 Lingulops? sp. nov. (platform obsolete).
 Leptobolus sp. near insignis.

Leptobolus? sp. nov. (has six strong radiating plications).
 Conularia sp. nov., with surface sculpture very similar to that of the Trenton *C. papillata* Hall.
 Conodonts of forms resembling those referred by Hinde to *Prioniodus* and *Polygnathus*.

The fauna of the Sylvan shale as far as known is generally remarkably similar to that of the Utica. The specific differences, however, are such as to distinguish them; yet a study of the fossil convinces one that the fauna of the Sylvan is a direct development from the much older fauna of the Utica shale and not of the intervening faunas of the Cincinnati group. From this evidence it would seem that the position of the Sylvan shale in the time scale is problematical. The highest known fauna of the Ordovician, that of the Richmond group, occurs at the top of the Viola limestone, beneath the Sylvan shale, and the Clinton occurs immediately above the Sylvan, in the base of the Hunton limestone. According to the present classification, therefore, the Sylvan shale should be correlated with the Medina, and the line separating the Ordovician and Silurian in the Arbuckle Mountains should be placed between the Viola limestone and the Sylvan shale.

The green clay shales of the Sylvan [Silurian] are succeeded abruptly by hard white to light-blue limestone of the Hunton formation. Usually the contact rock at the base of the Hunton is a massive bed of oolitic limestone. Locally hard bluish limestone beds are found at the base, with rarely a thin layer of brecciated limestone or limestone conglomerate in contact with Sylvan shale. * * *

The Hunton formation is composed of hard, thick crystalline limestones, thin earthy limestone, and marls. It may be separated into three fairly distinct members according to lithologic characteristics, and to a less extent according to color. Except where the formation is very thin * * * the three members can always be distinguished. An average section of the formation on the south side of the Arbuckle Mountains west of Washita River is approximately as follows:

Section of Hunton limestone.

	Feet.
Upper member: Semicrystalline limestone, in places cherty, interstratified with occasional thin marly layers.....	30
Middle member: Marly limestones and calcareous clays, with some hard limestone layers, more abundant in the lower part.....	170-190
Lower member: Thick-bedded crystalline limestone succeeded by hard thin limestone with occasional marly layers. At the base of this limestone is an oolite, 4 to 5 feet thick, which locally is silicified.....	35-40

The lithologic differences by which the members are distinguished are accompanied by faunal changes which afford a basis for age distinctions. The more massive crystalline beds in the lower part of the basal member, ranging in thickness from a thin bed to 25 feet or more, contain forms which are distinctly Clinton. Four Bryozoa and *Triplecia ortonii* are characteristic of the Clinton limestone of Ohio, and their horizon occurs in the St. Clair limestone of northern Arkansas. * * *

The hard thin limestone beds in the upper part of the basal member contain fossils which indicate Niagara age. * * *

The middle member of the Hunton limestone as a whole is abundantly fossiliferous. * * * There can be no question as to the Helderbergian age of this member of the Hunton formation.

The uppermost member of the Hunton formation is probably lower Oriskany in age and equivalent to the Camden chert of Tennessee. * * *

According to the classification of the Paleozoic rocks at present in vogue, this member should be called Devonian, but it is so intimately united, both faunally and structurally, with the under-

lying Helderberg member, that, for this region at least, it would be doing violence to the natural classification of the rocks to draw a line of systemic importance between them. According to a classification taking into account both the life history and structure of the strata, this divisional line should be drawn either between the flinty beds at the top of the Hunton limestone and the base of the black shale and chert of the overlying Woodford formation, or between the Niagara and Helderberg members. In the latter case the lower member only would be Silurian, and the two upper members Devonian.

I-J 16-17. ALABAMA, GEORGIA, TENNESSEE, WEST VIRGINIA, AND VIRGINIA.

In the zone of Appalachian folds from Maryland southward, the Silurian strata consist of the basal littoral formations and the overlying Clinton ("Rockwood" or "Dyestone") of the Southern States. The basal sandstones (Bays, Ordovician, and Clinch, Silurian) extend from Virginia along the valley of east Tennessee to the longitude of Knoxville. The Clinton or "Rockwood" alone is continuous to Alabama. Higher Silurian deposits, the equivalents of the Niagaran and Cayugan, thin and disappear in southwestern Virginia and northeastern Tennessee, as shown in the sections given below. The Helderbergian is here classified as Devonian, and the upper limit of the Silurian therefore falls in the lower part of the Lewistown limestone of the following sections. The Silurian outcrops in narrow belts intimately associated with and practically coextensive with the Devonian and is, in view of the small scale of the map, indistinguishable from the Devonian in the generalized drawing of the complex structure. The Silurian is therefore represented with the Devonian by the color of the latter south of northern Virginia.

In eastern West Virginia (Piedmont quadrangle) the Silurian has been classified by Darton ²²⁸ as follows:

Top.	Feet.
Monterey sandstone, in part; massive calcareous blue-gray sandstone (in part Devonian).	215-300
Lewistown limestone (equivalent to Lower Helderberg [Devonian], Salina, and Niagara):	
Cherty limestone (Lewistown chert lentil).....	130-300
Massive light blue gray limestone.....	20- 80
Shaly limestone.....	100
Dark-colored limestone.....	30- 60
Flaggy limestone.....	450-980
Thin beds of impure limestone with alternations of greenish and gray calcareous shale.	250-310
Rockwood formation (Clinton):	
Gray sandstone.....	12- 20
Gray, brownish, and greenish shale with iron ore and thin limestone beds.....	525-750
Cacapon sandstone: Red sandstone, mainly thin bedded.....	300
Tuscarora quartzite: White or gray massive quartzite.....	480
Juniata formation: Brownish-red sandstone and shale.....	750+

The Juniata, Tuscarora, and Cacapon Darton regarded as the representatives of the Medina of New York.

Traced through the Franklin quadrangle, south of the Piedmont, the divisions of the Silurian in the Staunton quadrangle, in central Virginia, are similar but reduced in thickness, as shown by Darton ^{226a} in the following section:

Silurian rocks in Staunton quadrangle, Virginia.

	Feet.
Monterey sandstone (Silurian and Devonian, Oriskany), in part calcareous.....	0-300
Lewistown limestone (Silurian): Cherty limestone, pure limestone.....	300-500
Rockwood formation (Clinton): Gray quartzite, sandy shale.....	150-200
Massanutten sandstone (Medina): Reddish sandstone, gray quartzite, red and gray sandstones.	500-600

in southwestern Virginia, in the Pocahontas quadrangle, Campbell¹²³ did not distinguish the "Monterey" sandstone (Oriskany) and Lewistown limestone but named the strata which occupy the interval between the Clinton and the Devonian the Giles formation. His section is as follows:

	Feet.
Giles formation (Oriskany and Lower Helderberg [Devonian]): Coarse yellow sandstone, cherty limestone, coarse reddish sandstone, blue limestone.....	30-200
Rockwood formation (Clinton): Heavy sandstone or quartzite, sandy shale and ferruginous sandstone with siliceous red fossil ore and hematite.....	20-400
Clinch sandstone (Upper Medina): Coarse white sandstone or quartzite.....	150-250
Bays sandstone (Lower Medina) [Ordovician]: Red sandstone and sandy shale.....	250-350

The Giles formation comprises strata which are grouped because they are usually covered and can not be distinctly traced. In the Kimberling Wilderness, in the eastern part of the Pocahontas quadrangle, Campbell recognized the following divisions:

Section of the Giles formation [Devonian].

	Feet.
Greenish sandstone locally containing pebbles of the limestone at the base of the group; thickness not determined.	
Cherty limestone or chert.....	30-40
Coarse ferruginous sandstone locally composed of small quartz pebbles cemented by iron oxide.	15-20
Blue limestone, shaly at the base.....	30-40

At the boundary between Virginia and Tennessee (in the Bristol quadrangle) the Silurian consists of the Clinch and Clinton or "Rockwood" formations, together with the Hancock limestone (Silurian and Devonian). Here the Bays, Ordovician (350 to 450 feet), and Clinch (250 to 450 feet) are thicker; the Clinton or "Rockwood" (200-300) is similar in thickness to the last section cited. The characters of these formations remain the same.

The Hancock is a blue fossiliferous cherty limestone. It also appears in the northwest corner of the Morristown quadrangle, Tennessee, in latitude 36° 30' north, longitude 83° 30' west, but does not occur farther south. Keith⁴⁷⁷ states:

In the Powell syncline are found the only areas of this formation [the Hancock limestone] in the valley of east Tennessee, and from its occurrence here in Hancock County it derives its name. The formation consists entirely of interbedded massive and shaly limestones of a blue, gray, or dove color. Massive beds are more frequent at the bottom and top of the formation and attain a thickness of 20 feet. Great numbers of fossils, largely brachiopods, corals, and crinoids, are found throughout the formation and show it to be of upper Silurian [Helderberg, Devonian] age.

In the Greeneville quadrangle, Tennessee (longitude 82° 30' to 83° west, latitude 36° to 36° 30' north), east of the Morristown quadrangle, the Silurian comprises the Clinch and part of the Clinton ("Rockwood"). The section as given by Keith^{481a} is as follows:

	Feet.
Rockwood formation: Green, red, and yellow sandy and calcareous shale.....	700+
Clinch sandstone: Massive white sandstone.....	300-500
Bays sandstone [Ordovician]: Massive and shaly red sandstone.....	50-400

In the northwestern part of the quadrangle the Clinton ("Rockwood") is lacking and the Chattanooga shale (Devonian) rests on the eroded Clinch sandstone.

In the Briceville quadrangle, 60 miles west of the Greeneville, the Bays (Ordovician) is a "red argillaceous and sandy limestone, 160 to 200 feet thick;" the Clinch sandstone is absent, and the Clinton ("Rockwood"), which rests conformably

on the Bays, consists of red and brown calcareous shales, is 400 to 500 feet thick, and carries beds of fossiliferous limestone 4 to 8 feet thick which constitute the fossil iron ores so far as the lime has been replaced by iron.⁴⁷⁸

The type locality of the "Rockwood" formation is in the Kingston quadrangle, Tennessee. The "Rockwood" is there the only representative of the Silurian, but no unconformity is noted either below it at the contact with the Athens shale or Chickamauga limestone (Ordovician) or above it at the contact with the Chattanooga shale (Devonian). Hayes⁴²⁰ states that the "Rockwood" (Clinton) varies widely in character and thickness within the quadrangle. About the head of the Sequatchie Valley "it is 165 feet thick and is composed of calcareous shales interbedded with blue limestone." Along the foot of the Cumberland escarpment "it is about 600 feet thick and consists of calcareous and sandy shales. Still farther east * * * the formation attains a thickness of 850 to 1,000 feet, a considerable part of which is coarse sandstone interbedded with sandy shales. Toward the top are sandy shales and a few calcareous beds, with which is associated the iron ore."

A similar description applies to the "Rockwood" (Clinton) as it occurs in the Chattanooga quadrangle, Tennessee, as far south as latitude 35°.

I-K 16. INDIANA, OHIO, KENTUCKY, AND TENNESSEE.

Silurian strata envelop the Cincinnati arch and the Nashville dome in the States of Indiana, Ohio, Kentucky, and Tennessee. There is in many places an unconformity at their base corresponding to the latest Ordovician. The strata themselves are very largely limestones, which differ locally in character and in faunal contents. They have been minutely classified, and the details are to be found in the State reports and in recent articles.^{336, 337, 340, 341, 342, 431}

The Silurian strata of Indiana may be divided, according to Foerste,³⁴² into—

	Feet.
Louisville limestone (at the top).....	55+
Waldron clay.....	4-20
Laurel limestone.....	40-48
Osgood clay and limestone.....	11-16
Clinton limestone (at the base).....	0-11

The "Clinton" is regarded by Foerste as distinct. The other four divisions he assigns to the Niagara.

The "Clinton" succeeds the Ordovician with local unconformity and contains rounded fragments of Ordovician rocks around the margins of islands, which it did not cover. It is in many places a detrital limestone but has also dense siliceous or clayey facies.

The Osgood consists chiefly of clay shale with 8 to 15 inches of limestone at the base. Where the shale gives place to lime the limestone thickens, and it is correlated with the Dayton limestone of Ohio.

The Laurel limestone is usually hard, white, and evenly bedded. Toward the south it becomes softer and more argillaceous.

The Waldron shale is a distinct bed overlying the Laurel, and is mainly a clayey shale having the facies of the Osgood shale. It becomes calcareous toward the north.

The Louisville limestone, which at Louisville is unconformably overlain by Devonian limestone and has a thickness of 55 feet, is described as thinning out toward the north and east. Foerste^{342b} comments as follows on the relations of Silurian and Devonian:

The absence of any mention of distinct unconformity at most localities so far examined suggests that the Silurian-Devonian contact is not marked everywhere by strong unconformity, but that at many points in northern Indiana the unconformity is slight. In the southern part of the State the Silurian-Devonian contact is also accompanied by a slight unconformity.

The Waldron shale and its abundant fauna constitute the subject of an article by Kindle and Barnett,⁵⁰⁴ who refer to the paleontologic work of Hall and state in part:

The Waldron shale is composed mainly of fine-textured blue to greenish clay shale. Thin bands of impure limestone and calcareous nodules sometimes occur in the shale but represent a comparatively insignificant proportion of the formation. The Waldron shale has a thickness ranging generally from 4 to 10 feet. So far as observed by the writers the Waldron beds are conformable with the Niagara limestone beds above and below. * * * Although a very thin formation, the Waldron is very persistent and extends southward from southern Shelby and Rush counties to the Ohio River, a distance of about 85 miles. The Waldron shale is not known north of the central part of the State. The heavy mantle of drift to the north of its northernmost exposures in Rush and Shelby counties conceals a large area in which important stratigraphic changes take place, the precise nature of which is unknown. All that we know certainly about them is that they result in a Silurian section in the Wabash Valley in which neither the Waldron shale nor its two accompanying limestone formations have been identified. It may be that the Cincinnati geanticline, which is believed to have been in existence during the Waldron shale interval, as pointed out elsewhere in this paper, swung to the westward across north-central Indiana, making distinct marine basins in northern and southern Indiana. Certain differences in the faunas as well as the stratigraphy of the Silurian of the northern and southern Indiana sections could be cited in support of this hypothesis.

The fauna of the Waldron, which comprises 160 species, is contrasted by Kindle and Barnett with that of the Louisville limestone, with which it has remarkably little in common. Full lists of fossils are given.

The faunas of the several divisions of the Silurian in Indiana are distinguished by Foerste,^{342a} who recognizes close affinities between those of the Laurel and Louisville on the one hand and between those of the Waldron and Osgood on the other.

The divisions enumerated are described particularly from occurrences in southeastern Indiana; in northern Indiana the Niagara strata are not differentiated. The identification of these Niagaran formations and their correlation with the New York section are considered by Foerste. He also identifies a water-lime rock occurring at Kokomo, Ind., as the probable equivalent of the Bertie water lime (lower Cayuga) of the New York State reports.

The Silurian of Ohio was classified by Prosser⁶⁵¹ in 1905 as follows:

Northwestern Ohio.	Feet.						
Monroe formation { <table style="display: inline-table; vertical-align: middle; border: none;"> <tr> <td style="padding: 0 10px;">Lucas limestone</td> <td style="font-size: 2em; vertical-align: middle;">}</td> </tr> <tr> <td style="padding: 0 10px;">Sylvania sandstone</td> <td style="font-size: 2em; vertical-align: middle;">}</td> </tr> <tr> <td style="padding: 0 10px;">Tymochtee member (?).</td> <td style="font-size: 2em; vertical-align: middle;">}</td> </tr> </table>	Lucas limestone	}	Sylvania sandstone	}	Tymochtee member (?).	}	50-600
Lucas limestone	}						
Sylvania sandstone	}						
Tymochtee member (?).	}						

Northern Ohio.	Southern Ohio.	Feet.
	Hillsboro sandstone Cedarville limestone Springfield limestone West Union limestone Osgood beds Dayton limestone	} 150-350
"Niagara group"		
Clinton limestone		10-50
Northern Ohio.	Southern Ohio.	
Medina shale (?)	Belfast bed (5 feet)	50-150

Detailed descriptions of the formations are given by Prosser⁶⁴⁹ in another article.

The Silurian and Devonian limestones of Tennessee and Kentucky are discussed by Foerste^{336a} in some detail. He locates the Cincinnati anticline in these States and says:

This fold was in existence in early Devonian, if not in Silurian times. No Silurian formations occur along the crest of the fold in central and southern Kentucky, or in northern and central Tennessee. * * * Surrounding this area and overlapping the Ordovician on the flanks and ends of the anticline are Silurian strata, the total thickness of which diminishes on approaching the crest of the fold.

The result is that Devonian strata rest on Silurian formations along the flanks and ends of the anticline, but along the crest, from north of central Kentucky to southern Tennessee, they rest directly on the Ordovician. * * *

There is * * * a remarkable similarity in the characteristics shown by the most southern Silurian exposures in Kentucky and the most northern outcrops in Tennessee. This similarity extends even to the minor subdivisions of the group. * * *

The most accessible of the Silurian sections in northern Tennessee is that along the Louisville & Nashville Railroad, near South Tunnel, about 10 miles south of the Kentucky border.

In several railroad cuts Foerste found the Chattanooga shale (Devonian) resting upon the Waldron shale (Silurian), and that in turn upon the Laurel limestone, 28 feet thick.

Both in Kentucky and Tennessee the top of the limestone [Laurel], especially the oolitic layer, contains fossils which also occur but in greater abundance in the Waldron shale. At South Tunnel *Whitfieldella nitida* occurs in the oolitic layer. *Orthoceras amycus* is found near the middle of the Laurel limestone. *Pisocrinus gemmiformis* is common near the base. This fossil is especially abundant at a fourth railroad cut. * * * The base of the formation is here a crinoidal limestone. In Indiana and northern Kentucky *Pisocrinus gemmiformis* occurs abundantly, both in the base of the Laurel limestone and in the limestone layers placed at the top of the Osgood beds. Farther south it becomes difficult to determine where to draw the line between the limestone layers belonging to the Laurel and those referred to the top of the Osgood beds. In Tennessee it is impossible to make such a separation, and here all of the limestone section is referred to the Laurel.

Foerste mentions localities where the Laurel limestone rests on clayey material which stratigraphically undoubtedly represents the Osgood shale of Kentucky though lithologically it is much less shaly.

At South Tunnel the Clinton is first seen in the form of fragments of fossiliferous chert. * * * The lower part of the Clinton is a bluish limestone, containing much less chert and only a few fossils. It resembles so much the top of the immediately underlying Ordovician rock, in which fossils are also scarce, that it requires patience to determine where to draw the line between the Silurian and the Ordovician rocks.

Foerste ^{340a} also discusses the limestones of western Tennessee, in part as follows:

In southern Indiana the Silurian strata are divided into the following beds, named in descending order:

Louisville limestone.
Waldron shaly clay.
Laurel limestone.
Osgood shaly clay.
Clinton limestone.

Southward, along the western flank of the Cincinnati geanticline, the equivalents of these beds may be traced with varying success even as far as northern Alabama. * * * Very little change is shown in the lithological characteristics of any of these subdivisions between southern Indiana and northern Tennessee. North and south of this area, however, the Osgood bed rapidly becomes more calcareous and is changed from a shaly clay to a soft limestone, weathering more readily than the Clinton limestone below or the Laurel limestone above. The Waldron bed also becomes calcareous northward and is replaced by limestone in central Indiana. Southward it may be traced as far as northern Alabama, but in central and southern Tennessee it is only 3 to 4 feet thick, and along the middle part of the bed the clay is replaced by a layer of limestone 6 to 10 inches thick. Both northward in Indiana and southward in Tennessee the Waldron bed maintains its characteristics as a shaly clay farther than the Osgood bed.

The thickest sections of the Osgood bed are found in central Kentucky. * * * At Bledsoe in northern Tennessee, the Osgood bed consists chiefly of soft clay. * * * In central and southern Tennessee the Osgood bed consists of rather thin bedded limestones weathering back more readily than the Laurel bed above and the Clinton bed beneath. Here its identity can often be established only with difficulty. The Waldron bed maintains its character as a shaly clay horizon much farther southward than the Osgood bed. It is typically developed along the Harpeth River near Newsom. At this locality it contains a large part of the fauna characteristic of this horizon at Waldron, Ind. In central and southern Tennessee a thin bed of limestone, 6 to 10 inches thick, replaces the clay along the middle of the bed. * * *

Along the western flank of the Cincinnati geanticline, in southern Indiana, Kentucky, and Tennessee, the name Louisville bed has been given to the Silurian rocks overlying the Waldron bed. In the Tennessee River valley, in western Tennessee, the Silurian section overlying the Waldron bed is so thick that it has been found necessary to subdivide it.

At the base is a series of limestones, varying from 30 to 45 feet in thickness, to which the name Lego limestone is here given. Stratigraphically this bed occupies the same position as the Louisville bed. Its paleontological equivalence, however, has not yet been determined, owing to the small number of fossils so far obtained in the Lego limestone. Overlying the Lego limestone is a series of red clays, 30 to 45 feet thick, to which the name Dixon clay is given. This clay has so far proved comparatively unfossiliferous. * * * Above the Dixon red clay is a section of white limestones and clays, exceeding 100 feet in thickness. This section is often richly fossiliferous. * * * To this section overlying the Dixon red clay the name Brownsport bed is here given.

Lithologically the limestones forming the middle and lower part of the Lego bed often resemble those forming the Laurel bed so much that, in the failure to identify the Waldron horizon, it is impossible to distinguish the same.

Foerste ^{340d} gives the early and later nomenclature applied to the strata and the equivalence of the limestones to other beds. The Clifton formation (the Meniscus limestone of Safford) includes all the Niagaran strata present in western Tennessee.

J 15. EASTERN MISSOURI AND SOUTHERN ILLINOIS.

According to Savage ^{703a} the Silurian is represented in southern Illinois only by thin-bedded dark-gray limestone with chert overlain by heavy-bedded pink or mottled limestone, the whole 29 to 75 feet thick, to which he applied the name Clinton. Savage states that the fauna corresponds to that obtained from the Clinton (so called) of Dayton, Ohio.

In eastern Missouri there is a white oolitic limestone followed by buff dolomite, 10 to 30 feet thick altogether, which may represent the Niagara ^{491b} or may be of Devonian age. It rests on Maquoketa shale (Ordovician) and is overlain by the Louisiana limestone (Mississippian). The occurrence is not shown on the map accompanying this volume.

J-K 11-12. NEVADA AND UTAH.

In the Eureka section, Nevada, the Eureka quartzite (Ordovician) is according to Hague ^{391a} unconformably followed by "steel-gray, almost black gritty limestone" and "dark bluish-gray limestone" about 300 feet thick, which contain Trenton fossils. There is no lithologic division but a gradual passage—

into light-gray siliceous limestone, with a peculiar saccharoidal texture, in places becoming almost white and wholly without bedding. On the surface the limestones weather brown and buff, their light colors throughout a great vertical range standing out in strong contrast with the other massive beds of the Paleozoic. It weathers in rounded outlines, breaking with an irregular fracture and presenting a monotonous appearance wearisome to the eye. Rock of this character makes up by far the greater part of the horizon, and then by slow, imperceptible changes it becomes darker in color, with more and more tendency to develop planes of stratification, and gradually passes into the overlying limestone of the Devonian.

As already mentioned, an unconformity exists between the Eureka quartzite and the Lone Mountain limestone. There is therefore no direct evidence in the district of the thickness of the limestone. The average thickness of strata exposed has been taken at 1,800 feet, but it is probable that this is under rather than over estimated, and at Lone Mountain they attain a somewhat greater development, at least 2,000 feet being exposed. * * *

Above the Trenton no good grouping of fossils has as yet been discovered until the Devonian rocks are reached. The other portion of the Silurian limestone presents a most forbidding aspect for the preservation of organic remains, and although diligent search has been made throughout the horizon it was rewarded only by finding a few imperfect corals, belonging to the species *Halysites catenulatus*, which is so characteristic of the Niagara of the East, and here found in what should be its true geological position. They have a wide range and occur nearly 1,500 feet above the summit of the Eureka quartzite. The same coral has been obtained from Lone Mountain and White Pine, and in both these latter localities associated with the genus *Zaphrentis*.

See also Walcott ⁸⁴⁷ on the paleontology of the Eureka district.

The distribution of the Lone Mountain limestone (now regarded by Ulrich as all Ordovician and so treated by Emmons ³²⁴ in a recent report) or its equivalent strata has been traced chiefly by Spurr ⁷⁷² and by Weeks (in an unpublished paper), from whose maps the formation is sketched.

A recent note on the occurrence of a Silurian fauna in Utah has been given by Kindle. ^{493b} The section corresponds with that at Eureka, the fauna occurring in a magnesian limestone 200 to 300 feet thick, below which is a much darker limestone of undetermined age and above which lie dark magnesian limestones of Devonian

age. The locality is in the Wasatch Mountains in northeastern Utah, and the same section was observed in Logan Canyon, 12 miles farther north.

Blackwelder ⁸⁴⁶ as a result of recent work says:

As exposed on the crest of the range [Wasatch] there is, between the Ordovician quartzite and the identifiable part of the Mississippian limestone, a succession of dark limestones * * * having a thickness of 1,000 to 1,500 feet. In the lowest beds there are corals such as *Halysites* and *Favosites*. At a slightly higher horizon there are abundant shells which Kindle thinks are the same as his *Pentamerus* fauna of the Bear River Range.

J-K 17-18. EASTERN NEW YORK, NEW JERSEY, PENNSYLVANIA, AND MARYLAND.

Grabau ⁸⁸⁴ describes the Silurian of New York and its relations to other sections in part as follows:

The following divisions of the New York Niagaran are in common use as the North American standard: Guelph, Lockport, Rochester, Clinton.

The Clinton of the best-known section, that of western New York, begins with the true or Upper Medina, which, along the Niagara River, admits of a number of subdivisions, which are, however, of only local significance.^a The total thickness is nearly 125 feet, with 25 feet of white quartzose sandstone (Whirlpool sandstone) at the base and about 8 feet of a similar sandstone at the top. The middle series consists of red sandstones and green and gray sandstones and shales. The red sandstones generally show eolian cross-bedding and appear to have accumulated above water. The green sandstones and shales are fossiliferous. The white Whirlpool sandstone exhibits beach features^b and probably marks the advance of the sea, though it is likely that the sand was originally dune sand, as suggested by A. W. G. Wilson.

The fossils are generally most abundant in the shales and thin-bedded sandstones. The heavy-bedded sands are either free from fossils or have only scattered shells of *Lingulæ*. At Lockport and elsewhere some layers are crowded with gastropod shells.

A list of fossils from the Medina follows, and Grabau continues:

This is a Lower Siluric [lower "Upper Silurian"] fauna, and favors more especially the Clinton and Rochester faunas. It is so far known only from western New York, with the exception of *Arthropycus harlani*, which is widely distributed. In western New York this species occurs at the top of a heavy-bedded unfossiliferous sandstone with an eolian type of cross-bedding, and just below the upper white quartzite. In east-central New York it is found at the base of the Oneida conglomerate, which is the approximate equivalent of the upper white sandstone of Niagara. In the Appalachians it is found mostly in the upper part of the Tuscarora and Clinch sandstones, the stratigraphic equivalent of the Medina. * * *

The Tuscarora has a thickness of 820 feet in Logan's Gap, Jack's Mountain, Mifflin County, Pa., but thins perceptibly westward and southward, being 400 to 500 feet thick in Bald Eagle Mountain and 287 feet in Wells Mountain and the Pennsylvania-Maryland line. This thinning appears to be due to failure of the lower beds, showing a true case of nonmarine progressive overlap. In New York the upper part is represented by the true Medina, which has a thickness of 125 feet and begins and ends with a pure white quartz sandstone. More strictly speaking, the upper white sandstone alone represents the true Tuscarora, but the lower beds, still partly red, and the shales probably are the equivalent of the lower reddish sandstones and greenish shales underlying the true white Tuscarora, and sometimes referred to the Upper Juniata. The Oneida conglomerate of central New York, 40 feet thick, is likewise the representative of the upper part of Tuscarora, though it may have had a more local origin. * * *

The Clinton shales succeed the Oneida conglomerate in Oneida and Herkimer counties, N. Y., and the Upper Medina quartzite in western New York. In the southern Appalachians

^a See Bull. New York State Mus. No. 45, pp. 88-95.

^b Fairchild, H. L., *Am. Geologist*, vol. 28, 1909.

the series is largely composed of sandstones (Rockwood), highly impregnated with iron and often containing beds of workable iron. It is generally succeeded by late Siluric (Monroan) or by Helderbergian or later beds, there being a pronounced unconformity at the summit of the Rockwood throughout. That part of the series in Virginia is of continental origin is indicated by the general character of the rocks, but marine intercalations are not uncommon. In some cases in eastern Tennessee the iron ore itself is fossiliferous, having replaced a marine limestone. In such cases the bulk of the formation is shale. In no case is the original thickness preserved, since the formation is everywhere bounded above by an erosion plane. In northern Virginia to-day the thickness is 750 feet (Piedmont folio), and not over 400 feet in southern Virginia. In southern Tennessee and northern Georgia it is from 1,100 to 1,600 feet thick, decreasing westward and northward. With our present knowledge of the formations, it is safe to say that the eastern sandy phase represents near-shore deposits, if not actually continental conditions, formed probably at the embouchures of several Appalachian rivers; and that westward these deltas merged gradually into true marine deposits, mainly sands and clays, with some limestones intercalated. That the Rockwood represents more than the Clinton of New York can not be questioned. Where the series is developed in its totality, it probably represents the entire Niagaran, if not a part of the Salinan as well. Along the Allegheny Front fossiliferous shales and iron ores represent this series, with a thickness of not less than 1,000 feet, on the western branch of the Susquehanna. The lower series, 700 feet thick, consists mainly of fissile shales, including an iron sandstone, and with *Buthotrephis* in the upper part. This is succeeded by 110 feet of calcareous fossiliferous shales; and this by 230 feet of fossiliferous shales and limestones with a Niagaran fauna. Above this follows 350 feet of red shales, probably representing the Upper Salina and separated by a hiatus from the fossiliferous Niagaran shales.

In eastern New York, at Swift's Creek, the type locality for the Clinton, this formation is 226 feet thick and is followed by 5 feet of Niagaran and then by the red shales of the Upper Salina. On the Niagara River the Clinton shale with the two succeeding limestones has a total thickness of 32 feet, followed by 68 feet of Rochester shale. The total of the Niagaran, including the Guelph, is from 270 to 325 feet, as shown by borings. This is followed by Lower Salinan. In the Rochester region the Clinton has a thickness of 80 feet, including the Irondequoit or upper limestone (17 feet), which Chadwick refers to the Rochester. The eastward thinning of the Upper Niagaran beds indicates either that these beds were eroded before the deposition of the red shales, probably during the Shawangunk epoch, or that the Rochester-Lockport of the west is in part represented by Upper Clinton in the east. The Guelph element may never have extended to the Clinton type region, which may have been above water and so subject to erosion.

Local details are given in papers by Darton,²²²⁻²²⁵ Ries,⁶⁷² Clarke,¹⁵⁶ Grabau,^{378, 380} Hartnagel,⁴⁰⁹⁻⁴¹² and Merrill⁵⁹² published in the New York State reports and elsewhere.

A critical and comprehensive report on the Silurian formations in New Jersey has been made by Weller.^{880b} The following is a condensed section of the formations which he distinguishes from the base up.

Shawangunk conglomerate: Coarse quartz conglomerate, of white or yellowish pebbles in a gray or red matrix; unfossiliferous; unconformable on Hudson (Ordovician) shale.	Feet. 1,500-1,600
Medina-Longwood sandstone: Soft, often somewhat shaly, and deep red; unfossiliferous.	2,300-2,400
Poxino Island shale: Greenish, calcareous, unfossiliferous.....	1-200 (?)
Bossardville limestone: Fine-grained, compact bluish-gray banded limestone, unfossiliferous.....	12-100
Decker Ferry formation: Sandstone with thin calcareous beds or limestone with some thin bands of greenish shale; highly fossiliferous; divided into three faunal zones and the uppermost into three subzones; correlated with the "Coralline" (Niagaran) limestone of eastern New York; presumably contemporaneous with but faunally not closely related to the Niagara limestone of the Mississippi Valley.....	

Rondout formation: Shales and earthy limestones; sparsely fossiliferous; name restricted to the upper cement bed of the section at Rondout.....	Feet. 39
Manlius limestone: Thin bedded, knotty, dark blue to black; fauna limited, exhibits from base to summit a passage from life conditions suitable only for <i>Leperditia</i> to normal marine conditions; gradual transition from Rondout faunally and stratigraphically; pronounced faunal break in passing to the overlying Coeymans (basal Helderbergian) Devonian limestone.....	35

4,424

The Silurian rocks described by Weller extend into Pennsylvania, but with changes which are described in great detail in the county reports of the Second Geological Survey of Pennsylvania under the names Lewistown limestone, Bloomsburg shale, and Bossardville limestone. The facts are assembled by Lesley.⁵³⁵ A typical section, which shows the great thickness of strata and their intimate lithologic similarities or gradual changes, is that of Logan Gap, Mifflin County, in the central part of the State. The descending section is summarized by Lesley^{535a} as follows:

j. Salina gray shale	164
k. Salina variegated shale }	348
l. Logan limestone..... } 423 feet.....	3½
m. Logan shale..... }	72
n. Salina upper red shale.....	432
o. Salina upper lime shale.....	326
p. Salina lower red shale.....	272
q. Clinton lower lime shale. }	251
r. Clinton upper olive shale }	38
s. Ore sandstone and ore beds.....	178
t. Clinton middle olive shale	7
u. Iron sandstone.....	571
v. Clinton lower olive shale.....	820
w. Medina white sandstone.....	1,280
x. Medina red sandstone and shale.....	309
y. Oneida red conglomerate.....	313
z. Oneida gray sandstone	5,384
a. a. Hudson River slates.....	

The Silurian rocks recognized in New Jersey have been traced southward through Pennsylvania. The strata become thinner to the south. The unconformities observed in New York and New Jersey at the base of the Silurian are not noted in the Pennsylvania sections, where the basal gray sandstone succeeds the Martinsburg ("Hudson River") shale (Ordovician) in apparent conformity.

The littoral and calcareous marine strata which constitute the Silurian in Pennsylvania pass across Maryland into Virginia. They have been described by Prosser⁶⁴⁶ and O'Harra.⁶¹⁹ The section, which measures 2,200 to 2,400 feet in thickness, is fully described and correlated by Prosser, the following being a condensed section of the subdivisions recognized by him, from the base up:

Juniata formation: Alternating beds of shale and sandstone, deep red, unfossiliferous, probably equivalent to the older part of the Medina of New York.....	Feet. 550+
Tuscarora formation: Quartzose sandstone, white to light gray; <i>Arihrophycus harlani</i>	250-300
Clinton formation: Shales, yellowish green to red, with thin fossiliferous limestones in upper part, and two beds of iron ore.....	550-600
Niagara formation: Thin-bedded blue limestone with thin shale partings, becoming shaly and blackish above; represents the Decker Ferry formation of New Jersey and is equivalent in time to Rochester shale and Lockport limestone or Niagara of New York.....	250-300
Salina formation [Cayuga group]: Shales, impure limestones including four cement beds, and sandstone, gray and blue, sparsely fossiliferous.....	700

The overlying Helderberg limestone is assigned by Prosser to the Devonian.

The Silurian of New Jersey has also been described by Kümmerl^{513b} as follows:

Contrary to long prevalent and apparently well-established belief, the lower and middle portions of the Silurian system are not represented in New Jersey. Their absence in this and adjoining regions is indicative of somewhat widespread earth movements unaccompanied in this region by folding, which closed the period of deposition indicated by the Martinsburg sediments or possible overlying beds afterwards removed by erosion and raised the region above the zone of sedimentation. When deposition began again, late in Silurian time, beds of coarse conglomerate were laid down, followed by sandstones, shales, and limestones, the earlier sediments being those of a low-grade delta in an arm of the Appalachian gulf.^a These conditions of deposition prevailed with but slight changes of elevation into Devonian time.

The Shawangunk conglomerate (the Oneida conglomerate of many previous publications) is chiefly a coarse quartzite and conglomerate composed of small white-quartz pebbles embedded in a siliceous matrix. Its color is generally steel-blue, but some beds have a yellowish tinge and reddish layers occur near the top. Layers of black shale a few inches in thickness are locally intercalated between thick beds of conglomerate and grit. Between this formation and the Martinsburg shale there is a gap representing the upper part of the Ordovician and all of the Silurian below the Salina of the full New York section, but there is no marked divergence of dip and strike where the two formations outcrop in proximity, and the actual contact is nowhere exposed in New Jersey. The beds overlying the Shawangunk conglomerate are red sandstone and shale, and the transition from the Shawangunk is made through a series of alternating red sandstone and gray conglomerate, so that the upper limit of the Shawangunk is not sharply defined. Its thickness is probably from 1,500 to 1,600 feet.

So far as known, the formation is barren of fossils in New Jersey, but at Otisville, N. Y., a eurypterid fauna has been found in the black shale intercalated with the conglomerate. In the Otisville section this fauna, which elsewhere appears only and briefly at the base of the Salina, repeats itself many times through a thickness of 650 feet.^a The Shawangunk conglomerate is followed by 2,500 feet or more of shales and limestones also referable to the Salina; hence for this region it represents only the lower portion of that group.

The red sandstone and shale which immediately overlie the Shawangunk conglomerate have until recently been regarded as the equivalent of the Medina sandstone of New York and have been so called, but, for the reasons just cited, it is evident that they are much younger than Medina and that they must be included in the Salina group. Moreover, they lie some distance below a limestone which is correlated with the Cobleskill of the New York section. The name High Falls has been applied to the red shales that overlie the Shawangunk conglomerate in Ulster County, N. Y., and has been adopted for New Jersey in place of Medina, which is not applicable.

The lower beds consist of a hard red quartzitic sandstone, intercalated with some green or gray sandstones and softer red shales which become more abundant in the upper part of the formation. The formation has an estimated thickness of 2,300 feet at Delaware Water Gap. It is not known to contain fossils, but its age is fixed by its stratigraphic position.

The formation known as the Green Pond conglomerate occurs in an isolated belt of Paleozoic rocks which extends through the middle of the pre-Cambrian Highlands of New Jersey. In constitution it is similar to the Shawangunk conglomerate, with which it is correlated, but, inasmuch as it is still an open question whether the Paleozoic strata of the Green Pond Mountain region were once continuous with the great mass of Paleozoic sediments which lie some distance to the northwest, or whether the Green Pond region represents a separate basin shut off on the northwest from the large Paleozoic sea although communicating with it to the northeast, it has seemed best to retain for the present at least both Shawangunk and Green Pond as names for these conglomerates in their respective fields.

^a Clarke, J. M., Bull. New York State Mus. No. 107, 1907, p. 303.

Immediately above the Green Pond conglomerate, and conformable with it, is a soft red shale [Longwood shale], in which an irregular cleavage is usually so highly developed that the bedding planes can be determined only with difficulty. The formation is not known to contain fossils, but, as it rests directly upon the Green Pond conglomerate and is followed by a limestone carrying a Salina fauna, it is probably of Salina age. Its stratigraphic position is, in general, the same as that of the High Falls formation, but the two may not be exactly synchronous.

The higher Silurian and the Devonian formations of New Jersey occur either in Wallpack Ridge, which lies along the northwestern border of the State in the upper Delaware Valley, or in the narrow belt of Paleozoic rocks in the midst of the highlands in the Green Pond Mountain region. In Wallpack Ridge they aggregate 1,300 feet or more, while in the Green Pond Mountain region they have a thickness of about 4,000 feet, of which all but 250 feet are referable to beds higher than any of those along Wallpack Ridge.

The top of the High Falls shale in New Jersey is everywhere buried by glacial drift which also conceals the beds immediately superjacent. The next recognizable formation is the Poxino Island shale, a buff or greenish calcareous shale in thin layers and nonfossiliferous so far as known. Its outcrops along the base of Wallpack Ridge in the upper Delaware Valley are few, small, and widely separated, and very little is known regarding it. In the adjoining portion of Pennsylvania it is reported to be 200 feet in thickness and to rest on a thin limestone formation which in turn rests on the High Falls shale. It is not known to occur in the Green Pond Mountain region.

A fine-grained, compact bluish-gray banded limestone, known as the Bossardville limestone, lies conformably upon the Poxino Island shale in Wallpack Ridge. It increases in thickness from 12 feet at the New York State line to about 100 feet where it crosses the Delaware River into Pennsylvania. Owing to its marked banding it was for many years known as the "Ribbon" limestone and was correlated by Cook and later geologists with the Ribbon or Manlius limestone at Rondout, N. Y. In reality it lies below the Manlius limestone. It is only sparingly fossiliferous but is immediately succeeded by a series of beds containing a well-defined Salina fauna. It has not been recognized in the Green Pond Mountain belt, but this may be from lack of exposures.

Under the name Decker Ferry formation a series of beds has been described, which are chiefly limestones at the north and calcareous sandstones at the southwest. Their thickness is 52 feet at the Nearpass quarry near Tristates, where the section can be accurately measured. Thin bands of more or less fissile green shale separate the limestone beds. A thin band of red, crystalline, highly fossiliferous limestone occurs about the middle of the series and is a striking feature. The lower 42 feet of these beds as exposed at the type locality are correlated ^a with the Wilbur limestone (the so-called "Niagara" or "Coralline" limestone of Hall and other authors) and the "black cement" beds—that is, the Salina "water lime" of the Rondout section of New York. These form the top of the Salina group, the base of which in New Jersey is the base of the Shawangunk conglomerate. The upper 10 feet of the Decker Ferry series contain fossils, particularly in the lower half, which render necessary their correlation with the Cobleskill limestone of eastern New York.

In the Green Pond Mountain region isolated outcrops of impure limestone occur a short distance above the Longwood shale, which contain a fauna that correlates them with the lower beds of the Decker Ferry formation—that is, to the part referable to the Salina group.

Along the upper Delaware the beds immediately above the Decker Ferry limestone and referred to the Rondout consist of more or less earthy shales and limestones the thickness of which is 39 feet. They are usually only sparingly fossiliferous, although in some beds the crustacean *Leperditia* is abundant. A typically marine fauna, with an abundance of brachiopods, trilobites, etc., is conspicuously absent in these beds. In general lithologic features this formation resembles the Rondout as developed in New York State, but the cement beds which are so characteristic of this formation farther north are not present here.

^a Hartnagel, C. A., Bull. New York State Mus. No. 69, 1903, p. 1152.

The Rondout is succeeded conformably by a somewhat thin bedded, knotty dark-blue or almost black limestone, 34 to 35 feet thick where best exposed. It is the bed which constitutes the quarry stone of the Wallpack Ridge and its outcrop is marked by a line of quarries and limekilns. It is referred to the Manlius or "Tentaculite" limestone of the New York series, although well-preserved specimens of the characteristic fossil *Tentaculites gyracanthus* Eaton are rare. In the lower beds there is evidence of environmental conditions similar to those of the Rondout. In the middle portion *Leperditia* is still abundant but is associated with a prolific brachiopod fauna, suggestive of the recurrence of more typical marine conditions. In the upper beds *Leperditia* has entirely disappeared and the fauna is normally marine. No beds referable to the Rondout or Manlius have been detected in the Green Pond Mountain region, although their attenuated representatives may occur.

K 10. TAYLORSVILLE DISTRICT AND KLAMATH MOUNTAINS, CALIFORNIA.

The Paleozoic section of the Taylorsville district, in the Sierra Nevada just north of the fortieth parallel, comprises at the base the Grizzly formation (400 feet, possibly Ordovician), the Montgomery limestone (10 to 60 feet), and the Taylorsville formation (1800 feet). The Montgomery limestone has yielded fossils which Walcott determined as representing the "Niagara horizon of the Mississippi Valley and Appalachian provinces." ^{271a}

In the Klamath Mountain region the Abrams and Salmon formations of Hershey ⁴³⁵ are assigned by Diller ^{276b} to a pre-Devonian age, as they are older than the fossiliferous Devonian.

The Silurian area of the Taylorsville district is too small to show on the scale of the map of North America.

K 15-16, L 16. IOWA, NORTHERN ILLINOIS, AND WISCONSIN.

Chamberlin and Salisbury ^{134c} have compiled the following section of the Silurian of Iowa from the reports of the Iowa Geological Survey:

Silurian formations of Iowa.

Formations.	Thickness (feet).	Characteristics.
Anamosa limestone.....	50-75	Soft, granular, evenly bedded dolomite; white to buff and gray; important building stone.
Le Claire limestone.....	50	Massive or heavy-bedded, highly crystalline dolomite. Upper surface undulating; cross-bedded on a large scale.
Delaware stage.....	200	Limestone containing large quantities of chert.
Unconformity.		

The middle formation of the section is described by Samuel Calvin ¹¹⁶ as follows:

The Le Claire limestone constitutes the second stage of the Niagara formation as it is developed in Iowa. The first or lower stage has been called the Delaware, from the fact that all its varying characteristics are well exhibited in Delaware County. The Delaware stage embraces many barren beds and presents a very great number of phases, but at certain horizons it abounds in characteristic fossils. The typical faunas of this lower stage embrace such forms as *Pentamerus oblongus* Sowerby, *Halysites catenulatus* Linnæus, *Favosites favosus* Goldfuss, *Strombodes gigas* Owen, *Strombodes pentagonus* Goldfuss, *Ptychophyllum expansum* Owen, and *Diphyphyllum multicaule* Hall. The beds of the Delaware stage furthermore contain large quantities of chert.

The Le Claire stage of the Niagara follows the Delaware. The exact line of separation between the two stages has not been and probably can not be definitely drawn. There are massive, barren, highly dolomitized aspects of both stages that, taken by themselves, can not be differentiated in the field. Under such circumstances the observer must work out the stratigraphic relations of the particular group of strata under consideration before referring it to its place in the geological column. In general the Le Claire limestone is a heavy-bedded, highly crystalline dolomite. It contains scarcely any chert, and in the lower part there are very few fossils. There are occasionally a few specimens of *Pentamerus*, of the form described as *Pentamerus occidentalis* Hall, and the principal coral is a long, slender, tortuous *Amplexus* which is represented only by casts of the vacant or hollow parts of the original corallum. On account of the complete solution of the original structure, the spaces occupied by the solid parts of the corallum are now mere cavities in the limestone. In the upper part of the Le Claire stage small brachiopods abound. They belong to the genera *Homeospira*, *Trematospira*, *Nucleospira*, *Rhynchonella*, *Rhynchotrepa*, *Atrypa*, *Spirifer*, and probably others. In most cases the fossils have been dissolved out, leaving numerous cavities. The calcareous brachial apparatus of the spire-bearing genera is often the only part of the original structure represented. No statement can well give any idea of the numbers of the small shells that crowded the sea bottom near the close of the Le Claire stage, nor of the corresponding number of the minute cavities that are now so characteristic a feature of this portion of the Le Claire limestone. In some localities in Cedar County the small brachiopods of this horizon are represented by very perfect casts that were formed by a secondary filling of the cavities left by solution of the original shell. The external characters are thus fairly well reproduced.

Compared with the beds of the Delaware stage, the Le Claire limestone as a rule lies in more massive ledges, it is more completely dolomitized, and its fracture surfaces exhibit a more perfect crystalline structure. It contains an entirely different fauna, a fauna in which small rhynchonellid and spire-bearing brachiopods are conspicuous. Its fossils are never silicified, and, in marked contrast with some portions of the Delaware, its upper part at least is notably free from chert. * * *

The Le Claire limestone is in some respects unique among the geological formations of Iowa. In the first place it varies locally in thickness, so much so that its upper surface is exceedingly undulating, the curves in some places being very sharp and abrupt. In the second place it differs from every other limestone of Iowa in frequently exhibiting the peculiarity of being obliquely bedded on a large scale, the oblique bedding often affecting a thickness of 15 or 20 feet. The phenomena suggest that during the deposition of the Le Claire limestone the sea covered only the southwestern part of the Niagara area, that at times the waters were comparatively shallow, and that strong currents, acting sometimes in one direction and sometimes in another, swept the calcareous mud back and forth, piling it up in the eddies in lenticular heaps or building it up in obliquely bedded masses over areas of considerable extent. The oblique beds observe no regularity with respect to either the angle or direction of dip. Within comparatively short distances they may be found inclining to all points of the compass. Again the waters at times were quiet, and ordinary processes of deposition went on over the irregular sea bottom, the beds produced under such circumstances conforming to the undulating surface on which they were laid down.

In Illinois and Wisconsin the Silurian is known simply as the Niagara dolomite or limestone, the formation varying in lithology in different areas. The formation in Illinois is thus described by Bain:^{51a}

Above the soft shale of the Maquoketa is a fine-grained dolomite, carrying more or less chert. This forms the uppermost member of the stratigraphic section in this area. The beds in the lead and zinc district form only the lower portion of the great thickness of strata which have long been known collectively as the "Niagara." There is no established local name for these particular beds, and since they were doubtless formed at some time within the "Niagara"

epoch the group term will be provisionally used for them. * * * A thickness of 150 feet is present.

* * * * *

The "Niagara" dolomite is distinguished from that of the Galena not only by the occurrence of certain characteristic fossils, of which *Halysites catenulatus* is probably most widespread and easily recognized, but also by fairly constant lithologic differences. In general, the "Niagara" is much lighter colored, finer textured, and is relatively free from the small irregular cavities which mark the Galena.

K-L 12. SOUTHWESTERN MONTANA AND WESTERN WYOMING.

Silurian strata may be absent in southwestern Montana and western Wyoming. They have not been identified by their fauna. In general the Cambrian, or the Ordovician where present, is succeeded by Carboniferous, but the Jefferson limestone (Devonian) intervenes in some sections and is underlain by strata that appear to represent the Silurian in seemingly conformable sequence.

Kindle^{499a} studied the distribution of the Jefferson limestone (see p. 320, Chapter VI) and discusses the Silurian in certain sections. For the section on Boulder Creek, west of Princeton, Mont., in the Philipsburg quadrangle, he says:

No fossils were procured from the 200 feet of beds [gray to brownish shale and sandstone, the latter predominant at the base] at the base of the Jefferson limestone, so that the age of the beds intervening between the Cambrian and Devonian faunas remains undetermined in this region. No evidence of any stratigraphic break in this part of the section was observed.

About 20 miles south of Princeton, on the east fork of Rock Creek, the Jefferson limestone occurs immediately above the following beds:

	Feet.
E. Shales and covered.....	30
D. White limestone.....	5
C. Brownish arenaceous thin-bedded magnesian limestone	90
B. Limestone [Upper or late Middle Cambrian].	

The beds C, D, and E represent both Ordovician and Silurian, unless there is an undetected hiatus. Kindle says:

No fossils were obtained from the beds separating this formation [Cambrian] from the Jefferson in either the Rock Creek or Boulder Creek sections. These beds, measuring 210 feet in thickness in the Boulder Creek section and 125 feet in the Rock Creek section, may provisionally be referred to the Silurian.

In southwestern Wyoming occurs a similar sequence of Cambrian limestone, unfossiliferous strata, possibly Silurian, and a limestone correlated with the Jefferson. Describing a section near Viola, Wyo., Kindle says:

We are without positive information regarding the age of the 700 feet of gray limestones below the saccharoidal limestones of the Jefferson. These beds may be in part of the same formation and age as the 40 feet of limestone at their base, the age of which is known by fossils to be Cambrian. It seems probable, however, that Silurian or Ordovician strata, or perhaps both, may be included in the series. The Ordovician is present in the Bighorn Mountains to the north, and both are present in northeastern Utah.

K-L 17-18. ONTARIO AND WESTERN NEW YORK.

The belt of Silurian strata which extends from Georgian Bay to western New York comprises the Clinton and other subdivisions of the Niagara, together with the Medina, below the Clinton, and several formations above the Niagara. The

latter are not uniformly extensive. In Canada they include the "Onondaga Salt group" and the "Water lime" (Bertie or Cayuga dolomite of Chapman¹³⁶), which was referred by Logan^{470, 544a, 919} to the "Lower Helderberg" but is now regarded by Clarke as a member of the Salina formation.

In New York the Guelph dolomite, the uppermost formation of the Niagara in Canada, has a restricted extent only.¹⁵⁸ The "Onondaga Salt group" (called Salina by Dana²¹⁵) and the "Water lime" are now included in the Cayugan, the recognized subdivisions¹⁵⁹ of which are known as Salina formation, Cobleskill limestone, Rondout water lime, and Manlius limestone. Their relations and the western representatives of the formations of New York are discussed by Grabau.³⁷⁷ In this part of Canada the "Lower Helderberg" of Logan and Chapman comprises only a part of the "Water lime" which in central New York underlies the strata which were formerly known as "Lower Helderberg" but which are now called Helderberg or Helderbergian and assigned to the Devonian.^{159a} Merrill, whose geologic map of the State⁵⁹² has (generally) been followed in the map of North America, placed the line between Silurian and Devonian at the top of the "Lower Helderberg." The North America map of 1906 followed this delineation. The present map does not depart therefrom, for the scale is too small to show the difference, but the Helderberg ("Lower Helderberg") is included in the Devonian in the citations contained in this volume.^{378, 642, 711a, 933}

L 16-17. NORTHERN MICHIGAN AND ONTARIO.

There seems to be some question as to the presence of the Clinton in Michigan. Certain beds which have been referred to by several authors as Clinton are, in the opinion of Ulrich, more likely to prove of Richmond age. Aside from these doubtful beds the Silurian consists of the dolomitic limestones commonly referred to the Niagara and the divisions which have been grouped by Lane and others under the term Monroe. Of the Niagara as mapped by the Michigan State Survey and others Lane⁵¹⁷ recognizes the following subdivisions: Clinton, 0 to 130 feet; Rochester shale, doubtfully identified, 20 to 30 feet; Lockport and Guelph dolomites, 270 to 600 feet, the greater thickness being in the northern part of the State. The two latter Lane combines under the name Manitoulin.

Rominger⁶⁷⁷ describes the "Niagara" of the Upper Peninsula of Michigan in detail for different localities and sums up the section as follows:

The rock beds of the Niagara group allow a subdivision in three well-marked sections. It is exclusively a limestone formation. The lower section is always very regular and even-bedded, composed of comparatively thin layers of a fine crystalline grain, or with a dull, more earthy fracture. In composition most of the strata are dolomites; only a few layers are found to be a pure limestone. Fossils are rare in it. The middle division is made up by more massive, highly crystalline dolomite ledges, which usually contain a large number of the casts of the *Pentamerus oblongus* and some ill-preserved corals. The upper division is a series of thin, uneven layers, with intermixture of much siliceous matter with the dolomite mass, and of seams and nodular concretions of hornstone. In this upper division, also, the greatest abundance of fossils is found.

With reference to the "Niagara" of Manitoulin Island, Bell^{67a} states:

The southern portion of the peninsula between South Bay and the eastern side of Manitoulin Island belongs to the Niagara formation, which has here a thickness of about 405 feet. It consists principally of heavy-bedded light-gray, light bluish-gray, and buff dolomites. Good fossils

are rare, although much of the rock is made up of comminuted fragments of organic remains. The thicker beds are rendered somewhat porous by the numerous small cavities left between these fragments. Most of the beds show a crystalline character on fresh fracture.

* * * * * * *

On the south end of Fitzwilliam Island and on the eastern part of the south shore of Manitoulin Island there is a thickness of about 100 feet of heavy-bedded, coarsely spongy gray and buff dolomite, which contains a few fossils like those of the Guelph formation.

Monroe is a term formerly applied by Lane to all the Silurian above the "Niagara" (that is, between the "Niagara" and the Dundee limestone), as he found it impracticable to separate the strata consistently. Although a division can not be made distinctly in the field, Lane⁵¹⁷ now recognizes the following subdivisions, in ascending order: Salina, or Lower Monroe; Bass Islands series, or Lower Monroe [in the restricted sense]; Sylvania sandstone, or Middle Monroe; and Detroit River series, or Upper Monroe. He discusses their thickness and character at length.

The "Salina" he defines as extending from the top of the "Niagara" to the uppermost salt bed. The base of the "Salina" should be marked, according to Grabau, as quoted by Lane, by a hiatus and "disconformity." According to Lane the strata thicken greatly northward from Monroe County, presumably by the addition of beds at the bottom in the deeper part of the basin. At Milan rock salt seems to occur almost directly above the "Niagara," whereas at Wyandotte there is 275 feet of dolomite below the rock salt and above the white dolomite.

The top of the "Salina" Lane would determine by measuring from the Sylvania sandstone down to the top of the first salt bed. He would then class all the beds between that stratum and the "Niagara" below as "Salina." He thus obtains thicknesses for the "Salina" which range from 370 feet (at Britton) to 959+ feet (at Royal Oak). Inasmuch, however, as the salt bed thus determined is by no means certainly at one horizon, and gypsum if not salt occurs above the Sylvania sandstone, the division is very indefinite and of little stratigraphic significance.

Although the top of the "Salina" is thus difficult to determine, it is made the base of a division which comprises all the Silurian above the "Salina" and which in distinction to that formation is strictly marine. Unfortunately the name "Monroe" has been given to this division in a limited sense excluding the "Salina," in contrast to the broader definition including "Salina," which has become established. This limited "Monroe" has been subdivided into three parts and the upper and lower of these each again into four members. Lane, Prosser, Sherzer, and Grabau⁵¹⁸ have published the following:

MONROE FORMATION.

The highest Siluric strata of America are represented by the Monroe formation of Michigan, using this term in its limited sense for the post-Salina Siluric. The Monroe formation is a strictly marine series succeeding the abnormal (nonmarine [Grabau]) Salina. It is traceable throughout lower Michigan westward into Wisconsin and eastward through Ohio, Ontario, and into western New York. Where recognizable a strong dividing line separates the lower from the upper part, and in general this division is emphasized by the occurrence of the Sylvania sandstone, a rock of pure quartz grains, and representing, according to Grabau and Sherzer, an eolian deposit formed under conditions similar to those now found in the Libyan Desert. According to this interpretation, the Sylvania sandstone represents a long time interval the depositional marine equivalent of which is still unknown. This long interval is further emphasized by the entire distinctness of the faunæ of the lower and upper divisions of the Monroe.

The subdivisions recognized so far in the Monroe, with their faunal characteristics (determined by Grabau), are as follows:

LOWER MONROE.

For this stratigraphic unit the name Bass Islands series is proposed, from the group of islands of that name in western Lake Erie. No other appropriate term seems to be available, though characteristic exposures of all the divisions are not found in these islands.

(a) *Greenfield dolomite*.—This term was proposed by Grabau in 1898, though previously used in a commercial sense, for the dolomite found about Greenfield, Highland County, Ohio, and exposed again in the regions about Ballville, in northern Ohio. The name is here accepted for this division, which is characterized by *Schuchertella hydraulica* (Whitfield), *Hindella? whitfieldi* Grabau, *H.? rostralis* Grabau, *Leperditia*, etc. The faunal zone may be called that of *Schuchertella hydraulica*. The thickness is 100 feet or more and the formation is the lowest known subdivision of the Monroe.

(b) *Tymochtee shales and limestones*.—This name was proposed in 1873 by N. H. Winchell for the shales and thin-bedded calcilutites of the Monroe (Waterlime) series exposed in the creek of that name in Crawford Township, Wyandot County, Ohio. The thickness there is something over 100 feet, but the relation to the overlying and underlying formation is unknown. Its fauna likewise is unknown, and the formation must be considered a tentative division of the Lower Monroe. It is not impossible that it represents in part one or more members recognized elsewhere.

(c) *Put-in Bay dolomites*.—This name is proposed for the extensive fossiliferous series of water lime exposed on Put-in Bay Island, one of the Bass Islands, and characterized by the fauna comprising *Spirifer ohioensis* Grabau, *Goniophora dubia* Hall, *Eurypterus eriensis* Whitfield, and *Leperditia*. From the abundance of the pelecypod, the paleontologic zone may be called that of *Goniophora dubia*. Something over 100 feet of strata is exposed on Put-in Bay Island, where the higher beds are in contact with the succeeding zone. The formation is also known from Marion County, Ohio. Its thickness is over 100 feet, but the base is unknown.

(d) *Raisin River dolomites*.—This name is proposed for the highest division of the lower Monroe exposed in Lucas and Wood counties, Ohio, and in Monroe County, Mich., especially along the Raisin River. It is perhaps 200 feet thick and contains several oolite zones. Its known fauna comprises nearly 20 species, of which the most significant are *Whitfieldella prosseri* Grabau and *Pterinea lanii* Grabau. These are restricted to this horizon, so far as known. *Spirorbis laurus* and numerous minute gastropods, besides plant remains, further characterize this horizon. From the abundance of the brachiopod mentioned, which is everywhere found and characteristic, the faunal zone is designated as that of *Whitfieldella prosseri*.

MIDDLE MONROE.

This is represented in Michigan only by the Sylvania sandstone. This is believed to represent a long interval at the end of which a new series of faunæ invaded this region upon reemergence. The thickness of the Sylvania seldom exceeds 150 feet.

UPPER MONROE.

For this stratigraphic unit the group name Detroit River series is here proposed, from the exposure of all its members along that stream. It comprises four subdivisions or faunal zones.

(a) *Flat Rock dolomites*.—These are exposed at Flat Rock, on the Huron River, and are also found in the lower part of the salt shaft at Oakwood, near Detroit. The fauna so far obtained is meager, comprising only the corals *Syringopora cooperi* Grabau, *S. cf. hisingeri* Billings, and *Favosites cf. maximus* Troost. The first mentioned seems to be characteristic and restricted to it, and the zone is provisionally called the *Syringopora cooperi* zone. The thickness of the formation varies from 40 to 150 feet or more.

(b) *Anderdon limestone*.—This name, suggested by the Rev. Thomas Nattress, was adopted by Sherzer and Grabau for the coral reef limestone exposed in the Anderdon quarry, Essex County, Ontario, 2 miles from Amherstburg, Ontario, and in the salt shaft at Oakwood, Detroit.

Its thickness is from 40 to 50 feet and its fauna a rich coral and Stromatopora fauna. It varies from a pure calcilute to a moderately coarse calcarenite. Six species of stromatoporoids and eleven of coral have been determined by Grabau. Among the former *Stylodictyon sherzeri* Grabau and *Idiostroma nattressi* Grabau are characteristic and restricted. From the abundance of the latter the faunal zone may be named the *Idiostroma nattressi* zone. Favosites of Devonian affinities are characteristic.

(c) *Amherstburg bed*.—This name is proposed by Sherzer and Grabau for the next higher stratum, a dolomite not over 20 feet thick and forming a transition zone to the overlying Lucas. This zone is rich in fossils, 52 species having been identified by Grabau, most of them being new and of Devonian affinities. The fauna unites the Anderdon and Lucas elements to a certain degree. *Panenka canadensis* Whiteaves, though not absolutely restricted to it, is its most characteristic fossil and may serve to name the zone. The genus *Heliophrentis* Grabau is further characteristic and distinctive, while *Schuchertella interstriata* links it with the Bullhead (Akron) dolomite of western New York, this and the Cobleskill being its eastern extension. Stropheodontas of Devonian aspect further characterize the faunæ. In common with the Anderdon, it has an abundance of *Conocardium monroense* Grabau, which is the zone fossil of the two formations combined. The spiriferoid genus *Prosserella* Grabau has species in the three upper members of the Upper Monroe to which it is restricted (*Prosserella* horizon).

(d) *Lucas dolomite*.—This name was proposed by Prosser in 1903 for the upper dolomites so well exposed in Lucas County, Ohio. Here they mostly rest directly on the Sylvania, the other beds being cut out by overlap. The fauna is rich and peculiar, European types of gastropods predominating. The genus *Acanthonema* Grabau, though represented in the Amherstburg, is most characteristic, and the faunal zone may be designated the *Acanthonema* zone. Its thickness varies up to 200 feet or over. *Cylindroheliium profundum* is restricted to it and may be regarded as another good zone fossil.

The proposed classification of these authors in tabular form is as follows:

Upper Monroe or Detroit River series (L., P., S., and G.); zone of *Prosserella*:

(d) Lucas dolomite (Prosser). (Zone of *Cylindroheliium profundum* and *Acanthonema*.)

(c) Amherstburg dolomite (Sherzer and Grabau). (Zone of *Panenka canadensis*.)

(b) Anderdon limestone (Nattress). (Zone of *Idiostroma nattressi*.)

(a) Flat Rock dolomite (Lane, Prosser, Sherzer, and Grabau). Zone of *Syringopora cooperi*.

Disconformity.

Middle Monroe: Sylvania sandstone.

Disconformity.

Lower Monroe or Bass Islands series (L., P., S., and G.); zone of *Leperditia*:

(d) Raisin River dolomite (Lane, Prosser, Sherzer, and Grabau). (Zone of *Whitfieldella prosseri*.)

(c) Put-in Bay dolomite (Lane, Prosser, Sherzer, and Grabau). (Zone of *Goniophora dubia*.)

(b) Tymochtee beds (N. H. Winchell).

(a) Greenfield dolomite (Grabau). (Zone of *Schuchertella hydraulica*.)

The characteristic faunas of the above-named divisions are listed by Sherzer and Grabau in a preliminary article⁷³⁸ and appear with full descriptions in a report published by the Michigan Survey.³⁸⁵ The authors deduce from the faunas and stratigraphic relations three interruptions in the process of sedimentation, or "disconformities," and comment on the relations as follows:^{738a}

A survey of these faunas brings out the remarkable fact that there is nothing in common (a few doubtfully identified gastropods excepted) between the Lower and Upper Monroe. So distinct are the faunas that they may be considered as derived from widely separated provinces. The Lower Monroe is apparently an Atlantic fauna or series of faunas, and we are led to believe that an embayment from the Atlantic extended as far as Wisconsin in post-Salina time and that the successive members of the Lower Monroe were deposited in this. The marine "Salina" described by Schuchert from Maryland most probably belongs here, the path of invasion being approximately across that region. There appears to be nothing in New York which corresponds

to this series, that State being apparently north of the embayment. The embayment covered Ohio, Michigan, and probably a part of Indiana and extended into Wisconsin.

Following the deposition of the Lower Monroe came a retreat of the sea and eolian deposits of quartz sands accumulated upon the limestone foundation. These are now seen in the Sylvania sandstone, the source of the material of which probably was the St. Peter sandstone. The Upper Monroe invasion was from the northwest, and it brought with it a wholly new fauna, in which the prevailing element was of Devonian aspect. A large proportion of the species of the Anderdon and Amherstburg beds is most nearly related to the Schoharie fauna, the similarity being often so great that species have been described as Schoharie or Onondaga forms.

For a list of species more nearly related to Middle Devonian forms than to known Silurian see the publication cited. On these species Sherzer and Grabau^{738b} comment as follows:

This list of species shows that the Anderdon-Amherstburg fauna is most nearly related to the Schoharie fauna of eastern New York, and that it probably represented the stock from which that fauna was derived. Coral-reef conditions existed in Michigan and Ontario at that period, the eastern extension of these conditions being first manifested in the water-lime deposits, and later in the Akron, and finally in the Cobleskill. This latter marks the period of reestablishment of connection with the Atlantic, and we find that this formation is especially characterized by an Atlantic fauna in its more eastern development (Halysites, etc.). The faunas mingled in the neighborhood of the Schoharie region.^a

With the opening of the Atlantic connections the late Silurian gastropod and cephalopod fauna entered this region and became characteristic of the succeeding Manlius-Lucas deposits, while the typical Anderdon fauna soon disappeared. A comparison of the Anderdon and the Lucas fauna shows scarcely a common species. In the Amherstburg, however, there is more or less of the commingling of the two faunas. That the junction with the Atlantic was effected while the Amherstburg beds were forming is shown by Silurian gastropod and cephalopod elements in its fauna, and their absence from the Anderdon fauna. The correlation of the Amherstburg and Cobleskill thus seems evidenced.

Considering the Anderdon fauna as a whole, we see a blending of types of the Silurian with those of Devonian affinities. Recognizing that this fauna is interpolated between two Silurian faunæ, we are forced to admit that here is an example coming perilously near satisfying the demands of Barrande's theory of colonies. Somewhere the Silurian fauna must have developed into the Devonian, while in other regions the Silurian fauna still lingered. That this Devonian aspect is that of the mid-Devonian fauna of America rather than the lower shows that this evolution was progressing along different lines from that of the Helderbergian fauna. This latter fauna is alien to North America, as is well known, having come to us from Europe. Somewhere in northwestern America an indigenous Lower Devonian fauna existed, which in turn gave rise to the Middle Devonian faunas of America. This indigenous American Lower Devonian must have been much like the Middle Devonian fauna, seeing that the indigenous Upper Silurian is already so far advanced as to have a decided mid-Devonian aspect.

It might of course be argued that the Upper Monroe is the indigenous Lower Devonian of America and that it existed contemporaneously with the Helderbergian fauna. On such an interpretation the Sylvania marks the Silurian-Devonian hiatus, and the upper hiatus representing the folding and erosion of the entire of Monroe and earlier rocks falls into the Oriskany. That period, as we know it, was scarcely long enough for the accomplishment of such extensive erosion as is implied in the pre-Onondaga hiatus, though it is known that a considerable amount was accomplished during that time. The strongest argument against such an interpretation is, however, the Silurian character of the fauna of the Lucas dolomite and the evident correspondence of the Amherstburg and Cobleskill horizons.

^a Grabau, A. W., Bull. New York State Mus. [No. 92, 1906], p. 131.

Lane ⁵¹⁷ states his views on the significance of the stratigraphy in the article already cited, together with details of well records.

L 17. LAKE TEMISCAMING, ONTARIO.

The Silurian outlier of Lake Temiscaming, first described by Logan, ^{543, 544n} has more recently been mapped and discussed in detail by Barlow. ^{15, 55a} At those points where the formation was deposited on the pre-Cambrian rocks there is a basal conglomerate, consisting in part of subangular talus blocks, in part of smaller pebbles of the adjacent older rocks in a calcareous cement. The deeper-water deposits are fine-grained yellowish limestone, with some shale and a considerable proportion of chert in some beds. The large collections of fossils from this section represent the Niagaran (including the Clinton).

L 18-19. SOUTHERN QUEBEC.

Isolated areas of Silurian strata occur in synclines southeast of the St. Lawrence. They are composed chiefly of limestone, characterized by Silurian corals. They lie unconformably upon the Ordovician strata. Detailed local descriptions are given by Ells. ^{310, 311a, 313b} A noteworthy correction of earlier descriptions is the determination of a so-called conglomerate of St. Helen's Island, Montreal, as a volcanic breccia "of later date than the Helderberg limestone."

In the Memphremagog area ^{313c}—

the formation is characterized by a considerable thickness of limestone, some of which is graphitic, while other portions are highly dolomitic and are associated with dolomitic grayish slates. * * * The structure in this area is that of a folded basin resting, on either side of the lake, upon fossiliferous lower Trenton rocks [Magog formation]. The rocks are altered from calcareous slates and limestones to talcose and mica schists or to graphitic crystalline marble, and are cut by numerous dikes, which are often of large size.

L 19. NEW HAMPSHIRE (LITTLETON).

In the township of Littleton, in northern New Hampshire, is an occurrence of fossiliferous strata, in part at least of Niagaran age, with possibly slates of Helderberg age as well.

Under the heading "Silurian and Devonian strata," Hitchcock ⁴⁵⁴ includes "the Coos mica schist and quartzite, the Niagara limestones, and slates, sandstones, and argillites." There is no good evidence as to the age of the mica schist.

The unaltered strata occur in Blueberry Mountain, which is believed to have a synclinal structure. If so, the sequence of formations in ascending order is as follows: Limestone, sandstone, coarse conglomerate, bluish and black slates. Hitchcock ^{454a} reports the following fossils from the limestone: "*Favosites basaltica*, *F. niagarensis*, *Zaphrentis*, *Astrocerium venustum*, *Halysites catenulatus*, *Pentamerus nysius*, a lingula, crinoidal fragments, a gastropod, *Dalmania limulurus*, and fragments of a *Lichas*," determined by Billings and Whitfield.

L 20. NOVA SCOTIA.

Under the heading "Siluro-Devonian rocks of Digby and Annapolis" (the southwestern counties of Nova Scotia) Bailey ⁴³ gives a detailed account of the slates and intercalated impure limestones which lie along the north side of the intrusive

granite and which contain fossils of late Silurian and early Devonian age, as determined by Sir William Dawson, by Logan, and on fuller collections by Ami.

Farther northeast in Pictou and Colchester counties, Fletcher^{335a} distinguishes strata which he assigns to Medina, Clinton, and Niagara horizons. Fossils determined by Ami include *Cyrtograptus grayia*, "characteristic of the lower half of the Silurian system."

The Silurian rocks of Arisaig, in Antigonish County, on the coast of Northumberland Strait, were first described by Honeyman.⁴⁶¹ Fletcher^{334a} gives a somewhat detailed section, from which the following is condensed:

	Feet.
Lower Helderberg, argillaceous sandy flags with thin fossiliferous limestone.....	1,038
Niagara, argillaceous, calcareous rocks with numerous layers of richly fossiliferous limestone (400 feet) followed by dark shales, also fossiliferous.....	1,293
Upper Clinton, green arenaceous shales and fine sandstone.....	148
(Break in section.)	
Lower Clinton, dark-gray, crumbly, papery argillites.....	345
Medina, greenish to gray, more or less massive sandstone	182

These strata lie in a "syncline, 6 miles long and 1½ wide, bounded on the south by a fault indicated by an escarpment of Cambro-Silurian rocks; on the north by pre-Cambrian; and on the west by Devonian and Carboniferous, which overlie them." The relation of conformity or unconformity to the "Cambro-Silurian" (Ordovician) is not clearly stated. With reference to the Silurian-Devonian contact Ami^{18a} suggests a possible unconformity, but says: "On the whole, the general trend and behavior of the strata referred to the Silurian and Devonian systems are fairly uniform and generally identical." On the other hand, the lower Carboniferous conglomerates and limestone extend with marked unconformity across the Silurian and Devonian.

The Arisaig section and other sections of the Silurian in Nova Scotia have been classified by Ami¹⁷ as follows:

The Silurian system as understood in Canada, and restricted to the upper division of Sir Roderick Murchison's Silurian, is extensively developed both in Nova Scotia and New Brunswick. At Arisaig, in Antigonish County, Nova Scotia, several thousand feet of more or less disturbed and inclined strata, including an almost regular succession of different members of this system, made up of sandstones, slates, iron ores, and black graptolitic slates and limestones, with mudstones, are well exposed and present a compact fauna, which in facies closely resembles rocks in Herefordshire, in Cumberland, Westmoreland, in the Kendal and Ludlow regions of England. The "Knoydart" formation, consisting of red shales and sandstones and calcareous bands holding pteraspidian and ostracoderm fishes and crustaceans referable to the Cornstone or lower Old Red sandstone of Great Britain, almost immediately overlies the Silurian strata, though no actual contact has been observed. The Silurian series at Arisaig consists of at least four distinct geological formations. Beginning above we have first the "Stonehouse" formation, consisting for the most part of dark-red, fine-grained shales and mudstones, holding a conspicuous lamellibranchiate fauna, of which *Grammysia acadica* Billings is a well-known species, together with a number of interstratified more or less thin calcareous bands holding brachiopods, gastropods, trilobites, and ostracods in abundance. Below this we find the "Moydart" formation, which consists of more or less heavy bedded light greenish-gray and rusty-weathering calcareous strata (in which the "Red stratum" of authors occurs) and holds brachiopods, gastropods, cephalopods, and crinoids. Beneath this again we have the "McAdam" formation, consisting for the most part of impure black carbonaceous shales, which are splintery

at times, holding a lamellibranchiate fauna and graptolites. At the base occurs the "Arisaig" formation, which comprises buff-weathering fine-grained compact sandstones and shales, containing corals (chiefly *Streptelasma*), brachiopods, gastropods, and trilobites. The thorough investigation of this series of strata, which, indeed, may require further subdivision, is expected to furnish data bearing on the settlement of the mooted question as to where the Silurian stops. * * *

In the county of Annapolis, Nova Scotia, and in the vicinity of Nictaux Silurian strata occur, including the Nictaux iron ore beds and the Torbrook sandstone formation, whilst near Kentville the Kentville formation is seen, as well as on Angus Brook, in the Gaspereau Valley, also at New Canaan, with *Dictyonema websteri* Dawson, and at Wolfville, in King's County, where coralline limestones, red and green graptolitic slates, and other strata, at times highly cleaved, squeezed, and metamorphosed, form conspicuous ridges and constitute the oldest sedimentaries in the vicinity of the Bay of Fundy and the Blomidon region in the "land of Evangeline."

In Cumberland County, along the northern slope of the Cobequids, isolated areas of Silurian strata have been mapped out and described by Mr. Scott Barlow and Mr. H. Fletcher, the Wentworth and Farmington areas being among the most important and best known. These appear to belong to the lower half of the Silurian.

L-M 19-20. MAINE, NEW BRUNSWICK, AND GASPE.

Northeastern Maine, northwestern New Brunswick, and the Gaspé Peninsula are occupied by a broad synclinorium of Silurian strata, which appear to lie unconformably upon folded and eroded Cambrian rocks and are overlain conformably by Devonian rocks.

A section which is typical for Maine and New Brunswick is that observed on Temiscouata Lake, just across the boundary in Quebec. This section was described in great detail by Logan^{544t} and has been reexamined by Bailey,^{47b} who has also traced out the distribution of the sediments in New Brunswick and Quebec as well as in Maine. As determined by him on fossils, the sequence of strata ranges from lower Niagara (Clinton) to "Lower Helderberg" (Helderberg), with possibly an unconformity also at the base of the latter. The section is partly concealed, the structure involves older beds apparently overlying younger, in consequence of overthrusting, and his Lower Helderberg rocks appear to overlap his earlier Niagara and lie upon the Cambrian. The strata dip southeastward, but the sequence from northwest to southeast is shown to be Cambrian, unconformity (?), Lower Helderberg, thrust fault (?), Niagara, unconformity (?), Lower Helderberg. For details we quote Bailey's report:

The rocks of Lake Temiscouata have been described in considerable detail and are given with sections illustrating the relations and probable thickness of the principal beds in the "Geology of Canada," 1863, pages 419-425. * * * The following section is a condensation of that in the "Geology of Canada," with such additional information as has been recently obtained. The section begins on the north side of Mount Wissick or Mount Lennox, where the rocks of the Silurian system may be seen to rest unconformably upon those of the "Quebec group."

Greenish-gray and black slates, alternating in thin bands, 2 to 3 inches wide, with gray or buff weathering dolomitic limestones. These beds occur on the northeast side of a small cove above Mount Wissick and are a part of a similar series of rocks, supposed to be of the same age as those of Point Levis which occupy all the upper part of the lake. They have been subjected to much crumpling and exhibit considerable irregularity of inclination, their dip, where nearest to the Silurian, being N. 40° W. <70°-80°. They have as yet yielded no fossils, and their thickness is unknown.

Measures concealed for about half a mile

	Feet
Gray quartzose sandstone, containing white quartz pebbles, mingled with fragments of limestone in a greenish sandy matrix. These grits or conglomerates apparently occupy a space across the measures of about 1,000 feet, and with a dip of S. 65° E. <40° would give a thickness of. . . .	642
White sandstone or quartzite in massive beds. These rocks are gray within but weather almost snow-white, with vitreous surfaces, often drusy with small quartz crystals. Some portions are pinkish or reddish and others spotted with small red dots. Their thickness, as given in the "Geology of Canada," is only 40 feet, but they were found to have a surface breadth of 250 paces, which, with an average dip of 50°, would give a thickness of.....	420
Coarse shaly and rubbly conglomerate, holding limestone pebbles (with some quartz). They dip S. 60° E. <70° and have a breadth of 60 paces, corresponding to a thickness of.....	114
Dark-gray sandstones. Dip S. 70° E. <20° Thickness about.....	10
Gray calcareous shales, filled with bands, nodules, and lenticular masses of limestone, abounding in fossils. [For partial list, see op. cit.] These beds are regarded by Mr. Ami, by whom the fossils have been examined and in part collected, as corresponding to the Chat River limestones, equivalent to the upper part of the Chaleur group, and about equivalent to the lower part of the Lower Helderberg formation. Dip S. 65° E. <60°. Thickness about.....	10
Red and green shale, in alternating bands, with green argillaceous sandstones. The dip of these beds where they overlie those last mentioned is S. 65° E. <15°, their strong slaty cleavage having an underlay of N. 65° W. <80°, but in following them along the precipitous face of the mountain they are found to fold over and exhibit a dip N. 40° W. <40°. They are also broken by a fault. Their estimated thickness is.....	125
Gray nodular limestones, conspicuously divided by vertical joints, which often present curved surfaces and produce an appearance resembling that of fluted columns. These beds rest directly upon the red and green shales and are probably arched with them, but toward the southern end of the bluff resume their normal dip S. 65° E. at an angle of 50°. The columnar limestones, which contain but few fossils, have a thickness of about 10 feet and are followed by about the same thickness of finely banded massive limestones, having at the top a zone, from 1 foot to 18 inches thick, filled with branching corals, chiefly Favosites; it also holds shells of <i>Atrypa reticularis</i> and Pentamerus. This is capped by more columnar limestone, the whole having an aggregate thickness of about.....	50
Gray hard sandstone, with beds of impure limestone, the sandstone containing remains of <i>Meristellæ</i>	30
Gray nodular limestone, without observed fossils.....	30
Gray banded limestone, filled with corals and other fossils, including <i>Favosites gothlandicus</i> Lamarck, <i>Strophodonta varistriata</i> Conrad, in great abundance and forming the typical representative of the zone [together with a number of other species; for list, see op. cit.]. (Mr. Ami considers these fossils also to indicate the horizon of the lower portion of the Lower Helderberg series.) Thickness about.....	30
Gray arenaceous limestones and sandstones forming the upper portion of Mount Wissick but sloping to the level of the lake, with a dip S. 70° E. <13°. These higher beds contain comparatively few fossils, among which are the following: A stromatoporoid form; crinoidal fragments, in abundance; <i>Chonetes</i> sp., a rather arcuate form, smaller than <i>C. nova-scotica</i> Hall and larger than <i>C. tenuistriata</i> Hall, resembling somewhat <i>C. melonica</i> Billings; <i>Meristella</i> sp. Their supposed thickness is about.....	500

The beds may, therefore, be correlated with the Lower Helderberg or with the Ludlow formation of Britain.

A summary of the above section is given in a later report by Bailey⁴⁸ from which the following is taken:

As represented upon Lake Temiscouata the portion of the Silurian system which immediately adjoins and overlaps the Cambrian strata to be presently described does not represent the lowest member of that system, being composed of white sandstones and overlying calcareous rocks, of which the fossils indicate an age ranging from the lower to the upper part of the Lower Helderberg horizon, while at a short distance south are heavy conglomerates followed by hard sandstones and shales containing fossils chiefly of the Niagara formation. * * *

Immediately to the south of the above undoubted Silurian strata is found the great series of slates first described in the "Geology of Canada" in connection with the Gaspé series and which has since been found to spread so widely over the northern portions of New Brunswick, as well as adjacent areas in Quebec and Maine. These slates, as seen along the lower half of Temiscouata Lake and on the Madawaska River, are of gray, bluish-gray, and dark-gray, rarely

black colors, often weathering to a dull olive-green, very fine grained but including harder bands, and generally more or less calcareous. They are throughout characterized by numerous and often intricate contortions and these, with a strongly developed slaty cleavage, make any attempt to determine their thickness or relations well-nigh hopeless. Neither on the lake nor on the Madawaska have they been found to contain any fossils, these having probably been obliterated by molecular movements; but the occurrence of fossils at many different points in the resembling strata which spread so widely to the east and south, and all of which indicate a Silurian horizon, seems to justify the position first assigned them as also Silurian, and as the equivalent of the upper part of the Gaspé series.

Southwestward from Temiscouata Lake the gray to olive-green slates called by Bailey Lower Helderberg occupy the basin of St. John River in northwestern Maine. Their relations to the overlying Devonian in Aroostook have been described by Bailey^{47d} and more recently by Williams and Gregory.⁹³⁷ (See Chapter VI, L 19, pp. 325, 328.)

Northeastward from Temiscouata Lake to the Metapedia section, the outline of the Silurian beds in relation to the Cambrian on the north has been retraced by Bailey and McInness.^{47a} Beyond the Metapedia Ells³⁰⁸ and Low⁵⁴⁸ determined their distribution between the Cambrian and the Devonian as far east as the Cascapedia, whereas from the headwaters of the Magdalen to Cape Rosier the lines are placed as worked out by Logan^{544s} and Ells.³⁰⁷ The areal geology of the peninsula south to the Bay of Chaleur is according to the same authorities.

The strata thus mapped as Silurian are those assigned to that period according to the past and current usage of the Canadian Survey, and they include the strata identified by Bailey as Lower Helderberg, which is now classed as Devonian, according to Schuchert⁷¹¹ and Clarke.¹⁵⁷ The literature contains a number of doubtful references to Silurian or Devonian, the uncertainty being due to the transitional character of the fauna, which has commonly been assigned to the uppermost Silurian but contains Devonian forerunners. Ells^{308a} cites observations of unconformity between Silurian and Devonian on the tributaries of the Cascapedia, and Bailey^{47c} infers an unconformity between the rocks identified by him as Niagara and Lower Helderberg on Lake Temiscouata, which might be at the same horizon. The overlap of the latter formation beyond the former seems to be well established. The base of the Niagara, as thus identified by Bailey, is a white sandstone associated with bodies of calcareous conglomerate, consisting of limestone pebbles and angular fragments in a sandy matrix. No fossils have yet been found in the limestone pebbles, but the position of the strata at the base of the rocks identified as Niagara and their relation to the near-by Cambrian rocks are such as to suggest their derivation from the Cambrian. A marked unconformity is thus indicated. Logan^{544u} describes two unconformable contacts seen on the coast near the line between Gaspé and Bonaventure counties, as follows:

The vertical strata of this group [the "Quebec group"] extend along the coast toward Anse à la Vieille, where they are overlain by the inclined strata of the Gaspé limestones, which in their turn support the Bonaventure conglomerates, the three series being unconformable with each other.

The proofs of this double discordance lie within a space of half a mile, a little less than 2 miles westward of the line between the counties of Gaspé and Bonaventure; and as there is no concealment of strata, the whole is readily apparent to the eye. The smoothly worn edges of

the vertical strata of the Quebec group here support an even layer of 4 feet of hard grayish-white strong siliceous conglomerate, which divides into layers of a foot or two, and would make good millstones. It dips S. 4° W. < 38° and is conformably overlain by a great series of fossiliferous limestones and shales. At a point about 230 yards along the beach from the millstone layer these calcareous strata dip S. 3° E. < 45°, in a cliff 100 to 120 feet high. Upon the basset edges of these the beds of the upper conglomerate are seen to repose, with a dip S. 42° E. < 20°. These stretch along for 200 yards, presenting a perpendicular precipice in front; while the underlying calcareous series forms a talus and occupies sometimes more and sometimes less than one-half the height of the cliff.

This unconformity is well established farther south. From the Bay of Chaleur the eastern margin of the Silurian extends southwestward across New Brunswick into Maine. The areal distribution is not well known, the structure being complicated, the Cambrian, Ordovician (?), and Silurian rocks being similar, and intrusive rocks abundant; but in the course of a resurvey of the line between the "Cambro-Silurian" (Ordovician) and the Silurian, Bailey⁴⁴ found "incontestable evidence of discordance along its whole length." He cites occurrences of conglomerates containing pre-Silurian rocks at the base of the Silurian strata.

Bailey^{47e} summed up the known facts of the stratigraphy of the Silurian of northern and southern New Brunswick as follows:

Sequence of Silurian strata in southern New Brunswick.

Mascareen Peninsula.		Feet.	Southern Queen's County.		Feet.
I. Gray feldspathic slates, about		400	I. Gray and dark-gray slates		400
II. Gray and black banded siliceous slates, with nodular layers		620	II. Dark-gray and black siliceous clay slates, distinctly banded		600
III. Gray flaggy sandstones, with some conglomerate. Shells of <i>Lingula</i> , <i>Modiolopsis</i> , and <i>Loxonema</i> ?, with comminuted vegetable matter		350	III. Dark-gray and greenish-gray, sometimes purplish sandstones, becoming slaty above		600
IV. Red and green slates and sandstones, with diorites and felsites		300	IV. Ash-gray and greenish-gray schistose beds, dioritic and amygdaloidal		300
V. Dark-gray and reddish porphyritic felsites		300?	V. Gray and dark-gray, sometimes reddish porphyritic felsites, with chloritic schist and breccia conglomerate		800+

In the same work Bailey details the relations of the strata of southern New Brunswick, northern New Brunswick, Quebec, and Maine, and sums up as follows:

Supposed sequence of Silurian strata in northern New Brunswick, Quebec, and Maine.

[Ascending section.]

Divisions I and II.—Gray argillaceous and siliceous slates, including (locally) heavy beds of conglomerate. Fossils somewhat numerous in upper part, including shells and graptolites, indicating a low Silurian horizon.

Conglomerates and succeeding slates of Black and Burnt points, on Lake Temiscouata; feldspathic and siliceous slates of Fish River and Alleguash River, Aroostook County, Me.(?). Conglomerates and graptolitic slates of Beccaguimic River, Carleton County, New Brunswick. Supposed to be equivalent to the Medina and Clinton groups of New York, divisions 2 and 3 of Anticosti group, or groups B and B' of Arisaig.

Division III, A.—Gray flaggy and massive sandstones, with some conglomerate, becoming frequently greenish or purplish and more or less amygdaloidal. Fossils rather numerous, including corals and shells, as well as worm tracks and comminuted remains of plants.

Sandstones and conglomerates of Pointe aux Trembles, Tuladi and Squatook rivers, Quebec; similar beds of Siegas River, New Brunswick; sandstones and conglomerates of Aroostook County, Me.; similar beds of Beccaguimic River and other parts of Carleton County, New Brunswick.

Niagara formation, or Wenlock group.

Division III, B.—Lower sandstones, shales, and limestones of the Gaspé Peninsula. Similar sandstones and limestones of the head-waters of the Chatte and Matane rivers, Metapedia Lake, Metis and Rimouski rivers, and lower part of Mount Wissick. Fossils numerous, marine.

Supposed to be equivalent to the Guelph formation of Ontario.

Divisions IV and V.—Red and green shales of Cape Gaspe; red and green slates and sandstones of Mount Wissick; similar slates on Fish River (Eagle Lake) and Aroostook River, Maine; red and green slates of Grand River and Carleton County, New Brunswick; often including argillaceous iron ores. (?) Felsites and associated trappean rocks of Campbellton and Bay Chaleur, Moose Mountain, New Brunswick, Haystack and Spider Lake, Maine.

Division VI.—Gray, often nodular or columnar limestones, abounding in fossils.

Upper limestones of Cape Gaspe; middle and upper rocks of Mount Wissick, regarded as equivalents of the lower portion of the Lower Helderberg.

Fossiliferous limestones of Square Lake and Ashland, Me.; Lower Helderberg.

Fossiliferous limestones of Carleton County, New Brunswick.

Fossiliferous slates and sandstones of Metapedia River, Restigouche, Victoria, Madawaska and Carleton counties, New Brunswick. Similar slates, etc., of Aroostook County, Me. Lower Helderberg (?).

Silurian strata of southern New Brunswick (Charlotte County) and adjacent parts of Maine have in later years been found to be more extensive than had been supposed, the Silurian age of certain metamorphic rocks and of slates previously assigned to older horizons having been determined.⁷⁰ The geologic relations are similar to those about Penobscot Bay, Maine. (See L 19, pp. 134–135.)

L-M 21. NEWFOUNDLAND.

Under the heading "Upper Silurian series" Murray, in 1864, described conglomerates, slates, and mica schists, together with intrusives of granitoid character, all of which are exposed in sections on Jackson's and Sop's arms of White Bay, Newfoundland. Murray⁶⁰⁸ states:

Jackson's Arm runs into the land nearly at right angles to the strike, and here these upper rocks have a transverse breadth of about 2 miles. The following section of them, in ascending order from the mica slates on which they are seen to rest, is taken from the north side of the arm, on which the measures appear to be broken by three considerable faults, causing what are supposed to be modified repetitions of some of the masses.

	Feet.
1. Coarse conglomerates, with a light-gray arenaceous-micaceous slaty matrix which is slightly calcareous. The masses inclosed consist of pebbles and bowlders of gneiss, large rounded fragments of whitish or light-gray mica slate, some of a darker-gray greenstone, reddish-gray quartzites, and occasional smaller masses of limestone; among these there is a good deal of finer material of the same character, slightly calcareous, and mica schist runs in irregular flakes and patches in the general direction of the stratification, but its cleavage often partially conforms to the rounded surface of the bowlders and pebbles. The beds are very massive, and they appear to be divided by gray micaceous schist.....	400
2. Sea-green slates, occasionally interstratified with dark-gray or blackish fine silky-surfaced slates, some of which are harder than others.....	300
3. Gray, coarse, rough arenaceous-micaceous schist, frequently passing into a fine conglomerate, with pebbles similar in mineral character to those of the coarse conglomerates beneath, but none of them exceeding the size of a hen's egg; the pebbles are sometimes arranged in regular layers, parallel to the stratification; bands of dark-gray clay slate are occasionally interstratified in the mass.....	400
4. Gray micaceous and arenaceous slates.....	250
5. Green and black slates at the base, succeeded by gray arenaceous slate, which is interstratified with thin bands of sandstone.....	650
6. Green, bluish, and blackish slates, interstratified with gray flaggy sandstones; the slates inclose nodules of pinkish calc spar, and veins of the same cut the strata.....	250
7. Grayish-blue limestone in a single bed.....	7
8. Gray calcareo-arenaceous slates, interstratified with grayish sandstones, with a heavy mass of gray, white-weathering sandstone at the top.....	543
	2,800

The above section can only be considered as giving an approximation to the truth. The three faults which dislocate the rocks and are all considered to be upthrows on the east side render it difficult to follow the sequence with exactitude; and some of the masses, which are

supposed to be in a general way equivalent on opposite sides of the faults, appear in different parts to be modified in volume and somewhat in lithological character by different degrees of metamorphic action.

The intrusive relations of the igneous rocks and the metamorphosed condition of the sediments, particularly on Sop's Arm, are described by Murray, who states further:

Between the conglomerates of Sop Island and those of the eastern end of Sop's Arm the rocks of the western part of Sop Island, of Goat Island, and of the main coast appear to be slates of various shades of green, often marked by pink calc spar in nodules, patches, and short veins; of occasional interstratified sandstones, sometimes fit for flagging, with calcareo-arenaceous bands; and occasional impure limestones, weathering brownish. East of Bartlet's Cove, which is an indentation on the south side of the southwestern extremity of Sop Island, there was seen a thickness of 50 feet of black slates. These rocks are, in several places, characterized by fossils, which are somewhat obscure; but though few of them could be specifically determined, they have yet, according to Mr. Billings, a general aspect allied to that of Upper Silurian types. It would, however, for the present, be impossible to say to what horizon in the series the different divisions of the rocks of Jackson's Arm and of Sop's Arm may belong, and it may be proper to remark that while no doubt is entertained of the general equivalency of the rocks of the two localities, all the places in which organic remains were observed occur in the neighborhood of Sop's Arm.

One of these localities is Bartlet's Cove. Here the fossils occur in calcareo-arenaceous flagstones, and the genera observed, in addition to numerous fucoids and crinoidal stems, were a *Murchisonia*, an *Orthoceras*, and a *Graptolithus*. At a point on the main coast halfway between Spear Point and the promontory occupied by the porphyry which strikes from Sop Island organic remains were met with in strata somewhat similar to those of Bartlet's Cove; they consisted of fucoids, crinoidal stems, and an *Orthoceras*. On the western side of Goat Island, still in the same description of strata, in addition to fragments of crinoidal columns, there were met a *Syringopora* and *Favosites gothlandica*.

In Murray's report for 1871,^{608a} based on Howley's exploration of Exploits and Gander bays and vicinity, the Silurian is described as the "Upper, unconformable formation," which is said to occupy a rudely elliptical trough.

The evidences, so far, tend to show that while the formations butt up against the Quebec group on the northern and southern sides of the trough, they overlap the junction of the latter at the eastern and western extremes.

The central part of this elongated trough has been greatly disturbed for the whole length of its course, from the head of the Red Indian Pond to the Dildo Run, where vast dikes were seen to cut through the strata at very many parts, while great areas are spread over by overflows of trap, or breccious intercalations. * * *

The base of the Upper and unconformable formation consists of conglomerate and sandstones, with slaty divisions, which, at Goldson's Sound, seem to come against the older and altered rocks in a slightly oblique direction, as if brought into their present position by a fault, the lower beds dipping about S. 55° E. <24°. The lower conglomerates are of a reddish general color, the matrix being constituted of fine reddish sand, sometimes slightly calcareous, which incloses well-rounded pebbles of quartz, red jasper, green jaspery slate, and fragments of magnesian rocks. The pebbles are not usually large, the largest being about the size of a hen's egg. The strata in ascending succession are still of conglomerate character, but the color gradually passes into gray, and there are numerous pebbles of gneiss and syenite mingled with the other qualities, and they are frequently characterized by the presence of hard blue or blackish cherty concretions, which weather a bright yellow, are sometimes concentric in structure, and of an elliptical shape. The islands of Goldson's Sound expose an alternation of conglomerates and red sandstones, with dark-gray slates, which are themselves occasionally finely con-

glomerate and were found to contain numerous stems of encrinites. The dip of the slates is south by west 80° . In front of the encrinal beds, on the long projecting point between the arms of the sound and on the islets at the head of the northern arm, some strong beds of coarse conglomerate are exhibited, which are overlain by black or dark-gray slates, with thin beds of gray sandstone, of from 1 to 6 inches thick. The conglomerate is often very calcareous and frequently contains irregular intercalations of limestone. The dip of these rocks is S. 20° E. $<60^{\circ}$. Both the conglomerates and associated beds above the encrinal slates were found to be very fossiliferous and in their strike up the southern shore of the eastern arm were there found to pass beneath another mass of coarse conglomerate, which forms the escarpment to the hills which strike in the direction of the point between Pike's and Little Cobb's Arm. The total thickness of this part of the formation, from the junction with the older group to the last-mentioned conglomerate, was estimated to be about 2,000 feet.

The fossils recognized in the strata alluded to appear to be types of the Middle or Upper Silurian series, or about the horizon of the Llandovery group of the British Survey. Some of those previously collected were referred to Mr. Billings, of the Canadian Survey, who identified the following genera and species: *Favosites gothlandica*, *Heliolites*?, *Zaphrentis bellistriata*, an encrinite referred to the genus *Glyptocrinus*, a coral referred to the genus *Heliophyllum*, *Orthis ruida*, *Leptæna sericea* or perhaps *transversalis*, ventral valve of an orthis like *O. davidsoni*, *Strophomena rhomboidalis*, *Atrypa reticularis*, *Stricklandinia lens*, *Modiolopsis*, *Ambonychia*, a trilobite, genus *Encrinurus*, and some others not determinable.

The conglomerates of the escarpment above mentioned are succeeded by a set of slates which are occasionally slightly micaceous, with beds of quartzite from 2 inches to a foot thick, the strata of which run out upon the coast on the southeast side of Goldson's Sound, usually called Burnt Arm, at the head of which arm the slates pass beneath a mass of limestone, with black slate and trap breccia. At this part trap intrusions are met with and the strata are violently disturbed and altered in some parts in such a degree as to assume somewhat the aspect of the inferior formation, but the occasional presence of fossils, amongst which was one resembling *Zaphrentis* and some *Encrinites*, was supposed to indicate a horizon of later date than the Quebec group.

M 11. ROCKY MOUNTAINS OF BRITISH COLUMBIA.

In a section examined along the Canadian Pacific Railway McConnell⁵⁵⁹ found the Castle Mountain group (Cambrian and Ordovician) to be succeeded in the eastern ranges of the Rocky Mountains by the "Intermediate" limestone and in the western ranges by the Ordovician "Graptolitic shales" and the "Halysites beds." Neither the "Intermediate" limestone nor the "Halysites beds" is stated to be of widespread occurrence, owing presumably to erosion and unfavorable structural conditions, and they have not been observed in contact. On paleontologic evidence the "Intermediate" limestone is assigned to the Devonian, whereas "*Halysites catenulatus*, *Favosites*, a coral like *Zaphrentis*, and some badly preserved brachiopods" indicate the Silurian age of the "Halysites beds." The latter consist of about 1,300 feet of dolomites and quartzites, the quartzite being at the base and the upper part of the formation missing through erosion of the syncline in which the strata occur.

This isolated occurrence and that in the Finlay-Omenica section (N-O 10) appear possibly to connect the Silurian dolomite of the Porcupine section, Alaska (Q 5-6), with the Silurian of Utah.^{498c}

M 20. ANTICOSTI ISLAND.

The Ordovician-Silurian sequence is unusually complete in the island of Anticosti, there being no apparent interruption of sedimentation nor any abrupt change of faunas in the passage from one system to the other. Logan ^{544m} gives a detailed section, which is presented below in condensed form, lists of fossils being omitted.

The strata of this [Hudson River] formation occupy nearly the whole of the north side of the island [Anticosti] and extend from Fox Point, which is toward the east end, to Junction Cliff, on the south side, about 4 miles from the west end. The remaining portion of the island is occupied by newer rocks, to which the name of the Anticosti group has been given. Their position in the geological series is that occupied by the Oneida conglomerate, the Madison sandstone, the Clinton group, and the Niagara group of the New York geologists, but these subdivisions, although apparent in the western basin, disappear in the Anticosti strata, which are lithologically unlike their equivalents in western Canada. * * *

The rocks of this group on the island of Anticosti may be considered in four divisions, * * * in immediate succession to the Hudson River formation, as follows, in ascending order:

1.		Ft. in.
1 to 3. Greenish argillo-arenaceous shale at base of yellowish-gray compact argillaceous limestone interstratified with light reddish-gray limestone beds of from 1 to 3 inches thick, with many fossils, all together.....	32	6
4. Measures partly concealed but supposed to be of the same character as the preceding, both lithologically and paleontologically.....	25	
5 to 7. Ash-gray argillaceous limestone, in beds from 1 to 3 inches thick, alternating with beds of calcareo-argillaceous shale of from 5 to 7 inches. Both of these are interstratified with light-gray pure limestone beds, 1 or 2 inches thick.....	67	
8. Measures concealed.....	21	
9 to 10. Gray limestone, interstratified with gray and sometimes greenish calcareo-argillaceous shale.....	17	
11. Yellowish-white coralline limestone.....	5	
12 to 14. Gray compact argillo-calcareous beds, slightly bituminous, interstratified with argillaceous bands.....	139	
	<hr/>	<hr/>
	306	6
2.		
1 to 2. Ash-gray and light reddish-gray limestones, in beds of from 2 to 6 inches thick, interstratified in the upper part with conglomerate beds of some thickness, at intervals of from 2 to 10 feet. The pebbles are calcareous, from 1 to 3 inches in diameter, and lie flat in the beds.....	120	6
3 to 5. Reddish-gray limestone, in beds from one-quarter of an inch to 3 inches thick, some of which weather to a reddish brown; interstratified with occasional conglomerate layers of from 2 to 4 inches thick (toward the top).....	143	6
6. Measures concealed.....	40	
7. Gray, yellowish-weathering limestone, containing but few fossils.....	34	
8. Measures concealed.....	17	
9. Ash-gray, smoke-gray, and reddish gray, slightly bituminous limestones.....	65	
10. Measures concealed.....	27	
	<hr/>	<hr/>
	447	
3.		
1. Measures concealed.....	27	
2. Greenish-gray and brown fine arenaceo-argillaceous shales, interstratified with one another, in thin beds; no fossils are seen.....	60	
3 to 7. Ash-gray and light-drab limestones interstratified, both slightly bituminous and crowded with <i>Stricklanida lirata</i> (near the top).....	157	9
8. Measures concealed, with 1 foot of light-drab argillaceous, slightly bituminous limestone in the middle.....	51	
9. Light-drab argillaceous limestone, slightly bituminous, in beds of from half an inch to 3 inches.....	87	6
10. Measures concealed at the bight of the cove, north of Southwest Point.....	157	6
	<hr/>	<hr/>
	540	9

4.

	Ft. in.
1 to 3. Yellowish-white granular limestone, in beds of from 3 to 18 inches thick; often separated by thin partings of green argillo-calcareous shale, which is also disseminated in small patches through the bed.....	57 3
4. Yellowish-white granular limestone, in beds of from 6 to 18 inches thick; consisting of masses of organic remains, of which crinoidal columns constitute the larger part; some of them being three-fourths of an inch in diameter.....	16
	69 3

This is the highest series of strata met with on the island, and its lithological characters are so well marked that it is scarcely possible to mistake it for any of those which precede.

For the sequence of faunal zones, according to which these lithologically similar beds of argillaceous limestone and shale are distinguished by Logan, his original account should be consulted. The general faunal relationships and correlation were thus summed up by Billings: ^{82a}

MIDDLE SILURIAN—ANTICOSTI GROUP.

Division 1.—The rocks of division 1 rest directly and conformably upon those of the Lower Silurian, above noticed, with no apparent physical gap between them, although there is a paleontological break. It has been already stated that 41 of the species of the lower fauna pass this break. They are here joined by 45 additional species, making the whole fauna of this division to consist of 86 species, so far as is yet known. Of these, 18 pass upward into division 2, 13 into division 3, and 11 into division 4.

Of the 41 species which are received from the Lower Silurian the following are known to occur in Canada West and New York and are variously distributed throughout all the formations from the base of the Quebec group to the top of the Hudson River formation.

Stenopora fibrosa. Halysites catenulatus. Beatricea undulata. Lingula quadrata. Strophomena alternata. S. planumbona. Leptaena sericea. Orthis porcata. O. lynx. Orthisina verneulli. Ambonychia radiata.	Subulites elongata. Murchisonia gracilis. M. ventricosa. Bellerophon bilobatus. Pterotheca transversa. Orthoceras formosum. Ascoceras newberryi. Asaphus megistos. Calymene blumenbachi. Cheirurus pleurexanthemus.
---	--

Among the 45 species which here made their first appearance in the rocks of Anticosti we find *Strophomena rhomboidalis*, *S. pecten*, and *Atrypa marginalis*, all three very characteristic of the Middle and Upper Silurian. The new species include *Atrypa umbonata* and *A. prinstanta*, members of the group of which *A. tumida* may be regarded as the central form, a type almost unknown in the Lower but very prolific of species in the Middle and Upper Silurian. This group becomes extinct in the Devonian. The genera Favosites, Heliolites, and Helopora, which here first appear in force, are more characteristic of the upper than of the lower half of the Silurian series. Most of the other new species belong to the ordinary Silurian genera.

The fauna of this division is partly Lower and partly Middle Silurian but is more strongly tinged with the former than the latter.

Division 2.—From this division we have only 39 species, of which 18 are received from division 1 and 21 here first made their appearance. Out of the whole fauna 23, or more than one-half, pass into division 3 and 16 into division 4. As before stated, the only species very characteristic of the Lower Silurian are *Strophomena alternata* and *Murchisonia gracilis*. The most prominent fossil is *Pentamerus barrandi*, which occurs in vast numbers. Owing to the inaccessible character of the coast in bad weather, it was not practicable to make a thorough search for fossils in this division.

Division 3.—In this division there are 53 species, of which 23 are received from division 1, and 26 pass upward. We here meet for the first time with *Pentamerus oblongus*, *Stricklandinia lens*, *S. lirata*, *S. brevis*, and *Laptocelesia hemispherica*. These are all strongly characteristic of the Middle Silurian and occur in this division and also in division 4 in great abundance.

Division 4.—There are 70 species from this division, of which 26 are received from below.

CONCLUSION.

The great abundance of such species as *Strophomena rhomboidalis*, *S. pecten*, *S. antiquata*, *Leptæna transversalis*, *Orthis davidsoni*, *Pentamerus oblongus*, *Stricklandinia lens*, *S. lirata*, *S. brevis*, *Cyrtia myrtea*, *Spirifer plicatella*, and *Leptocælia hemispherica*, together with the general aspect of the whole fauna of divisions 3 and 4, render it quite certain that this part of the series represents the Upper Llandovery rocks of England and, perhaps, the Lower Llandovery also. They may not be exactly synchronous, for it seems to be now pretty conclusively demonstrated that a fauna may appear somewhat earlier in one region than in another. But, so far as we can at present decide the question by fossil evidence, these rocks are of the same age. I use the word fauna in a purely zoological sense, with no reference to geographical distribution. With regard to the Llandovery formation, Mr. Salter^a makes the following remarks: "The Lower Llandovery, or, as I prefer to call it, with Prof. Phillips, the Llandovery rocks, are intimately united with the Caradoc, and pass up from them with a great admixture of Lower Silurian, not Upper Silurian, forms. The May Hill sandstone, on the contrary, as Sedgwick showed in 1853, is unequivocally the base of the Upper Silurian, and contains scarcely any true Lower types." Now, the only deposit, as yet known in America, which exhibits such an admixture, is division 1 of the Anticosti group. If, then, the extinction of the Lower Silurian fauna occurred in the ancient British seas at the same time that it did in the American waters, it follows that division 1 is Lower Llandovery; and that the Hudson River is Caradoc.

It is, however, very difficult to correlate all the divisions of the English Middle and Lower Silurian with those of America, and I shall take this occasion to make a few observations on the other members of the series not found in Anticosti. From what we know of the origin and mode of accumulation of sedimentary strata, it is highly improbable that each of the minor formations of one country should have its exact equivalent in another land several thousands of miles away, although the larger groups, of which these smaller ones are the component parts, may be well represented, and paralleled in a general way. Everywhere we find a number of breaks or gaps, and the probabilities are vastly against these breaks having been all occasioned at the same time in distant localities. It is more consistent with the nature of things that many of the breaks in America should stand opposite—so to speak—the formations in England, and vice versa. Perfect parallelism of the minor groups may be looked for as the exception, not the rule.^b

M-N 13-14. LAKE WINNIPEG, MANITOBA, AND SASKATCHEWAN.

The Silurian of northwestern Manitoba is a thin-bedded limestone, which varies in character from bed to bed. The lower portion, well exposed at Grand Rapids,

^a Geol. Mag., vol. 3, p. 240.

^b Prof. A. C. Ramsey (Anniversary address to the Geological Society, 1863: Jour. Geol. Soc., vol. 19) gives the following account of the breaks in the English series from the Lingula flags up to the Wenlock shale:

Lingula flags.

Break very nearly complete both in genera and species, and probable unconformity.

Tremadoc slate.

Break very nearly complete, both in genera and species, and probable unconformity.

Llandeilo and Caradoc beds.

Large break, especially in species, and probable unconformity.

Lower Llandovery beds.

Break and decided unconformity.

Upper Llandovery beds.

Break and strong unconformity.

Wenlock shale, etc.

on the Saskatchewan, consists of 54 feet of white or yellow limestone, partly magnesian, partly chalky, and partly ripple-marked and containing impressions of salt crystals. The base is not seen, but limestone of Trenton age lies not far below. Fossils are lacking in the lower 10 feet but numerous above, and the strata are compared by Tyrrell^{817a} with the lower part of the Niagara of Wisconsin. Above the lower portion is a considerable thickness, "possibly a few hundred feet," of dolomites and dolomitic limestones of upper Niagara age. The beds exhibit impressions of salt crystals and are in some places "fragmental." Tyrrell gives a list of 41 species of fossils determined chiefly by Whiteaves. Near Lake St. Martin (latitude 51° 45') the strata of Niagara age rest on granite of an island in the rocks of Trenton age, which elsewhere underlie them. Gypsum occurs not far away. Near by, on the eastern shore of Lake Manitoba, "the thin-bedded upper Niagara dolomites are overlain by a few feet of a thick-bedded massive stromatoporoid magnesian limestone, which yielded a few corals, including *Pycnostylus guelphensis*."

N-O 8. SOUTHEASTERN ALASKA.

The Wales "series" of southeastern Alaska comprises argillites, of great thickness but unknown age, and younger limestone, 2,000 feet or more thick, from which Kindle⁴⁹⁶ lists Silurian fossils. He says:

Two horizons of the Silurian have been recognized. The older of these is represented by a small fauna which has been found on the northwest coast of Kuiu Island. In the limestones northeast of Mead Point the following fauna occurs:

Diphyphyllum? sp.
 Conchidium knighti (Sow.).
 Whitfieldella sp.
 Holoepa cf. servus Barr.
 Murchisonia sp.

None of the species are abundant, with the exception of *C. knighti*, which is represented by great numbers of large shells in one thin bed of limestone.

C. knighti is one of the characteristic fossils of the Aymestry limestone of the Ludlow group of England. It is known also from Russia and Bohemia. There appear to be no authentic records of its occurrence in the Silurian faunas of the United States. The nearest equivalent of this fauna in eastern America is the Niagara fauna. While none of the species collected are identical with Niagara species, *Conchidium knighti* is very closely related to *C. nysius* of the Niagaran fauna.

The Kuiu Island fauna occurs in the midst of a limestone series which appears to be 2,000 feet or more in thickness. Other portions of the series which were examined appeared to be barren. Upward these limestones seem to terminate with volcanic breccias, while below they pass into cherts and argillites of undetermined age.

The later Silurian horizon does not appear to be present in the Kuiu Island section. It occurs at Freshwater Bay, where more than a thousand feet of gray limestones, which precede the beds carrying Devonian fossils, outcrop along the south side of Freshwater Bay. The lower two-thirds of this series comprises dark-gray, thinly laminated limestones. Leperditias of an undetermined species occur abundantly in certain beds in the lower part of the series. A few fragments of another and larger crustacean, probably a *Ceratiacaris*, are associated with them. These crustaceans comprise the fauna of the lower 700 feet of the section, so far as discovered.

In the upper 300 feet of the limestones of the section a crustacean fauna predominates, but the types represented are unlike those of the preceding division. One of the conspicuous forms in this fauna is a largely undescribed ostracod provisionally referred to *Isochilina* by

E. O. Ulrich, having a length of $1\frac{1}{4}$ inches. Fragmentary specimens indicate the presence of one or more other species of large ostracods, which together with a new species of *Ceratiacaris* are associated with the large *Isochilina*. Other forms occurring in this portion of the section are *Zaphrentis* ? sp., represented by a single specimen, *Meristella tumida* Dalm.?, and *Megalomus* sp. undt. The *Megalomus* is a large and very thick shelled bivalve comparable in this respect with *Megalomus canadensis* of the Guelph and identical with a species occurring in the limestone at Glacier Bay.

While none of the forms occurring in the two lowest divisions of this section have been identified with known species, the dominance of the large ostracods and the massive-shelled *Megalomus* and thick-shelled *Murchisonias* point to a late Silurian age of the fauna. The horizon represented is apparently about that of the Guelph.

The Silurian fauna of Freshwater Bay is found also at Glacier Bay, to the northwest. A small collection in the National Museum made by Cushman and a much larger collection by Mr. F. E. Wright show the faunas of the two localities to bear the closest resemblance.

The horizon represented by the fauna at Freshwater and Glacier bays is not known as yet elsewhere in Alaska. The Kuiu Island Silurian fauna differs very materially in its facies from other known Silurian faunas of Alaska, but the same horizon appears to be represented by the Silurian found by the writer on the Porcupine River, in northeastern Alaska, during the last summer.

N-O 10. FINLAY AND OMENICA RIVERS.

Beneath the "Devono-Carboniferous" Banff limestone, in the Peace River pass, British Columbia, McConnell^{562b} observed beds containing *Halysites*, which may represent the Silurian. They apparently correspond with the strata holding a similar stratigraphic position and also containing *Halysites*, which occur east of Columbia River on the main line of the Canadian Pacific Railway and immediately overlie graptolite-bearing slates of Black River to Trenton age (Normans Kill fauna). (See p. 191.)

N-O 15-17. SOUTHWEST COAST OF HUDSON BAY.

The mapping of Silurian rocks on the southwest coast of Hudson Bay rests upon collections of fossils from a few isolated localities, which do not suffice to delimit the formation in relation to the Ordovician rocks of the same district. The most noteworthy of these occurrences is at Port Churchill, where fragments of a white limestone yielded fossils related to the Silurian of the Saskatchewan and of Anticosti.⁸¹⁸ Farther south the limestones have been observed and fossils collected, especially on Ekwan and Attawapiskat rivers. Dowling^{291a} states:

The valleys of all the streams entering the western side of James Bay are cut down through the drift deposits to a flat-lying limestone, which forms a wide belt around the west shore of the bay and along the southern shore of Hudson Bay. On the Albany River the upper part of the series is proved to be of Devonian age, and beneath, at a greater distance from sea, Silurian limestones are exposed. These beds probably overlap any older ones that may be beneath and rest directly on the Archean.

Descriptions and lists of fossils may be consulted.^{291, 924}

P 6-7. SOUTHERN ALASKA, COOK INLET TO YAKUTAT BAY.

Metamorphic rocks of sedimentary origin constitute in southern Alaska a great and extensively exposed series, the Valdez group, which is probably chiefly Paleozoic and includes Silurian, but no definite section can be thus correlated. (See note on metamorphic Paleozoic in Alaska, Chapter VII, p. 353.)

P 19. UNGAVA BAY.

Akpatok Island, in Ungava Bay, is described by Robert Bell ^{68a,69} as consisting of a great thickness of "Cambro-Silurian" rocks. The fossils which he collected are stated to represent the "Hudson River" terrane.

According to Low, ^{550b} the fossils of Akpatok Island range from "Lower Galena-Trenton to Lower Helderberg."

P-R 9-10. BEAR RIVER AND MACKENZIE VALLEY.

Bear River, the outlet of Great Bear Lake, passes from Cretaceous to Paleozoic rocks in cutting through a ridge of which Mount Charles is the highest point in the vicinity. J. M. Bell ^{64a} ascended the mountain in 1899 and reports:

Ordovician or possibly Silurian rocks occur at "The Rapid" on the Bear River where the mountain range crosses it. Mount Charles, the most prominent part of these mountains, is a hill of about 1,500 feet in height and consists of a large anticline, embracing subordinate folds. The rocks are interstratified conglomerates, quartzites, and magnesian limestones, the latter of great thickness. I found thin layers of gypsum in several places, interstratified with dark-gray shaly dolomite.

Bell does not cite any fossils. Dawson ^{257c} quotes Meek on the Devonian age of the limestones of the Mackenzie Valley, which were earlier referred to the Silurian by Isbister and others. "Amongst all the collections under examination from various localities along Mackenzie River and its tributaries, between Clearwater River and the Arctic Ocean, a distance by course of the valley of more than 1,000 miles, there are no Carboniferous or characteristic Silurian forms." If Bell and Meek are both correct, the anticline crossed by Bear River brings up Silurian strata not generally exposed along the Mackenzie.

P-S 10-17. ARCTIC REGION.

The southern islands of the Arctic Archipelago are extensively covered by Silurian strata, probably in most places underlain by the late Ordovician, with which they constitute the base of the stratified sediments that dip gently northward from the "Laurentian" gneisses of the mainland. These Silurian deposits are by their fossils so related to the strata occurring near Lake Winnipeg and in the Mississippi Valley as to demonstrate the extent of the sea over northern central North America. Waters affording the same habitat and supporting the same faunas were continuous to the northern shores of Russia and spread widely over Siberia. ^{804, 876}

Dawson's comments on the views formerly held and now deemed reasonable as to the presence of Ordovician strata in the Arctic have already been quoted (p. 222). The following account of the Silurian rocks is Houghton's description as given by Dawson. ^{257f}

The Silurian rocks of the Arctic Archipelago rest everywhere directly on the granitoid rocks, with a remarkable red sandstone, passing into a coarse grit, for their base. This sandstone is succeeded by a ferruginous limestone containing rounded particles of quartz, which rapidly passes into a fine grayish-green earthy limestone abounding in fossils, and occasionally into a chalky limestone, of a cream color, for the most part devoid of fossils. The average dip of the Silurian limestone varies from 0° to 5° NNW., and it forms occasionally high cliffs and occasionally low flat plains, terraced by the action of the ice as the ground rose from

beneath the sea. The general appearance of the rocks is similar to the Dudley limestone and would strike even an observer who was not a geologist. This resemblance to the Upper Silurian beds extends to the structure of the rocks on a large scale. Alternations of hard limestone and soft shale, so characteristic of the Upper Silurian beds of England and America, arranged in horizontal layers, give to the cliffs around Port Leopold (northeast part of North Somerset) the peculiar appearance which has been described by different polar navigators as "buttress-like," "castellated;" this appearance is produced by the unequal weathering of the cliff, which causes the hard limestone to stand out in bands.

A few fossils procured by Hall on the west shore of Kennedy Channel, at Cape Leidy, Cape Frazer, and other points, were examined by Meek,⁵⁸⁴ who reported 12 species and commented:

From the foregoing list, it is believed that geologists will agree that the rocks at this highest northern locality at which fossils have ever been collected belong to the Upper Silurian era. The most remarkable fact, however, is that they are nearly all very closely allied to and some of them apparently in all respects undistinguishable from species found in the Catskill shaly limestone of the New York Lower Helderberg group.

Authorities for the distribution of Silurian strata throughout the Arctic region are given by Dawson^{257e} in his detailed account of the scattered data gleaned by him from the writings of many explorers. The localities noted are named below. Dawson also gives a list of localities at which fossils have been obtained.

P-Q 16-17.....	Southampton Island.
Q 18-19.....	Baffin Land.
R 10.....	Cape Parry; Baring or Banks Land.
R 14-15.....	King William Land and Boothia Peninsula.
R 17.....	Melville Peninsula.
R-S 11-13.....	Mainland Coast, Wollaston and Victoria lands.
R-S 14.....	Prince of Wales Island.
R-S 15-16.....	Gulf of Boothia.
S 15.....	North Somerset.

Jones,^{472a} Salter,⁶⁹² and Schuchert⁷¹² may also be consulted.

Low^{550a} describes an area of Ordovician and Silurian limestones covering all but the northeast coast of Southampton Island, most of Coats Island, and all of Mansfield Island and reappearing on Akpatok Island, in Ungava Bay, though not seen on the intervening southern shore of Hudson Strait. The fossils from the south shore of Southampton Island constitute "a fauna closely resembling that of the Lake Winnipeg basin, and extend over a period from the Galena-Trenton to the Guelph and Niagara."

Q 3. SEWARD PENINSULA.

The Nome group of Seward Peninsula comprises mica schists and probably three massive limestones, which, according to P. S. Smith,⁷⁶⁷ range in age from Cambrian to probably post-Ordovician. The Port Clarence limestone is the oldest division of the Nome group which is known to contain fossils. The faunas of this limestone have been listed by Kindle,⁵⁰³ who states "that a magnesian limestone on Fish River yielded a heavy-shelled lamellibranch comparable with *Megalomus canadensis* and identical with a species which occurs in the limestone of late Silurian age at Glacier Bay and at Freshwater Bay in southeastern Alaska. (See p. 262.)

^a Personal communication, January, 1910.

On the map the Silurian is not distinguished, being included in the unaltered and probably also in the metamorphosed Paleozoic rocks.

Q 5-6. YUKON-TANANA REGION.

The Fortymile group of crystalline limestone and quartzite with some graphitic schist was provisionally correlated by Brooks^{101a} with the Nome group and the Skajit formation of northwestern Alaska. Later investigations by Brooks and Kindle on Porcupine River have resulted in more definite determination of the Silurian age of a massive limestone which may be equivalent to that of the Forty-mile group.

With regard to the Porcupine section, Brooks¹⁰² says: "The Silurian is represented by at least 2,500 feet of magnesian limestone with some quartzites and slates, which are probably conformable to the Ordovician. Its correlation with the Fortymile series of Spurr is suggested but not proven."

Kindle^{498a} gives a list of 37 species collected from this limestone and comments:

The Porcupine River fauna contains species which link it with the Silurian faunas of both Europe and America. Of these *Rhynchotreta cuneata*, *Spirifer nobilis*, and *Pentamerus oblongus* have long been known in both European and American faunas. The peculiar little twisted brachiopod *Streptis greyi* has been recognized at but one other American locality, however. Williams has reported it from the St. Clair limestone fauna of Arkansas. In Europe it occurs in the Silurian of Bohemia, in England, and at the island of Gotland.

The Silurian fauna of the type represented by the species listed here is known to have a wide distribution throughout the world. It is well known in various parts of Europe and has been recognized in regions as remote as China, New Zealand, and Australia. This fauna occurs in a magnesian limestone of considerable thickness—probably 2,000 feet. It is preceded in the section by Ordovician limestones containing Maclureas. It is followed by a somewhat later phase of the Silurian and by the Devonian.

Q-R 5. ENDICOTT RANGE.

The Skajit formation of the Endicott Range, northern Alaska, consists of heavy-bedded crystalline limestone and mica schist, in which a few obscure fossils, apparently Silurian, were found by Schrader.⁷⁰⁸

T 16-17. ELLESMERE LAND.

A thick section of Ordovician, Silurian, and Devonian strata occurs on the north shore of Jones Sound, southern Ellesmere Land, and has been described in detail by Schei,^{550d} as follows:

There are at Havnefjord, in Jones Sound, above some layers of quartz sandstone, which entirely cover the gneiss granite there, a series of limestone conglomerates with marly schists and pure limestones of a thickness of 1,200 to 1,500 feet. These are again overlain by a series of beds at least 2,000 feet thick, of hard, impure limestones, brown or yellowish gray in color and often remarkably heavy.

At South Cape, which is entirely composed of this brown limestone, are found in the lower parts *Maclurea* sp., and *Halysites* sp., referable to the Middle Silurian [probably Ordovician], while west of it, at Bjorneborg, the upper parts of the series contain badly preserved remains of *Orthocerata*, corals, and *Pentamerus* cfr. *tenuistriatus*. Hereafter the upper part of the limestone seems to be equivalent to the older Upper Silurian (Landrover). This brown limestone occurs from South Cape westward to Kobbbugten, in Hell Gate, and is broken at Lille Sandor, tectonic disturbance bringing up the underlying conglomerate series and even the Archean. * * *

On the south side of Rendalen appears the brown limestone of the capes, series A, with a flat dip to the north-northwest; but on the north side of the valley is a division of dark schist [shale], series B, lying conformably above the beds of brown limestone. Associated with these schists, particularly in their lower and upper parts, are numerous layers of pure dark limestone, frequently fossiliferous. In Rendalen and in Kobbebugten, where this same division also appears, a quantity of material was collected, of which 15 species are provisionally determined, among them being *Favosites* sp., *Strophomena* cfr. *euglypha*, *Neristella* in numbers, *Rhynchonella* cfr. *borealis*, *Pentamerus* cfr. *galeatus*, *Spirifer* cfr. *elevatus*. The period of this division in series B is Wenlock.

The upper part of series B appears, among other places, at the headland north of Tunnaldalen, in Hvalrosfjord. Above a black shale containing *Monograptus* sp. and *Leperditia* cfr. *phaseolus* is a bed of fragmentary limestone with *Favosites*, *Strophomena* cfr. *pecten*, *Atrypa reticularis*, *Pterinea* cfr. *sowerbyi*. From a locality in Gaasefjord, on the same horizon, were taken *Favosites* cfr. *hisingeri*, *Favosites gothlandicus*, *Thecia swinderenana*, *Spirifer elevatus*, *Spirifer* cfr. *crispus*, *Strophomena corrugatella* Dav., *Pterinea* sp. According to these, the period of this upper part of series B should be Ludlow. The thickness of the series is about 1,000 feet.

In Hell Gate, as well as in Gaasefjord, these strata are overlain by series C, in its lower parts consisting of interstratified light and dark marl schists, which are somewhat sandy, while in its upper part appear pure quartz sandstone beds and argillaceous sandstone. The collective thickness of these strata is about 1,000 feet in Gaasefjord, while in Hell Gate it is probably somewhat greater. No fossils were found in this series.

At the base of the high cliffs at Indra Eide and Borgen appears series C. In both these places it is overlain by a dark limestone and black shale, partially fossiliferous. This dark limestone and shale are the lowest layers in a series of strata at least 1,500 feet in thickness, series D, which appears in the profiles on both sides of Gaasefjord, from Borgen to the foot of Vargtoppen (Wolf Top), and from Indra Eide to Skrabdalen.

In series Da occurs *Atrypa reticularis* in great quantities, but little else. On the other hand, there are preliminarily determined in Db about 55 species, of which may be mentioned *Favosites* sp. div., *Columnaria* sp., *Cyathophyllum* sp. cfr. *hexagonum*, *Receptaculites* sp., *Fenestella* sp., *Homalonotus* sp., *Burmeisteria* sp., *Dechenella* sp., *Proetus* sp., *Orthis striatula*, *Leptæna* sp., *Strophomena*, *Streptorhynchus*, *Atrypa reticularis aspera*, *Rhynchonella (Pugnax)* cfr. *reniformis pugnax*, *Productus* cfr. *prolongus*, *Spirifer* of the *verneuilli* Murch. type, a peculiar *Pentameride*, *Terebratula* cfr. *Dielasma*, *Pterinea* sp., *Modiolopsis* sp., *Lucina* sp. div., *Bellerophon* sp., *Platyceras* sp., *Orthoceras* sp., *Gomphoceras*, gigantic nautilus, and ganoid scales.

The fauna in Dc is merely a repetition and, in the case of certain species, a further development of the forms found in Db. It will thus be seen that there is a spring in regard to the fauna between the upper layers in series B and the lower ones in series D, which more particularly resemble Lower or Middle Devonian. The concordantly embedded(?) series C might, therefore, be thought to represent uppermost Silurian as well as lowest Devonian.

Divisions Dd and Df are poor in fossils and are partly shale divisions. In the impure limestone of Dg occur again numerous fossils, among which are *Atrypa reticularis*, *Rhynchonella* cfr. *cuboides*, *Spirifer* cfr. *undifera*, *Productus* sp., *Terebratula* cfr. *Dielasma*, *Pterinea* sp., *Avicula* sp., *Modiolopsis* sp., *Pleurotomaria* sp., *Proetus* sp. Traces of placoderm fish are also met with. Above these strata are beds of pure limestone, Dh, and above these again some less pure, Di. The uppermost strata of Di alternate with strata of light-gray quartz sandstone terminating in a clay sandstone, which in places is richly fossiliferous, though the fossils are in a bad state of preservation. Among these are *Lamellibranchiata*, *Dechenella* sp., remains of *Holoptychius*, etc.

This argillaceous sandstone is simultaneously the last link in series D and the first in series E. This is a huge collection of quartz sandstone strata building up the mountains on both sides of the inner part of Gaasefjord. The lowest part, which is 900 to 1,200 feet in thickness, consists almost exclusively of quartz sandstone. On the north side of Skrabdalen

in the sandstone profile, occur conglomerate strata, half an inch to an inch in thickness. In these were found considerable remains of *Coccosteus* sp., *Holoptychius* sp., and *Modolia angusta*. In the same strata with these were also seen indeterminable plant fossils. Slightly higher up in the profile, however, in a black shale which occurred in two lentiform masses, 18 inches and 6 feet in thickness, were found numerous plant fossils.

Prof. Nathorst, of Stockholm, who has kindly undertaken the examination of these, says that among others are *Archæopteris fissilis* Schmalh. and *Arch. archetypus* Schmalh., both characteristic of Upper Devonian. In examining the material collected, Prof. Nathorst also found with the plant remains some remains of fishes.

Low,^{550e} who quotes the foregoing description from Schei, comments on it as follows:

From the above it will be seen that on the southern side of Ellesmere there is a complete succession of strata, bearing fossils from Middle Silurian age up to the Upper Devonian. These strata have an aggregate thickness of 8,000 feet and form the thickest and most carefully measured section of the Silurian and Devonian beds of the Arctics.

The southern shore of Jones Sound presents a different section, which is thus described by Low:^{550f}

On the southern and southwestern parts of North Devon the Silurian strata are much thinner than those described by Schei. At Cuming Creek the Archean gneisses were found overlain unconformably by red and purple arenaceous shales and thin-bedded sandstones having an aggregate thickness of 50 to 100 feet. These in turn were succeeded by beds of impure limestone of light-gray or creamy color. The beds are usually under 2 feet in thickness and separated by thinner beds containing a considerable amount of clay. These light-colored limestones have a thickness of over 1,000 feet in the cliffs on both sides of the creek. The sides of the cliffs are covered with broken limestone, so that it was impossible to measure a section up them, but in two or three places a darker-colored limestone conglomerate was found, made up of small pebbles cemented by a dark shaly matrix. Fossils are only found in the beds immediately overlying the dark shales and sandstones of the base. These show that the lower limestone is of Silurian age, about the horizon of the Niagara.

Similar conditions prevail in the cliffs at Beechey Island, where a large collection of fossils was obtained from the lower limestone beds, while others, picked up loose but evidently fallen from the cliffs above, showed that the upper beds passed close to if not into the Devonian.

Similar Silurian limestones constitute the island of Cornwallis, to the westward of North Devon, while in the remaining Parry Islands farther west the Silurian strata are lost beneath the Devonian and Carboniferous rocks of those islands.

CHAPTER VI.

DEVONIAN.

Color, dark blue.

Symbol, 15.

Distribution: Eastern-central United States, eastern Canada, northwestern Canada, and Cordillera of the United States, Canada, and Alaska.

Content: Devonian as commonly defined through the Appalachians, including Helderberg at the base and higher formations to Chemung and Catskill, inclusive; in the northeast, from Gaspé to New York, Helderberg is included with the Silurian in mapping; in the Appalachian zone south of latitude 38°, the Devonian color on the map includes Silurian; throughout the Cordillera from Mexico to Alaska the Devonian where present is mapped with Carboniferous undivided (14), except that it is distinguished in the Klamath Mountains, California.

Devonian areas.

FIGURE 8.—Sketch map showing the distribution of Devonian rocks represented on the geologic map of North America and the key to references in the text.

H-I 12. SOUTHERN ARIZONA AND NORTHERN SONORA.

The sections at Globe and Bisbee, described by Ransome,^{657a, 659} include limestone which contains late Middle or Upper Devonian fossils. At Globe the formation is continuous upward with Carboniferous (Mississippian) limestone, as are the Ouray limestone of Colorado and the limestones described by Dumble.²⁹⁶

At Bisbee the Martin limestone (Devonian), 340 feet thick in the type section, is distinguished from the Abrigo limestone (Cambrian) below and the Escabrosa limestone (Mississippian) above it. The fauna is described and correlated by Williams,^{658b} who concludes that its affinities are with the Neo-Devonian of New York but that in Meso-Devonian time the fauna occupied the Arizona province in migration from Russia.

Williams comments on the fauna as follows:

The species *Atrypa reticularis* is present in 25 of the 30 faunules. Some one or more of the corals are found in 11 of the faunules. [Six of] the faunules * * * contain several species of the reef-building corals and probably represent a common fauna.

Associated with these corals are species^a which indicate distinctly the fauna so well developed in the Devonian rocks at Rockford, Iowa. On the supposition that *Spirifer hungerfordi* and *Spirifer whitneyi* are characteristic species of that fauna, the following species, associated with them in the Bisbee quadrangle, are now added to it—that is, *Dielasma calvini*, *Productella speciosa*, *Spirifer* cf. *jeremejevi*. These twelve species, at least, are therefore probably present in a common fauna of this Arizona region, which is also represented in Iowa, and is certainly of Devonian age.

Its comparison with New York and northern Appalachian faunas indicates close affinity with a fauna occurring at the base of the Chemung formation of New York, above the typical Ithaca formation. In the High Point zone of Naples, Livingston County, N. Y., the species of the genus *Strophonella* reported is *S. reversa*. The form reported in the above list is *S. cæolata*, which occurs in the *Stropheodonta cayuta* fauna of the southern counties of New York and across the border in Tioga and Bradford counties, Pa., but not, so far as I have observed, in the High Point fauna. In this southern extension it is associated with typical *Spirifer disjunctus*. The *Productella* of the Arizona region is also of the same type as that represented in this upper (Chemung) zone rather than in the underlying typical Ithaca zone of *Productella speciosa*. The evidence is therefore confirmatory of the opinion that this western American fauna did not reach the upper Appalachian region, in its full complement, until after the deposition of the zone of the Ithaca formation.

It is to be observed, however, that in Russia the fauna with which this Arizona fauna shows closest affinity is classed by Tschernyschew as middle Devonian rather than upper Devonian and occurs below the Cuboides fauna. It is also regarded by him as equivalent to the Stringocephalus fauna, which in western Europe is strictly Mesodevonic. This is further correlated by Tschernyschew with the Hamilton group of North America.

* * * * *

There can be little doubt as to the close affinity of the Arizona and Russian faunas here referred to. Comparison of *Spirifer hungerfordi*, as it occurs both in Iowa and Arizona, with Russian specimens of *Spirifer anossofi* demonstrates the two to be closely related, as Tschernyschew maintained; but the rounded cardinal angle as well as coarser radiating striæ mark the figures of *S. anossofi* of Tschernyschew (as well as actual specimens seen by me), from the *Sp. hungerfordi* as it is seen both in Iowa and Arizona. There are figures in the original

^a For list see the work cited.—B. W.

description of De Verneuil, which have the angular terminations of the cardinal area. Also some young specimens from Iowa in my collections show distinctly rounded cardinal angles.

Associated with that species are *Productus hallanus* and *Rhynchonellas* of the Pugnax type (*R. acuminata*), which distinctly belong to this fauna as developed in America.

As I have reported in other places, this *Pugnax pugnus* fauna occurs in the New York section, both in Ithaca and High Point zones, which are both above the representative of the *Cuboides* zone (Tully limestone) of that region, and before the appearance there of the typical *Spirifer disjunctus* fauna. But in New York the species which dominates in the Iowa, Arizona, and Russian faunas (*Spirifer hungerfordi* and *Spirifer anosofi*) is entirely absent, or certainly very rare even if eventually it should be discovered. From this and other similar peculiarities presented by the New York faunas, I am inclined to think that the horizon at which the Pugnax fauna enters the New York sections is later chronologically than that of the formations holding the fauna in Russia, and possibly also appreciably later than the zone marked by it in Iowa and Arizona.

Although *Spirifer whitneyi* presents many characters of the general *Spirifer disjunctus* type, its range in the Russian and also in the west European Devonian confirms this same view. The Arizona fauna does not present any very close affinity with the distinctly Chemung (*Spirifer disjunctus*) fauna of New York.

This earlier age for the *Spirifer hungerfordi* fauna is also indicated by the development of *Productus*. All the representatives of that genus reported from Arizona and from the same fauna as expressed in Iowa indicate an earlier stage of its development than that exhibited by the *Productellas* of the Chemung formation of New York.

From these and other considerations it seems reasonable to adopt Tschernyschew's view that the zone in Russia containing the *anosofi* fauna is the equivalent of the *Stringocephalus* zone of western Europe as well as of the Hamilton formation of North America; and therefore that the fauna is properly a Mesodevonian rather than Neodevonian fauna. On these grounds we should place the formation bearing this fauna in Arizona in the Mesodevonian, although its representatives do not appear in the New York fauna until the opening of Neodevonian time.

The stratigraphic relations of the limestones at Globe and Bisbee exhibit a hiatus from Cambrian to Devonian but the strata are apparently conformable throughout to the close of the Carboniferous.

In the Clifton-Morenci district Lindgren⁵⁴¹ found a formation, the Morenci, which consists of 75 feet of compact fine-grained argillaceous limestone below and 100 feet of clay shale above. The strata are conformable to the Ordovician and Carboniferous. They have yielded a meager fauna, which indicates a Devonian horizon, though it might be Silurian or Carboniferous.

I 12. ARIZONA.

Reagan⁶⁶³ states in regard to the Devonian of the Fort Apache region, in Arizona:

Immediately overlying the Silurian on the periphery are alternating chert and flint strata followed by massive, very fossiliferous light-colored fine-grained marble limestone, which in turn is followed by a grit. This formation, like the Silurian, is exposed as a narrow strip encircling the Ellison dome from the Nantan Mountains on the southeast around by the north-east to the Tonto Basin, where it forms one of the "rim" series of that basin. The strip thus formed is sometimes more than 3 miles wide, though it is usually much less. Besides this belted strip several of the buttes of the Tonto region belong to this formation, one of which is situated 3 miles northeast of Ellison. This butte is called Juniper Butte on the Government

maps, but among the settlers it is called Shell Mound, because of its numerous shell fossils. The formation is Devonian, as is indicated by the fossils obtained, *Orthis livia*, *Spirifer formacula*, and *Acerularia davidsoni*, and corresponds very much to the Devonian formation at the falls of the Ohio.

I 12-13. SOUTHWESTERN NEW MEXICO.

At Kingston, N. Mex., in the southwestern part of the Territory, Gordon and Graton³⁷² observed the occurrence of Devonian limestone similar to the Ouray limestone of Colorado. The fauna of the Ouray has recently been figured and described by Kindle.⁵⁰¹ Lindgren^{542a} states:

The Devonian is present in an area extending from the Mimbres Mountains westward to the Arizona line and everywhere appears as a thin formation of dark clay shales, usually calcareous in the upper portion. The maximum thickness (465 feet) was noted at Silver City. In the Mimbres Range, where Gordon has given the name Percha shale to the formation, it is only 200 feet thick and its upper part contains a rich and characteristic Devonian fauna. The Devonian is not present in the Franklin Mountains of Texas but appears with a thickness of 200 feet at Clifton, Ariz. The Devonian shale is believed by Gordon to overlie the Ordovician limestone with an unconformity of erosion, but the shale and underlying limestone are conformable at Georgetown, Lone Mountain, and Silver City, and also at Clifton, Ariz. At any rate the Devonian period in southern New Mexico was characterized by shallow muddy deposits, uniform over a large area.

I 14-15. SOUTHERN OKLAHOMA.

Taff and Ulrich^{808c} distinguished "Siluro-Devonian" and late Devonian and early Carboniferous strata in the Arbuckle Mountains. The "Siluro-Devonian" rocks were mapped as the "Hunton limestone" and include strata which carry faunas ranging from Clinton to Oriskany. (See pp. 228-230, Chapter V.) The late Devonian and early Carboniferous strata are the Woodford chert, which is described as follows:

Excepting the flinty Oriskany limestone occurring locally at the top of the Hunton limestone and possibly the Helderberg member of the latter, Devonian rocks in the Arbuckle region are limited to a single formation of chert and black shale, known as the Woodford chert. While this chert is apparently conformable with the limestone below in any single locality, it appears that this is not true in a broad sense. The Oriskany beds at the top of the Hunton limestone, consisting of several feet of cherty limestones, are present in one place but do not occur in another. In the northeastern part of the uplift, notably near Franks, cherty limestones are present at the top of the Hunton. Near the western end of the uplift, on the southern side of the Washita Valley, this upper member of hard limestone is absent and the thickness of the entire formation is reduced to a little over 100 feet. In all places there is an abrupt change in sedimentation from the top of the Hunton limestone to the chert or shale of the Woodford formation.

The Woodford chert has an estimated average thickness of 650 feet. It varies somewhat in lithologic character. In places massive chert rests upon the limestone; in other places black shale occurs at the base of the formation. As a rule, however, the formation becomes less cherty from the base upward. It is usually even bedded, occurring in layers from a few inches thick to thin laminae. In places, especially in the northeast side of the uplift, the formation is composed almost entirely of thin, fissile siliceous and distinctly bituminous black shale. In this part of the region, a few miles west of Hunton, lentils of almost pure flints were noted interstratified with the black shale near the base. In the western part of the region bluish shales were seen

interstratified with the black shale in the upper part of the formation. At various positions in the section, especially in the more cherty beds, are small, rounded, marble-like concretions of a calcareous nature. In places there are large segregations of a similar character, concentrically banded, which occur intersecting several layers of cherty shale.

* * * * *

Fossils are very rare in the Woodford chert, and those found are not well preserved. In the lower part of the formation in the western part of the region a small *Lingula* of the type *L. spatulata* Hall and a few conodonts have been observed. In the shales of the upper part the only recognizable fossils seen are two concentrically plicated species of *Productella*, one of which seems referable to *P. concentrica* Hall.

* * * * *

This formation is believed to be of the age of the Chattanooga formation of Tennessee, the Ohio shale of Ohio, and the Portage and Chemung of New York. At the top it doubtless includes strata corresponding in age with the Noel shale of northern Arkansas and the basal shale of the Tullahoma formation of Tennessee, which are believed to be of Kinderhook age, or, according to the present classification, earliest Carboniferous.

At present it is not possible to determine the exact parting between the Devonian and Carboniferous, since there is no clear stratigraphic distinction in the shales, and fossils are rare.

I 15. ARKANSAS.

The Chattanooga shale (Devonian) is represented in northern Arkansas^{6, 656} together with a local basal member known as the Sylamore sandstone. The formation consists of a persistent black shale, with locally a dark phosphatic sandstone or conglomerate (Sylamore member) at the base, and represents a late stage of advance of the sea upon the Ozark land. In places it reaches a maximum thickness of 150 feet, but the areas are too small to be shown on the map.

I 16, J 17. THE APPALACHIAN VALLEY (ALABAMA, GEORGIA, TENNESSEE, THE VIRGINIAS, AND MARYLAND).

Along the trend of the Appalachian Valley and Mountains the Devonian formations exhibit a very marked change. In Maryland their sequence is still complete from the Helderberg limestone up and their thickness in Allegany County is 7,875 to 10,200 feet; but they thin out toward the south, the lower formations appear only locally or not at all, and in Georgia and Alabama the Upper Devonian (Chattanooga shale) overlaps unconformably upon older strata and is reduced to a thickness of 10 or 15 feet only.

The Maryland section is typical for adjacent areas of Pennsylvania and Virginia. Prosser^{646a} in 1901 summed up the results of investigations carried on by the Maryland Survey. He describes the Helderberg limestone (upper part of the Lewistown limestone), as thin-bedded bluish-gray ringed limestone, more or less shaly, 400 feet thick, followed by massive darker-blue limestone to a total thickness of 750 to 900 feet. The strata are fossiliferous and according to Prosser comprise representatives of the Manlius, Coeymans, New Scotland, and Becraft limestones of the New York section. The Cayugan strata (Manlius of Prosser) are now separated from the Helderberg in Maryland.

The Oriskany sandstone Prosser describes as bluish-black cherty limestone, 75 to 100 feet in thickness, above which comes a white calcareous sandstone

350 feet thick, the whole the equivalent of the New York Oriskany and the same as "the Monterey sandstone of the Piedmont folio."

The Romney shale is described by Prosser as consisting of thin black shales, sharply distinguished from the Oriskany, followed by drab and bluish argillaceous to arenaceous shales and thin sandstones, the whole 1,600 to 1,650 feet thick, and as representing the Marcellus and Hamilton of New York. Kindle⁵⁰² has since differentiated the Onondaga in Maryland at the base of the Romney.

Of the Jennings formation, the lower part is composed of thin black argillaceous shales, regarded by Prosser as the equivalent of the Genesee shale of New York; followed by olive to bluish argillaceous shales, regarded by Prosser as representing the Naples of the Portage of New York, and green arenaceous shales, containing a Chemung fauna; the total thickness is 3,800 to 4,000 feet.

The Hampshire formation is described by Prosser as consisting of alternating red, flaggy, and massive sandstones and arenaceous or argillaceous shales, 2,000 feet thick, equivalent to part of the Catskill of New York.

An important description of the Lower Devonian and Silurian of Maryland is given by Schuchert,⁷¹⁴ who lists the species of each horizon and correlates the strata with the New York section.

I-J 16. TENNESSEE, KENTUCKY, AND NORTHWESTERN ALABAMA.

The Devonian formations of Ohio and Indiana thin toward the south where they lap unconformably upon the low land surface of Silurian limestones. Kindle^{403a} states:

The Devonian formations below the New Albany shale are frequently entirely absent in the Kentucky sections, and where present they are usually represented by only a few feet of strata. The Sellersburg beds have not been seen south of Louisville. The attenuated character of the lower Devonian beds in Kentucky has been generally explained as due to thinning out. Prof. N. S. Shaler did not recognize any stratigraphic break at the base of the New Albany shale and regarded it as the equivalent of the New York Devonian formations down to the Oriskany, where the Corniferous was wanting in the Kentucky section. The writer has found sections which show unconformity between the New Albany shale and the beds below in Kentucky. This interval of erosion which has been detected at the base of the Black shale explains the entire absence of the Devonian limestone at many localities and its extreme thinness where present.

According to Schuchert^{711d} and Foerste^{340b} the Devonian formations in western Tennessee represent, where present, Helderberg, Oriskany, Onondaga, and later Devonian time, the highest strata being the black Chattanooga shale. The distribution of these strata is very irregular. In many places they are absent and locally they are represented only by beds from 1 foot to a few feet in thickness. Their normal sequence is as follows: Linden formation (basal Helderbergian age), Camden chert (lower Oriskany age), limestone of Onondaga age, and Chattanooga shale, with phosphatic beds at its base and Hardin sandstone member and shales above.

The following notes on the Linden are abstracted from the article by Foerste:

The Linden at Perryville, Tenn., immediately succeeds the Brownsport (Silurian). It consists of "fairly solid crinoidal rock," 10½ feet, at the base, with comparatively few fossils (*Orthothes worthanus*, *Rhipidomella oblata*, and *Striatopora issa*); softer, partly crinoidal, partly fine-grained rock more or less interbedded with clay, 11½ feet, richly fossiliferous (*Stropheodonta*

beckei, *Strophonella punctulifera*, and *Orthotheses woolworthanus*, common; *Dalmanites micrurus*, not rare; *Uncinulus schucherti*, very scarce); fossiliferous clay, 15 feet; overlain by thin limestone layers, 1½ feet, full of bryozoans. Upon these lies a sandy bed, which may be the Hardin sandstone member, the Camden chert being absent.

In other local sections noted by Foerste the Linden varies in thickness, being 101 feet at Pyburn Landing, on the Tennessee, and thinning rapidly eastward. It is succeeded in some places by the Camden chert, in others by the Hardin sandstone member.

The Camden chert was first distinguished by Safford, who recognized the Oriskany facies of its fauna. It is 60 feet thick at Camden, Benton County; is strongly developed west of Tennessee River in Henry, Benton, and Decatur counties; and thins toward the east. The Camden fauna was collected and studied by Schuchert,^{711a} who states:

The fossils of this formation are, as a rule, natural casts both of the interior and exterior of the organism, and preserve in detail the finest markings. This fauna is closely related to that described by Meek and Worthen^a from the "Clear Creek limestone" of southern Illinois, in Alexander, Jackson, and Union counties. From this region are known but 11 species, and 8 of these are also found in Tennessee. They are *Anoplia nucleata*, *Anoplothea flabellites*, *Eatonia peculiaris*, *Spirifer worthenanus*, *S. hemicyclus*, *Megalanteris condoni*, *Amphigenia curta*, and *Strophostylus cancellatus*.

The "Clear Creek limestone" of Illinois is intimately connected with the Helderbergian below and is not less than 200 feet thick, being followed by a "quartzose sandstone" from 40 to 60 feet in depth. The latter is probably equivalent to the Upper or typical Oriskany of New York and does not appear to be present in western Tennessee. From Prof. Safford's description of the Camden chert, it is evident that the Lower Oriskany thins rapidly southward. In Tennessee it is about 60 feet in thickness, while it is not less than 200 feet thick in Illinois, exclusive of the Upper Oriskany, which is entirely absent in the former State.

The Camden chert fauna contains 32 species, and 6 of these are restricted to southern Illinois and western Tennessee. Of the entire fauna, 24 species are found either in the Helderbergian or in the Lower Oriskany of other regions, and 20 occur in the Upper Oriskany, or Onondaga. After removing the 13 species common to both the Lower and Upper Oriskany and the 2 restricted forms, 17 remain. Of these 10 occur either in Helderbergian or Lower Oriskany rocks of other regions, while 6 are found in higher beds. This evidence, therefore, indicates clearly a Lower Oriskany age for the Camden chert of Tennessee and the "Clear Creek limestone" of Illinois, which indication is the more marked because of the absence of such characteristic Upper Oriskany species as *Hipparionyx proximus*, *Chonostrophia complanata*, *Spirifer arenosus*, *Rensselaeria ovoides*, *Meristella lata*, *Camarotæchia pleiopleura*, *C. barrandei*, or *C. speciosa*.

Concerning the representative of the Onondaga in western Tennessee, Foerste^{340c} says in part:

On the western flank of the Cincinnati geanticline, along Harpeth River, between Newsom and the bridge west of Pegram, the Silurian is directly overlain by a thin bed of Devonian limestone, varying in thickness from 12 feet at the west to 3 feet at the most eastern point of outcrop. * * * *Nucleocrinus (Olivanites) verneuili* is a characteristic species. *Stropheodonta demissa*, *Stropheodonta perplana*, *Rhipodomella penelope*, and *Nucleospira concinna* are also found. This white and comparatively pure limestone is overlain by a darker and more sandy limestone.

^a Geol. Survey Illinois, vols. 1, 2, and 3.

Foerste notes another occurrence, 4 miles north of Bakerville, where a limestone 3 feet thick has yielded *Heliophyllum* and *Blothrophyllum*, closely resembling forms in the "Corniferous at the Falls of the Ohio, Louisville, Ky." Several species of *Cystiphyllum*, *Cyathophyllum*, and *Cladopora*, a very large form of *Atrypa reticularis*, and *Reticularia fimbriata* were found. These occurrences he correlates with the Jeffersonville limestone of Kentucky and Indiana, regarded as the equivalent of the Onondaga limestone of the East.

The Chattanooga shale and its members, the Hardin sandstone and the Maury green shale of Safford, in western Tennessee are described by Hayes and Ulrich ^{431c} as follows:

Excepting the bottom and top, which will be described separately, the mass of this formation is a nearly black, rather tough bituminous shale, splitting generally into thin plates. It is the well-known and sharply defined formation so often called the Black shale. The formation as a whole is remarkably persistent in its distribution, being found nearly everywhere in Tennessee and adjoining States to the south, west, and north, where its proper horizon is exposed. Its occasional absence is due either to nondeposition or to erosion preceding Carboniferous deposition. Generally throughout middle Tennessee there is at the base of the formation a thin bed which is entirely different in character from the black shale above. In the western part of the Columbia quadrangle, particularly in the valley of Swan Creek, this bed consists largely of calcium phosphate and forms the source of the Tennessee black phosphate. Its appearance varies somewhat from place to place, as well as its chemical composition. It may be gray, bluish black, or black in color, and it may be composed of grains large enough to be seen by the naked eye or may have a dense, fine-grained structure. When examined with the glass small oval grains are generally found to be more or less abundant, sometimes making up the mass of the rock. These have polished surfaces and a brown or amber color. In many cases they are the casts of minute coiled shells. The phosphate bed passes by gradations laterally into a bed of coarse sandstone or conglomerate containing varying amounts of phosphate. The grains are in part phosphatic ovoids and in part quartz, with less abundant waterworn fragments of other rocks and fish bones.

The phosphate bed is also replaced, particularly toward the southwest, in Hardin, Wayne, and Perry counties, by a fine-grained gray or black sandstone, which reaches a maximum thickness of 12 feet in Hardin County, where it has been called the Hardin sandstone by Safford. It may consist of a single massive bed or may have a shaly structure, and is generally more or less phosphatic.

It is evident that the black phosphate, the conglomerate, and the fine sandstone are merely three phases of the same member of the Chattanooga formation and represent deposition during approximately the same time, their difference in composition being due to differences in the sources from which their materials were derived. Occasionally, and this is particularly true of areas in which the Chattanooga formation rests on the Clifton and Fernvale formations, the conglomeratic phosphate layer is replaced or represented by black shale like that making up the body of the formation. Except in these cases the basal bed everywhere follows a more or less easily determined unconformity, and was deposited over a nearly submerged land surface. This subsidence began in the Oriskany and, continuing through the Onondaga and Hamilton ages, resulted finally in the submergence of the whole of the middle Tennessee dome. This submergence occurred in the Portage and continued through the Chemung, these late Devonian ages being represented by the Chattanooga shale.

At the top of the formation there is very generally a thin stratum of greenish shale and earthy sandstone, which has recently received the designation "Maury green shale" from Prof. Safford. He says it ranges "from a few inches to 4 or 5 feet in thickness;" but so far as our observation is concerned, it does not exceed 2 feet in this area and usually varies between 12 and 18 inches. Nearly always this green shale has embedded in it smooth dark nodules or

concretions of lime phosphate. The nodules vary greatly in size, shape, and relative abundance. Some are spherical and from a half to several inches in diameter; others are flattened or irregular ellipsoids, sometimes as much as 2 feet in length and over 6 inches thick; and they may be loosely disposed in the shale, or closely packed. The green color is due to the presence of glauconite or greensand, a silicate of iron and potash. Rarely, as in the upper part of East Fork of South Harpeth Creek, the green shale is absent or not distinguishable, and in these cases the black shale seems to pass very gradually into overlying green shale, which constitutes the base of the full Tullahoma section.

Fossils are almost if not entirely restricted to the lower member of the Chattanooga formation. In the dark-gray variety of phosphatic rock, which is really a conglomerate, casts of minute coiled and bivalve molluscan shells, washed out of the Ordovician rocks forming the surface of the land that was being gradually submerged, are very abundant. Waterworn bones of large fishes not infrequently occur with them. In the basal shale and fine-grained sandstone a species of *Lingula*, probably *L. spatulata*, is frequently seen, while the shiny teeth, jaws, and cephalic plates of conodonts, supposed to be small fishes related to myxinoids, are often found, sometimes in great numbers.

In the table of correlations of the Columbia folio ^{431a} the Chattanooga shale of western Tennessee is placed as the equivalent of the Portage and Chemung of New York.

J 15-16. MISSOURI AND ILLINOIS.

A narrow belt of thin Devonian strata extends from southern Illinois northward into Missouri as far as Jefferson City. Keyes ⁴⁹¹ distinguished the Grand Tower limestone, 100 feet, and the Callaway limestone, 70 feet thick, the latter overlain by Kinderhook (Carboniferous) strata. The Grand Tower he referred to the Oriskany and Onondaga epochs, and the Callaway to the Hamilton epoch. The Onondaga fauna was also recognized by Weller ⁸⁷⁹ near Grand Tower, Ill. Buckley, ¹⁰⁶ in a recent paper, describes the Devonian of southeastern Missouri as composed of Clear Creek limestone (Oriskany age), at the base, overlain by Grand Tower limestone (Hamilton and Onondaga age), with the Sulphur Springs formation, composed of several members, at the top. Weller ⁸⁸² and Ulrich ^a regard the Sulphur Springs formation as being of Mississippian age and a part of the Kinderhook.

The relations of the Devonian strata of northeastern Missouri to those of Iowa, the significance of the unconformity between the Silurian and Carboniferous in central Missouri, and the correlation of the Devonian of southern sections are considered by Keyes ⁴⁹² in a general paper.

The Devonian of Illinois has been discussed by Weller ^{875; 883} and Savage. ^{703b}

Weller's article in 1897 is a detailed study of the zones which may be recognized in the "Bake Oven" section, near Grand Tower, on Mississippi River. He distinguished seven conspicuous divisions comprising 26 faunal zones, from each of which he gives a list of fossils. He concludes: ^{875a}

It is believed that the facts here set forth satisfactorily demonstrate that the Devonian faunas in southern Illinois are not related to the Iowan Devonian faunas, as has sometimes been suggested, but are a western extension of the faunas of the New York province. At the "Bake Oven" section the fauna of the lowest beds is of an age corresponding to the lower portion of the Upper Helderberg period, while the uppermost faunas are of Hamilton age. The line of demarcation between the Upper Helderberg and Hamilton faunas can not be exactly drawn.

^a Personal communication.

The discussion by Savage ^{703b} is in part as follows:

The rocks of Helderbergian age in Illinois correspond with the New Scotland formation of New York. They succeed the Clinton after an exceedingly long land interval, represented by all of the Silurian after the Clinton, and the Coeymans of the Lower Devonian.

* * * * *
 The New Scotland formation in Union and Jackson counties has an aggregate thickness of more than 160 feet. The lower portion, for a thickness of 100 feet, consists of shaly limestone with interbedded bands of chert. * * * In the cut made by the Frisco Railroad Co. a short distance south and west of Tower Rock 10 species were collected. * * *

The upper 58 feet of the New Scotland formation is composed of light-gray, heavy-bedded, coarsely crystalline limestone. * * * The beds furnished 17 species.

The Clear Creek formation consists of light-gray to yellowish colored cherts that are usually in thin layers, but which in the lower part are sometimes 3 to 5 feet in thickness. * * *

This formation rests, with erosional unconformity, upon the New Scotland beds at the south end of the Back Bone Ridge. It corresponds in age to the Camden cherts of western Tennessee. The beds represent deposits of the Upper Oriskany time, as is indicated by the interwedging of the upper chert layers with those of the basal portion of the succeeding Onondaga. The chert formation has a thickness, in Illinois, of about 327 feet. Fossils are somewhat rare in the lower portion, but in the middle and especially in the upper portion there is a rich fauna.^a * * *

The sedimentation of the Upper Oriskany time continued without a break into the Onondaga or Corniferous. The latter period was initiated by disturbances to the westward, in Ozarkia, which increased mechanical sedimentation in the Illinois area. These resulted for a time in the deposition, along the eastern shore of Ozarkia, of layers of sand containing Onondaga fossils alternating with the return of the Oriskanian limestone conditions. Eventually sand deposition prevailed and there was spread over the basin the basal sandstone of the Onondaga formation, containing [10 species].

Early in the Onondaga time an elevation in the southern portion of Union and in Alexander County put a stop to further deposition in these regions, while farther north, in Jackson County, sedimentation was uninterrupted.

At the cut through the Back Bone and at the Bake Oven, a short distance north of Grand Tower, there is exposed a continuous section of the Onondaga formation showing a thickness of 115 feet. The beds consist largely of light-colored, regularly bedded, more or less crystalline limestone, which becomes arenaceous in the lower part. Fossils are abundant throughout the section.^a * * *

During the Onondaga and the succeeding Hamilton time the warm waters from the Gulf region, with their successive faunas, spread toward the northeast across Illinois and Indiana, passing around the north end of the Cincinnati axis, and mingled with those of the eastern embayment in western New York. Such water connections permitted continued migrations within this sea and account for the close correspondence between the various Middle Devonian faunas of southwestern Illinois and those of western Ontario and New York.

Throughout Hamilton time the Kankakee barrier, or peninsula, extending from Ozarkia toward the northeast across Illinois, was largely effective in preventing the waters of the Interior or Mississippian sea from uniting with those of the northwestern or Dakotan basin toward the northwest. As a result of this separation the deposits and the faunas of Hamilton time, in Illinois, belong to two distinct provinces. The phase of the Hamilton in the vicinity of Rock Island and in Jersey and Calhoun counties belongs to the northwestern or Dakotan province; while that of southwest Illinois belongs to the New York province.

The New York faunal phase of the Hamilton is well developed in the south part of Union County, in the N. $\frac{1}{2}$ sec. 34, T. 13 S., R. 2 W.; and farther north in the NE. $\frac{1}{4}$ sec. 34, T. 11 S., R. 2 W. The formation is also represented in the upper beds near the north end of Back Bone Ridge, in Jackson County.

^a For list of fossils see the work cited.—B. W.

At the first-mentioned exposure there is at the base of the Hamilton 28 feet of yellowish-blue shale, which contains *Leiorhynchus limitare*. Both the character of the sediment and the fossils remind [one] decidedly of the Marcellus shale of New York. This shale rests unconformably (erosional) upon the basal sandstone member of the Onondaga. It is succeeded by a few feet of limestone, which in places is much leached and very fossiliferous, *Athyris spiriferoides*, *Delthyris sculptilis*, *Rhipidomella penelope*, *Spirifer granulosus*, and *Stropheodonta concava* being very common. At points farther north the lower beds of the Hamilton consist of dark-colored impure limestone which succeeds the Onondaga without any apparent break. The characteristic fossils of these layers are *Microcyclus discus*, *Athyris vittata*, *Eunella attenuata*, *Spirifer fornacula*, *Conocardium cuneus*, and *Onychodus sigmoides*.

The middle portion of the Hamilton limestone is dark colored and evenly bedded and contains *Ambocælia umbonata*, *Chonetes yandellanus*, *C. pusillus*, *Cranæna romingeri*, *Parazyga hirsuta*, *Pholidops oblata*, and *Spirifer pennatus*. Above this horizon occurs about 25 feet of yellowish-brown impure siliceous limestone with few fossils. Near the top of the formation come in a few feet of hard gray limestone containing *Chonetes coronatus*, *Rhipidomella vanuxemi*, *Spirifer audaculus*, *S. pennatus*, *Tropidoleptus carinatus*, and *Vitulina pustulosa*.

During Upper Devonian time the Mississippian sea continued to expand, spreading the materials of this formation more widely than the preceding. In the NE. $\frac{1}{4}$ sec. 34, T. 11 S., R. 2 W., the lower deposits of the Upper Devonian are conformable upon the Hamilton. There is here exposed a thickness of 33 feet of yellowish-brown (black where unweathered) siliceous shale or shaly limestone, cherty near the top, and marked by *Leiorhynchus globuliformis*, *L. mesacostalis*, *Reticularia lævis*, and *Spirifer pennatus*. At other points the upper cherty phase is succeeded by 50 or more feet of greenish to black, almost barren shales. These siliceous and dark-colored shales are probably the equivalent of the "calico rock," a mottled and leached siliceous shale, present farther south in Union and Alexander counties. They doubtless correspond with the Chattanooga black shale, Ohio black shale, New Albany black shale, and the Lower Portage beds of other States.

Generalized section of the pre-Mississippian strata in southwestern Illinois.

System.	Correlations.	Location of sections.	Descriptions of horizons.	Feet.
Devonian.	New Albany black shale=Chattanooga black shale=Ohio black shale=Lower Portage, 86 feet.	NE. $\frac{1}{4}$ sec. 34, T. 11 S., R. 2 W., and SE. $\frac{1}{4}$ sec. 1, T. 13 S., R. 2 W.	Greenish-blue shale, fossils almost none.....	29
			Black shale with few fossils, but carrying numerous very small balls of iron pyrite from $\frac{1}{8}$ to $\frac{1}{2}$ inch in diameter.....	21
			Brown to black, siliceous shale or shaly limestone with <i>Leiorhynchus globuliformis</i> and <i>Reticularia lævis</i>	36 $\frac{1}{2}$
Devonian.	Hamilton, 70 feet.	NE. $\frac{1}{4}$ sec. 34, T. 11 S., R. 2 W., Union County. Section at Back Bone near Grand Tower.	Light-gray siliceous limestone, in part oolitic, characterized by <i>Chonetes coronatus</i> , <i>Cranæna romingeri</i> , <i>Spirifer pennatus</i> , <i>S. audaculus</i> , <i>Tropidoleptus carinatus</i> , and <i>Vitulina pustulosa</i>	7
			Yellowish-brown siliceous or shaly limestone with few fossils.....	25

J-K 11-12. GREAT BASIN, NEVADA AND UTAH.

In the Eureka section, Nevada, the Lone Mountain limestone (Ordovician) passes by imperceptible gradations upward into the Nevada limestone, which is followed by the White Pine shale, both assigned to the Devonian by Hague and measuring about 8,000 feet. Hague^{391b} describes the relations as follows:

The Lone Mountain and Nevada limestones taken together present an immense thickness of beds, lying between the Eureka quartzite and the White Pine shale. Together they measure about 7,800 feet in their broadest development. The division into Silurian and Devonian is based mainly upon paleontological grounds. The transition in sedimentation from characteristic Silurian to unmistakable Devonian is so imperceptible that a boundary between them is impossible to establish, and, as is usually the case where the beds form a continuous, conformable limestone series, a line of separation based upon faunal changes must always remain more or less arbitrary. Lithologically, in their broader features, the Silurian and Devonian limestones are quite distinct; it is only in the intermediate beds that no line can be drawn. The light-gray and white siliceous beds that form the mass of the Lone Mountain present a wide vertical range, and in these beds are occasionally seen obscure impressions of Niagara corals, and in other localities, in similar rocks not much higher up in the series, occur *Atrypa reticularis* and other forms foreshadowing the Devonian. It is known that the characteristic Lone Mountain beds carrying *Halysites catenulatus* extend for nearly 1,500 feet above the Eureka quartzite, and that beds easily identified by their organic remains bring the Devonian down to about 6,000 feet below the summit of the great limestone belt lying between the Eureka quartzite and the White Pine shale. *Halysites* and *Atrypa reticularis* were never found associated

together, although it can not be definitely stated that the former fossil does not appear as low down in the limestone as the highest occurrences of the characteristic coral.

* * * * *

Conformably overlying the Nevada limestone occurs a heavy body of black shale, which has been designated as above, it having been first recognized as a distinct horizon in the White Pine mining district to the southeast of Eureka. It occupies a clearly defined stratigraphic position with a marked change of sedimentation and a fauna distinct from both the underlying and overlying horizons.

* * * * *

Impressions of plants, which are exceedingly rare in Paleozoic rocks of the Great Basin, are very abundant and form a distinctive feature of this epoch, notwithstanding that everything which has been collected has been of a fragmentary nature. The most promising specimens for identification were submitted to Sir William Dawson, who, in his report, called attention to the poor state of preservation of the plants. Under date of Montreal, June 11, 1889, he writes:

“One slab contains a small ribbed stem referable to Goeppert’s *Anarthrocanna*, a doubtful Calamitean plant. The specimen is not unlike those found at Perry, in Maine, and Bay de Chaleur. On the large slab is also a slender branch stem which I suppose may be the stipe of a fern, and from its character and angle of ramification probably belongs to the genus *Aneimites*, but no trace of the pinnæ can be seen. The evidence, so far as it goes, would indicate the Upper Devonian (or Erian, as I prefer to call it), rather than the Middle Devonian or the Lower Carboniferous.”

It will be seen that this determination as to the age of the plants is quite in accord with the geological position of the beds above the Nevada limestone of the Devonian and directly below the Diamond Peak quartzite of the Carboniferous.

Girty^{363c} in 1905 tentatively placed the White Pine shale in the Carboniferous and correlated it with the Caney shale of Arkansas. He says:

In the White Pine district of Nevada the beds called “Lower Carboniferous” by Mr. Walcott, which are suggested to be of Pottsville age, are underlain by a black shale—the White Pine shale—which he assigned to the “Upper Devonian.” I have long been of opinion, however, that the age of this bed is not Devonian, but Carboniferous. The White Pine fauna, however, is not without forms suggestive of the Devonian, to which period it was also tentatively assigned by Meek. One of the most striking of these is a *Leiorhynchus* resembling *L. quadricostatum*. *Productus hirsutiformis* and a *Posidonomya* (*Posidoniella*?) also lend it a Devonian aspect. A *Leiorhynchus* like *L. quadricostatum*, a *Productus* like *P. hirsutiformis*, similar *Goniatites*, and similar *Posidoniellas*, are found near the base of the Caney shale in Indian Territory, and in the Spring Creek limestone and Fayetteville shale of Arkansas. These facts, together with a similarity in lithologic character and an identity in stratigraphic position, in point of which each occurrence is immediately beneath beds supposed to represent about the same horizon, while not sufficient to demonstrate stratigraphic equivalence, for which a thorough comparison of the entire faunas would be necessary, lend a strong color of probability to it.

Eastward from Nevada the Devonian thins notably. It was supposed to be represented in the Wasatch section by the Ogden quartzite of King,^{505a} but the formation has since been determined to be the Middle Cambrian quartzite repeated by an overthrust. Blackwelder^{84e} says:

Kindle^a has recently shown that the Jefferson limestone of Montana, with a sufficient Devonian fauna, extends southward into the mountains of Utah, and he has traced it along the east side of Cache Valley, in the Bear River Range. He has also identified in the same locality a limestone containing Silurian fossils conformable beneath the Jefferson formation.

^a Kindle, E. M., Bull. Am. Paleontology No. 20, Ithaca, N. Y., 1908.

It was to be expected that the same formations would soon be found also on the west side of Cache Valley, in the Wasatch Range proper. As exposed on the crest of the range, there is, between the Ordovician quartzite and the identifiable part of the Mississippian limestone, a succession of dark limestones, with some ash-gray brittle dolomites having a thickness of 1,000 to 1,500 feet. In the lowest beds there are corals such as *Halysites* and *Favosites*. At a slightly higher horizon there are abundant shells, which Kindle thinks are the same as his *Pentamerus* fauna of the Bear River Range. All the specimens, however, are poorly preserved, and show best upon the weathered surfaces. Between the Silurian horizon and the fossiliferous Mississippian there is a thick, dark limestone which corresponds satisfactorily with Kindle's Devonian Jefferson formation east of Cache Valley. Further search may be expected to reveal the Jefferson fauna in these beds.

Kindle^{498b, 499b} examined the sections in several canyons south of Logan Canyon, in the northern part of the Wasatch Mountains. He distinguishes 1,000 to 1,200 feet of dark magnesian limestones as Devonian, the equivalent of the Jefferson limestone of Montana. The formation lies between Silurian and Mississippian limestones. (See p. 320.)

In the Uinta Range the Devonian is not present, the Ordovician quartzite being immediately overlain by limestones of lower Mississippian age.

In the Grand Canyon section, Arizona, a limestone 94 feet thick is classed as Devonian by Walcott.⁸⁵² It rests on Cambrian rocks, as does the Ouray limestone in some areas in Colorado, and is overlain by the Redwall limestone (Carboniferous), 962 feet thick. In Gilbert's original account^{360a} of the Redwall he says: "The base of the system is arbitrarily assumed at the first marked lithological change, and it is not impossible that it has been placed so low as to include Devonian, or even Upper Silurian, if those formations are represented in the series."

B. S. Butler^a has recently found Devonian underlying Mississippian limestone in the Star Range, Beaver County, Utah.

J-K 12-13. WYOMING AND COLORADO.

In western Wyoming the Devonian is represented by the Jefferson limestone. It is not present in the Bighorn Range, according to Darton, and does not occur near Rawlins, according to Kindle. Blackwelder says that it probably occurs in the Teton and Gros Ventre mountains and perhaps in the northwestern part of the Wind River Range.

In southwestern Colorado the Devonian is represented by the Elbert formation and the lower part of the Ouray limestone. The Elbert consists of calcareous shales, thin limestones, and local quartzite beds, characterized in many places where shaly by casts of salt crystals and carrying at several horizons fish remains of Upper Devonian age (*Bothriolepis* and *Holoptychius*). It usually rests unconformably upon the Cambrian (Ignacio quartzite). It is conformable to the overlying Ouray limestone, the division between the two being marked by a band of red shale, the top of the Elbert. The Ouray limestone is in greater part dense and compact, yellowish, somewhat sandy in the lower layers, and in places coarsely crystalline in the upper ledge. It is 100 to 250 feet thick. The lower part contains a Devonian fauna and the upper part a Mississippian (lower Carboniferous) fauna.

^a Personal communication.

No line of division can be traced between the two, however, and therefore all the beds are included in one formation.

Girty¹⁹⁴ states:

In general the Devonian fauna of the Ouray belongs to upper Devonian time. It is but distantly related to the Devonian faunas of New York, and its relation to those of the Mississippi Valley, or even to other known western Devonian faunas, is not close. It shows many points of approximation to the Athabascan fauna described by Whiteaves and is somewhat strikingly similar to the Devonian of Russia.

J-K 17-18. SOUTHEASTERN PENNSYLVANIA, MARYLAND, AND VIRGINIA.

Until recently the Onondaga has been supposed to be absent from the Allegheny region south of northeastern Pennsylvania. In regard to the occurrence of the Onondaga Kindle^a says:

This fauna, in a slightly modified form, extends southward from New York through the Allegheny region as far as the northern boundary of Tennessee. The Onondaga fauna occurs throughout this region in the lower part of what has been called the Marcellus shale in the Pennsylvania reports, the Romney shale in Maryland and northern Virginia, and the base of the Chattanooga shale in southwestern Virginia. The beds holding this fauna in the Allegheny region represent an argillaceous facies of the Onondaga. They are chiefly drab or olive-green shales with more or less argillaceous limestone interbedded. This set of beds is separated from the Hamilton above by fissile black shales differing in no important features from the Marcellus shale of New York.

Swartz⁸⁰⁵ has identified the Portage and Chemung in western Maryland. He describes local sections, gives extended lists of faunas, and concludes:

It is very difficult to determine [the Portage-Chemung boundary] when the brachiopod facies of the Portage immediately underlies the Chemung. Of the New York section Clarke remarks: "It is extraordinarily difficult to fix on a division plane between the Ithaca and the overlying Chemung faunas." If this be true in New York, it must be still more true when an attempt is made to correlate that section with those of other States, and the results attained must be open to revision as fuller investigations give increased data. Nevertheless, it seems reasonably probable from the preceding studies that the horizon in question is to be placed between the strata bearing the *Spirifer disjunctus* and *Spirifer mesacostalis* faunas, giving the following succession:

Chemung, *Spirifer disjunctus* fauna.
 Portage { *Spirifer mesacostalis* fauna.
 { *Spirifer pennatus* var. *posterus* fauna.
 { Naples fauna.
 Genesee, Black shales with *Buchiola* fauna.

Lithologically the horizon is not well defined, the conditions varying at different localities. In general the Portage is characterized by smooth fissile shales and interbedded sandstones and the Chemung by a larger percentage of sandstones, while its shales are softer and break with a hackly fracture. The transition from Portage to Chemung is, however, not sharply defined by any lithological features.

Certain facts seem to harmonize with those of New York.

1. The general succession of forms seems to be that of New York: At the base occurs the Genesee, thinning eastward, followed by the Naples fauna of the Portage. Above the latter is found *Spirifer pennatus* var. *posterus*, succeeded by *Spirifer mesacostalis*, and finally by *Spirifer disjunctus*.

^a Comment on manuscript.

2. There is a greater development of the Naples fauna in the west and of the Ithaca fauna in the east.

3. The shore line was probably eastward, as indicated by the fact that there is a marked development of conglomerates eastward, as at Millstone. These diminish toward the west, where the lower Jennings is largely composed of argillaceous shales, as at Allegany Grove.

The thinning of these formations southward through the Virginias may be traced in general stratigraphic terms in folios of the Geologic Atlas of the United States by Darton^{226, 228, 229, 231} and Campbell;^{121, 123, 124, 125} also in other papers by Darton,²²¹ Campbell,¹²² and Prosser.⁶⁵⁰

Devonian formations in Piedmont, Franklin, Staunton, and Monterey quadrangles.

System.	Formation.	Thickness (feet). ^a				General character.
		Piedmont.	Franklin.	Staunton.	Monterey.	
Carboniferous (Mississippian).	Pocono sandstone.	30-80	85-700	700	70-90	Conglomerate and sandstone.
Devonian.	Hampshire formation.	2,000-2,300	1,600-2,200	1,000-1,400	1,500-1,800	More or less thinly bedded sandstone and shady shale, generally red, with gray and greenish-gray beds.
	Jennings formation.	3,300	2,100-3,800	2,800-3,400	3,000-3,800	Gray to buff sandstone interbedded with gray, olive, and buff shale.
	Romney shale.	1,100-1,300	1,100-1,300	600-1,000	1,000-1,300	Shale, black and fissile below, with thin limestone layer, lighter colored and more sandy above.
	Monterey sandstone.	215-300	200-300	0-300	50-200	Calcareous sandstone, weathering to brown porous sandstone.
Silurian.	Lewistown limestone.	[In part equivalent to Helderbergian (Devonian). See Chapter V, p. 239.]				

^a The measurements range south through the Piedmont, Franklin, and Staunton quadrangles from latitude 39° 30' to 38° and west from the Staunton to the Monterey, longitude 79°-80°, in West Virginia and Virginia.

Two quadrangles which lie southwest of the Monterey quadrangle, between 80° and 81° west and 37° 30' and 38° north, have not been surveyed. Next southwest come the Pocahontas and Tazewell quadrangles (81°-82° west, 37°-37° 30' north), which have been mapped by Campbell.^{123, 124} In the interval the distinction between the Jennings and Hampshire is lost, as shown in the following section from the Pocahontas and Tazewell folios:

Devonian formations in Pocahontas and Tazewell quadrangles.

System.	Formation.	Thickness (feet).		General character.
		Poca- hontas.	Taze- well.	
Carboniferous.	Price sandstone.			(Transition; no distinct boundary.)
Devonian.	Kimberlingshale. [Approximate equivalent of Jennings and Hampshire.]	3,000-3,250	2,000?-3,000	Green, sandy shale and thin sandstone containing one or more beds of quartz conglomerate near the top.
	Romney shale.	400-600	300-500	Black carbonaceous shale.
Silurian.	Giles formation (Oriskany and Lower Helderberg).	30-200	100-200	Coarse yellow sandstone. Cherty limestone. Coarse reddish sandstone. Blue limestone.
	Rockwood formation (Clinton).			

Kindle's collections from southwestern Virginia have shown that the typical Chemung fauna extends southwestward as far as Bland County and that the greater part of the Kimberling shale is the equivalent of the Chemung of New York.^{938a}

The portions of the Pocahontas and Tazewell quadrangles in which the preceding sections were observed lie in southwestern Virginia. In the extreme southwestern part of the State, 30 miles beyond them, is the Estillville quadrangle, which presents the following section north of Clinch River according to Campbell:¹²¹

Devonian formations in Estillville quadrangle.

System.	Formation.	Thickness (feet).	General character.
Carboniferous.	Newman limestone.	700-930	Pure blue limestone in the lower part; cherty toward the base.
Devonian.	Grainger shale.	420-500	Calcareous sandstone above sandy shale, merging into black shale below.
	Chattanooga black shale.	530-1,000	Chiefly black carbonaceous shale; with ash-colored sandy member in the middle.
Silurian.	Hancock limestone. [a]	180-275	Blue fossiliferous limestone, very sandy at the top and bottom.

^a According to Kindle (personal communication) the Hancock limestone is of Silurian age in lower part and of Devonian age in upper part.—B. W.

The change of names from the Tazewell to the Estillville quadrangle indicates the uncertainty attending the selection of formational and also of systemic boundaries in the two sections. The relations of the Kimberling shale to the Grainger shale and of the Romney shale to the Chattanooga shale have not been traced across an unsurveyed gap of a few miles. The Grainger may include part of the basal Mississippian.

The Grainger shale has been mapped by Keith through the Morristown and Maynardville quadrangles, Tennessee, to the vicinity of Knoxville (longitude 84° west, latitude 36° north), and it is accompanied by the Chattanooga shale, which extends beyond to Georgia and Alabama.

Along the base of the Cumberland escarpment across Tennessee, from the Briceville through the Kingston and Chattanooga quadrangles, into Georgia, the Devonian is represented only by the Chattanooga shale, which ranges in thickness from 80 feet in the northeast to as little as 10 feet in the south. In its occurrences in Georgia and Alabama the Chattanooga shale is remarkable for the persistency with which it retains its character, although everywhere very thin.

In the Coosa Valley of Georgia and Alabama the Frog Mountain sandstone (of Oriskany age) lies unconformably upon Ordovician rocks. Hayes⁴¹⁸ described the occurrence as follows:

There are between Indian and Weisner mountains several small areas occupied by a formation which comes in contact with all the older formations thus far described. It consists of coarse ferruginous sandstone, in some places white, resembling quartzite, and in others yellow or gray and weathering to incoherent beds of sand. Beneath this sandstone and usually deeply covered by its débris are shales, also variable in composition and appearance. No satisfactory measurement has been made of their thickness, but this is probably as variable as their physical appearance.

Schuchert^{711f} determined the following Oriskany forms from this sandstone:

- Orthis* (*Rhipidomella*) *musculosa* Hall.
- Stropheodonta* *magnifica* Hall.
- Anoplothea* *fimbriata* Hall.
- Spirifer* *tribulis* Hall.
- Meristella* cf. *walcotti* Hall and Clarke.
- Ambocelia* *umbonata* Conrad.

K 10. KLAMATH MOUNTAINS, NORTHERN CALIFORNIA.

Among the Paleozoic strata of the northern Sierra the Devonian is recognized by an Onondaga fauna. The fossils are corals, which in places form reefs, and the terrane itself consists of limestone, 50 to 70 feet or more thick, which is associated with schists and eruptive rocks.²⁸³

Diller has brought together the available information regarding the Devonian of northern California. He distinguishes the southwestern and northeastern belts, which may be recognized on the map. Concerning the former he says:^{276c} "In the southwestern belt there is a line of Devonian limestone lentils (formerly doubtfully referred to Jura-Trias) which may be traced with many interruptions for over 100 miles parallel with the South Fork of Trinity River." In the detailed descriptions

of several localities, the intimate association of the limestone with more or less vesicular igneous rocks that break through it, inclose it, and form the greater mass of the material is repeatedly mentioned. The fossils from one locality (near White Rock) were determined by Schuchert as Upper Devonian, those obtained at six other localities as Middle Devonian.

Concerning the northeastern belt Diller ^{276d} states:

The northeastern belt of Devonian limestones and shales lies chiefly in the Sacramento drainage, extending northward into the Klamath and Rogue River region. The southern part, lying within the Redding quadrangle, and as far north as Gazelle, has already received much attention. The principal limestone bodies rich in fossils occur near Klamath and on Hazel Creek. Smaller masses outcrop near Horsetown and at a number of points 6, 8, and 11 miles northeast of Redding, where they lie close to the Carboniferous in line with a larger mass 2 miles northwest of Baird.

One of the best sections of these rocks, but not including the whole Devonian series, may be obtained on Backbone Creek $3\frac{1}{2}$ miles north of Kennett, where nearly 900 feet of sediments are quite fully exposed.

[Top.]	Feet.
1. Conglomerate; many quartz pebbles and numerous holes from dissolved limestone fragments, some of which contain fossils like those of the limestones below. Unconformable on 2. Possibly Carboniferous.....	30
2. Shales, mostly dark, with some thin sandy beds.....	140
3. Limestone, rather massive, light colored; little chert but full of corals, etc. (locality 6242) ..	160
4. Thin-bedded sandstones and shales which are cherty and gray below. Near middle part is limestone lens 10 to 15 feet thick.....	300
5. Limestone, thin bedded and crowded with massive, branching, and cup corals (6244). Cherty nodules and bands in bluish limestone becoming whitish and without chert below	250
6. Siliceous shales; 10 feet of banded chert at top, with sandy shales, black shale, and fine shaly sandstone, very thin bedded, resting on the igneous rocks below.....	75

A large number of fossils were collected from the Devonian of the Redding quadrangle, and these may in large part be referred to the section given, although but few of the fossils were actually collected at the point where the section was measured. After enumerating a number of the species found at various localities, Mr. Schuchert concludes as follows:

"The section of locality 6242 given me by Mr. Diller, the thickness of which he estimates to be about 900 feet, has one general fauna indicative of the Middle Devonian. The general age has been known for some years, but the collections of 1902 have given us a definite section and also species that are known to occur in other American localities. This is especially true of the fossils of the lower shale zone, which repeats the fauna of the Eureka and White Pine districts of Nevada and the Middle Devonian of Iowa. The species that are common to at least two of these regions are *Schizophoria striatula*, *Stropheodonta canace*, *Gypidula lotis*, *Pugnax altus*, *Atrypa missouriensis*, and *Cyrtina missouriensis*?"

Taking these species in connection with the corals of the limestones, as *Heliolites porosa*, *Endophyllum* or *Spongophyllum*, and *Phillipsastræa*, one sees plainly that the California Middle Devonian belongs to the "Euro-Asiatic province." This province extends east in North America as far as central Missouri, eastern Iowa, Milwaukee, Wis., and Petosky, Mich. East of these places occur the Middle Devonian faunas of the "North American type."

These Devonian strata are described as the Kennett formation, their stratigraphy, details of occurrence, and paleontology are presented, and their conformable relations to older volcanic rocks are stated in the Redding folio.²⁷⁹

K 15. IOWA.

The following section of the Devonian of Iowa was compiled by Chamberlin^{134c} from the Iowa Survey reports:

Generalized section of the Devonian for Iowa.

Formation.	Thickness (feet).	Characteristics.
Lime Creek formation.....	80	Dark-colored argillaceous shales, highly fossiliferous, and locally calcareous.
State quarry beds.....	20-40	Light gray; good building stone. Fish teeth.
Sweetland Creek shales.....	20-40	Black and greenish; Upper Devonian fossils.
Unconformity.		
Cedar Valley limestone.....	250-300	Pure to argillaceous limestone and dolomite; sometimes massive, sometimes finely laminated, frequently brecciated.
Wapsipinicon formation (Independence, Fayette, Davenport).	100-150	Carbonaceous shales with bands of impure concretionary limestone; brecciated limestone.

These strata represent Middle and Upper Devonian, a local unconformity or change in fauna distinguishing the two. The Middle Devonian beds overlap northward as they rise in the series and rest in part on Silurian, in part on Ordovician. Calvin¹¹⁷ states with reference to strata in the extreme northern part of the State:

The lowest beds seen in Howard County belong to a horizon far above what has been recognized as the base of the Devonian in the southern part of the area of its distribution. The beds which rest directly on the Maquoketa contain *Stropheodonta demissa* Conrad, *Productella subalata* Hall, *Atrypa aspera* Schlot., *Spirifer pennatus* Owen, and *Cyrtina hamiltonensis* Hall. The fauna indicates a horizon equivalent to that represented about the middle of the quarries at Independence, in Buchanan County. In this zone in Howard County, *Productella* is the most abundant and most characteristic fossil, and it is convenient to refer to the horizon as the *Productella* beds. This zone belongs to the Upper Davenport beds of Norton, below which, before reaching the base of the Devonian in Linn, Cedar, and Scott counties, there are divisions of the Wapsipinicon stage which have been described as Lower Davenport, Independence, Otis, and Coggan.

With reference to the distinction of Devonian and Carboniferous Weller⁸⁷⁷ concludes:

The succession of faunas exhibits a somewhat gradual transition from the earlier faunas with quite marked Devonian characters to the later ones which are typically Carboniferous in aspect. The Devonian element in the faunas is for the most part exhibited by the pelecypods, while the brachiopods are usually Carboniferous in aspect. This overlapping and intermingling of Devonian and Carboniferous faunal elements makes it impossible to draw a sharp line separating the Devonian and Carboniferous systems such as is recognized in the continental interior between the Ordovician and Silurian in the Medina formation, and between the Silurian and Devonian in the Waterlime formation. The Devonian-Carboniferous dividing line is more nearly analogous with the Cambro-Ordovician division.

K 16. WISCONSIN.

In the vicinity of Milwaukee the Devonian is represented by the Milwaukee formation (of Hamilton age). According to Alden,¹¹ as nearly as can be determined from partial exposures and drilled wells the order and maximum thickness of the members of the formation are as follows:

Generalized section of the Devonian beds of Milwaukee, Wis.

	Feet.
Black shale.....	15
Soft bluish "soapy clay" or shale.....	80
Bluish magnesian limestone, "cement rock".....	12
Bluish limestone, and softer bluish "soapy clay".....	31

These beds, with the exception of the upper black shale, are highly fossiliferous, showing a great variety of invertebrate forms as well as plates and teeth of armor-plated fishes. * * * Beneath this group of beds is the brownish limestone provisionally referred to the Cayuga group [Waubakee formation, Silurian].

K 17. ONTARIO.

In Ontario the Devonian formations, as determined by boring, are listed by Brummel^{105a} as follows:

Devonian:	Feet.
Portage and Chemung.....	25-200
Hamilton, about.....	350
Corniferous.....	160-300
Oriskany.....	6-25
Silurian:	
Lower Helderberg.....	}300-1,000
Onondaga.....	

These formations, their distribution, and their relations to the New York equivalents as then understood were described in detail by Logan.^{54p} Concerning the Oriskany he states that it enters Canada at Waterloo, on the Niagara.

In its lithological characters it does not seem to differ materially from the same rock in New York. The lower beds appear in several places to be composed of chert or hornstone, frequently containing large quantities of iron pyrites, and occasionally beautiful specimens of purple fluorspar. * * * Resting on these beds there is a sandstone, which is somewhat different in different localities. In the township of Dunn, near Haldimand, it is frequently made up of large angular pieces of hornstone; which, with the numerous large corallines and other fossils present, render it almost useless as a building stone. In the townships of Oneida and North Cayuga * * * there are large exposures of the rock. It is composed of fine grains of white quartz, in some parts so closely cemented as to assume the characters of a white compact quartzite. In other parts it is made up of coarser grains of quartz, some of them being an eighth of an inch in diameter and pretty well rounded. With these there are occasionally grains of feldspar. The rock in these cases, being sometimes slightly calcareous, disintegrates by exposure to the weather. The beds are massive and from 6 inches to 6 feet thick. * * * The sandstone in some parts very much resembles the white beds of the Potsdam formation; but it passes from white to light gray and, in some places, through yellowish to brown. * * * The greatest thickness of the mass may be about 25 feet; but though now and then attaining 10 feet, it seldom exceeds about 6, and it is frequently wanting between the Waterlime series and the overlying Corniferous formation.

The rock abounds in organic remains.^a

Concerning the "Corniferous" Logan states:

In western Canada we find that many of the fossils of the Corniferous limestone pass up from the Oriskany sandstone; and the intermediate Onondaga limestone, with its encrinites, can no longer be recognized as a distinct formation. We therefore unite the two limestones under the name of the Corniferous formation.

^a For list of species see the work cited.—B. W.

The surface occupied by this formation in western Canada is probably between 6,000 and 7,000 square miles. A great part of this however is deeply covered by drift, so that the exposures are comparatively few. * * *

The generally small dip of the strata and the frequent occurrence of slight undulations render it very difficult to find the succession of the beds, or to determine with accuracy the whole thickness of the Corniferous formation. The great extent occupied by it in western Canada, however, makes it probable that it must be much more considerable here than in New York. In the townships of Woodhouse and Townsend, where there are frequent exposures, the breadth at right angles to the strike is upward of 10 miles. The fall of the surface, in that distance, is estimated at 140 feet; so that if the average slope does not exceed 30 feet in a mile, there would here be a thickness of about 160 feet of the Corniferous limestone. The strata which in Michigan are considered as the equivalents of this formation have, according to Prof. Winchell, a thickness of about 350 feet; so that it would appear that the thickness gradually augments to the westward.

The formation enters Canada from New York, nearly opposite Buffalo, and is traceable in a narrow belt along the shore of Lake Erie, resting on the Oriskany sandstone, or, where this is wanting, on the Waterlime series. * * * Some portions abound in chert, which forms beds of from 1 to 4 inches or exists in nodules like flints in the limestone. Many of the beds contain silicified organic remains. These in some localities, as in North Cayuga and at Port Colborne, are found weathered out and loose, in great abundance, at the surface of the ground. Some of the beds are little more than an aggregate of silicified organic remains, with so little calcareous matter that the whole mass coheres, after the carbonate of lime has been dissolved out. * * *

To the west of the Grand River, in the counties of Haldimand and Norfolk, the Corniferous limestones are often seen resting on the Oriskany formation and forming small eminences, which present escarpments, with the sandstone at their base. These limestones are here of a drab color and abound in chert. * * *

Higher in the series, along the same line of country, blue limestones, sometimes to the amount of 20 feet, with gray beds in less volume, are associated with cherty layers, and interstratified with bands of a drab-colored limestone. * * *

The limestones of this formation are all more or less bituminous, and bitumen exists in many of them in a liquid form, as petroleum or rock oil, filling the cells of the corals and other fossils. The corals often prevail in distinct bands, some of which will be saturated with the oil while those above and below will have little or none. In working Mr. Horn's quarry, which has already been mentioned, on the thirteenth lot of the second range of Bertie, the oil is seen to impregnate particular beds, which are in great part made up of the remains of a species of *Heliophyllum*. These corals, in various attitudes, are arranged in bands varying in breadth from 3 to 6 inches; and in their open cells the petroleum is lodged. The intermediate parts of the rock, which contain no oil, are composed of a mass of broken organic remains, chiefly encrinurites, while in the coral-bearing beds these comminuted crinoids serve as a paste to fill up the interstices among the corals.

Logan defines the stratigraphic limits of the Hamilton formation of Ontario as follows:

In the western part of Canada we have not been able to distinguish either the Marcellus shales or the Tully limestones from the Hamilton group, and we shall therefore, in describing the rocks of that region, include under the name of the Hamilton formation all the strata between the Corniferous limestones and the Genesee shales. This formation occupies the lowest portion of the saddle-shaped depression noticed in the previous chapter as crossing the peninsula from Lake Erie to Lake Huron and separating the Corniferous formation into two areas. The space thus occupied is very much covered by drift and the contact between the Corniferous and Hamilton formations has not yet been seen, so that it is not easy to assign their precise stratigraphical place to the exposures which are met with.

The strata comprised in this interval are described as gray calcareous shale, gray limestone composed of remains of encrinites, and soft shales. There are also black shales which may indicate the passage from the Marcellus to the Hamilton. Logan cites several partial sections, and Brummel¹⁰⁵ gives well records which include the Hamilton.

Under the name "Portage and Chemung group" Logan^{544q} cites the occurrence of black bituminous shales, which may represent the Genesee and which occupy a small area at Kettle Point, on Lake Huron. He says:

Here, in a low cliff, on the west side of the cape, is a section of between 12 and 14 feet of very fissile black bituminous shales, weathering to a leaden-gray, and often stained brown by oxide of iron. A yellow earthy coating of oxalate of iron is sometimes found in the surfaces of the shales, which also contain nodules and crystals of iron pyrites, besides peculiar spheroidal concretions, whose fancied resemblance to inverted kettles has probably given its name to the point. They vary in size from 3 inches to as many feet in diameter, and are sometimes nearly spherical and at others somewhat flattened, generally on the under side. Occasionally a smaller spheroidal mass is implanted on the top of a larger one. These concretions are readily broken and are then seen to be composed of brown crystalline carbonate of lime, which is confusedly aggregated in the center and sometimes contains blende. Around this are arranged slender prismatic crystals, which extend from the nucleus to the circumference, the whole having a radiated columnar structure, which, not less than the terminations of the prisms at the surface of the spheroidal masses, gives them very much the aspect of fossil corals.

On the east side of the point the upper beds of the section are concealed, but the lower ones come from beneath the bank at a little above the water's level and cover an area of several acres, the whole surface being studded with these spheroidal concretions, which remain when the softer shale around them has been partially worn away.

This black shale is fossiliferous and contains a fucoid resembling a variety of the *Fucoides cauda-galli* of Vanuxem, which is very abundant in the lower beds. Flattened stems of *Calamites inornatus* (Dawson), which are sometimes 7 or 8 feet long, and 3 inches wide, occur about the middle of the section and are occasionally converted into coal. Besides these, according to Dr. Dawson, there occurs here a stem which belongs to *Sagenaria veltheimiana* (Goeppert). An undetermined *Lingula* is found with these plants, together with numbers of what appear to be microscopic orbicular shells.

The fauna of the Oriskany of Ontario has been carefully studied by Schuchert,⁷¹⁰ and that of the Hamilton by Whiteaves.^{915, 921} Shimer and Grabau⁷⁴⁰ have published measurements of local sections at Thedford, Ontario, and lists of fossils from the several divisions, together with a discussion of correlation and faunal migration.

K 17-18. PENNSYLVANIA AND NEW JERSEY.

The Devonian formations of New York can be traced southward into Pennsylvania and New Jersey, as was shown by Williams⁹³⁰ in 1884, by the work of the respective State surveys, and by recent studies of several observers. Some of these formations, however, notably the Tully limestone, are exceptionally limited and are not known to occur south or west of northeastern Pennsylvania and northern New Jersey. The Ithaca fauna, which is lacking in western New York, extends across Pennsylvania in a belt that passes southeast of Altoona. The contemporaneous fauna of the Portage of western New York occurs at Altoona, the two faunas being inshore and offshore, as brought out by Williams and Kindle.⁹³⁸

The section near Altoona, as determined by Butts,¹¹² is as follows:

Section of Devonian rocks near Altoona, Pa.

Formation.	Thickness (feet).	Character.
Pocono sandstone (Carboniferous).		
Catskill formation.....	2,000	Red shale and red or brown sandstone, with some gray or green shale or sandstone. Unfossiliferous.
Chemung formation.....	2,500	Lower 1,400 feet gray or green sandy or clay shale; upper 1,000 feet large proportion chocolate shale and thin layers of chocolate sandstone; fossiliferous; conformable with Nunda.
Nunda (Portage) formation.....	1,400	Base soft pale-brown clay shale, splitting easily into thin, smooth plates; above, change to greenish-gray sandy shale with some layers of hard bluish fine-grained sandstone. Fossiliferous.
Genesee shale.....	80	Black clay shale, very fissile, containing plentiful calcareous concretions; conformable with both Nunda and Hamilton.
Hamilton formation.....	3,100	Very dark green, olive-green, and gray shale and dark-green sandy, slightly micaceous shale; infrequent bands of fine-grained bluish sandstone.
Marcellus shale.....		
Oriskany sandstone.....	20-50	Thick-bedded, generally coarse-grained gray or buff siliceous rock.

Kindle⁴⁹⁵ comments in detail, with faunal lists, on the faunas of the Altoona section.

The Devonian formations in New Jersey present different characters in two districts, the Delaware Valley and Green Pond Mountain. Kümmel^{513c} states:

The Devonian formations of the upper Delaware Valley are of marine origin and are chiefly fossiliferous calcareous shales and limestones having a thickness of about 1,000 feet. Those of the Green Pond Mountain region are chiefly arenaceous shales, sandstones, and conglomerates, carrying comparatively few fossils and aggregating over 4,000 feet in thickness.

The Helderbergian or lowermost Devonian faunas in New Jersey are essentially the same as those in New York, and the same faunal zones are recognized. The first formation carrying these faunas is the Coeymans limestone.

Coeymans limestone.—In the Nearpass section the Coeymans limestone has an estimated thickness of 40 feet, though only the lower beds are exposed. It rests conformably upon the Manlius limestone, from which it differs lithologically in its coarser and more crystalline texture and lighter color. Frequently more or less chert is mingled with the limestone. The Coeymans fauna is far more prolific than that of the Manlius and differs markedly in composition, the most characteristic species being *Gypidula galeata*. A coral bed carrying more or less completely silicified masses of *Favosites helderbergix* and a concentrically laminated stromatoporoid occurs in the base of the formation.

Stormville sandstone.—In the southern half of the Wallpack Ridge in New Jersey, a thin sandy layer occurs at the top of the Coeymans limestone. It is in general an inconspicuous formation, owing to its thinness and heavy deposits of glacial drift. It becomes more conspicuous toward the south and according to White^a it gradually replaces the overlying calcareous and shaly strata until it occupies the entire interval between the Coeymans limestone and the Oriskany sandstone. It has not been recognized in the Nearpass section near Tristates nor at any point north of Hainesville, N. J.

New Scotland beds.—The New Scotland beds, which overlie the Coeymans limestone in the Nearpass section, consist of about 20 feet of a very hard cherty limestone followed by a series of calcareous shales, having an estimated thickness of 140 feet. Nowhere in the State is there exposed a continuous section of these beds as is the case with several of the lower formations. The fauna is a prolific one and is especially characterized by the abundant representation of the genus *Spirifer*. Its differences from the Coeymans fauna are of such an essential

^a Second Geol. Survey Pennsylvania, Rept. G6, 1882, pp. 132, 133.

character as to indicate a separate immigration from the exterior into this region.^a As indicated above, south of Hainesville a thin sandy bed intervenes between the Coeymans limestone and the New Scotland beds and gradually replaces the latter. At Flatbrookville, where these strata cross the Delaware into Pennsylvania, the lower cherty limestone member of the New Scotland beds has disappeared and the Stormville sandstone contains a fauna characterized by *Spirifer macropleurus*.

Becraft limestone.—A hard gray cherty limestone overlies the shaly layers of the New Scotland beds, forming a resistant layer which outcrops frequently along Wallpack Ridge. Its entire thickness has never been observed, but it is estimated to be about 20 feet. Its fauna is closely allied to that of the New Scotland beds, a few new forms appearing and a few old ones disappearing. There is also some difference in the proportionate number of individuals of some species, notably of *Leptaena rhomboidalis*, which becomes especially abundant. The bed is correlated with the Becraft limestone of New York.

Kingston or Port Ewen beds.—A series of strata, nowhere exposed, occupies the interval between the Becraft limestone and the base of the Oriskany. They are probably shaly beds which easily disintegrate and thus become covered with débris. Their thickness is roughly estimated as 80 feet. The only basis for their correlation is their position, which corresponds to that of the Port Ewen (Kingston) beds of New York. In Pennsylvania, the same beds have been called the Stormville shales by White.^b

Oriskany formation.—A series of strata, aggregating about 170 feet in thickness, succeed the Port Ewen beds and are referred to the Oriskany. They are for the most part siliceous limestones, but the summit of the formation along the southern half of the Wallpack Ridge becomes a sandstone. The arenaceous facies is said to become more marked to the southwest in Pennsylvania and to embrace lower and lower beds until all the strata to the top of the Coeymans limestone are sandstones. The fauna of the Oriskany beds in New Jersey comprises three well-defined faunal zones, the lowest characterized by *Dalmanites dentatus*, the second by *Orbiculoidea jervensis*, and the third by the great abundance of *Spirifer purchisoni*.

In the Nearpass section the beds bearing the *Dalmanites dentatus* fauna are about 30 feet thick and form the crest of a high ridge which is the southern extension of the "trilobite ridge"^c east of Tristates. There is a mingling of Helderbergian and Oriskanian forms in this fauna, and there has been some difference of opinion as to whether these beds should be placed in the Port Ewen or Oriskany, but recent workers^d unite in referring them to the Oriskany.

Esopus grit.—The Esopus grit which overlies the sandstones and siliceous limestones of the Oriskany forms the crest of Wallpack Ridge for the greater part of its extent in the State. It is a nearly black gritty rock with well-developed cleavage, which obscures the bedding planes. The fucoid "cauda galli" markings can frequently be recognized on the bedding planes when the latter can be distinguished. Apart from these markings fossils are very rare. The average thickness of the formation in New Jersey is estimated to be 375 feet.

Onondaga limestone.—The Onondaga limestone overlies the Esopus grit along the north-western slope of Wallpack Ridge. Toward its base the formation is somewhat shaly and there is apparently a rather gradual transition from the grit to the limestone. The latter is hard, cherty, and regularly bedded in layers ranging from 3 inches to 1 foot in thickness. The beds are assigned to the Onondaga on the basis of their position and lithology rather than faunal evidence, since the recognizable forms are not sufficiently characteristic for close correlation.

Marcellus shale.—Fissile black shale, referable to the Marcellus, has been reported to occur in New Jersey along the bed of the Delaware River a few miles below Port Jervis, but in recent years the exposures have apparently been buried by silting up of the channel. This is the highest of the Devonian beds exposed in the State along the Delaware River, but in the Green Pond Mountain area still younger beds occur.

^d Weller, Stuart, op. cit., p. 96. Shimer, H. W., op. cit., p. 184.

DEVONIAN FORMATIONS IN THE GREEN POND MOUNTAIN AREA.

Kanouse sandstone.—The Kanouse sandstone, the lowest Devonian formation of the Green Pond Mountain region, is a thick-bedded, fine-grained conglomerate below and a greenish sandstone above, having a thickness of about 215 feet. Although fossils are not rare, yet as a rule they are obscure and many of them are so greatly distorted that their identification is impossible. So far as recognized they indicate an Onondaga fauna, and these beds may be interpreted as the shoreward correlatives of the Onondaga limestone. It is the formation which in the New Jersey Geological Survey reports has been called the Newfoundland grit.

Its outcrops form a narrow belt parallel to the Decker Ferry limestone but separated from it by a narrow interval. In the upper Delaware Valley, as noted above, there are seven formations aggregating nearly 900 feet in thickness between the Decker Ferry and the Onondaga. In the Green Pond Mountain region none of these has been recognized and, if present at all, it can be only in very attenuated form.

Pequanac shale.—The Kanouse sandstone apparently grades upward into a black and dark-gray thick-bedded slaty shale (the "Monroe" shale of Darton and others). Cleavage is usually strongly developed so that the bedding planes are not always readily discernible. The thickness is estimated at 1,000 feet. This formation is probably conformable upon the Kanouse sandstone, but the contact has nowhere been observed. It contains a somewhat meager fauna, among which, however, is the characteristic Hamilton species *Tropidoleptus carinatus*, so that its reference to this period is beyond question.

Bellvale sandstone.—The Bellvale sandstone is scarcely more than a continuation of the Pequanac shale, but the beds are coarser and more sandy. The average thickness is estimated at 1,800 feet. The few fossils found are all Hamilton species.

Skunnemunk conglomerate.—The Bellvale sandstones grade upward into a coarse purple-red massive conglomerate, the white quartz pebbles of which are sometimes 6 or 7 inches in diameter. Beds of red quartzitic sandstone alternate more or less frequently with the conglomerate and there are many gradations between the two. It forms the great mass of Bearfort Mountain in New Jersey and of Bellvale and Skunnemunk mountains in New York. It is the youngest Devonian formation in New Jersey and rests upon beds known by their fossils to be of Hamilton age. Whether it is the exact equivalent of the Chemung-Catskill can not be determined.

K 17-18. NEW YORK.

According to the nomenclature of the present New York State Survey, the classification of the Devonian of that State is as follows:³⁰²

Summary of classification of the New York Devonian.

[According to John M. Clarke. Descending order.]

System.	Group.		Stage.
Carbonic.	Pennsylvanian.		Olean conglomerate.
	Mississippian.		Knapp beds. Oswayo beds (Panama conglomerate). Cattaraugus beds, including Wolf Creek conglomerate.
Devonic.	Neodevonic.	Chautauquan.	Chemung beds (Catskill sandstone, local facies).
		Senëcan.	Portage beds (Naples, Ithaca, Oneonta, Sherburne beds, local facies). Genesee shale. Tully limestone.
	Mesodevonic.	Erian.	Moscow shale. Ludlowville shale. } Hamilton. Skaneateles shale. } Cardiff shale. Marcellus shale.
		Ulsterian.	Onondaga limestone. Schoharie grit.
	Paleodevonic.	Oriskanian.	Esopus grit. Oriskany beds.
		Helderbergian.	Port Ewen limestone. Becraft limestone. New Scotland beds. Coeymans limestone.

These formations vary greatly in thickness from east to west and north to south. The Helderbergian strata do not occur in the western part of the State. The Oriskany sandstone overlaps westward into Ontario; but the Schoharie and Esopus are of local distribution only. The Onondaga limestone and the Hamilton and Marcellus shales are relatively widespread, as is the Genesee, or its equivalent; but the Tully and Portage are more restricted. The Chemung and particularly the Catskill are very thick near-shore and the latter in part continental deposits of the Bay of New York and its southern extension into Virginia, and they are represented farther west by the Upper Devonian shales.

Hall³⁹⁷ described the "Lower Helderberg" as follows:

The Lower Helderberg group, which constitutes the more important portion of the strata from which are derived the fossils of the present volume, has been so termed from its very complete development along the base of the Helderberg Mountains, constituting, in this part of New York, an important fossiliferous group. In some parts of the Helderberg Mountains

and along the Hudson River at Rondout and at Schoharie and elsewhere the lowermost beds of this group rest directly upon the Waterlime beds, which we regard as the uppermost member of the Onondaga salt group, indicated as a separate formation by reason of its economical importance and likewise characterized by certain peculiar fossils, while the marls of the Salt group are usually nonfossiliferous.

The lowest member of the Lower Helderberg series is a thin-bedded, often thinly laminated dark-blue limestone, which, from the abundance of its tentaculites, has been termed the Tentaculite limestone. Its color, texture, and composition contrast strongly with the rock below.

The second member of this group is a thin mass of limestone, consisting almost entirely of the coral *Stromatopora*, and constitutes a very persistent member of the group; to this succeeds a limestone charged with great numbers of the broken shells of *Pentamerus galeatus* and known as the *Pentamerus* limestone. This graduates above into a shaly formation, which was designated in the New York reports as the *Delthyris* shaly limestone, from the abundance of this genus of fossils. It is the most fossiliferous member of the group. * * * This shaly limestone, in physical character and composition, corresponds nearly with the shaly member of the Niagara group and contains numerous similar or representative forms.

To this succeeds a compact crinoidal limestone, and above this is a mass of bluish-gray limestone, charged with Brachiopoda, among which a *Pentamerus* similar to *P. galeatus* is so abundant that the rock has been termed Upper *Pentamerus* limestone.

A comparison of the species shows that the fossils of the Lower Helderberg rocks are analogous to those of the Niagara group and contain among them certain species which we regard as representative forms of the Silurian species in Europe; and we can not do otherwise than retain this series as a member of the Silurian system.

In 1874 Hall³⁹⁸ published a detailed description of the distribution of the "Lower Helderberg" and its relations to the Niagara and the intervening "Onondaga salt group," with a map of the eastern United States illustrating the occurrence of the three terranes.

Schuchert^{711b} quotes Hall's description and gives an account of the representatives of the Helderbergian in several States and Canada, together with an extended discussion of the faunas, from which he concludes:

With these facts there is presented a great paleontological break between the Siluric and Devonian at the top of the Cayugan group. The succumbing of the normal marine faunas of the Niagaran group is undoubtedly associated with the red gypsiferous and saliferous sediments of the Cayugan group. If the latter had a normal marine fauna instead of one of peculiar Crustacea, the continuity of life from the Niagaran to the Helderbergian would be probably complete. However, in most areas outside of New York and Ohio, there is a great hiatus between the Niagaran and the Helderbergian, which tends to make a clear and easily discoverable line for field geologists in separating the Siluric from the Lower Devonian.

* * * * *

From the foregoing summary of the Helderbergian fauna it is evident that most of the characteristic Siluric genera of trilobites, brachiopods, and crinoids are there absent. This might be expected, for, as has been seen in the previous chapter, about 2 per cent of the Helderbergian fauna are derived from the Siluric. On the other hand, in some of the trilobites, Bryozoa, and pelecypods, many of the gastropods, but more particularly in the diversified brachiopods, are met organic groups which in their culmination are characteristic of the Devonian. It can not be denied that the Helderbergian fauna has a Siluric facies, yet these types either have greater differentiation in species or the forms attain a larger size. The fact that 9 per cent of the Helderbergian fauna pass into a generally accepted Devonian horizon, the Oriskany, outweighs the evidence of a Siluric facies and specific derivatives. The writer therefore concludes that the Helderbergian has a fauna unlike the Siluric, but one in harmony with the Devonian and its position near the base of that system.

Neither of the Helderbergian zones can be regarded as the deeper-water facies of the littoral Oriskany, not only because the fauna of the latter has a more decided Devonian aspect, but also for the fact that wherever the two formations are present the Oriskany always overlies the Helderbergian. As far as known, there is no interlamination, and in New York, where the stratification is simple, there is a regular sequence. Where the older Oriskany is absent there is a slight unconformity between the Helderberg and the later Oriskany. This unconformity becomes a decided one in going from eastern to central New York, because the later Oriskany gradually comes to overlie successively the various members of the Helderbergian and finally the Cayugan.

The Oriskany sandstone is thus described by Hall: ^{397a}

The Oriskany sandstone everywhere succeeds to the upper members of the Lower Helderberg group and at several points extends beyond the known geographical limits of the latter. In the greater number of localities within the State of New York the transition from the upper calcareous beds of one group to the siliceous or sandy beds of the other is very abrupt, while in other instances there is an intermingling of calcareous matter in the lower beds of the sandstone. In these instances, however, as well as in others, the siliceous material appears to have been to a considerable degree in the condition of gelatinous silex, producing a rock approaching in character to hornstone; while other examples present an appearance as if the grains of silex had been softened, or agglutinated by a siliceous paste. In its more fossiliferous parts the rock is a mixture of silica and carbonate of lime, and the action of the weather, dissolving and removing the latter, leaves a grayish-brown porous mass, embracing the casts of the interior and molds of the exterior of the fossil shells. In many places the rock consists of a sandstone of nearly pure white, or graduating from white to buff-colored; in more southern localities it often presents the aspect of a siliceous limestone, not differing greatly from the succeeding limestones.

Schuchert ^{711c} gives the following account of the character of the Oriskany in New York:

In a general way it may be said that the Oriskany formation extends with many interruptions along the eastern and northern flanks of the Helderberg Mountains of New York. Along the northern side the Upper Oriskany only is known to be present, exceedingly variable in thickness but never more than 30 feet, diminishing in volume and resting westwardly upon the successive lower horizons of the Helderbergian and finally on the Siluric. In the region of Cayuga Lake it is sparingly present, and is practically absent west of Ontario County, the Corniferous or Onondaga then resting directly on the Salina or Waterlime. Beyond the Niagara River, to the northwest of Cayuga, in Ontario, the Oriskany reappears irregularly over a very limited area, again overlying the Salina, and is from 6 to 25 feet thick. Southerly, along the western side of the Hudson River, the Upper Oriskany is very intermittent and often but 2 or 3 feet thick. On Becraft Mountain there is an outlier of Oriskany. In Orange County the Oriskany again appears to thicken, and in the Neversink Valley the thickness is about 125 feet, and at this point it is intimately connected with the Helderbergian. In New Jersey, and particularly in the eastern Appalachian folds of Pennsylvania, the Oriskany in its lithologic character is ever changing from sandy shales, sandstones, and chert beds to coarse conglomerates. Its thickness also increases from north to south; in northeastern Pennsylvania it is from 50 to 125 feet thick, and on the Lehigh River, below Bowmans, it is fully 200 feet.

Clarke ^{157a} has thus stated the distribution and relations of the Helderbergian and Oriskany:

In New York the deposits constituting the earliest members of the Devonian series are, at the bottom, (1) the Helderbergian and, overlying, (2) the Oriskanian. There is a demonstrated gradation of the sediments and the faunas of the lower into the higher, and those at the summit of the Helderberg series—Port Ewen beds—carry so large a representation of Oriskany species,

as shown by recent analyses, that they may be wisely regarded as indicating the passage of the earlier into the later fauna.

The Helderbergian rocks (in the Helderberg Mountain region comprising the following divisions from below upward: (1) Coeymans limestone, (2) New Scotland limestone and shale, (3) Becraft limestone) enter New York from the southeast along the New York-New Jersey line and end northward in an abrupt escarpment facing east and north in the southern angle of the present Hudson and Mohawk rivers. Of this heavy sheet of calcareous strata there is no trace in New York east of the Hudson River save two small synclinal outliers in Columbia County, Becraft Mountain and Mount Bob. As the formation progresses northward from its entry into the State its thickness increases to where it is abruptly cut off in an erect wall. The Helderberg escarpment carries in its very topography the evidence of a former wide extension on toward the east and northeast. The continuation of this formation westward in New York is notable for its rapid thinning and quick disappearance. The subdivision at the Helderberg Mountain is soon lost westward. The lower division or Coeymans limestone appears to be that extending farthest, as far as the eastern limits of Onondaga County, but the narrow east and west extent of the Helderberg sea is shown by the entire absence of the higher divisions far west of Schoharie Creek.

The Oriskany period succeeding was a time of transgression over the Helderberg deposits beneath. Then the northern coast line in western New York was broken and embayed. While calcareous deposits were formed in the deeper water of the southern reaches, the shore deposits of sand extended westward to Buffalo, in part over eroded surfaces of Siluric limestones to which the Helderbergian sediments had not extended. We have had occasion to show that from the Helderberg westward the sandy shoal-water deposits of this Oriskany time are lenses and thin sheets, often disconnected, in some places rising to considerable thicknesses of friable quartz shore sand into which the waters have rolled the organic remains of the outer sea. These lenses we conceive were separated by tongues of land dividing the embayments of the shore line. The Oriskany in our view presents in New York a twofold facies, that of the deeper littoral represented by the calcareous deposits from the Helderberg southward to Port Jervis and that of the shallow littoral from Schoharie westward; yet it is quite possible that the latter deposits are of later date than most of the former and represent the final transgression of shore sands over the sinking land of Helderbergian time.

The Oriskany sandstone is succeeded by the Esopus shale, which is described by Darton.^{227a} The Esopus is said to be "in greater part a fine-grained arenaceous deposit of dark-gray color."

About Schoharie and westward to its termination it is a moderately hard sandy shale varying in color from dark gray or buff to light olive, but east and south with increasing thickness the color becomes darker, the texture of the rock is harder, and slaty cleavage is general. * * * The formation has a thickness of 110 feet at Clarksville.

The Ulsterian of the New York State Survey comprises, in addition to the Esopus shale, a locally developed but not extensive formation known as the Schoharie grit and the widespread Onondaga limestone.

Darton²²⁷ describes these formations, together with others of the Helderberg Mountains.

The Schoharie grit is a local deposit which is characteristically developed near Schoharie and extends through Schoharie and Albany counties to Ulster County. It is a very arenaceous limestone which merges into the Onondaga above but is more sharply separated from the underlying formation. It is locally absent and the Onondaga then rests on the Esopus shale.

The Onondaga limestone, as the term has been applied since 1894, comprises a lower and an upper member called by Hall^{396a} "Onondaga" and "Corniferous," respectively, and covers the original application of the descriptive name "Corniferous" of Eaton. The extension of the geographic term Onondaga to the whole was made by Hall.³⁹⁹ In 1843 Hall³⁹⁶ described the lower member thus:

Throughout the greater part of the Fourth district the impure limestone terminating the Onondaga salt group is succeeded by the Onondaga limestone, with usually the intervention of a few inches of sandstone before noticed, which in ordinary observations might be entirely overlooked. There is also sometimes a thin band of nonfossiliferous bluish-gray limestone. The range of this formation is in an undulating line having a general east and west direction throughout the district, extending eastward to the Hudson River and westward far beyond the Niagara into Canada. Its northern outline is everywhere well marked, forming together with the next succeeding rock the second great limestone terrace, which rises to the south of the valley marking the range of the Onondaga salt group.

* * * * *

This rock is subordinate in thickness and continuation to the next succeeding mass, and was not separated from that by Prof. Eaton. Indeed for all practical purposes they may be regarded as one formation, the lower part, where fully developed, being marked by an assemblage of fossils which sufficiently distinguish it.

Its usual characters in the Fourth district are a light-gray color often approaching to white, more or less crystalline in structure, and containing numerous fossils. In many instances this mass, like the encrinal limestone at Lockport, seems almost entirely composed of broken and comminuted fragments of crinoidea and corals, sometimes extremely attenuated, and at other times fragments of large size are preserved.

* * * * *

Sometimes the mass is fine grained, more compact in texture, and of a darker color; when it has this character, few fossil remains are detected in it. The layers are usually separated by thin seams of greenish shale, which often divide blocks of the stone into wedge-form and irregular laminae.

* * * * *

The Onondaga limestone in many places contains nodules or thin interrupted layers of chert or hornstone (usually called flint), and sometimes the Favosites are partially dissolved and the cavities lined with silex in the form of chert, chalcedony, or crystals of quartz. The alimentary canal of the crinoidal columns is frequently lined with crystals of quartz, and the chambers of Orthocera, as well as the cavities of other shells, often present the same appearances.

Its characteristic features, when well developed, and which are always much more prominent than the lithological or mineral characters, are the presence of Cyathophylli, Favosites, and fragments of crinoidal columns. These always accompany it in situations where it is sufficiently developed to be of much importance either in economical consideration or geological interest.

Regarding the upper member of the Onondaga limestone Hall^{396b} says:

This rock is one of the most persistent of any in the series, and at the same time maintains a uniformity in lithological character and in the occurrence of certain fossils scarcely possessed by any other. It is known to extend from the Helderberg Mountains, on the Hudson River, to the Niagara River, and thence far into Canada.

* * * * *

Under the Corniferous limerock of Prof. Eaton were included this rock and the Onondaga limestone of the reports, the latter constituting his "Ceratal rock," so named from the abundance of Cyathophylli which it contains. The name Corniferous is continued as being peculiarly applicable to this rock, though the other limestones contain the same mineral. This is the highest limestone of importance in the series, which continues throughout the district.

In lithological character this rock varies to a considerable degree in its range through the district, being at the eastern extremity a fine-grained, compact limestone, scarcely presenting any crystalline grains. Its color varies from a light grayish blue to dark blue or black, and it is sometimes even of a light-gray or drab color. It contains numerous nodules of hornstone and the strata are sometimes separated by irregular layers of the same. In other localities these layers of hornstone increase in number and thickness to the almost entire exclusion of calcareous matter, and they then present a very harsh outline. * * *

At the eastern end of the district the hornstone is intermingled and interstratified with the calcareous strata, the whole very dark colored.

* * * * *

The rock for the greater part seems to have been composed of finely levigated calcareous mud, probably derived from the destruction of corals at distinct points, while at the same time siliceous matter often formed no inferior part in its production. The characters which distinguish the last rock, viz, the presence of corals and Crinoidea, are rare in this and form no essential feature. Fossils are generally few and for the most part consist of shells. Some portions, it is true, though of small extent, appear as if they may have resulted from the destruction of corals.

A later account of the Onondaga is given by Grabau.³⁸¹

The Erian of the New York State Survey, which comprises the Marcellus and Hamilton shales, has been the object of extensive investigations. Hall^{396c} thus described the Marcellus:

This rock admits of two divisions. The lower is very black, slaty, and bituminous and contains iron pyrites in great profusion; some portions are calcareous, and it is always marked by one or more courses of concretions or septaria, which are often very large. This division terminates upward by a thin band of limestone, above which the shale is more fissile, and gradually passes from black to an olive or dark-slate color.

In general characters the lower part resembles the Utica slate and is not distinguishable from the Genesee slate in its general aspect; it is, therefore, more properly a slate than a shale, if the distinction is to be continued. For practical purposes there is little advantage in separating the upper division of this shale from the Hamilton group. The line of separation is nowhere well marked, the change in lithological character being gradual, while some of the fossils continue from one to the other.

The finely levigated mud composing this rock indicates a period of great tranquillity in the waters, moved probably only by currents sufficient to transport the materials over the wide extent we find them. The nature and condition of the fossils also indicate a quiescent period, for their forms are among the most delicate and their parts are usually preserved in the greatest perfection. In some instances, however, from their great numbers, they are packed closely together and fracture on the separation of the laminae.

* * * * *

In many places this rock contains so much bitumen as to give out flame when thrown into a fire of hot coals.

Under the title "Hamilton group" Hall^{396d} describes the middle Devonian:

This group consists of several members which may be considered distinct, but which, when viewed in connection, present so many features in common that they are all recognized as the products of one period, and thus constitute one great group. In the Fourth district, the only changes recognized in lithological products are from shaly to calcareous, with occasional thin beds of limestone, and more rarely of sandy shale.

The group, as a whole, presents an immense development of dull olive or bluish-gray calcareous shales, which, on weathering, assume a light-gray or ashen tint; some portions become brownish on exposure, but these are of small thickness in this district. At a few points the shale becomes darker or black and exhibits a tendency to slaty structure, but as a general

character the cleavage is irregular and oblique to the planes of stratification. On weathering, where the edges are exposed, there is manifested a slight tendency to slaty cleavage.

From the wide and even distribution of the materials of this group, it was evidently produced during a period of great tranquillity, when the finely levigated mud was transported over wide areas by gentle oceanic currents. The great profusion and variety of organic forms proves also the quiescent condition of the ocean, which, together with the slightly calcareous nature of the mud, favored the growth and distribution of the Testacea.

The upper part of this group, in the Fourth district, bears a very close analogy in its lithological nature to the shale of the Niagara group, and in abundance of organic remains it is even more prolific. The forms of the latter are, however, of entirely different species, though corals and shells of similar genera abound, and trilobites of the same and different genera.

Concretions or septaria, in well-defined and often fantastic forms, are common in every part of this group. In many instances the calcareous matter has concreted around some organic body, or a nodule of iron pyrites seems to have been the center of attraction. In such instances we often find numerous fossils embedded in them or attached to their outer surface. The greater number, however, are well-defined spheroidal masses, with or without seams of crystalline matter and not containing any organic body. Others, and particularly in the lower part of the shale, are small, spherical or elongated, and with a small perforation through their center, in the manner of the common nodules or other concretionary forms in recent clay beds.

Organic forms abound throughout the group, but they vary somewhat in the different parts. In the lower division the most abundant are those of *Orthis*, *Atrypa*, and *Strophomena*, with some spiral univalves; while above this portion great numbers of *Avicula*, *Cypricardia*, *Nucula*, and other similar forms abound, with fewer of the genera *Orthis*, *Delthyris*, etc. In the next division *Delthyris*, *Strophomena*, and *Atrypa* abound, to the almost entire exclusion of the forms before mentioned. In the same situation with these we find numerous species of corals; *Cyathophylli*, *Favosites*, and other forms are abundant, while fragments of crinoidal columns are everywhere scattered through the mass or, spread evenly over the surface, form thin layers of themselves. Many of the species of this division are discontinued and their place supplied by others of the same genera in the higher part of the group. * * *

Although this group is so widely spread and evenly distributed and of uniform character over the western part of the State, still at its eastern extremity the lithological character is widely different. The shales are more or less arenaceous and some parts are well-marked sandstone. The proportion of siliceous and argillaceous earth is nearly reversed from what it is in the same rocks farther west. The mass varies from sandy shale to shaly sandstone and even tolerably pure sandstone. This character gradually changes to the westward, the sand diminishing and the clay increasing. The features presented by this group at its two extremes and along its whole length offer one of the most instructive exhibitions of the varying character of mechanical deposits. The facts prove the origin of the materials to have been at the east or southeast. The force of the current which drifted them into the ocean was sufficient only to carry onward the coarser particles to a certain distance, where they were deposited. The finely levigated mud was carried beyond this point, being floated by less force than the sand. Some portion of the clay was deposited with the sand toward the central part of the State, and but little of the latter extended beyond this point. Finally the current became more gentle and the clay was deposited to a certain extent, beyond which the power of the current was insufficient to carry even this material, and the deposit consequently thinned out in that direction. * * *

This change in the nature of the materials is accompanied by an equally marked change in the fossils embedded in the different parts of the group. In the eastern part of the State *Avicula* and *Cypricardia*, with *Nucula*, etc., prevail in immense numbers, while at the extreme western margin, though in precisely the same position, they are of the rarest occurrence, while numerous forms of *Delthyris* and *Atrypa* abound.

The above-quoted descriptions by Hall apply particularly to the Fourth district of the early Geological Survey of the State—that is, the region south of Lake

Ontario and west of Cayuga Lake. Similar accounts with local variations are given in the reports of Vanuxem⁸²⁹ and Mather.⁵⁷⁸

With reference to the Hamilton as exposed on the southeastern shore of Lake Erie, Grabau³⁷⁶ may be consulted. He gave the following classification:

The following formations are exhibited in the sections:

- Chemung group (Portage stage):
 - Naples shales.
 - Genesee slate.
- Hamilton group:
 - Hamilton stage:
 - Moscow or upper shales.
 - Encrinal limestone.
 - Hamilton or lower shales.
 - Marcellus stage:
 - Transition shales.
 - Marcellus shales.

The Hamilton of Cayuga Lake, New York, was made the subject of a special study with reference to its fauna by Cleland,¹⁶⁰ who states:

The Hamilton formation, including the Marcellus shales, is in this region, as shown by the Ithaca well section, 1,224 feet thick. It is bounded above by the Tully and below by the Onondaga (Corniferous) limestone.

Cleland divided the Hamilton of the Cayuga section into 25 faunal zones, each of which is described in detail in his report, together with the composition of the faunules.

Williams's later studies in classification^{935, 935a} led him to the following arrangement of the Ithaca section:

Revised classification and nomenclature of the section passing through Ithaca, N. Y.

Series.	Formation.	Members and lentils.	Thickness (feet).
Erie division or series of Vanuxem.	Chemung (shale and sandstone)	Fall Creek conglomerate lentil.....	0-10
		Wellsburg sandstone member.....	600-650
		Cayuta shale member.....	600
	Nunda (shale and flagstone).	Enfield shale member.....	550-800
		Ithaca shale member.....	^a 80-460
		Sherburne flagstone member.....	188-260
	Genesee shale.		125
	Tully limestone.		10-30
Hamilton shale.		1,035	
Marcellus shale.		125	
Onondaga limestone.		125	
Oriskany sandstone.		0-4	

^a In the chart as published in Science (vol. 24, p. 366) this figure is 300 feet.

It is difficult to follow any description of the Middle and Upper Devonian of New York without a knowledge of the conditions which have led to different classifications by several geologists for sections occurring in the eastern or western parts of the State. The strata are chiefly shale, sandy shale, shaly sandstone, or sandstone, which in any one section may present distinctly recognizable differences but which do not retain the same characters or distinctions from place to place. The faunas also vary in vertical and horizontal distribution and are to some extent recurrent. The divisions particularly involved in this vaguely classified series are those above the Hamilton, namely, the Tully limestone, Genesee shale, Portage group, and Chemung formation.

The Tully limestone was well described by Hall^{396e} and has been made the subject of a special paleontologic and correlative study by Williams,⁹³¹ who states:

The Tully limestone is a zone of argillaceous limestone, ranging from a few feet to over 50 feet in thickness, the outcrop of which crosses the middle counties of New York State from Ontario to Chenango counties but is not clearly recognized in the sections south of New York. In New York the outcrop is lost to the eastward and to the westward, not so much by thinning out as by a decrease, until unrecognizable, of the calcareous elements, and a failure of the peculiar species. In the central part of its outcrop this limestone appears at the top of the Hamilton formation, which consists of a series several hundred feet thick of soft shales, with a few more or less calcareous zones; and it is followed immediately by a black shale which gradually loses itself by alternate oscillation in a gray, more or less arenaceous shale and argillaceous sandstone, known in New York as the Genesee shale and the Ithaca group, and the more sandy portion above as the Portage group. In the region where the Tully limestone is well developed the black shales contain a fauna corresponding to that of the *Cardiola retrostriata* zone of Europe, and there is in the sandy shales above a fauna rich in Goniatites where best developed. * * *

For this study the more important species in the Tully limestone of New York are the brachiopods.^a * * * Besides these are species belonging to other orders.^a

* * * * *

I have examined a large amount of material from genuine Tully limestone, and also considerable more doubtfully referred to that horizon. In most places the Hamilton rocks are richly fossiliferous immediately under the Tully limestone. These former, though mainly shales, contain limestone beds which in hand specimens are rarely distinguishable from the genuine Tully above; but the characteristic species of the Tully are wanting and characteristic Hamilton species are abundant in them. Much confusion has thus arisen, and the Tully fauna, as reported in lists,^b is very imperfect by the inclusion of many species which do not belong in the limestone.

There are about 50 genuine Tully limestone species. Of these less than 25 are at all common, and the other 25 are Hamilton species which do not appear above the Tully, or are unique forms of Hamilton types. Of the more or less common Tully forms fully one-half are also clearly Hamilton species or their descendants, or are unique forms.

The change in fauna which begins with the Tully limestone and makes the characteristic upper Devonian fauna includes the appearance in New York of at least ten or a dozen species which have closer affinities with species of the middle Devonian in Europe than with any previous species in the New York series.

^a For lists see the work cited.—B. W.

^b See list furnished by S. G. Williams (Sixth Ann. Rept. State Geologist, Albany, 1887, p. 26). A considerable number of the species reported in this list I have examined in the collection made by the author of the list and find them and the rock containing them indistinguishable from specimens obtained at the same locality below the Tully limestone layers filled with Hamilton species but never in the Tully limestone itself.

Regarding the strata above the Tully limestone, Hall's remarks^{396f} "preliminary to the following rocks and groups" may still be read to advantage:

In the Fourth district the Tully limestone terminates all those deposits in which calcareous matter forms an essential part. In all the higher rocks this material, when existing, is the result of the destruction of organic bodies; and in the few instances where it appears the origin is unquestionable, for the fossils still retain so much of their original form as to be readily recognized. This rock forms a strong line of demarcation not only in this respect, but also as regards fossils, very few forms which are known below continuing into the rocks above. The lithological character of the products above this rock are throughout more or less similar, while they differ from those below; and, with a single exception, lithological character is a sufficient guide for distinguishing the different strata.

This contrast of character is more marked toward the western extremity of the district than it is farther east, and finally, on its eastern extreme, there is a greater similarity in the lithological features. This change is likewise attended with the occurrence of some of the fossils of the lower group in the rocks of the higher, the nature of the two being very similar, although the Tully limestone is in its greatest force; while at the west, where it does not exist, no such mingling of the fossils is known.

At Ithaca, for example, where we are far above the Tully limestone and where the rocks are well marked by an abundance of fossils peculiar to themselves, still we find the *Microdon bellastriata*, the *Modiola concentrica*, and some others, and I have even detected the *Calymene bufo* and *Dipleura dekayi* in the same association. Still farther east there is a greater mingling of species of the lower rocks with the upper and a nearer approach constantly in materials of composition. These circumstances, in the eastern portion of the State, render it difficult to point out the line of demarcation between the lower and higher rocks of this division.

At the eastern extremity of the State, also, the Tully limestone does not exist, and therefore that guide to the line of division between the lower and higher groups is wanting. The absence of this rock and the similarity of lithological products, as well as the mingling of the organic remains of the lower rocks, render it impossible to make a distinction in groups with the same degree of satisfaction as farther west. By reference to the section along the Genesee River it will be seen that the Genesee slate, a black carbonaceous mass, is succeeded by shale of a deep-green color and well defined above. This is succeeded by flagstones, which alternate with shale of a less deep green color and often with black shale. These again are followed by a greater proportion of sandstone, often thick bedded, and presenting far less of the characters of those below.

These rocks are well exposed on the Genesee River, and there can be no possible room for error in their examination. The whole thickness here exposed is scarcely less than 1,000 feet; and throughout this thickness there is as yet no fossil known which occurs in the Chemung group to the south and above these rocks. These circumstances led to the separation of this portion of the system and the adoption of Portage or Nunda as the locality designating the group. Farther east the green shale (Cashaqua shale) is often darker in color and more sandy, becoming largely interstratified with flagstones which have much the character of those which lie above it on the Genesee, except in the absence of a peculiar species of *Fucoides*. At the same time the small *Avicula*, which is so abundant in the Genesee slate, is almost equally abundant in the green shale and flagstones at Penn Yan.

Again, when we go westward as far as Lake Erie, we find that instead of the flagstones succeeding the green shale, as on the Genesee, a black shale is the first mass above. This soon gives place to green shale, and we have alternations of green and black shale for many hundred feet, before coming to the thin-bedded sandstones.

Proceeding with the description of the rocks, Hall says regarding the Genesee shale:

Superimposed upon the Tully limestone, or, in its absence, resting upon the Moscow shale, we find a great development of argillaceous fissile black slate. Where its edges only are exposed it withstands the weather for a great length of time and often presents mural banks in the ravines, river courses, and upon the shores of lakes. Where the surface of the strata are exposed it rapidly exfoliates in thin even laminæ. On disintegration, it is often stained with iron, owing to decomposition of pyrites; but in many instances and the greater number of localities it retains its deep black color. In this it is distinguished from some beds of black slate in higher situations, which always become stained with hydrate of iron on their edges and upon the surface of the laminæ.

In color and general characters it greatly resembles the Marcellus shale; and aside from position, it would be difficult to distinguish the two in the absence of fossils. * * *

In lithological character this rock is entirely uniform throughout the district, presenting itself upon the margin of Cayuga Lake and upon Lake Erie, having the same deep black color and laminated slaty structure. Neither is there any change in its organic remains; the same forms, and many of them almost equally abundant, are found throughout its entire extent. The greater portion of this rock is destitute of fossil remains, and it is only toward the upper part that they occur.

Under the heading "Portage or Nunda group" Hall^{396g} states:

This group presents an extensive development of shale, shales and flagstones, and finally some thick-bedded sandstone toward its upper part. Like all the other mechanical deposits of the system, as they appear in New York, it is extremely variable in character at different and distant points. * * *

From its superior development along the banks of the Genesee River in the district formerly included in the town of Nunda, now Portage, it has received that name to distinguish it from the higher rocks, which possess some differences in lithological characters but a more striking dissimilarity in organic remains.

Hall distinguished the Cashaqua shale, Gardeau shale and flagstones, and Portage sandstone as formations of his "Portage or Nunda group" and described their characters in detail in the chapter devoted to that group. Clarke¹⁵³ has thus summarized Hall's account:

The succession of strata exhibited in a series of beautiful exposures along the course of the Genesee River was described in some detail by Prof. James Hall in the fourth "Annual report of the survey of the fourth geological district of New York" (1840).

The beds which lie directly above what was there termed the "upper black shale" (thus contradistinguished from the "lower black shale," the former now known as the Genesee slate and the latter as the Marcellus shale) were designated as the Cashaqua shales, taking their name from the creek entering the Genesee River from the east at Mount Morris. These are olive-green or gray clay shales alternating with bituminous shaly beds and with interbedded thin shales, sandstones, and flags. Upward in the rock series there is in general a gradual increase in the amount of arenaceous sediment, the sands and flags becoming increasingly predominant and the shale beds themselves more arenaceous. While the transition to these beds from those below is in all respects an easy one, yet there is a possibility of distinguishing them in the mass, and hence the upper beds were termed the "Gardeau or Lower Fucoidal group;" the adjective term referring to the abundance of the so-called *Fucoides graphica* over the lower surfaces of the flags. A thick mass of heavy-bedded greenish or gray feldspathic and quartz sandstones above the Gardeau flags, representing the culmination of arenaceous sedi-

mentation of this cycle, was termed the "Portage or Upper Fucoidal group," many of the layers containing vertical annelidan borings filled with mud, which have commonly passed under the name of *Fucoides verticalis*.

In recognition of the fact that the distinction thus instituted in parts of this series would be difficult of application in actual practice, the same author, in 1843, applied the term "Portage or Nunda group" to the entire series lying between the uppermost beds of the Genesee slate and the upper limit of the heavy beds of Portage sandstones. Since that date not only have the rock strata thus delimited in these western sections of New York been known in geologic literature as the "Portage group," but this term has been also, and properly, applied to all formations in whatever sections of this State and bearing whatever faunas, between the horizon of the Genesee slate beneath and the earliest strata characterized by the incoming Chemung fauna above.

Recent investigations indicate that the historical delimitation of the Portage group in the typical Genesee section does not express the complete upward range of the fauna of this group. In the Genesee Valley the Portage sandstones are overlain by sandy shales and thin sandstones from 100 to 200 feet in thickness and in lithologic character, not unlike the Gardeau layers beneath; and through these beds the Naples or *Intumescens* fauna ranges, with slight accretions. Strictly speaking, this fauna is mainly confined to the more argillaceous layers, while toward the top a Chemung fauna appears in the more arenaceous strata. But this alternation concerns only the upper portion of these beds. To this series of strata representing the prolonged existence of the Naples fauna the term Wiscoy shales and sands has been applied. In protracting, upon the evidence of the contained fossils, the scope of the Portage group to include these beds, we shall not appear to violate propriety, for they did not escape the observation of Prof. Hall, who at the close of his description of the Portage group says (1843, p. 248): "The Portage sandstone is succeeded by olive shaly sandstone and shale and this by black micaceous slaty shale with septaria; to this follow shales and coarse sandstones with fossils of the Chemung group."

In the pages succeeding this quotation and in the second part of his contribution on the Naples fauna¹⁵⁴ Clarke describes and illustrates with maps the stratigraphy, paleontology, and geography of the later Devonian of New York.

The "Ithaca group" was early distinguished by Hall, but later^{396h} included by him in the Chemung in the following terms:

In the annual reports this name was adopted for designating the highly fossiliferous shales and shaly sandstones, so well developed at the inclined plane of the railroad and on the Cascadilla and Fall Creeks, near Ithaca. Subsequently an examination of the highly fossiliferous strata along the Chemung River, and particularly in Chemung County, resulted in the adoption of that name as designating this portion of the system.

Succeeding examinations satisfied me of the identity of the formations at Ithaca with those of Chemung, and this opinion was advanced in the annual report of 1841.

The reasons for merging the two in one were stated to be the impossibility of identifying them as distinct by any characteristic fossils. The same opinion is still entertained, after a full examination of the strata and a comparison of the fossils collected here and elsewhere in well-authenticated localities of the Chemung. There is scarcely a fossil known at Ithaca which is not found at numerous other localities; though it is true, not only of Ithaca but of many other places, that some of the fossils are confined to the single locality in which they occur.

By careful and extended examination the Chemung group may be subdivided locally where it is most perfectly developed, but these divisions will hold good only over small districts of country, position and lithological character having had much effect in producing these distinctions dependent on fossils.

Later work has not sustained the identification of Ithaca with Chemung. Williams^{93a} first showed that Ithaca and Portage are equivalent. He said:

Although the faunas [of the Ithaca and Chemung] are very similar, there can be no doubt that along the present meridian they represent two distinct geological stages. That they blended in some measure farther east may be possible, in the same way that it is probable that on going westward the Marcellus and Genesee stages blended.

Although I do not know that the Ithaca fauna is an early stage of the Chemung fauna, I am persuaded that the two may be readily distinguished by their fossils.

That the typical Chemung fauna is thus distinct from that of the Ithaca group and characteristic of a later stage, is shown, paleontologically, by the following considerations:

The genera Spirifera, Orthis, Strophodonta, and Productella are common to both faunas, and are represented by numerous individuals at almost any fossiliferous exposures of either group. But for each genus the species are different. Spirifera is represented in the Ithaca group by *Sp. mesocostalis* var. *acuminata* and the first variety of *Sp. mesostrialis*.

The Chemung group is characterized by *Sp. disjuncta*, *Sp. mesocostalis* 2d var., a large, coarsely plicated, broad form, and *Sp. mesostrialis* 2d var., the wide mucronate form, neither of which is seen in the Ithaca group.

Orthis, in the Ithaca group, is *O. impressa* of the narrow variety, rarely wider than long.

In the Chemung group *O. impressa* is the second variety; wide form, with broad sinus; also there are *O. tioga* and *O. carinata*, neither of which is known in the Ithaca group.

The Strophodontas of the Ithaca group are *Str. mucronata*, and the closely allied variety of *Str. perplana* var. *nervosa*.

In the Chemung group *Str. cayuta* is the prevailing form, and a coarser, more irregular form of *Str. perplana* var. *nervosa*.

Str. demissa is reported from both groups but is extremely rare in either.

Productella is represented in the Ithaca group by *P. speciosa* and a small form I have identified as *P. speciosa*, small variety. In the Chemung it is *P. lachrymosa* and *P. costatula*.

Besides these genera, Streptorhynchus is common in the Chemung group, and it is extremely rare, if it appear at all, in the Ithaca group.

Ambocælia umbonata var. *gregaria* is abundant in some stages of the Chemung group but is rarely ever seen at Ithaca. The latter two forms are seen below the Ithaca group, hence their absence there is evidence of modified fauna rather than extinction.

These differences in the prevailing varietal or specific characters of common genera, which (as genera) are known to be common for a considerable range below and above the stages under consideration, I take to be more reliable evidence of actual difference in horizon than would be any number of distinct species of different genera in the two faunas.

In the study of the Devonian of New York to which the bulletin just cited was a first contribution, Williams has developed essential general principles regarding the geographic and chronologic relations of faunas. The principles and the discussion of the evidence do not pertain to this account of stratigraphy, but the application to the relations in New York is appropriate. Under the heading "Faunal dissection of the Devonian," Williams^{93f} expresses the results of special studies as follows:

Previous work in correlation had been conducted on the fundamental assumption that identity of fossils is sufficient evidence of identity of the formations containing them. In other words, it had been assumed that for purposes of classification in the time scale the formation and the fauna are identical. The way in which fossils have been customarily labeled has prevented a testing of the truth of this assumption. If there be any distinction in time value between the formation and its fauna, it is difficult to demonstrate it so long as the only name and designation of the fauna is that of the formation in which it was originally found.

If the "Chemung formation" be extended below the fossiliferous strata of Ithaca, as it was in the literature before 1880, then the fossils in the "Ithaca group" belong to the Chemung fauna. When the Ithaca fauna was dissected and it was shown that the species were not those of the Chemung fauna above but were rather modified successors of the Hamilton fauna, it became clear that, faunally, the Ithaca group was not a part of the Chemung formation. Nevertheless, the term "Chemung" was still retained in general literature for the "period" which included both the "Ithaca" and "Chemung" epochs, so that the real issue was still obscured by the imperfection of the nomenclature which used "Chemung" with two meanings.

The terms "Portage," "Hamilton," "Trenton," and "Niagara" are also applied in this double sense in the classification of formations, making it almost impossible to frame a statement which will express the thought that formations and faunas are discriminated upon different bases and that their limitations may not be identical.

In order to demonstrate the actual facts in the case, it has been found necessary to collect a large number of statistics regarding the actual faunal contents of each zone in some well-known formation, and also regarding the separate faunules taken from outcrops of the same formation over an extended area.

* * * * * * * *

It is now possible to state that the *Tropidoleptus* fauna of the Hamilton formation persists in its integrity above the top of the Hamilton formation; that in eastern New York it occupies a place in the column which is occupied in central New York by the Ithaca formation and in the Genesee Valley by a portion of the Portage formation.

This state of things has been already demonstrated in respect to the position of the Catskill formation in the geological column. But the significance of the facts was obscured in that case by the fact that the Catskill as a pure formation is distinguished by its red sedimentation, which, therefore, was easily discerned in the field by the stratigraphical geologist; but the fossil evidence of the Chemung, though constantly annoying him, had not in his mind the distinct stratigraphical significance which he attached to the color ingredient in the Catskill. The evidence of the Catskill was clear, and if the fossils told another story, so much the worse for the fossils. This was his attitude.

In the present case the faunas are of the same kind, made up of marine invertebrate fossils. They are distinctly marine in all cases, and the demonstration may be expressed in mathematical values. The statistics are sufficient and are gathered from a field that is wide enough to make possible the comparison of the faunules in terms of composition, frequency, and abundance. The variation of species, though not yet demonstrated by the statistics, is strongly indicated by the increasing uncertainty in identification of the species in one direction, while the species are always positively identified in the central region. Great promises of future discoveries in this direction are offered by the facts, and in the future we may expect to see the laws of variation associated with transgression of the faunas clearly demonstrated.

Enough evidence is already in sight to show that at any particular point of time, as represented by a common geological horizon or zone in a given formation, the inhabitants of one sea differed in species within a relatively small distance (50 miles); and within 200 miles the faunas may be entirely different, having not a single species in common.

The facts also give clear evidence of the shifting of the fauna with the accumulation of the sediments, so that the center of distribution of each fauna changes as we ascend in the formation. The evidence points to this shifting of the total fauna as the occasion of rapid modification and variation of the species, and the inference is drawn that great changes of conditions were coincident with great shiftings of the fauna. During the prevalence of a fauna in a common center of distribution very little evolution took place for long periods of time, as measured by thickness of sediments, but slight shifting in the geographical position of the fauna is coincident with the appearance of new varieties and, in general, with disturbance of the faunal equilibrium.

The work of dissecting the contents of a fauna into its constituent faunules and then of the analysis of these faunules into their specific composition was begun at Ithaca, in the midst of

the abundant Devonian fossils of the formations outcropping in that region. The first attempts to define the separate faunules and to apply names to them were imperfect on account of the absence then of any knowledge as to the range, distribution, and relative abundance or rarity of the component species. These statistics were gathered as the investigations progressed. Although those first attempts at classification on the new basis are now superseded by classification based on the full appreciation of the laws of shifting of faunas, the record of the steps by which the progress has been made will indicate how from the study of conspicuous local phenomena broad general laws have been developed.

Williams enumerates the several classifications developed for the Upper Devonian by the special faunal studies, and finally says:

Revising this classification now in the light of the fuller exhibition of the facts, some of the distinctions made in 1885 are believed to be too refined and local for perpetuation in a general classification, but a few of the points then made may be adopted for general use in discussing the faunas of the whole continent and in comparison with the faunas of the world.

The fauna of the typical Hamilton formation (A) may be appropriately called the *Tropidoleptus carinatus* fauna. That species is more characteristic of the fauna as it appears in its purity in the eastern New York province than is *Spirifer (mucronatus) pennatus* Atwater.

The second fauna, of the Black shales (B), may be appropriately called the *Lingula spatulata* fauna, as that species is characteristic of it far and wide when in its purity, is rarely entirely absent, and may be found, if diligently searched for, in a typical black Devonian shale almost anywhere in the interior continental basin.

The third fauna, of the Portage shales (C), may be called the *Cardiola speciosa* fauna. Although, as Hall has shown, this is not a *Cardiola*, as strictly interpreted, and the name *Glyptocardia* was proposed as a new generic name in 1885 to take its place, the fact that in Europe as well as in this country this generic name has been applied to this species and its European representative makes it not inappropriate as a name for the fauna. As Hall observed in discussing this species (*Glyptocardia (Cardiola) speciosa* Hall): "It is probably identical with the *Cardiola retrostriata* (von Buch) of various authors, and with *Cardium palmatum* of Goldfuss." Its citation by numerous authors shows its wide distribution in Europe."

The fourth fauna of the list (D)—that of the Chemung formation of the east—is the *Spirifer disjunctus* fauna. The species *Spirifer disjunctus* is undoubtedly identical, specifically, with the form which is more commonly called *Spirifer verneuili* by European geologists. There are several varieties of it which are present in some regions in which the typical form *Sp. disjunctus* is wanting.

Regarding the Chemung, Hall³⁹⁶¹ said in part:

This group consists of a highly fossiliferous series of shales and thin-bedded sandstones, sometimes in well-defined and distinct courses, and an infinite variety resulting from the admixture of the two ingredients. Except in a few localities, there is no very strongly marked line of division between this group and the one below. The distinction consists in the presence of numerous fossils and the coarser-grained sandstones, which are usually more impure from argillaceous admixture than those below. Its lithological characters, however, are variable; and though well marked across a single line of section from north to south, still another at a short distance east or west of this presents considerable variation.

These rocks, however, can everywhere be described as a series of thin-bedded sandstones or flagstones with intervening shales, and frequently beds of impure limestone resulting from the aggregation of organic remains. The whole series weathers to a brownish olive, and even the deeper green of the shales assumes this hue.

The shales vary in color from a deep black to olive and green, with every grade and mixture of these. The sandstones are often brownish gray or olive, and sometimes light gray. More

generally, however, there is a tinge of green or olive pervading these strata. Toward the upper part of the group, in many places, there is a tendency to conglomerate; and in a few localities the mass becomes a well-characterized puddingstone, still retaining the fossils of the shales and sandstones. This conglomerate nowhere attains sufficient thickness or importance to merit a distinct description, but in hasty observations it may sometimes lead to erroneous inferences, since it resembles in many respects the distinct and well-defined conglomerate which rests upon this group in the western part of the State, but which is totally distinct from the same.

Many of the shaly sandstones and shales of this group are highly micaceous, and toward the upper part of the whole the shales are reddish, coarse, and fissile, with much mica in small glimmering scales. There is also in these shales a slight change in the character of the prevailing organic forms.

Two observers, Prosser and Williams, have specially studied the Chemung and also the earlier Devonian. Prosser^{643,644} described in great detail the sections of the strata in south central and eastern New York, and in his later report he concludes:^{644a}

Succeeding the Tully limestone and Genesee slate, or farther east, where these formations have disappeared, the Hamilton formation, is a mass of thin bluish sandstones and smooth shales of Portage age, for which Vanuxem proposed the name "Sherburne flagstone," which has been adopted and used as the name for the formation. It has a thickness of 250 feet in the Chenango Valley and may be readily traced westward to the meridian of Cayuga Lake, west of which Prof. J. M. Clarke has shown that it gradually passes into the Naples beds. Eastward from the Chenango Valley the Sherburne formation crosses Chenango, Otsego, and Schoharie counties, entering Albany County, where it turns south-southwesterly, and apparently extends to the Delaware River crossing Greene, Ulster, Sullivan, and Orange counties. Where the Sherburne formation is separated from the Hamilton by the Tully limestone and Genesee slate, fossils are comparatively rare in it, but to the east of the Chenango Valley, in Otsego and Schoharie counties, they are more common and constitute a modified Hamilton fauna. In eastern New York across Greene and Ulster counties the upper part of the flagstones or "North River blue stone" is apparently in the Sherburne formation but contains scarcely any fossils except occasionally a few species of plants.

Above the Sherburne is the Ithaca formation, which has a thickness of 500 feet in the Chenango Valley and extends from the vicinity of Keuka Lake, where it has been shown by Prof. Clarke that the "Portage or Naples fauna prevails largely to the exclusion of representatives of the Ithaca fauna,"^a eastward across Schuyler, Tompkins, Cortland, Chenango, Otsego, and Schoharie counties. In eastern New York across Albany, Greene, Ulster, and Sullivan counties the physical conditions which existed during the deposition of the Oneonta and Catskill formations appear to have also prevailed during Ithaca time and perhaps they began in the Sherburne, so that there is very little evidence of the Ithaca fauna, the fossiliferous bluish and grayish shales of the more western counties being replaced by the unfossiliferous red and greenish shales and sandstones. In Orange County and northeastern Pennsylvania there is some representation of the Ithaca fauna, the reds appearing later as one follows this series to the southwest. Prof. Clarke has clearly shown that the Ithaca fauna in the Chenango Valley is composed of "a more abundant representation of unmodified Hamilton species" than in the Ithaca region,^b which is also true to the east of the Chenango Valley, as demonstrated by the numerous lists of fossils given in this report.

From the Chenango Valley eastward the Ithaca is capped by the Oneonta formation, which is composed of red and green shales, reddish sandstones, and coarse-grained grayish to greenish-

^a Fifteenth Ann. Rept. New York State Geologist, p. 81 and "Geological map showing the distribution of the Portage group."

^b *Idem*, pp. 46-63.

gray sandstones. These rocks are nearly unfossiliferous, containing only an occasional specimen of *Archæopteris* and *Amnigenia catskillensis* (Van.) Hall. The formation has a thickness of 550 feet in the Chenango Valley and as the physical conditions under which the Oneonta was deposited appeared earlier to the eastward, it gradually thickens in that direction till in Albany and Greene counties it completely replaces the Ithaca formation.

The Chemung formation east of the Susquehanna River rapidly thins to the eastward on account of the earlier appearance of the physical conditions which prevailed during the deposition of the Catskill formation, so that the lithologic characters of the Chemung are gradually replaced by those of the Catskill, and as this change takes place the Chemung fauna disappears till the farthest east it was noted was near Spring Lake, northwest of Delhi, where a small Chemung faunule occurs above red shales. Search in the rocks occurring at the horizon of the Chemung formation east of the Delaware River was not rewarded with any fossils, and the lithologic appearance of these rocks is similar to that of those composing the Oneonta and Catskill formations.

In eastern New York in Albany, Greene, Ulster, and Sullivan counties the physical conditions under which the Oneonta and Catskill formations were deposited began as early as Sherburne time and continued throughout the remainder of the Devonian period. The representation of the Ithaca or Chemung faunas is very slight and this great mass of rocks consists mainly of alternations of red and green shales and sandstones and gray to greenish-gray coarse-grained sandstones, with some conglomerates in the Catskill Mountains. In the Delaware Valley the red rocks do not appear as early and there is some representation of the Ithaca fauna, which is more pronounced in northeastern Pennsylvania. As this series of rocks is followed along the Appalachians southwesterly across Pennsylvania, Maryland, and the Virginias it is found that the reds gradually appear later and the Chemung fauna is present. For in western Maryland, succeeding the black shales with a Genesee fauna at the top of the Hamilton, are first nearly barren smooth shales and sandstones like the Portage of western New York, then rougher shales and rather mealy sandstones containing an abundant Chemung fauna with numerous specimens of *Spirifer disjunctus* in Garrett County, and finally the red and grayish shales and sandstones of the Catskill. This change from the Catskill Mountain region to the southwest is found to be quite similar in general characters to the change from these mountains westward across southern New York, the story of which was excellently told some years ago by Prof. Stevenson in his address before the American Association for the Advancement of Science.^a

K-L 16-17. MICHIGAN, INDIANA, AND OHIO.

The Michigan section of the Devonian comprises the Dundee limestone, Traverse formation, and Antrim shale.

Lane⁵¹⁷ describes the divisions of the Devonian, and from his description the following notes have been derived.

The Dundee limestone is a persistent stratum throughout Michigan, with a general thickness of 200 to 253 feet. "Beginning with a thickness of an even 100 feet in the southeast corner of the State, it thickens slowly to Port Huron. Going west and north it at first thickens until it gets its full thickness of about 250 feet, and then begins to thin." It is nearly the equivalent of the Onondaga ("Corniferous") limestone of New York. "It is very uniformly a high-grade limestone, with only a small percentage of magnesia, not infrequently over 98 per cent CaCO₃, light colored, or brown with oily matter * * * and sometimes, not always, cherty."

^a The Chemung and Catskill (upper Devonian) on the eastern side of the Appalachian basin: Proc. Am. Assoc. Adv. Sci., vol. 40, 1892, pp. 219-248.

The relation of the Dundee to the underlying Monroe formation is one of unconformity, marked by some erosion of the uppermost Monroe. Lane^{517a} says:

At the close of the Monroe the State [Michigan] was so elevated that slight folds which occurred at the same time could be planed off, and the underlying formation in numerous places from Mackinaw to Monroe County, made into a dolomite conglomerate. * * * So far as we know it remained above water during the opening stages of the Devonian Helderbergian. * * * The same disturbance that cut Michigan off once more may have opened up New York to the Helderbergian, so that while the Coeymans and Port Ewen beds were forming in New York, 300 or 400 feet in all, Michigan was mainly out of water, and not until the Schoharie did deposition that has been recognized by its fossils begin in Michigan.

Grabau³⁸² first described the occurrence of the Schoharie fauna in the Dundee.

Lane uses Traverse to designate a division of the Devonian of Michigan which overlies the Dundee and underlies the Antrim. This is a more restricted use than that of Grabau,³⁷⁹ who employed "Traverse" to include the Dundee and Traverse of Lane.

In the restricted sense Traverse is classed by Lane^{517b} as equivalent to Hamilton and Marcellus, or Erian of Clarke and Schuchert's latest classification of the New York section, and as the representative of the Delaware limestone of Ohio. Of it he says:

As this group is much thicker and better exposed in the north end of the State and its very existence along the south line of the State has been doubted, we begin our description from the north, where it outcrops on Grand and Little Traverse bays and thence is frequently exposed around to Alpena and Thunder Bay, and is nearly uniform in thickness (600 feet with a basal shale, Bell shale, 80 feet, which corresponds to the Marcellus and is persistent throughout the State.)

Following Grabau, Lane divides the Traverse as follows:

	Feet.
Chert beds; Naples goniatite fauna at top.....	45-50
Petoskey limestone; Stromatopora and buff magnesian.....	360
Acervularia beds; Bryozoa beds.....	110
Bell shales.....	80
	600

The Antrim shale is described by Lane^{517c} as dominantly shale, "black and bituminous at the bottom, then blue, and at the top, where it passes into the Berea grit, or the horizon thereof, red or interstratified with sandstones and gritty." It is regarded by Lane as equivalent to the Senecan of the New York State Survey classification. It may or may not include a representative of the Genesee shale, according to Lane. Of the Ohio divisions it is regarded by him as the equivalent of Huron, Chagrin, Cleveland, and Bedford formations. The thicknesses cited by Lane from well records range from 140+ to 480 feet.

The passage from the Devonian to the Carboniferous in Michigan is not readily placed. Generally the Antrim shale has been regarded as uppermost Devonian and the Berea sandstone as the base of the Carboniferous. The plane at the top of the Antrim is not determinable, however, where the Berea is absent and the Antrim shale is followed by the Coldwater shale, and even where the Berea is present and the lithologic division can be established, the assignment of strata to Devonian or

Carboniferous is subject to question. It has been customary to draw the line theoretically and so far as practicable in fact at the top of the Antrim, on paleontologic grounds. Lane ^{517c} says:

In order to get consistent results and thickness one must recognize that the transition to the Berea grit is gradual and a great thickness of Berea grit or strata ascribed thereto is at the expense of the Antrim. * * *

To put the base of the Carboniferous at the base of the Bedford we should have to split the Antrim in a very impracticable way, though we could readily enough follow Ulrich's suggestion and place it lower. [Lane states that Ulrich would transfer the Antrim to the Carboniferous.] It is noteworthy that just as the Sylvania is confined to the east side of the basin along the Cincinnati anticlinal, so is the Berea grit, and when the Berea grit does not appear, then the upper strata of the Antrim have a red facies like the Bedford of Ohio, or the Richmond top to the very similar Lorraine. This red facies is, it seems to me, very likely due to exposure to the weather. Where the Berea grit is well developed it is, I believe, never found. It therefore may indicate the uplift generally taken to mark the close of the Devonian and beginning of Carboniferous.

This is the Michigan phase of the Waverly problem. (See also papers by Girty. ^{361, 363})

In northern Ohio the Cleveland shale is regarded by Prosser ^{649a} as the uppermost Devonian, whereas the Bedford shale is placed at the base of the Carboniferous. According to Lane both of these formations are represented in the Antrim shale, and thus, to be consistent with the Ohio scale, the line should be drawn in Michigan in the Antrim itself. This Lane regards as impracticable.

Following the general usage we discuss the Berea sandstone and overlying formations as Carboniferous. (See pp. 420-421.)

In 1905 Prosser ⁶⁵¹ published a classification of the geologic formations of Ohio, which has since been republished with the New York equivalents by Stauffer. ⁷⁸⁹ In another paper ⁷⁹⁰ Stauffer describes the Middle Devonian as follows:

The Middle Devonian of Ohio naturally falls into three divisions, of which the lowermost is known as the Columbus limestone, the middle as the Delaware limestone, and the upper as the Olentangy shale. This division is based on both lithological and faunal differences which in some respects are more apparent in the vicinity of Columbus, although not wanting in any of the belts of the outcrop. The thickness of each of these three formations varies through a considerable range in different parts of the State.

The Columbus limestone presents two rather persistent lithological differences which are excellently illustrated in the outcrops along the Scioto River and are not absent even in the northern sections. These two phases of the formation sometimes blend with each other, but occasionally localities are found where the change is abrupt and the characteristics of each portion decided.

The lower portion of the Columbus limestone consists of a rather porous massive brown limestone, frequently containing a large amount of bituminous matter and very little chert, but generally having numerous cavities or pockets filled with crystals of calcite. At some places near the base it has been observed to have a pitted or honeycombed structure. It sometimes shows a strong oblique jointing and frequently few definite bedding planes. A fresh surface shows a saccharoidal appearance but occasionally glistens with cleavage faces of calcite. There is also a tendency to a banded structure which may be seen in the blocks of most if not all exposures in central Ohio. This banding, frequently of a wavy appearance, seems to be due to the presence of finely divided bituminous matter. The fossils, except in the extreme upper

and lower parts, are poorly preserved and rather rare in most localities. Chemically the limestone from this part of the formation is found to be high in its percentage of magnesium. A sample from Dublin yielded 41.07 per cent of magnesium carbonate, while several from Bellefontaine gave even a higher percentage for this constituent.

The upper part of the Columbus limestone, which includes about two-thirds of the formation, consists, in the main, of light-gray limestone in even beds varying from a few inches to several feet in thickness. At places it contains a considerable amount of white or light-gray fossiliferous chert, which is mainly restricted to a few zones, where it occurs in concretionary masses which are arranged in somewhat definite layers. The upper layers of the limestone are the thinner and often of a bluish color. The heavy beds, where long exposed, weather into rather thin irregular layers which break into angular blocks and fall to the base of the cliff, forming the usual talus slope. This portion of the formation always shows a crystalline or subcrystalline structure. It is high in its percentage of calcium carbonate, which ranges from 81.14 to 93.28 per cent in samples taken from Marble Cliff quarries. While all layers seem to contain abundant fossils, many are literally crowded with the remains of the various species which swarmed in the waters of this warm Devonian sea.

The base of the Columbus limestone rests upon the Monroe formation, this contact being that between the two great systems, the Silurian and the Devonian. There is thus a great time gap or unconformity between these two formations, which is strikingly illustrated by the decided change in character and abundance of animal remains. In some localities the lowest layers of the Columbus contain an abundant fauna which in many respects resembles that of the upper part of the same formation, but where these lower layers have been observed in Franklin, Delaware, and Union counties a basal conglomerate is found which consists of large and small waterworn pebbles of the underlying formation embedded in a matrix of Columbus limestone. Where this conglomerate is developed few fossils are found, probably because the organic remains which existed in these localities at the time the layers in question were being deposited were ground to a shapeless mud by the continuous action of the waves among the pebbles of a rocky coast. This conglomerate was formerly supposed to represent the Oriskany sandstone of New York and was so mapped by the geologists who made the first county reports, as well as by Newberry himself; but since this basal conglomerate is not continuous and has not been proved to be Oriskany, it has been customary of later years, and perhaps wisely, to drop the Oriskany sandstone from the Ohio scale and include these deposits with the Columbus limestone, to which they are at least very closely related.

The upper limit of the Columbus is no less interesting, since it terminates in the famous "bone bed" first described by Orton. This layer or bed comprises the upper 6 or 8 inches of the formation and is frequently made up of an "assemblage of millions on millions of generally imperfect but mostly recognizable organs or fragments of the bony structure of the forms of fish life most characteristic of the Devonian age." These teeth and dermal plates are often in an excellent state of preservation, retaining even their original luster. Contrary to what has usually been supposed, this limiting layer of the formation may be traced northward to Sandusky, where it has proved of invaluable assistance in determining the line of division between the Columbus and Delaware limestones.

The Delaware limestone extends from the "bone bed" upward through a thickness of about 36 feet to its contact with the Olentangy shale. It is extremely variable in its appearance, consisting sometimes of thin shaly layers, beds of chert, and fairly massive limestone and again almost entirely of rather massive limestone with very little chert and no shale. Usually it has a deep-blue to slate color, which becomes brown on weathering. The chert which it contains is mostly black and nonfossiliferous, but in sections where little occurs it is often a light bluish white or even pure white and somewhat fossiliferous. In general the Delaware limestone is less fossiliferous than the upper part of the Columbus, but its fauna is by no means small, and frequently layers are found which are very fossiliferous. The variable chemical composition of this formation is easily seen by a reference to the analysis of various samples collected at different localities.

The Olentangy shale extends from the top of the Delaware limestone to the base of the Ohio shale, a vertical distance of about 31 feet in Franklin County. It has been found to be almost invariably present in the central strip from Sandusky southward. In Pickaway County, where the Devonian limestones last appear, this shale occurs, and from thence southward overlaps on the older rocks until at Bainbridge it rests on Niagaran limestones. The Devonian shales cross the Ohio River at Vanceburg, and even near Fox Springs, Fleming County, Ky., the basal shale has the appearance of the Olentangy. As seen in the river bank at Delaware, the Olentangy is a soft bluish shale, with numerous disklike argillaceous limestone concretions near the basal portion and layers of impure limestone in the middle and upper portions. The formation contains few fossils in central Ohio but becomes quite fossiliferous in the Sandusky region, where it includes a limestone member at the top, which has been known as the Prout limestone. The thickness of the formation is there also greatly increased.

Stauffer⁷⁸⁸ states that the Columbus limestone is the equivalent of the Dundee limestone of Michigan and the Jeffersonville limestone of Indiana, which are represented in New York by the Onondaga. He places the Delaware limestone of Ohio as equivalent to the Marcellus and correlates the formations of Michigan, Ohio, and New York thus:

Michigan.	Ohio.	New York.
Traverse group.	{Olentangy shale.	{Hamilton beds.
	{Delaware limestone.	{Marcellus shale.
Dundee limestone.	Columbus limestone.	Onondaga limestone.

Devonian strata outcrop in three widely separated areas in Indiana—on the Wabash, near Pendleton, and in southern Indiana. The intervening stretches are completely covered by drift. In all sections showing the lower and upper limits of the Devonian in the State the base rests upon Silurian limestones and the top is overlain by Mississippian strata. Kindle^{494a} gives the formations present in the northern, central, and southern sections and states the correlation with the New York Devonian as follows:

Devonian formations in Indiana.

Southern Indiana area.	Pendleton area.	Wabash area.
New Albany shale.	Drift covered. (?)	New Albany shale.
Sellersburg beds. Jeffersonville limestone. Geneva limestone.	Pendleton sandstone.	Sellersburg beds. Jeffersonville limestone.

When the first attempts were made to determine the age of the New Albany shale, its known fauna was limited to one or two species of Lingula. Since the discovery of the Lexington fossils by Borden in 1874^a the formation has been correlated with the Genesee of the New York scale. The discovery by the writer of a new fauna in the New Albany shale at Delphi throws some additional light on the difficult problem of the true position of this formation in the time scale. Associated with several species which are new or undetermined, we find in this fauna *Spathiocaris emersoni*, a well-known representative of the Naples fauna of New York. This fossil is not known in the Genesee in the New York sections but occurs in the Portage and even as high as the Lower Chemung.^b

^a Geol. Survey Indiana, 1874, pp. 112-134.

^b Clarke, J. M., Bull. U. S. Geol. Survey No. 16, 1885, p. 47.

Of the species which have been previously known in the New Albany shale at least three are characteristic Genesee species; one is common to the Portage and the Genesee. The presence in the New Albany shale of a Genesee fauna and a Portage fauna seems to justify the conclusion that this formation is the western representative of both the Genesee and the Portage.

The *Styliola fissurella* fauna does not bear any stronger evidence of the Genesee age of the New Albany shale than does the *Spathiocaris emersoni* fauna of its Portage age; these two faunas, however, are not intermingled in the New Albany shale. While there is no evidence that either one occupies a higher stratigraphic horizon than the other, they are found in unlike sediments. The *Styliola fissurella* fauna is confined to the fissile black shale, while the *Spathiocaris emersoni* occurs in a soft drab shale which is interbedded with the black shale in northern Indiana. The New Albany shale of northern Indiana contains in its fissile black strata and its drab sandy beds the lithologic elements of both the Genesee and the Portage, but neither these beds nor the elements of the Genesee and Portage faunas which they contain are sharply differentiated, as they are in the eastern Devonian province.

The problem of the correlation of the Devonian limestones with the New York scale is much more difficult for some parts of the Indiana province than for others. In the vicinity of the Falls of the Ohio we find two quite distinct and well-marked faunas. These are the *Spirifer granulatus* and the *Spirifer acuminatus* faunas and represent respectively the Hamilton and Corniferous faunas of New York. Near the Falls of the Ohio the Sellersburg beds and the Jeffersonville limestone which carry these faunas are sharply differentiated lithologically, the Jeffersonville limestone being a nearly pure limestone and representing clear-water conditions during its deposition, while the Sellersburg beds are composed of an impure argillaceous limestone. In the northern part of the southern Indiana area these two formations cease to be sharply differentiated lithologically and merge into each other in a limestone which is neither so pure as the Jeffersonville limestone nor so argillaceous as the Sellersburg beds near the Falls. Associated with the loss of individuality of these two formations occurs a mingling of their two faunas which renders them indistinguishable as separate faunas.

In the Wabash area the faunas of the Devonian limestone are even more distinct than at the Falls of the Ohio. In the lower one *Spirifer acuminatus* is an abundant fossil and the fauna does not differ greatly from that in the Jeffersonville limestone at the Falls of the Ohio. The upper fauna is a distinctly Hamilton fauna, but entirely different from the Hamilton fauna of southern Indiana. Two of the most abundant fossils in it are *Spirifer pennatus* and *Chonetes manitobiensis*. Neither of these species is known in the southern Indiana area.

Hopkins and Foerste⁴⁶³ follow Kindle's classification, with additional local distinctions, and give the following description of the strata:

In southern Indiana the New Albany black shale is exposed over considerable areas. It is a black to blue-gray fissile shale containing much iron sulphide and a great deal of bituminous matter. The bituminous matter is so plentiful in places that it will burn freely and the volatile gases have been distilled from it. The shale is 104 feet thick at New Albany, and elsewhere it has been reported as much as 140 feet in thickness. The outcrop covers an area from 8 to 15 miles wide, as shown on the map.

The Sellersburg limestone of Kindle includes both the crinoidal and the hydraulic limestones, but Siebenthal limits the term Sellersburg to the upper or crinoidal division and the lower hydraulic limestone he calls the Silver Creek hydraulic limestone. The Sellersburg limestone is a white to gray crystalline limestone that lies between the overlying black shale and the underlying hydraulic limestone. Frequently the basal portions are sandy and sometimes there is a layer of pebbly sandstone separating it from the underlying hydraulic limestone. The shining black pebbles are said to be rich in phosphates.

The Silver Creek hydraulic limestone lies between the overlying Sellersburg limestone and the underlying Jeffersonville limestone. It is a fine-grained, massively bedded argillaceous magnesian limestone, light to dark drab in color, becoming buff on exposure. It is 15 to 16 feet thick at Silver Creek, 8 to 10 feet at Charlestown, and 5 to 6 feet in the vicinity of Lexington.

The Jeffersonville limestone is a white to bluish-gray crystalline fossiliferous flaggy limestone, lying between the Silver Creek hydraulic limestone and the underlying Niagara limestone. It has been correlated with the Corniferous of New York. It is exposed at the Falls of the Ohio River, and from it are obtained many fine coral fossils. In this part of the area there was a great coral reef, not greatly unlike many forming at the present time, except the corals are a different class from the living ones.

The irregular contact representing the unconformity between the Devonian and underlying Silurian has been recognized locally. Kindle has noted it at a point 55 miles south of Indianapolis and in northern Indiana; farther south, according to Kindle,⁴⁹⁴ physical evidence of this unconformity between the Devonian and Silurian has not been observed. Along their contact north of Indianapolis later Devonian strata overlap northwestward beyond earlier strata, indicating the gradual submergence of the Wisconsin-Illinois peninsula; and a similar relation is noted on both sides of the Cincinnati arch in Indiana and Ohio.

The Devonian of Ohio (Columbus limestone to Ohio shale, inclusive) comprises the equivalents of the New York section from the Onondaga ("Corniferous") limestone to the somewhat indefinite horizon where the Devonian passes into the Carboniferous.

L 12. SOUTHWESTERN MONTANA.

The type section of the Paleozoic of southwestern Montana is that of Threeforks, near latitude 46°, longitude 111° 30', originally described by Peale. It includes the Jefferson limestone and Threeforks shale, which lie between the recognized Cambrian and lower Carboniferous strata.

The Jefferson limestone and Threeforks shale were first described by Peale^{631, 632} as representing the Devonian and possibly including some Silurian at the base and some Carboniferous at the top. Peale states the occurrence of pebbly limestones of Upper Cambrian or Lower Ordovician age, and in the folio text says:^{632a}

DEVONO-SILURIAN.

The pebbly limestones pass imperceptibly into a series of black magnesian limestones which for several hundred feet are, so far as examined, devoid of fossils. It is possible, as the pebbly limestones have every indication of being on or near the border line between the Cambrian and the Silurian [Ordovician], that their upper beds and a part of the overlying black limestones may eventually be referred to the Silurian [Ordovician and Silurian]. There is little doubt that the sedimentation was continuous, and we need not be surprised if sometime in the future this now barren interval should somewhere furnish a mingling of Silurian and Devonian forms.

DEVONIAN.

The black limestones referred to under the head of Devono-Silurian have been provisionally referred to the Jefferson formation, because the fragments of fossils found in the middle and upper part, although few and very indistinct, were recognized to be the same as those occurring in the Threeforks shales, which are, without much doubt, Devonian. The total thickness referred to the Devonian is about 870 feet.

The Jefferson limestone forms the base of the formation, consisting of several hundred feet of black or mud-colored limestone, which is generally crystalline and magnesian from top to bottom. It is well exposed in all parts of the Threeforks region and at most localities is non-fossiliferous, only a few forms having been obtained from near the top of the formation, and these only in the region north of the East Gallatin River.

The Threeforks shales, which rest conformably upon the Jefferson limestone, may be divided into three parts—the lower or orange-colored shales, about 50 feet in thickness; a band of grayish-brown argillaceous limestone, 20 feet thick; and the upper green, black, and argillaceous shales, some 50 feet in thickness, which are crowded with Devonian fossils and capped by a band of yellow laminated sandstone 25 feet thick. These Devonian fossils were found both in the northern and in the southern portion of the district, and doubtless occur wherever the beds are found. A coal-black slate is seen near the upper part of the shales in the vicinity of the head of the Missouri River. In the Jefferson Canyon this has developed into a bed of coal, in which are found limestone nodules containing the same Devonian forms that are elsewhere found in the shales. The shales are near the border line of the Devonian and Carboniferous and their organic remains contain a mingling of forms of both, but the preponderance of evidence is in favor of their Devonian age.

On examining fossils collected in course of the survey of Yellowstone Park, Girty^{393c} confirmed the determination of the Devonian age of the Threeforks shale and noted the relation of the fauna to the Devonian of the White Pine district, Nevada. Fuller collections have been made by Kindle⁴⁹⁹ in a special study of the Jefferson limestone and by Raymond⁶⁶² from the Threeforks shale. Kindle concludes that the Jefferson is "earlier than Upper Devonian" and probably includes both Lower and Middle Devonian. Raymond describes the fauna of the Threeforks shale as Upper Devonian.

Kindle says, in part:

The Jefferson limestone has a wide distribution in the northern Rocky Mountain region. In Montana its distribution seems generally to coincide with that of the Madison limestone, which immediately follows it in the sections where the highest formation of the Devonian system is absent. Its distinctive composition and color have enabled geologists to identify the Jefferson limestone over a rather wide area in Montana and northwestern Wyoming. The writer has recognized the formation still farther south in western Wyoming and northeastern Utah. [Details follow.]

The evidence now at hand indicates that the eastern edge of the formation lies somewhere near the one hundred and ninth parallel in the States of Montana, Wyoming, and northern Utah. What its southern and western limits may be remains to be determined. The formation has a known east-west extent of about 150 miles in Montana and a north-south extent of about 425 miles. Its actual extent is probably much greater. The paleontologic evidence of the identity of this formation with the Nevada limestone of Nevada is presented elsewhere in this paper.

Sections in Montana.—Some of the stratigraphic evidence on which the extent of the Jefferson limestone as outlined above is based may be shown by consideration of a few typical sections which include this formation and exhibit its relations. The section at Threeforks, Mont., the type locality of the Jefferson, as given by Peale, is as follows:

Section at Threeforks, Mont.

	Feet.
Carboniferous: Madison limestone.....	Jaspersy limestones..... 575
	Massive limestones..... 350
	Laminated limestones..... 325
	1,250
Devonian: Threeforks shales.....	Upper shale..... 70
	Limestone bed shown in section.
	Lower shales..... 65
	135
Silurian (?) [Devonian of Kindle]: Jefferson limestones.....	Black limestones..... 640
Cambrian: Gallatin formation.....	Pebbly limestones..... 145
	Dry Creek shales..... 30
	Mottled limestones..... 260
	Obolella shales..... 280
	Trilobite limestone..... 120
	835
* * * * *	*

The Threeforks shales appear to have a much more limited distribution than the Jefferson limestone. They are present, however, in the Melrose section, on Camp Creek, some 30 miles west of Threeforks. The following section is seen along Camp Creek:

Section on Camp Creek, Mont.

	Feet.
K. Gray nonmagnesian limestone (Madison limestone).....	300±
J. Bluish-gray argillaceous shale, buffish shale in lower part, with limestone bands near middle (Threeforks shale).....	200±
I. Black magnesian limestone, with minor beds of gray limestone distributed through the series (Jefferson limestone).....	500±
H. Buff-gray hard magnesian limestone, with some shaly bands.....	30
G. Buffish-gray nonmagnesian limestone, 1-inch to 3-inch laminae, separated by thin bands of shale.....	35
F. Dark-red sandy shales.....	20
E. Light-gray magnesian limestone, with some dark bands in lower half.....	500±
D. Shale.....	100
C. Shale and thin-bedded brownish sandstone.....	50
B. Gray shale.....	40
A. Quartzite weathering brownish buff.....	65

The Jefferson limestone seems to reach its maximum thickness in the western part of the State. In the Philipsburg [quadrangle] nearly 1,000 feet of the Paleozoic section is represented by the dark limestones of the Jefferson formation. The following section indicates the relationship of these beds in this region, as seen along Boulder Creek, west of Princeton:

Section along Boulder Creek, Philipsburg quadrangle, Mont.

	Feet.
E. Dark-gray to white heavy-bedded and flaggy limestone, shaly toward the base (Madison limestone).....	500±
D. Gray to black limestone in alternating beds, the latter predominating and distinctly magnesian, generally with saccharoidal texture (Jefferson limestone).....	800
C. Gray to brownish shale and sandstone; the latter predominates at the base.....	210
B. Bluish-gray limestone, with thin siliceous, argillaceous, and shale films at intervals of 1 inch to 3 inches. These intermediate laminae weather brownish and show in relief thin, flat, pebble-like concretionary (?) sheets.....	275
A. Light-gray to cream-colored hard magnesian limestone.....	300

This section differs from the two preceding sections in the absence of the Threeforks shale, which seems to be everywhere wanting in the Philipsburg quadrangle.^a

* * * * *

^a For list of fossils see the work cited.—B. W.

Other sections in southwestern Montana might be given which would present the same general sequence with reference to the Jefferson limestone. All the sections show a limestone series in which dark to nearly black limestones predominate, followed by the Madison limestone, which is locally separated from the Jefferson by the Threeforks formation. The Jefferson in all the Montana sections is preceded by limestones and shales in which the latest observed faunas are of Cambrian age.

Sections in Wyoming.—The Montana sections show a close correspondence in these characteristic features to the southwestern Wyoming section, which follows. This section occurs in the westward-dipping beds of Labarge Mountain, northeast of Viola post office and west of the Sayles coal mine.

Section northeast of Viola, Wyo.

	Feet.
J. Light to dark-gray limestone, oolitic in lower 20 feet (Madison limestone).....	500±
I. Drab shales and shaly thin-bedded magnesian and siliceous limestone.....	80
H. Buff to gray limestone with much black magnesian limestone in the upper part, saccharoidal in texture, and weathering with roughly pitted surface; covered in part (Jefferson limestone).....	1,000±
G. Gray limestone, partly covered.....	700±
F. Gray limestone, with Cambrian trilobites abundant.....	40
E. Green shale and covered.....	300±
D. Drab shale and covered.....	30
C. Thin-bedded gray limestone, with Cambrian trilobites abundant.....	10
B. Drab shale, mostly covered.....	100
A. Lead-gray limestone, checked by innumerable small joints, which are generally calcite filled.....	120

In this section the gray and black limestone series is preceded by beds holding a Cambrian fauna and followed by a limestone holding the usual Madison limestone fauna. The shale formation (I) at the top of the magnesian limestone formation appears to occupy the position of the Threeforks shale, but it is barren of fossils. Composition, texture, manner of weathering, and relationship to the section all indicate that the magnesian limestone series of the section is the same formation as the Jefferson limestone of the Montana sections.

The Jefferson limestone of the Labarge Mountain section is nearly barren of fossils. The only fossils obtained in it were *Zaphrentis* and fragments of another undetermined coral.

* * * * *

Devonian rocks in Idaho.—The only data we have relating to the Devonian in Idaho are based on a small collection of fossils made by Mr. F. B. Weeks during the summer of 1907. This collection was procured from a dark limestone “in southeastern Idaho, east of Manson station, Oregon Short Line Railroad.” The three species represented in the collection are *Atrypa reticularis*, *Productella* cf. *subaculeata*, and *Spirifer disjunctus* cf. var. *animasensis*. The first species is the most abundant in the fauna. The presence of *Sp. disjunctus* seems to indicate an Upper Devonian horizon. The fauna is not sufficient to show whether or not the Jefferson limestone is represented by it. Probably, however, it is from this formation. The appearance of the rock, which is dark, somewhat magnesian limestone, is highly suggestive of the Jefferson limestone. The evidence of the small fauna, though inconclusive, points to the Jefferson limestone rather than to the Threeforks shale as its source.

About 60 miles southeast of this locality, in northeastern Utah, the Jefferson limestone is well developed.

Sections in Utah.—Field studies in Utah were limited to the northern part of the Wasatch Mountains. Numerous excellent sections of the Paleozoic are exposed by the deep canyons east of Cache Valley. The canyons cut at right angles the general trend of the structure, which is of the moderately folded type, few of the heavier dips exceeding 30°. Nearly vertical cliffs 2,000 feet or more in height alternate with slopes of every degree of inclination along the sides of the canyons. * * *

Examination of half a dozen of the canyon sections to the south of Logan Canyon has shown that the Carboniferous and Devonian portions of the section may be distinguished both by physical and faunal characters. In the Devonian series, generally 1,000 to 1,200 feet thick,

dark magnesian limestones are the predominant element, although nonmagnesian limestones and in some places argillaceous rocks appear as minor components of the formation. In the Carboniferous the dark magnesian limestones of the lower series are replaced by lighter-colored nonmagnesian limestones. The Carboniferous and Devonian series of these sections show about the same kind and degree of contrast which is found between these series in the Montana section. The Devonian beds of these northern Utah sections appear without question to be the southern continuation of the Jefferson limestone. The following is a representative section occurring nearly east of Paradise post office, in Green Canyon:

Section in Green Canyon, Utah.

	Feet.
D. Gray nonmagnesian limestone, partly covered.	900±
C. Dark-gray to black magnesian limestone, generally with saccharoidal texture.	1,100±
B. Thin-bedded limestone, buff or brownish near top, with peculiar concretionary development, with thin-bedded bluish-gray limestone in lower part.	100
A. White to light-gray magnesian limestone, with chert or siliceous beds locally developed [Silurian, Kindle].	150
	2,250

Kindle mentions the contrast between the Jefferson fauna and that of the Ouray limestone of Colorado, and also comments on the close equivalency of the Jefferson limestone of Montana, Wyoming, etc., and the Nevada limestone of Nevada and their faunas. He says in part:

The fauna of the Jefferson limestone as known at present is a small one, numbering about 32 species. Like many other western faunas, it includes very few species which are common to the standard sections east of the Mississippi. Of the five species which are common to the well-known eastern sections all except *Atrypa reticularis* are characteristic Devonian species, a sufficient number to make evident the Devonian age of the fauna. * * *

In attempting to determine just what part of the Devonian is represented by the fauna of the Jefferson limestone we find that two of the five species which are common to the Jefferson limestone fauna and the eastern Devonian fauna are *Atrypas*. One of these, *A. reticularis*, has no diagnostic value, while *A. spinosa* has a recorded range from the Corniferous to the Chemung. The other three species, *Schuchertella chemungensis arctostriatus*, *Productella spinulicosta*, and *Martinia mæja*, are known in the eastern sections only in Middle Devonian horizons. The absence from the fauna of any of the large *Productellas*, which generally characterize the late Devonian faunas, together with the presence of an Upper Devonian fauna following it in the section, both supplement the intrinsic evidence of the fauna that it is earlier than Upper Devonian. The known range of the fossils which are common to eastern sections suggests a Middle Devonian age for at least a part of the Jefferson limestone. The fauna contains no coarsely plicated Spirifers or other fossils generally characteristic of the early Devonian, but other evidence strongly supports the view that the Jefferson limestone represents both Lower and Middle Devonian.

No evidence of a stratigraphic break between the Jefferson and the preceding formation has been observed by the writer in any of the sections examined by him. None of the folios which describe the Jefferson limestone record any unconformity at its base. * * * In Utah the writer has found conditions that seem to indicate there the continuity of sedimentation from the Silurian to the Devonian, which, although probable in Montana, has not been demonstrated. * * *

The fauna of the Threeforks shale, which immediately follows the Jefferson limestone in some of the sections in Montana, is composed for the most part of alien species. Dr. Raymond's list of the Threeforks shale fauna at Logan and Threeforks, Mont., showed but three species which are known in the Jefferson limestone. Evidently very few of the indigenous species of the Jefferson limestone survived the conditions which inaugurated the deposition of the shales that terminated the Devonian in this region.

Raymond's notes on the Threeforks shale refer to the type locality in southwestern Montana. He says in part:⁶⁶²

It is the purpose of the present paper to announce the discovery in the Threeforks shales, near Threeforks, Madison County, Mont., of an Upper Devonian fauna containing *Clymenia*, *Entomis*, and goniatites.

* * * * * * * *	
The Threeforks shales were divided by Dr. Peale into three portions:	
	Feet.
3. Upper shales, with many fossils.....	65
2. Grayish-brown limestone, without fossils.....	15-20
1. Lower shales, without fossils.....	50

Division 3 is subdivided as follows:

	Feet.
D. Yellow sandstone, the lower part calcareous.....	25
C. Coal-black shale.....	5
B. Gray limestone.....	10
A. Green shales with bands of limestone.....	30
* * * * * * * *	

In the 65 feet of strata constituting the upper shales at Threeforks there are five zones in which the lithology and faunules differ somewhat. 1, 2, and 3 make up A above; 4 is the same as B; and 5 equals D. From C no fossils were obtained. These zones, beginning with the lowest, are as follows:

1. *Red shale zone*.—The shales of this zone are hard, reddish, and fissile, the layers weathering into small, sharp-pointed fragments. The fossils are preserved in pyrite, which is often partially altered to limonite, and they weather out on the surface in numerous bare spots along the strike of the beds. * * *

2. *Green shale zone*.—These are the green shales described by Peale (part of A, above). Fossils abound and further collecting should reveal a much larger fauna. *Clymenia* and *Entomis* are abundant, associated with a great number of brachiopods and lamellibranchs. * * *

3. *White blocky shale*.—The exact horizon of this zone is not known, as the fossils were obtained at a locality where the layers seemed to be somewhat disturbed. In the field it appeared to be above the green shale, but it could not be located in any place where the beds were undisturbed. The faunal list is short, but the fossils are abundant. * * *

4. *Gray limestone zone*.—This limestone weathers readily and produces great quantities of fine fossils, mostly brachiopods. Two species of *Clymenia* occur in this zone, but the goniatites are very rare. This same limestone is well exposed in the Devonian ravine at Logan, but no specimens of *Clymenia* were found at that locality; it has, however, furnished two fragments of cups of crinoids, one of which has been identified as a species of *Mariacrinus*, by Mr. Frank Springer. This is of interest, as it is the first crinoid reported from the Devonian of the Rocky Mountains. * * * This seems to be the upper limit of the range of *Clymenia*.

5. *Yellow sandstone zone*.—This sandstone or sandy limestone forms the capping bed of the Devonian both at Threeforks and at Logan. A few beds are very fossiliferous and the fauna indicates a transition into the Mississippian (Madison limestone).^a

L 18. ST. HELENS ISLAND, MONTREAL.

A very small exposure of Devonian agglomerate on St. Helens Island, Montreal, has yielded Devonian fossils that appear to present a unique association. Schuchert⁷¹³ reviewed the faunas and the conditions of their occurrence and concluded:

The foregoing evidence shows clearly that two distinct faunas are represented on St. Helens Island—one, the Helderbergian, older than the agglomerate, and another, from a block in the agglomerate, of Middle Devonian age.

^a For lists of fossils from the several zones see the work cited.—B. W.

The Helderbergian fauna is apparently related with that of New York, and belongs to the facies occurring on the western side of the Appalachian folds. The writer has collected this fauna at Dalhousie, New Brunswick, and from the Gaspé region, Quebec, and both are of another facies and belong to another basin.

The presence of *Rhipidomella* recalling *R. musculosa*; *Spirifer concinnus*; an early variety of *S. purchisoni*; *Spirifer* n. sp., connecting phylogenetically *S. concinnus* and *S. arenosus*; *Camarotoechia pleiopleura*; *Gypidula pseudogaleata*; and *Rensselaeria acquiradiata* shows that the St. Helens Island Helderbergian is not as old as the New Scotland zone. *Spirifer concinnus* and especially *G. pseudogaleata* and *R. acquiradiata* are characteristic Becraft zonal species. However, the Oriskanian reminders, like *R. musculosa*, *S. purchisoni*, *S. near arenosus*, prove that the St. Helens Island Helderbergian is pretty well up toward the top of the New York section, and may represent both the Becraft and Kingston zones.

Spirifer macra and *S. granulosus* establish the fact that, in the region of Montreal, there was once a formation of marine origin later than the Helderbergian and as recent as the Onondaga (Corniferous); further, that the agglomerate of St. Helens Island and other places about Montreal is not older than late Middle Devonian time. Its age is probably more recent, and there may be further paleontologic evidence in the agglomerate.

L 18-19. QUEBEC, SOUTHEASTERN TOWNSHIPS.

Ells³¹³ states that "areas of Devonian rocks occur at several widely separated points in the area east of the Sutton Mountain anticline and its extension northward." Small outliers are known on the Chaudière. "While detached areas of Silurian (Lower Helderberg) occur at a number of places between the Chaudière and the United States boundary, to the southwest, the only outcrops of strata holding typical Devonian fossils are found on the western shore of Memphremagog Lake." These rocks had been previously described by Logan and Billings and had been assigned to the "Corniferous" horizon by Dana and by Ells. They are plumbaginous limestones, underlain by somewhat dolomitic flaggy slates and shales, which Ells describes as resting upon fossiliferous "Silurian" strata [Devonian Helderberg limestone]. They are penetrated by intrusive dikes. With reference to the relations of these Devonian rocks to the Silurian and to the Devonian of the Gaspé Peninsula, Ells^{313a} states:

No well-defined break between the upper Silurian (Lower Helderberg) and the overlying Devonian has been found, the conditions of deposition presumably being similar to those in the Beauce [Chaudière] district or in the similar beds of the Gaspé Peninsula, described under the head of the Gaspé Limestone series in the "Geology of Canada," as well as in subsequent reports.^a In all these localities there appears to be a mingling of forms of upper Silurian and lower Devonian horizons, in so much that it has been found very difficult, and in some cases impossible, to define the exact line of separation between the two systems.

L 19. SOUTHERN NEW BRUNSWICK AND EASTERN MAINE.

In southern New Brunswick Devonian rocks occur in two areas—one in Charlotte County south of the Carboniferous basin, the other in St. John County, consisting of the Mispec and Lepreau basins. The rocks of the latter area extend across the international boundary and occupy the Perry Basin in eastern Maine.

The belt which is mapped as Devonian in Charlotte and Queens counties south of the Carboniferous basin was thus described in 1880:⁴⁹

The largest area of rocks of this age is that occurring in the northern part of Charlotte County and extending eastward into Queens County. These rocks have been described in the

^a Geology of Canada, 1863, pp. 406-428; Rept. Progress, Geol. Survey Canada, 1880-82, pp. 3-16DD.

report of 1870-71, and are also briefly mentioned in the report of 1876-77. They comprise the former so-called pale argillite group. They are superimposed upon Cambro-Silurian rocks and extend from the St. Croix River, near Spragues Falls, to the Charlotte County line and thence into York. At the line of contact the dips are nearly vertical, but there is in places an apparent conformability between the dark argillite portion of the Cambro-Silurian and the series under discussion. It is probable, however, that faults occur at the line of contact, as the beds of fossiliferous Silurian so well developed about Oak Bay, on the south side of the Cambro-Silurian belt, are entirely wanting along the northern margin. The Devonian age of these rocks has been based by Mr. Matthew upon the occurrence of remains of *Lepidodendron*, * * * as well as from certain graphitic films, supposed to be the impression of fern leaves, found in the eastern extension of these beds into Queens County. They also possess many points of resemblance, lithologically, to the typical Devonian Mispec, and hence they have provisionally been assigned to this horizon.

Doubt is cast upon the Devonian age of these rocks, as the Mispec group is now known to be meso-Carboniferous.^{22a} (See p. 331.)

The Devonian rocks of the St. John-Lepreau-Perry area have been the subject of much discussion as to their true age and have been considered Carboniferous on account of lithologic resemblances. The latest contribution from the Canadian Survey is by Ells,³¹⁵ as follows:

One of the most interesting of the geological formations which occur in this portion of New Brunswick is that known as the Perry sandstone group. * * * The rocks consist of conglomerates, sandstones, and shales, generally reddish in color, but occasionally, in the lower portion, some of the heavier sandstones and conglomerates become grayish. Plant stems are quite abundant in some of the shale beds, both in the rocks of Perry and near St. Andrews. These were carefully studied many years ago by Sir William Dawson and several papers relating to their character and age were published by him between 1861 and 1870, in which their horizon was placed as the upper portion of the Devonian system. The same conclusion had been reached at an earlier date by Dr. Jackson and adopted by Prof. Rogers, after an examination of the material from the plant beds of Perry, Maine.

In the report by Bailey and Matthew, 1870-71, the opinion is expressed that the rocks of this group are referable to the base of the Lower Carboniferous, rather than to the Devonian, from a supposed lithological resemblance to certain conglomerates which are found in Kennebecasis Bay, an arm of the St. John River, where these rocks are assigned to the Carboniferous horizon.

In Charlotte County the Perry group can be well studied in the peninsula extending from the base of the Chamcook Mountain to the point at St. Andrews where the exposures are practically continuous for a distance of about 5 miles. The beds are cut across by several dikes of green diabase which have altered the sediments at their contact. Similar dikes are seen on Minister's Island to the east.

The lowest beds of the group at Chamcook Mountain consist of a coarse, heavy conglomerate with pebbles, often of large size, for the most part derived from the felsitic rock of which the mountain is composed. These conglomerates are a conspicuous feature in many places at the base of this series of rocks, and they also occur occasionally as intermediate beds higher up in the series. They are well exposed in the bluff east of Chamcook Harbor, on the islands and on the shore at the entrance to Digdeguash Harbor and further east on Bliss Island, L'Etang Head, and Pea Point, and again around the shores of Lepreau Harbor, which is the extreme eastern part of the county.

The dip of the strata in the St. Andrews Peninsula is uniformly to the south or southeast, at angles from 10° to 25°. At an average inclination of 15° over a distance of 5 miles, since the southern margin of the basin is not here reached, the thickness for the beds at this place will not be far from 7,000 feet. No well-defined faults or repetitions of the strata are seen in this section. This estimate of thickness far exceeds that hitherto made for any portion of the lower Carboniferous as developed in southern New Brunswick.

* * * * *

The outlines of this formation were carefully traced along the shores from the St. Croix River to Point Lepreau, and in some places, as at Pea Point, and L'Etang Head, the basal conglomerate was found to have a great thickness, aggregating not far from 4,000 feet. At Lepreau Harbor, where these rocks are well exposed, they apparently rest directly and conformably upon the Devonian shales and sandstones of the Mispéc and Little River groups of the St. John Devonian basin. As they elsewhere underlie the basal beds of the lower Carboniferous, including the marine limestones of that series, it would now appear that the rocks of the Perry River group, as a whole, represent the upper portion of the Devonian system of southern New Brunswick, as was early suggested by Sir William Dawson and others from the evidence of the contained plants.

The above statement by Ells that the rocks of the so-called "Perry" of Lepreau Harbor rest conformably upon Devonian rocks of the Mispéc group raises a question as to the relation of the "Perry" at Lepreau with the true Perry formation of Maine. If the Mispéc rocks are meso-Carboniferous (see p. 331) strata which rest conformably upon them must be middle Carboniferous or later; whereas the true Perry is Devonian, probably Upper Devonian. Furthermore, plant remains which, like those of the Mispéc, are now referred to the middle Carboniferous have been found near Lepreau Harbor. In view of the great thickness and highly disturbed condition of the strata it is probable that more than one terrane is represented in that vicinity.

The Devonian age of the Perry formation in the type locality in Maine has recently been placed beyond question by the investigation made by Smith and White,⁷⁵⁹ who have assembled in the field and from the literature the essential facts of stratigraphy and paleontology. They thus describe the Perry formation:

The Perry formation as exposed in the towns of Robbinston and Perry is divisible into four members. Two of these members consist of sedimentary strata, while the other two are interbedded lavas and associated volcanic breccia. The section may be described thus:

Upper lava: Green lava with columnar parting and amygdaloidal texture. Includes one bed of conglomerate and sandstone.

Upper sandstone: Coarse red and brown sandstone and conglomerate, with small amounts of shale. Includes one flow of lava near base.

Lower lava: Basaltic lava and breccia. Includes one thin bed of conglomerate near top.

Lower conglomerate: Coarse conglomerate and red sandstone, with thin beds of sandy shale.

The thickness of these members can not be definitely given. The lowest member is evidently the thickest, but probably its thickness varies considerably in different parts of the area. As will be noted later, the Perry sediments were largely shore deposits, so that the distance from the source of the material would control largely the thickness of the beds. In case of the volcanic members the different lava flows give the impression of being rather more persistent in thickness than might be expected.

White made a thorough study of the plant remains originally described by Sir William Dawson, and of others including new collections from the Perry. He describes the species, discusses their distribution, and concludes:^{759a}

Of the entire flora described^a from Perry, *Sphenopteris filicula* and *Bepidocystis siliqua* are types which appear to belong to groups more or less distinctly characteristic of the lower portion of the lower Carboniferous. The fragment described as *Palæostachya?* sp., and the forms earlier published as *Lycopodites comosus* and *Carpolithes lunatus* are too little known or

^a *Lepidodendron gaspianum*, a characteristic Devonian plant, unknown in the Carboniferous, and reported from Perry by Dawson, is omitted from the list as insufficiently represented for identification in the Perry material which I have seen.

too ambiguous to be at present of stratigraphic value. The correlative significance of *Sporangites jacksoni*, which has not been found elsewhere, is also as yet undetermined. The remaining species which comprise the main body of the Perry flora are Devonian.

As will have been seen in the foregoing review, the evidence of the geologic distribution, so far as known, of the identical species, of the genera themselves, and of the most nearly related plant forms indicates distinctly and overwhelmingly a Devonian age for the Perry formation. The stratigraphic range of most of the species and their allies strongly points to a place in the upper Devonian, the preponderance of the evidence being in favor of the Catskill-Chemung stage. Allowing for the full weight of the two or three species of close lower Carboniferous affinities, the flora can not at latest be assigned to a stage above the upper Catskill as developed in northeastern Pennsylvania and southeastern New York. Compared with the flora of other continents the closest paleontologic affinities of the Perry flora are found in the plant associations of the Donetz and of the Arctic Devonian.

The occurrence of closely related species of Barinophyton and Leptophlæum together with Archasopteris in the Devonian of Australia affords an interesting example of the remarkable intercontinental distribution of the later Devonian plant types.

The conclusions as to the age of the Perry beds recorded long ago by Sir William Dawson are fully corroborated by the study of more extensive material and the discovery of additional plants.

The Devonian of Aroostook County, Maine, is discussed by Williams and Gregory.^{937a} Williams gives the following classification of the local subdivisions:

Recent investigation of the rocks of the northern part of Aroostook County has brought to light a few facts regarding the stratigraphic terranes, which may be stated with some degree of precision.

There are a few well-marked groups of rocks which are distinguishable by their lithologic characters, and the relative age of which is determined by their contained fossils. The order which the present knowledge of the faunas seems to indicate is as follows:

Devonian:

9. Mapleton sandstone.
8. Moose River sandstone.

Silurian:

7. Chapman sandstone. [a]
6. Square Lake limestone. [a]
5. Ashland limestone.
4. Ashland shales.
3. Sheridan sandstone.
2. Graptolite shales.
1. Aroostook limestone.

Below the Aroostook limestones are slates, which it is believed are of Cambrian age, but positive evidence of the age is wanting.

The lower seven belong to the Silurian; the upper two to the Devonian. The paleontologic evidence is clear in placing 1 to 5 below the Lower Helderberg horizon of the New York series.

The Aroostook limestone, on both stratigraphic and paleontologic grounds, is believed to be older than any other of the terranes mentioned in this list.

The Ashland limestone, Ashland shales, and Sheridan sandstone are faunally closely associated and belong together as the representatives of the Clinton-Niagara of the New York standard.

The Graptolite shales the writer believes to be of Clinton age, but their stratigraphic position in the Maine series is not satisfactorily established. They may belong in the midst of the

^a Now known to be of Devonian age.—B. W.

series 3, 4, 5, or even above them; more evidence will be needed to determine their position with certainty.

The Chapman sandstone fauna is younger than the Square Lake fauna; the present opinion is that it corresponds closely with the Lower Oriskany of the New York and interior series. The identification of the fauna with Honeyman's zone D Arisaig and with the "Tilestone" fauna of Wales establishes its place at the top of the Silurian. (See *Am. Jour. Sci.*, 4th ser., vol. 9, p. 203.)

The Moose River fauna is a facies of the Eodevonian and represents the Oriskany.

The Mapleton sandstone is the representative of the higher parts of the Gaspé sandstone, and is the Old Red sandstone facies not expressed in New York until a point higher up, in the Catskill sandstone, is reached.

Besides these terranes, determinable by their fossils, there are slates and crystalline rocks, the precise age of which is undetermined. The slates are presumably Cambrian or pre-Cambrian.

L 20. NOVA SCOTIA.

The supposed Devonian rocks of Nova Scotia were described in 1886 and 1890-91 by Fletcher,^{334b, 335c} who distinguished a "lower conglomerate group," a "middle gray sandstone and slate group," and an "upper red slate and sandstone group."

In his second report Fletcher gave the following general account:

Most of the metamorphic areas of the hills of Antigonish, Pictou, and Colchester counties consist of rocks whose geological position is between the group containing marine fossils of Lower Helderberg age, and the Carboniferous or Mountain limestone, also characterized by the occurrence of marine types, whereas all the fossils found in the intervening Devonian consist of shells indicative of shallow-water origin, and of plants both drifted and erect, indicating land conditions. Between this series and those underlying and overlying, there is everywhere the clearest evidence of enormous unconformity, and although from the abundance of their plant remains they have sometimes been confounded with Millstone grit and even higher strata, their relations to the Carboniferous limestone at the East Mountain of Onslow and Penny's Mountain, at Shubenacadie, Stewiacke, Walton, Cheverie, Parrsboro, and wherever the two series are in contact, and the ease with which they can be traced from point to point, show that they are to be compared rather with the Mispick and Little River groups of New Brunswick, and that the Carboniferous limestone rests unconformably on the slates.

In spite of their disturbed and partly altered condition, these rocks have yielded fossils, which show that a considerable part of the supposed Devonian contains a middle Carboniferous fauna and flora. The stratigraphic evidence of Devonian age has been controverted by the paleontologic evidence of Carboniferous age. Ami²² has recently summed up the results of investigations covering both lines of evidence as follows:

For many years it was taken for granted that the highly fossiliferous beds of carbonaceous shales, etc., known as "the fern ledges" of New Brunswick, were of Devonian age, although the character of the flora, even at first sight, is one of decidedly Carboniferous facies. The 80 or more species representing the flora of that period are preeminently Carboniferous, and recently Mr. David White has recorded no less than 17 species of Pottsville forms, which came originally from the "fern ledges." The Lancaster formation of the author was defined as that series of strata which held this very characteristic flora, and it is capped by another Carboniferous formation consisting of red shales and conglomerates, with but few species occurring therein; to which formation the designation Mispick formation of New Brunswick was applied. These two formations, the Lancaster and the Mispick, find their equivalents in the Union and Riversdale of Nova Scotia, which Sir William Dawson always held to be of Middle Carboniferous age (Middlestone grit).

The main argument advanced by those that held that these four Middle Carboniferous formations were "Devonian" was based on the supposition that the Lower Carboniferous limestones rested unconformably on these same or equivalent formations.

In two of the crucial localities in Nova Scotia visited by the writer some time ago, where Carboniferous shale rested unconformably on shales, etc., it has been ascertained beyond a doubt that in one instance (at West Bay, near Partridge Island and Parrsboro, in Cumberland County, Nova Scotia) the Carboniferous limestones proved, on examination of the organic remains entombed in them, to be of true and undoubted Upper Carboniferous age and not Lower Carboniferous, while in the other instance (in the MacArras Brook region of Nova Scotia, where the "Lower Carboniferous" strata rested unconformably on the so-called "rocks of Union," or Union formation) the writer finds that the subjacent strata are in no sense equivalent to the rocks of the Union formation at all (as they are developed at the type locality near Union station, on the Intercolonial Railway, just below Riversdale). The Lower Carboniferous strata at MacArras Brook rest unconformably on the upturned edges of the lowest Devonian of that region, as the fossil evidence obtained very clearly showed. The Knoydart formation, of Eo-Devonian age, as seen and developed at MacArras Brook, contains a fauna, which is so nearly allied and identical with that of the lower "Old Red sandstone" strata of Scotland and Great Britain generally that the two can very well be classed as homotaxial and belonging to the same period in the history of the earth's crust—a horizon or formation which had not been previously recorded in America and which, nevertheless, occupies a definite position, not at the summit of the Devonian, as some geologists would have us believe, but indeed at the very bottom of the system or division of the time scale.

The error of correlating the rocks of MacArras Brook with those of the Union has led to confusion, and the paleontological evidence, which has been obtained by the writer in both series of strata has conclusively shown that the one (Knoydart formation) indicates a typical "Old Red sandstone" fauna that is lowermost Devonian in age, while the other formation is distinctly referable to the Middle Carboniferous, being associated with and intimately related to the "rocks of Riversdale," containing a typical Meso-Carboniferous flora and fauna, which opinion Messrs. R. Kidston, Prof. David White, Dr. Wheelton Hind, Prof. Charles Brongniart, and Dr. Henry Woodward and others have shared with the writer. The fact that these "rocks of Union" and the "rocks of Riversdale" had for so many years been referred to the Devonian by Canadian geologists led the writer to seek diligently for Devonian types and forms in those strata, and it must be distinctly stated here that I utterly failed to obtain any horizon markers of Devonian aspect in the true rocks of Union and Riversdale. All types found were of decidedly Carboniferous facies and well up in that system. The fossil plants, the fossil fishes, the Crustacea, the insects, etc., all pointed to a horizon of Meso-Carboniferous age, and there we are constrained to place them.

I desire here to correct an error made by myself in following and accepting without verification the statement made by stratigraphical geologists that the "rocks of Union" and the "rocks of Riversdale" were always found overlain by the marine limestones of the "Lower Carboniferous" and were therefore older. On the contrary, I find that the so-called "rocks of Union" as they are developed at MacArras Brook, are the only strata that can in any sense be referred to the Devonian; in which instance it so happens that these so-called "rocks of Union" are not at all the same as those of the Union formation proper. This error on my part in taking for granted that all the strata were one and the same formation, and which had been referred to the "rocks of the Union" and the "rocks of the Riversdale" as unconformably below the limestones of the Lower Carboniferous, as the stratigraphical geologists had said, led me to make the further statement that the "rocks of Union" and the "rocks of Riversdale" were Eo-Carboniferous in age. In referring these strata to the Carboniferous, I was guided by the fossil remains entombed in them, whereas I was misled by the succession as given by the stratigraphical geologists without any qualifications. It was only when the faunas of the Knoydart formation, from the so-called "rocks of Union" in the MacArras Brook region, were obtained

and determined by Dr. A. Smith Woodward and Dr. Henry Woodward and others, that the confusion that existed was evident to me, and the necessity of separating these two sets of strata became apparent. This led to the separation of the Knoydart formations from their supposed equivalents "the red rocks of Union." I have no hesitation in saying now that the Union and Riversdale formations, as they are developed at the type localities at the Union and Riversdale in Colchester county in Nova Scotia, are Carboniferous in age, and are Meso-Carboniferous at that. Further, it is also evident that the New Brunswick equivalents of these two formations, namely, the Mispick and the Lancastér formations (the latter sometimes designated as the Little River group), can not any longer be classified as Devonian, but as truly Meso-Carboniferous formations, with an abundant flora found the world over, and in all countries other than Canada referred to as the Middle Carboniferous.

In view of the conclusion that the supposed Devonian of the original descriptions is in part Carboniferous, it is difficult to determine what the Devonian rocks of Pictou, Antigonish, and Colchester really are. A basal Devonian formation is, however, distinguished by Ami¹⁸ as the Knoydart formation of Antigonish County. A detailed section of the rocks by Fletcher^{18c} shows 684 feet of red sandstone and shale with greenish layers and thin flinty or calcareous or carbonaceous layers, some of which consist of volcanic ash. The included fossils are ostracoderms, constituting a very primitive and early type of fishes and establishing a close correlation with the lower Old Red sandstone of Great Britain.

The Silurian and Devonian iron-bearing formations of Digby and Annapolis counties, southwestern Nova Scotia, are thus described by J. W. Dawson:²⁶⁶

In Nova Scotia the rocks older than the Carboniferous system have all undergone more or less alteration and disturbance. This, with the imperfect preservation of their fossils and their inland position, renders the working up of their details of structure very difficult. Large tracts of country thus remain in a state of uncertainty, their rocks being manifestly older than the Carboniferous, but yet otherwise of uncertain age. In the case of the Devonian, the only place in which it has been clearly made out as distinct from the Silurian is the belt of hilly country extending along the south side of the Annapolis Valley. Here, in the section of the Nictaux River, the first old rocks that are seen to emerge from beneath the New Red sandstone of the low country are fine-grained slates, which I shall describe in the sequel as Upper Silurian. Their strike is N. 30° to 60° E., and their dip to the southeast at an angle of 72°. Interstratified with these are hard and coarse beds, some of them having a trappean aspect. In following these rocks to the southeast, or in ascending order, they assume the aspect of the New Canaan beds; but I could find no fossils except in loose pieces of coarse limestone, and these have the aspect of the Upper Arisaig series, or newest Silurian of the eastern part of Nova Scotia. In these and in some specimens recently obtained by Mr. Hartt I observe *Orthoceras elegantulum*, *Bucania trilobita*, *Cornulites flexuosus*, *Spirifer rugæcosta?*, and apparently *Chonetes novascotica*, with a large *Orthoceras*, and several other shells not as yet seen elsewhere—all Upper Silurian. These fossils appear to indicate that there is in this region a continuance of the upper Arisaig series nearly to the base of the Devonian rocks next to be noticed.

After a space of nearly a mile, which may represent a great thickness of unseen beds, we reach a band of highly fossiliferous peroxide of iron, with dark-colored coarse slates, dipping S. 30° E. at a very high angle. The iron ore is from 3 to 4½ feet in thickness. The fossils of the ironstone and the accompanying beds, as far as they can be identified, are *Spirifer arenosus*, *Strophodonta magnifica*, *Atrypa unguiformis*, *Strophomena depressa*, and species of *Avicula*, *Bellerophon*, *Favosites*, and *Zaphrentis*, etc. These, Professor Hall compares with the fauna of the Oriskany sandstone; and they seem to give indubitable testimony that the Nictaux iron ore is of Lower Devonian age. * * *

To the southward of the ore the country exhibits a succession of ridges of slate holding similar fossils and probably representing a thick series of Devonian beds, though it is quite possible that some of them may be repeated by faults or folds. Farther to the south these slates are associated with bands of crystalline greenstone and quartz rock and are then interrupted by a great mass of white granite, which extends far into the interior and separates these beds from the similar nonfossiliferous rocks on the inner side of the metamorphic band of the Atlantic coast. The Devonian beds appear to dip into the granite, which is intrusive and alters the slates near the junction into gneissoid rock holding garnets. The granite sends veins into the slates and near the junction contains numerous angular fragments of altered slate.

* * * * * * * * *

At Moose River the iron ore and its associated beds recur on the western side of the granite before mentioned but in a state of greater metamorphism than at Nictaux. The iron is here in the state of magnetic ore but still holds fossil shells of the same species with those of Nictaux.

Still farther westward, at Bear River, near the bridge by which the main road crosses this stream, beds equivalent to those of Nictaux occur with a profusion of fossils. The iron ore is not seen, but there are highly fossiliferous slates and coarse arenaceous limestone and a bed of gray sandstone with numerous indistinct impressions apparently of plants. In addition to several of the fossils found at Nictaux, these beds afford *Tentaculites*, an *Atrypa*, apparently identical with an undescribed species very characteristic of the Devonian sandstones of Gaspé, and a coral which Mr. Billings identifies with the *Pleurodictyum problematicum* Goldfuss, a form which occurs in the lower Devonian in England and on the continent of Europe.

Westward of Bear River rocks resembling in mineral character those previously described, and probably of Devonian and Upper Silurian age, extend with similar strike but in an altered condition and in so far as I have been able to ascertain destitute of fossils quite to the western extremity of the peninsula, where they turn more to the southward and are, as I suppose, repeated by a sharp synclinal fold, after which they are succeeded by the Atlantic coast series, of lower Silurian date and consisting of quartzite and clay slate, with chlorite and hornblende slates at Yarmouth and its vicinity, and farther to the southeast of mica slate and gneiss.

I can not certainly indicate the Devonian system in other parts of Nova Scotia. There are, however, in various places, at the margin of the Carboniferous areas, or projecting through these beds, rocks which may be Devonian, though, not having afforded characteristic fossils, their age must remain doubtful, as they might possibly prove to be altered members of the Lower Carboniferous or rocks of Silurian date. They are usually hard gray or purplish sandstones or quartzites, associated with gray or purplish slates or shales.

The above description is quoted by Bailey,^{43a} who adds:

In 1892 a collection of fossils from Nictaux, Bear River, and Mistake settlement was made by the writer and Mr. W. H. Prest and tended to confirm the conclusions of Sir William Dawson, so far at least as regards the beds of Nictaux and Bear River. They were examined by Dr. H. M. Ami, who states,^a as to the two former points at least, that the beds are transitional, being either at the summit of the Silurian or at the base of the Devonian epoch, the weight of evidence being perhaps in favor of the Eo-Devonian. The fossils from Mistake settlement indicate a Silurian tract.

Bailey then gives detailed descriptions of localities with lists of fossils collected at definite localities in the Nictaux-Torbrook, Clementsport, Bear River, and Mistake settlement districts.

^a In Report (by L. W. Bailey) on southwestern Nova Scotia, vol. 6, pt. Q, 1892-93, p. 14.

M 11. ROCKY MOUNTAINS OF BRITISH COLUMBIA.

In the eastern range of the Rocky Mountains, at the gap of Bow River, Alberta, Ordovician strata are followed with apparent conformity by a quartzite succeeded by dolomites of Devonian age. These strata do not occur in the western range, where the "Halysites beds" (Silurian) are present. McConnell^{559c} describes the Devonian ("Intermediate limestone") as follows:

The Intermediate limestone underlies the Banff limestone conformably, and passage beds partaking of the lithological character of both groups occur at the junction of the formations. It is mainly composed of a great series of brownish dolomitic limestones and has a thickness of about 1,500 feet. The typical dolomites of this formation are dark brownish in color, are finely crystalline, and are often irregularly hardened by concretionary action. They have, in many places, a blotched appearance, due to small cavities becoming filled with calc spar, are cherty, and are characterized throughout by an abundance of corals. In some sections a light-grayish variety is not infrequent. It is more coarsely crystalline than the dark variety and is unfossiliferous. In addition to the dolomites, beds and bands of sandstone, quartzite, and calcareous limestone are found all through the series. A light-yellowish siliceous band, varying in thickness from 100 to 400 feet, occurs near its base, on the south fork of Ghost River and along the eastern part of Devil's Lake valley, and is also found at the entrance to the White Man's Pass.

A good section across this series was obtained in the first range, near the Gap of the Bow. Here it dips to the west, at an angle of 40°, and is inclosed between the Castle Mountain and Banff limestones. The former, at this point, is terminated above by some shaly nondolomitic limestone, overlying which is about 40 feet of reddish and bright-yellowish weathering sandstones and quartzites, forming the base of the intermediate formation. Above these come several hundred feet of brownish-weathering, irregularly hardened magnesian limestone, holding cherts and corals, succeeded by light-colored, regularly bedded crystalline dolomites. The latter grade upward into a series of alternating beds of the two last varieties, associated with some beds of quartzite. Then comes a small band, consisting of soft greenish crumbling argillaceous sandstone, and hard yellowish-weathering quartzites, overlying which are 20 feet of grayish limestone. This limestone is succeeded by magnesian limestones and quartzites, above which come 50 feet of heavily bedded brownish-weathering dolomites, forming the top of the series and underlying the bluish massive beds of the Banff limestone. This section affords a fair general illustration of the relative lithological importance of the different members of the series, but could not be even approximately duplicated half a mile away, owing to differences in local detail.

* * * * *

The fossils of the Intermediate limestone are usually badly preserved and consist mainly of almost structureless corals.

M 19. NORTHERN NEW BRUNSWICK.

A small area of Eo-Devonian is shown on the map at the west end of Chaleur Bay. The rocks are red sandstone and gray shale associated with intrusive traps and with gray and purple feldspathic ash rocks. Coarse sandstones and conglomerates occur and carry Devonian plant remains.³⁰⁵

On the Restigouche, at the western extremity of Chaleur Bay, occurs a small area of Devonian strata which have afforded an interesting fish fauna and some plant remains. Whiteaves⁹²² narrates the early discoveries and summarizes the facts as follows:

The first of these discoveries led to further investigations by officers of the Canadian Survey in 1880, 1881, and 1882, which revealed the existence of a remarkable assemblage of fossil

fishes and land plants of Upper Devonian age at Scaumenac Bay, and of an entirely different series of fishes and plants, of Lower Devonian age, on the opposite or New Brunswick side of the river, near Campbellton. Large collections were made at each of these localities, especially of the fossil fishes, which were described by the writer in 1880,^a 1881,^b and 1883,^c and described and illustrated in 1887^d and 1889.^e Many of these specimens were exhibited and described at the meeting of this association at Montreal in 1882.

Comments on the species and references to the literature follow in Whiteaves's account.

M 20. GASPE PENINSULA.

Logan^{54r} described from this region the Gaspé limestones and Gaspé sandstones and assigned them respectively to the Silurian and Devonian. Ells³⁰⁶ reviewed their distribution and stratigraphy in the field and concluded that—

Of these Gaspé limestones it is now considered that only the two lower members, representing a thickness of 160 feet, can with propriety be assigned to this system [Silurian] while the preponderance of fossils of Devonian aspect, even in the basal bed, renders it probable that the whole may ultimately be transferred to the Devonian system.

This statement by Ells is quoted with agreement by Clarke^{157b} in a monographic work on the Gaspé section. Clarke, however, goes further and places all of the Gaspé limestones, including Logan's divisions 1 and 2 (St. Alban), in the Devonian as equivalents of the Helderbergian of New York.^{157c} The Canadian Survey has not accepted this correlation and the map of North America expresses the classification and distribution determined by Ells.

According to Logan the Gaspé limestones "comprise about 2,000 feet. They are intimately interbedded with calcareous argillaceous shales and exhibit intraformational contortions and conglomerates." The Gaspé sandstones, which aggregate approximately 7,000 feet, are partly conglomeratic and vary in color from drab to red. They contain plant as well as marine animal remains and are interpreted by Clarke as the deposit from a land of strong relief in a lagoon communicating from time to time with the sea.

The fossils from the Gaspé sandstones are described by Billings,⁸³ who gives a condensed statement of Logan's section.

The age of the Gaspé sandstones has been discussed by Williams, Schuchert, and Clarke. Williams⁹³⁶ briefly states the problem:

In the York River beds at the base of the Gaspé sandstones there is found a number (at least a dozen) of fossils which if found alone would be interpreted as positive evidence of an Oriskanian fauna; associated with these is another lot of fossils, at least as many, which if found alone would be as positive evidence of a Hamiltonian fauna. The sediments were deposited at some particular epoch of the geological time scale. What does this composite fauna signify as to the epoch to which the York River beds belong?

Dr. Clarke in the volume referred to gives the decision in favor of the Hamiltonian epoch, apparently on the ground of the greater number of species identical or closely related to Hamil-

^c Am. Naturalist, vol. 17, p. 158.

^d Trans. Royal Soc. Canada, vol. 4, sec. 4, p. 101.

^e Idem, vol. 6, sec. 4, p. 77.

tonian forms. If we accept his view it follows that the associated Oriskanian forms continued to live on after the epoch of the Oriskanian fauna into Hamiltonian time.

By the interpretation here offered it is assumed that the Hamiltonian types of the fauna are possible ancestors of Hamiltonian species living in the Oriskanian epoch, which by some movements of the currents of the ocean were brought together in the Acadian province before the revolution which upset the biologic equilibrium of the Oriskanian fauna had completed its work.

The further conclusion is that it was the same events which caused the cessation of the distinctive Oriskanian fauna, which brought into this area the ancestors of the Hamilton species, and that the geologic time of the events was approximately equivalent to the Schoharie epoch of New York State.

M-N 14. MANITOBA.

The Devonian of Manitoba consists of about 500 feet of strata, chiefly dolomite which represent Lower, Middle, and Upper Devonian terranes. They are described by Tyrrell ⁸¹⁷ as follows:

	Feet.
Upper Devonian or Manitoban:	
Light-gray hard, brittle limestone containing <i>Athyris vittata</i> , etc., underlain by red argillites, outcropping at Rose Island and in the vicinity in Swan Lake, and at Point Wilkins.....	100
Light-gray hard limestone, seen at Onion Point, Snake Island, Beady Island, etc.....	40
Red and gray shale, seen near the mouth of Bell River, south of Weston Point, etc.....	70
Middle Devonian or Winnipegosan:	
Whitish or light-yellow hard, tough, generally compact dolomite containing <i>Stringocephalus burtini</i> and numerous other fossils. It outcrops chiefly on the island and shores of Dawson Bay, and southward to Point Richard on Lake Manitoba.....	100
Porous spongy yellow dolomites of Pemmican Island, Devil's Point, Macoun Point, etc.....	100
Lower Devonian:	
These beds have not been clearly defined, but they appear to be composed of red and other shales.....	100

Whiteaves ⁹¹⁷ has described the fossils from these Devonian rocks and says:

It has already been stated that all the fossils that are enumerated or described in the present paper are probably from the Middle and Upper Devonian. The Middle Devonian appears to be represented in this region by the *Stringocephalus* zone and the 100 feet or more of fossiliferous dolomite immediately beneath it, and the Upper Devonian by all the beds above the *Stringocephalus* zone and beneath the Cretaceous.

The discovery of dolomites in which *Stringocephalus burtini* is one of the most characteristic fossils, at many localities on the shores or islands of Lakes Manitoba and Winnipegosis, is of considerable interest to the geologist. In Manitoba the *Stringocephalus* zone appears to occupy much the same stratigraphical position as the *Stringocephalus* limestone of Germany and England, and it is noticeable that among the fossils of the *Stringocephalus* zone of Manitoba there are several which can be identified with well-known European species.^a

The "Cuboides zone" appears to be represented in this region by those beds on the Red Deer River and elsewhere.

M-N 16-17. JAMES BAY, ONTARIO.

In 1875 Bell ⁶⁵ reported the occurrence of dark-gray bituminous limestone at the Grand Rapids of the Mattagami (latitude 50°, longitude 82°) and collected fossils, which Whiteaves reported as being of Devonian age, of the horizon of the "Corniferous" limestone. The strata are exposed in a cliff 40 feet high. They are flat lying and rarely outcrop in the district, but extend north beneath James Bay and beyond Albany River. Dowling ^{291b} states that the Devonian rocks do not reach

^a For list of fossils see the work cited.—B. W.

the Attawapiskat on the north but are confined to the southern part of James Bay and the adjacent country extending a short distance north of the Albany.

Parks⁶²⁹ describes the strata exposed on Kwataboahagan River as limestones of a yellowish-brown color, literally filled with organic remains. A grayish limestone, poorer in mollusks but richer in corals and brachiopods, also occurs, but the relations of the two were not determined. Many species are described and figured.

N 9, O 8. SOUTHEASTERN ALASKA.

Devonian limestones occur intercalated with igneous rocks in the islands of southeastern Alaska. The recent work of Wright and Kindle has resulted in collections of fossils which have marked European affinities and represent Lower, Middle, and Upper Devonian but which are not related to the American contemporaneous faunas. No complete section of the series is known. Exposures on Long Island, Kasaan Bay (latitude 55°, longitude 133°), show 470 feet of Middle Devonian limestone, conformably overlying bedded igneous rocks. Lower Devonian limestone occurs at Freshwater Bay, Chichagof Island (latitude 58°, longitude 135°). On the west coast of Prince of Wales Island fossils of the Upper Devonian have been collected.^{496a}

N-O 12-13. ALBERTA AND SASKATCHEWAN.

Devonian limestone extends horizontally beneath the superficial deposits of parts of Saskatchewan and Alberta, outcropping here and there in river gorges and occasioning rapids in the streams. On the east it rests upon "Laurentian" and on the west it is overlain by horizontal Cretaceous beds ("Tar sands," referred to the Dakota by McConnell).^{561b} The section on lower Peace River, according to Macoun,⁵⁶⁸ exhibits thin-bedded limestone strata made up almost wholly of branching corals and carrying beds of white gypsum. Higher up the stream the limestone is evenly stratified, is light grayish or cream-colored, and alternates with softer, more argillaceous bands.⁵⁶¹

O-Q 9-12. MACKENZIE BASIN.

East of the Rocky Mountains in the Mackenzie basin Devonian rocks have a wide distribution. The strata classed as Devonian may include Silurian below and exhibit a transition phase toward the Carboniferous above. McConnell⁵⁶⁰ states:

Devonian rocks * * * underlie the greater part of the country bordering the Mackenzie, all the way from Great Slave Lake to below old Fort Good Hope, a distance measured in a straight line over 700 miles. They were found all around the western arm of Great Slave Lake and were traced up Hay River to the falls and up the Liard to the "Long Reach." South of the Liard and extending as far south as the Peace River, the Devonian outcrops at the surface in a broad band, averaging fully 150 miles in width, striking in a northwesterly and southeasterly direction, parallel to the western margin of the Archean axis. On the southwest it is generally overlain by the Cretaceous and on the northeast overlaps all the older Paleozoic formations and comes directly in contact with the Archean. In all this region the beds are practically undisturbed and are seldom affected by dips exceeding a few feet to the mile.

Throughout the Mackenzie district the Devonian is generally divisible lithologically into an upper and lower limestone, separated by a varying thickness of shales and shaly limestones, but in some cases limestones occur throughout. The upper division has an approximate thickness of 300 feet and consists of a compact yellowish-weathering limestone, occasionally almost

wholly composed of corals, interstratified with some dolomitic beds. This limestone is well exposed at the falls on Hay River and also at the Ramparts, on the Mackenzie. In both these places it is underlain by several hundred feet of greenish and bluish shales, alternating with thin limestone beds. At the "Grand View," on the Mackenzie, the shales are hard and fissile and are blackened and in places saturated with petroleum. At the Rock by the River Side and at other places where the beds are tilted and older rocks exposed the middle division is underlain by 2,000 feet or more of grayish limestones and dolomites interbedded occasionally with some quartzites. No fossils were collected from the lower part of this series, and rocks older than the Devonian may possibly be represented in it.

Representative collections of fossils, showing a mixture of Hamilton and Chemung forms, were obtained from the upper part of the shales on Hay River, at a point about 40 miles above its mouth, and from the same horizon at the Ramparts, on the Mackenzie. The lithological characters and the stratigraphical relations of the limestones at these two points, notwithstanding the fact that they are separated by a distance of over 570 miles, are almost identical. The fossil faunas also at the two points show similar close relations, the principal differences being the presence of *Rhynchonella cuboides* and *Spirifera disjuncta* at Hay River and of *Stringocephalus burtini* at the Ramparts. This might seem to indicate that the beds at the Ramparts are slightly older than those at Hay River, but Mr. Whiteaves thinks that both are referable to the Cuboides zone.

Fossils collected from the Devonian of the Mackenzie basin by early expeditions were described by Meek,^{585a} who gives an account of the history of exploration and of the fossiliferous localities. Whiteaves⁹¹⁶ has discussed the collections subsequently made by the Canadian Survey parties. He describes the Devonian species from the Mackenzie represented in the museum of the Canadian Survey and lists them according to localities from southeast to northwest. He then comments:

An analysis of these lists shows that 22 of the species are found also in the Hamilton formation of Ontario or the State of New York. [List follows.]

In the Mackenzie River district, however, the subdivisions of the Devonian system that exist in the State of New York and Ontario are probably not recognizable, and there are strong reasons for supposing that the whole of the fossils reported upon in these pages belong to the "Cuboides zone."

It is true that *Rhynchonella cuboides* itself has so far been found only on the Peace and Hay rivers, where it is invariably associated with *Spirifera disjuncta* (or *verneuili*), but other fossils eminently characteristic of the Cuboides zone will be noticed in nearly all the foregoing lists of species from the Athabasca and its tributaries or from the Mackenzie.

The paper concludes with a discussion of the Cuboides fauna and a comparative list of 29 identical species from the Mackenzie basin and the European side of the Atlantic.

P 4-5. ALASKA RANGE AND SOUTHERN ALASKA.

Devonian rocks are included in the Paleozoic complex that forms the western slope of the Alaska Range, in the strike of the formations which occur throughout the Yukon-Tanana region, but they have not been differentiated.^{101d} Middle Devonian fossils have been found in a blue siliceous limestone at several localities.

In the Copper River district the Nikolai greenstone, composed of volcanic flows, resembles the Rampart group (Devonian) of the Yukon and is shown by Brooks¹⁰¹ to occur stratigraphically at a similar horizon. Later studies, however,⁵⁹⁹ have tended to prove a later age (late Carboniferous or Triassic) for the Nikolai greenstone.

The Wellesley formation (conglomerate and slate) of upper Tanana and White rivers is either Carboniferous or Devonian. It is correlated with the Chisna formation of the Copper River district and possibly with the Cantwell formation of the Nenana River section and may represent the base of the Devonian, lying unconformably on older rocks. In a recent paper^{104a} Brooks places the Chisna, Wellesley, and Cantwell in the Carboniferous.

P 8. YUKON TERRITORY.

The Ogilvie Range, which forms the divide between Stewart and Peel rivers, is said by Keele⁴⁷⁴ to consist largely of Devonian strata—limestones, ferruginous slates, and quartzites. These rocks are mapped as altered Paleozoics. Camsell^{128d} collected on Braine Creek, a tributary of Stewart River, and at Braine Pass (latitude 64° 30', longitude 135°), at its head, fossils which Whiteaves identified as *Favosites*, *Productella*, and *Atrypa reticularis*.

The Braine Pass and section are described as follows:¹²⁸

Topographically the country between Beaver River [a tributary of the Stewart] and Wind River [a tributary of the Peel] is one of rather rugged relief. This is the backbone of the great Rocky Mountain system, which here trends northwest and southeast, swinging slightly from its almost north and south trend farther south. This particular section is called the Ogilvie Range. Few prominent peaks occur, and from the tops of any of them a general accordance of level can be noticed. The summit of Braine Pass is estimated at about 3,400 feet, and the elevation of the highest peaks in the neighborhood at 6,800. * * *

A section across the summit from the Beaver River to the Wind shows a series of closely folded and sometimes faulted limestones and slates with some quartzites and conglomerate. Cutting these are some diabase dikes and intrusive rocks. The succession in descending order is somewhat as follows: Massive dove-colored limestone becoming shaly at the base; bands of black slate; massive granular limestone containing fossils; ferruginous slates, weathering red; and black-weathering conglomerate at the base. * * *

The great valley at the head of Braine Creek, which forms the pass across to the Wind River, is apparently a great line of weakness, which has resulted in [from] an overthrust fault, thus bringing up the underlying ferruginous slates to the surface.

Some fossil corals and brachiopods collected from the limestone at the summit and lower down Braine Creek have been identified by Dr. Whiteaves as Devonian forms.

Q 3. SEWARD PENINSULA.

In the southeastern part of Seward Peninsula, north of Golofnin Bay, Devonian fossils have been found on Fish River. Somewhat farther northeast, on the Darby Range, fossils which are regarded as Devonian or possibly Carboniferous have been obtained.^a

Q 6-7. YUKON-TANANA REGION.

The Rampart group, consisting of volcanic rocks with intercalated slates and limestones, was assigned by Brooks^{101e} on fossil evidence to the Devonian, "probably to the Middle Devonian." In general terms the Devonian of the Yukon-Tanana region may be said to be made up of shales, slates, and cherts, with some limestones; locally ancient lava flows and tuffs predominate over the sediments. On the Yukon the igneous rocks are much more abundant than the sediments; on the Porcupine sediments are most abundant. The thickness of the group is much in doubt but

^a Smith, P. S., personal communication.

can not be less than 3,000 feet and may be twice as great. The relation of the Devonian to the Silurian is unknown, but is probably one of unconformity.¹⁰²

The following notes on the Porcupine Valley are taken from a paper by Kindle:⁴⁹⁷

The lowest division of the Devonian is a limestone formation about 325 feet in thickness. It is a massive light-gray to blue limestone weathering buff and considerably broken by joints. It rests apparently unconformably on the graptolite shales described above and is followed in the section by brown shale. The lower 5 feet of this shale may be seen resting directly on the limestone on the bank of the Salmontrout River just above its mouth. The total thickness of this shale is unknown, but, judging from the covered slope extending upward from the limestone along the Salmontrout River, it probably amounts to several hundred feet. Outcrops of the limestone described occur on both banks of the Porcupine immediately above the Salmontrout River, and it is proposed to call this formation the "Salmontrout limestone," from the Salmontrout River, which is the nearest geographic feature having a name available for a formation name. Fossils are abundant throughout this limestone. Its strike and dip are concordant with that of the subjacent Silurian shale and limestone and afford no evidence of deformation at the close of Silurian sedimentation.

Although no angular unconformity is shown in the relations of the Silurian and Devonian series where observed, unconformable relations between the two are attested both by the lithology and the faunas. In passing from the Silurian to the Devonian the lithologic change is an abrupt transition from black shales to very pure limestones. The faunal change is from a Silurian graptolite fauna to a Middle Devonian fauna, the Lower Devonian fauna being absent. The Devonian limestone forms a continuous outcropping cliff 100 to 200 feet high for 1 mile above the Salmontrout River, along the east bank of the Porcupine. It also outcrops on the opposite side of the river in isolated exposures.

Kindle gives a provisional list of 54 species preliminary to a full description of the fauna and concludes:

There are present in it several species which are either closely allied to or identical with species which first appear in the better-known American sections at a Middle or Upper Devonian horizon. Since characteristic Lower Devonian species appear to be absent from the fauna, its age seems to be either Middle or Upper Devonian. The list contains some species not known below the Upper Devonian in the United States. One of the best known of these is a variety of *Pugnax pugnus*, a species which ranges from the Rocky Mountains to New York State and into the Mackenzie River district. *Stropheodonta arcuata* and *S. calvini* are also known to have a wide distribution in the Upper Devonian. *P. pugnus* and *S. arcuata* first appear in the New York section at the horizon of the Ithaca fauna. Associated with these Upper Devonian forms we find several species characteristic of Middle Devonian horizons. Among these are *Pholidostrophia* cf. *iowensis*, *Cyrtina* cf. *hamiltonensis*, *Schuchertella chemungensis* var. *arctostriatus*, *Reticularia fimbriata*, *Nucleospira* cf. *concinna*, and species resembling the European forms *Gypidula* cf. *biplicatus* and *G.* cf. *galeatus*. Two possible explanations of this association of Middle and Upper Devonian species in the same fauna present themselves. It has been shown by Williams and Kindle that Middle Devonian species sometimes persist till late Devonian time and appear in certain New York sections associated with Upper Devonian species.^a It appears most probable, however, from what we know of the relations of *Pugnax pugnus* and its associated fauna to the Upper Devonian of New York, that the occurrence of Upper and Middle Devonian species in the same fauna at Old Rampart is not the result of late persistence of the earlier fauna. This species evidently migrated into the New York province from the northwest in Upper Devonian time. The two significant facts of its association with Middle Devonian fossils in an Alaskan fauna and its abrupt appearance in an Upper Devonian fauna in the United States, taken together, point very strongly to the probability that intercommunication between the eastern Alaska province and the interior American

^a Am. Jour. Sci., 4th ser., vol. 13, 1902, p. 429.

province was cut off during Middle Devonian, but became free about the beginning of Upper Devonian time, when conditions became favorable for the dispersal and migration of such forms as were adapted to it. Some of the species which had during Middle Devonian time been confined to this northern basin spread southward and helped to give a distinctive character to the Upper Devonian fauna as we know it in the United States. This appears to be the probable explanation of an association of species which upon casual examination seems to afford contradictory evidence as to the age of the fauna. If correct, the horizon represented is Middle Devonian.

The Devonian limestone outcrops on both sides of the Salmontrout River near its mouth. Brownish-colored shales overlie the limestone here and extend apparently to the top of the high ridge lying to the south of the stream and represent a thickness of several hundred feet. No fossils were found in these shales, but they are supposed to represent the Upper Devonian, because their relation to the Devonian limestone is similar to that held by shales holding Devonian fossils along the Yukon River. Carboniferous beds replace the Devonian outcrops along the Porcupine about 1 mile below the Salmontrout River. These seem to be of Upper Carboniferous age. Evidence of faulting which appears on the north bank of the river here indicates that the Lower Carboniferous and perhaps a portion of the Upper Devonian may be concealed by a fault. The horizon of the brown shale appears locally to be largely occupied by beds of basalt representing old sea-bottom outflows during the Upper Devonian.

The shale series which terminates the Devonian probably has a considerable thickness, though no estimate can be made from the exposures mentioned, because the thickness exposed to view is probably reduced by a fault lying to the southwest of the Salmontrout River.

The shale horizon appears to be occupied locally by basalt flows of late Devonian age. A considerable thickness of such beds, which are believed to be of Devonian age, forms the lower end of the Upper Ramparts. This rock is a close-grained dark-greenish to black rock, showing bedding planes. These strike about north and south and dip east at about 40° for nearly half a mile above Redgate. Near the top of this igneous series a belt of sedimentary rocks is sandwiched into the basalts, showing the following beds:

Section one-half mile above Redgate.

	Feet.
Gray limestone.....	4
Red and green shale.....	14
Brecciated limestone with included masses of shale.....	8
Light-gray limestone.....	35
Red shale.....	30

Two or three miles west of the Coleen River the basalts occur again. Here they overlie a considerable thickness of drab and pale-red shales. Black shales are interbedded with the upper belt of basalt at this point.

Q 8. PEEL RIVER.

Peel River, flowing north from the Rocky Mountains of Yukon Territory to the Mackenzie delta, traverses two canyons in folded black slates, which are alternately thick and thin bedded and in places bituminous, and crystalline limestone, which apparently underlies the slates. These strata are assigned by Camsell^{128b} to the Devonian on the ground of their lithologic resemblance to the Devonian of the Mackenzie Valley.

Q-R 5. ENDICOTT RANGE.

Nothing definite is known regarding the age of the pre-Carboniferous rocks of the Endicott Range, but the Fickett "series" and the Stuver "series" may include Devonian rocks, and the Bettles group is referred to the Devonian by Schrader, who found fossils of Devonian or Carboniferous age in gravels of Chandalar River. Brooks,^{101c} however, regards the Bettles as possibly Silurian.

R 3. CAPE LISBURNE.

At Cape Lisburne Collier^{164,165a} found 2,000 feet of sandstone and slate, conformably underlying Carboniferous (Mississippian) strata, and provisionally assigned them to the Devonian.

S 27. EASTERN COAST OF GREENLAND.

The Devonian of northeast Greenland is described by Nathorst,^{609d} who says:

The Silurian strata, as we have seen, are folded and compressed and partly metamorphosed. If this bears any relation to the formation of a mountain range, the folding took place before the deposition of the Devonian strata, for the latter show only a relatively slight amount of disturbance. Otherwise it must be surmised that the folding was the result of a depression of the Silurian strata along a fault at their eastern border, or perhaps between such a fault and another which can be imagined as passing west of the present boundary of the Archean.

On the eastern side of Waltershausen Glacier, north of the mouth of the Myskox Fiord, the wall of the fiord is composed of a light-gray, nearly horizontal sandstone, upon which are situated two hills of red sandstone. At the place where North Fiord turns toward Josefs Fiord there is a slight syncline, the center of which is composed of red sandstone. As the height of the mountain here, according to Desen's calculation is 1,500 meters, the thickness of the formation in question ought to be still somewhat greater. On the south side of Franz Josefs Fiord the Silurian strata south of Cape Weber are overlain by gray sandstone, dipping eastward, and this is in turn followed by red sandstone. The dip then changes to west, so that the gray sandstone crops out again, then again dips east, and disappears. At Cape Graah (the point north of Dusen's Fiord) the dip is again west and a gray-green sandstone is again visible. But I am not sure whether this belongs to the lower gray sandstone or is a member of the red; the latter view seems to me to be the most probable. In the gray-green sandstone, which is very micaceous, I collected at our place of anchorage, the 30th of August, some faint impressions of fossil plants, like those found in the Devonian strata of Spitzbergen, and a fish scale; and in the red sandstone, which overlies the green, I and Forester Nilson found many fine specimens which, according to A. Smith Woodward, belong to *Holoptychius nobilissimus*. Ag. Dusen, who botanized in the mountain to the south, said he found mollusks in the sandstone there. On a little outjutting point just east of here the rocks changed, being more brownish red and tough, with yellowish layers. * * *

The Devonian strata on Ellas Island are separated from the Silurian by a fault. This Devonian part possibly lies only in a local depression. But also north of Cape Weber there is a sharp fault between the two systems; the Devonian is lower in relation to the Silurian. On the south side of Franz Josefs Fiord the Devonian strata appeared to rest conformably upon the Silurian, although the Silurian strata appeared to have been deformed. Nearly everywhere this appeared to be the case near the contact between the two, and in my notebook I used a special term, "the irregular red," for this zone of deformation.

S-U 15-20. ARCTIC ARCHIPELAGO AND NORTHWESTERN GREENLAND.

The occurrence of Devonian strata on the eastern coast of Grinnell Land was mentioned by Dawson.^{257g} A full section is described by Schei from the southwestern shores of Ellesmere Land. (See pp. 266-268, Chapter V.)

CHAPTER VII.

PALEOZOIC UNDIVIDED.

Color, light reddish purple.

Symbol, 19.

Distribution: Little-known regions of the northern Cordillera, Montana, and Canada. (See fig. 9.)

Content: Paleozoic in general, where data do not suffice to map the divisions separately. Includes some known marine Triassic in the Canadian Rockies.

METAMORPHIC PALEOZOIC UNDIVIDED.

Color, light reddish purple with light dashes.

Symbol, 20.

Distribution: Venezuela, northeastern Appalachian region, northern Cordillera, California to Alaska. (See fig. 9.)

Content: Metamorphic sedimentary rocks of known or supposed Paleozoic age, together with possibly pre-Paleozoic schists and some igneous intrusive rocks, which have not been separated. Includes some known marine Triassic in the Canadian Cordillera.

Areas mapped as Paleozoic undivided.

B-C 18-19. VENEZUELA.

For the geology of Venezuela, we refer to Sievers's work ⁷⁴¹ on the Cordillera de Merida. Under the heading Archean, Sievers describes the granite, gneiss, mica schist and other crystalline schists, and clay slate. After describing the distribution of the granite, gneiss, and crystalline schists and giving in particular many local details which are beyond the scope of this work, he says of the clay slates that they constitute the uppermost division of the Archean, are of general occurrence, and rest as a rule upon crystalline schists, but in part upon the gneiss and also directly upon the granite. From these relations it is apparent that the clay slates are distinguished from the other rocks of Sievers's Archean by an unconformity. The compilers of the map of North America have endeavored to maintain the distinction which appears on Sievers's map and have mapped the clay slates and the underlying crystalline rocks as separate divisions, assigning the former to the metamorphic Paleozoic and

FIGURE 9.—Sketch map showing the distribution of Paleozoic rocks that are undivided on the geologic map of North America and the key to the references in the text.

the latter to the undifferentiated pre-Cambrian. In so doing they have followed only the suggestion of the lithologic descriptions, as there is no evidence on which to assign either division to a particular geologic age. Sievers states:

The clay slate is mostly thinly laminated, grayish, brownish to reddish, or bluish to black in color, and frequently has the character of roofing slate. It occurs chiefly in the middle zones of the Cordillera, from 900 to 3,000 meters, and has an extraordinary development. It is a striking fact in the distribution of the clay slate that in the western portion of the mountains it occurs chiefly south of the gneissic chain; elsewhere, in the eastern mountains, it occurs north of the chain.

Following these general notes are several pages devoted to the local distribution of the clay slate.

C 20. TRINIDAD.

The geology of Trinidad was described in 1860 by Wall and Sawkins,⁸⁶³ geologists of the Geological Survey of Trinidad. Their work appears to have been so thorough that it is still the basis of our knowledge of the island. They say in part as follows:

It is proposed to term that series of micaceous slates, sandstones, limestones, and shales which are the constituent strata of the northern littoral range of Trinidad the Caribbean group, since it forms the southern boundary of the Caribbean Sea; and, from reasons to be adduced hereafter, probably the littoral chain of Venezuela, partly composed also of mica slates and associated rocks, may present a continuation of the same formation.

The central range comprises an indurated formation of lower Cretaceous age and is apparently a fragment of an immense series which contributes very largely to the Cordillera of northern Venezuela. These deposits are perhaps equivalent to the series of strata observed very extensively in New Grenada and other parts of South America, and described as corresponding to the Neocomian horizon. However this may be, till further investigation more fully exposes the relations of all these deposits, it is well to localize their occurrence; and as this formation was first observed on the shores of the gulf which separates the island from the main, it may be appropriately associated with the name of that sea, and will be described as the older Parian group.

A considerable proportion of Trinidad is occupied by a series of Tertiary strata, probably of Miocene age, but since the precise equivalency is not yet established, this series may, for reasons similar to those above stated, be conveniently designated as the newer Parian group. * * *

The most prevalent beds of the [Caribbean] series consist of mica slates, presenting numerous varieties, sometimes appearing as layers of quartzose matter, separated by thin plates of mica; at others, merely as repetitions of micaceous laminæ with little associated substance, frequently possessing extreme hardness and often degenerating into soft micaceous shales. There are several localities where peculiar black slates of ambiguous nature occur. On closer examination, these seem to be also micaceous schists, the plates of that mineral inclosing pellicles of graphitic matter.

The mica often possesses a peculiar glossy appearance and presents numerous shades of white, yellow, green, brown, red, and black. Of these, green occurs most frequently, after which yellow.

Some of the schists of finer texture are analogous to clay slates but really consist of smaller particles of mica, with finely divided feldspathic matter.

Quartzose slates frequently occur and, what is rarer, ferriferous slates—that is, foliated rocks in which quartz alternates with oxides of iron, characterized sometimes by great regularity, but more generally the ferriferous laminæ occur at unequal intervals.

Of sandstones there are a considerable variety, from fine to coarse grained, some externally soft and others of the hardest consistency.

It is not unusual to meet with varieties, especially the coarse grained, in which the mica is sufficiently abundant as, by the parallelism of its plates, to communicate a laminar and even fissile structure.

The term quartzite must be understood in this report as implying siliceous strata, whose matter exhibits no granular structure but is continuous and yet perfectly distinct from vein or segregated quartz.

Beds of this substance are of common occurrence, generally assuming a vitreous character, but in some instances rather that of hornstone. They are intimately associated with the sandstones and seem occasionally to graduate into the latter.

Shales, which are also numerous, appear sometimes ferruginous or highly carbonaceous, often associated with mica, and generally soft. * * *

Calcareous rocks are represented by two varieties in this series, viz, crystalline limestones contained in the slates and alternating with them, and compact limestones, either quite unconnected with the schistose group or only associated with its upper strata. The former occur sometimes in massive beds, varying from white to blue in color, often with scattered spangles of silvery-white mica, and distinguished by decided crystalline structure. Thinner beds of similar lithological characters, from a few inches to several feet in thickness, exhibit repeated alternations with the slates or shales.

Calcareous slates are beds of calcareous base, but with a considerable proportion of earthy matter and a laminar or schistose structure.

The Caribbean terrane is much folded and sheared. The report cited contains many striking illustrations of the structure. The sequence of the component formations of the group was not satisfactorily made out, and the age, beyond the fact that it is pre-Cretaceous, also remains undetermined.

D 16. NICARAGUA AND HONDURAS.

The pre-Triassic rocks of Honduras are assigned by Mierisch and Sapper to the Paleozoic and are so mapped. Sapper⁶⁹⁶ states:

The occurrence of Paleozoic rocks in southern Central America has not been demonstrated with certainty, as it has not been possible to find fossils in the strata. Nevertheless, it appears to be highly probable that there belong to the Paleozoic those rocks which Mierisch assigned to that age, namely, the very steeply dipping limestones, calcareous mica slates, phyllites, clay slates, quartzites, talc, gneisses and amphibolites, talcose and chloritic schists of northeastern Nicaragua; but whether they belong to the Devonian, Silurian, or Cambrian, as Mierisch thought, or may perhaps be of the same age as the Carboniferous terranes of Guatemala, Chiapas, and British Honduras, can not be surmised. According to Mierisch the area covered by these formations in Uli and Uani, as well as in the mining districts of Concepcion and El Dorado, is considerable, although this fact does not appear on his geological map.

Sapper goes on to mention several localities in Nicaragua and Honduras in which he has observed slates, quartzites, conglomerates, and other rocks which are mapped as Paleozoic, though without any specific evidence. He says:

In regard to the age of these rocks I can only suggest an inference. It seems to me most likely on grounds of lithologic similarity that these formations are to be assigned to the Paleozoic, along with the slates of the Rio Coco; but it is not impossible that they may be a part, and in that case the lower part, of the Tegucigalpa formation [Triassic].

E 19. SANTO DOMINGO AND PORTO RICO.

Hill⁴⁴⁴ makes the following statement with regard to Santo Domingo:

In general, the geology of the island is similar to that of Cuba and Jamaica, more especially the eastern ends, being composed of four principal formations—the older mountain rocks, of

Cretaceous and Tertiary age, made up of igneous rocks and clays, mantled by gravels and crystalline limestone; the white limestones, of Tertiary age; recent alluvial formations; and the coast limestone of elevated reef rock. No recent volcanic rocks are known. The geology and minerals of Santo Domingo have been the subject of special reports by many writers, including three American geologists, Messrs. Blake, Gabb, and Marvin.

The terrane which is mapped as undivided Paleozoic on the island of Santo Domingo corresponds to the Sierra group of Gabb, who placed it in the Cretaceous. According to his description he collected distinct Cretaceous fossils in the southern part of the island, but elsewhere the strata are metamorphosed to such an extent that no fossils have been found. In view of the facts that much of the terrane is highly metamorphosed and that the discovery of fossils has been limited to the southern margin of the uplands, it seems not unreasonable to suppose that some of the rocks may be not only older than Cretaceous but possibly pre-Mesozoic. Were they colored as Cretaceous they would naturally be associated with the fossiliferous Cretaceous limestone of the West Indies and the adjoining continent. The compilers have therefore distinguished them by placing them in the somewhat indistinct class of undivided Paleozoic rocks, including areas of younger strata. That portion of the strata in which Cretaceous fossils have been found is mapped as Cretaceous. Gabb ³⁵² says:

No formation older than the secondary era has been found on the island, the oldest group being the great mass of slates, conglomerates, and limestones which form its core. These are uptilted and broken by numerous intrusive masses of crystalline rocks which may be, for convenience, grouped under the generic term of syenite, since they almost invariably consist of the three necessary minerals quartz, feldspar, and hornblende.

Flanking the slates, etc., of the Sierra there is a broad development of Tertiary marking all the northern and a part of the southern side of the island, and this in turn is bordered by a more recent deposit of limestones and gravels which I shall call the Coast formation.

The Sierra group forms all of the great mountain mass of the interior, extending the entire length of the Republic.

It also constitutes the greater part of the Peninsula of Samana and appears as a single little outlier, under the Tertiary, near Puerto Plata. It everywhere shows the evidence of active subterranean forces, being not only metamorphosed, with hardly a single local exception, but is everywhere much uptilted and usually strongly folded. Over much of its area the metamorphic action has been so complete as to destroy the traces of stratification or to so nearly obliterate them that they are apt to be confounded with cross fractures. * * *

But enough of the stratification is preserved to show conclusively that these beds lie in a series of east and west folds, the line of folding and upheaval corresponding very closely with the axis of the mountains. The thickness of the deposit is very difficult to determine, since no continuous section exists, where one can be certain of having all the beds and of not being deceived by repetitions. On a very rough estimate, not based on measurements, however, but only on the broadest kind of vague generalization in the canyons of the Ocoa and Nigua rivers and again on what I saw of the formation in the vicinity of the Pico del Gallo, we might set down the total thickness at anywhere between 2,000 and 4,000 feet. It must be understood that this broad margin is not the result of want of care in observation but arises from the almost absolute impossibility of finding a reliable section. In one region a group of conglomerates occurs; in another, within 40 or 50 miles, these same beds are represented by limestone, without a pebble; and on the same strike within another 20 miles neither limestone nor conglomerate is to be found; all is a semitalcose slate too friable to yield a hand specimen and with no distinguishable stratification. Add to this the partial obliteration of character by different degrees of metamorphism, and the sometimes total obliteration of bedding, and the reasons of my cautious statement must be sufficiently obvious.

In the interior of the mountains, especially in the western two-thirds, the disturbance has been greatest, and the reason appears in the existence of great masses of eruptive rock which have pushed up the slates, broken them, and in some cases penetrated them by dikes to a distance of several miles from the parent mass. In some cases pieces of the wall rock are found embedded in the syenite; and pebbles one-half syenite and the other half jaspery are not rare.

In its original state this group of beds seems to have consisted of a series of clay shales, thinly bedded, others more heavily bedded and with layers of sandstone, conglomerate, limestone, and heavy-bedded sandstones. The changes produced in these rocks by metamorphism are almost infinite. On the Ocoa River the shales are so nearly unaltered that I have repeatedly searched in this region in hopes of finding fossils. In the canyon of the river they are gray and friable, with an occasional bed of sandstone; farther south they are red and give rise to numerous salt springs; still farther south they contain more numerous beds of sandstone and are brown and more sandy in texture. These same shales are modified at Recol into a granular greenish-black material resembling an impure serpentine, while on the Nigua they appear as green, gray, or brown jaspers with broad conchoidal fractures, gradually changing again within a few miles to a more serpentinitoid form, to reappear as the same jasper on the Jaina and to again change, on the Upper Jaina and in nearly all the mountains eastward, into a whitish rock, more or less talcoid and profusely stained with iron. On the north side of the island the modifications of the shale are just as great. The sandstones also undergo an equal number of variations, appearing of all colors from black or dark-gray sandrock to a white granular quartzite. In short, nearly every color is represented, and naturally all degrees of texture, from the coarse conglomerate of San Jose de las Matas, or Maniel, to the shale above described. In one place only did I find siliceous segregations like the chalk flints, or more probably, like the Corniferous limestones of the New York geologists. In the hill just west of Bani the rock is a limestone, and in it are numerous streaks, lying in the plane of stratification, of a light-brownish limestone, very tough and breaking with an irregular fracture. Near the base of the series, apparently, are strata of conglomerate, made up of pebbles very similar to those of the surrounding beds. These pebbles seem to have been brought from long distances, since they are almost invariably rounded by attrition. They are largest on the upper Ocoa, near Maniel, and on the north flat of the range near San Jose de las Matas, but at these points they are rarely more than a few inches in diameter. I have endeavored in vain to find the probable source of these pebbles. They are certainly not from the adjoining beds, although lithological researches were not wanting. They are not derived from any deposit encountered by us on the island, since the conglomerate strata extend nearly, if not entirely, to the base of the stratified rocks. It is not probable that further examination to the westward, in the yet unknown portions adjoining Haiti, or lying within its borders, will develop their origin, since such a discovery would be foretold by increase in the size and angularity of the pebbles in that direction. They must therefore have been derived from some land then existing, most probably to the north or northwest of the present island, but now submerged or destroyed. The conglomerate is variable in its character and the changes take place over comparatively limited areas. On the north side it is almost always cemented by a coarse-grained red sand, the surfaces of the contained pebbles being stained by the ferruginous nature of the matrix. This is the rule where the metamorphosis is not very perfect. In one place, west of San Jose, the whole mass is rendered nearly homogeneous in texture, the fracture crossing matrix and pebbles alike. In another, on the Mao River, the whole is changed to a dark olive-green, the coloring matter having stained even the interior of the pebbles. On the Ocoa some of the conglomerate is cemented by lime instead of sand, and in this case the pebbles are not so numerous as to be always in contact. This peculiarity gradually changes to the eastward, so that the conglomerate is represented on the Nigua by a group of beds, in part pure limestone, in part an impure limestone, containing occasional pebbles. This last is the stratum from which fossils were obtained.

Statements relating to the discovery of fossils of Cretaceous age are given in Chapter XV (pp. 642-643).

With regard to Porto Rico Hill⁴⁴² states:

The mountains are composed largely of black or other dark-colored basic igneous rocks, occurring as tuffs, conglomerates, and sills of hornblende andesite, cut by dikes of diorite. While these rocks are of volcanic origin, there are nowhere any signs of recent or late geologic volcanism, such as craters, unburied lava flows, cinder cones, etc., all original volcanic forms of topography having been destroyed by erosion, to which are due the present features of configuration. Besides, much of this volcanic material has been worked over into sediments in prehistoric ages and now occurs in well-defined strata.

Included in this mass of volcanic rocks are two limestone formations, interbedded with them and relatively inconspicuous in area. One of these, found on the crest of the island near Cayey and Aibonito, is a black bituminous shaly limestone interbedded with the volcanic conglomerate. This calcareous horizon is fully 1,000 feet thick, apparently upholds the crest of the Sierra, and weathers into soils noted as the best tobacco lands on the island. The other is a light-gray crystalline limestone with Cretaceous fossils (Rudistes). * * *

The geologic history of the island may be briefly summarized as follows:

The earliest positive chronology that can be fixed at present is Cretaceous time, when the island, in common with the other Great Antilles, was the site of active volcanism, which resulted in the piling up of vast heaps of igneous rocks now constituting its mass.

At the close of Cretaceous time and during the beginning of the Tertiary this volcanic material was water sorted and converted into marginal sea sediments, as represented in the stratified tuffs, conglomerates, and fossiliferous Cretaceous and Eocene rocks. The history of Porto Rico during Oligocene time is obscure, the vast thicknesses of white limestone of that age which occur in Cuba, Jamaica, and Santo Domingo not having as yet been detected upon the island. It is supposed, however, that the island, together with the other Great Antilles, suffered great subsidence during this epoch.

In late Tertiary time all the aforesaid rocks were uplifted and deformed into their present mountainous aspect, in common with the general Antillean uplift of that epoch. The exact period of this uplift in the later half of the Tertiary has not as yet been fixed, but it was largely accomplished before the close of the Miocene epoch. The tilted Piñones strata of Miocene age, at the northwest corner of Porto Rico, clearly show that the movement was not completed until after the close of the Miocene. In Pleistocene time the island suffered minor oscillations of elevation and subsidence, resulting in the present erosion and configuration of the coast-border topography.

F 17-18. CUBA AND ISLE OF PINES.

The following notes have been prepared for this volume by T. W. Vaughan:

Serpentines, granites, slates, and schists constitute the oldest rocks known on the island of Cuba, except perhaps some limestones of doubtful Paleozoic age in the vicinity of Trinidad, and form the basement upon which the subsequent geologic formations were deposited. Slates and schists occur in small patches in the Province of Santa Clara, some 3 or 4 miles south of the city of that name. They are much folded and metamorphosed, and apparently the serpentine has been intruded into them. Outcrops of serpentine occur in every province of the island. The most westerly occurrence at present known is near Guanajay, in the Province of Pinar del Rio. There are large areas in the vicinity of Havana and Guanabacoa, northwest of Matanzas between Matanzas and Cardenas, and east of Cardenas in the vicinity of Hato Nuevo. Extensive areas also occur in the central portion of the Province of Santa Clara and near the city of Trinidad in its southern portion. Serpentine also constitutes the surface formation of large areas in the northern and central portions of the Provinces of Camaguey and Oriente.

Outcrops of granite were observed at the south coast of the Province of Oriente and south of the city of Santa Clara. A granite porphyry of doubtful age occurs in Oriente Province.

Semicrystalline blue limestones of fine texture outcropping in the vicinity of Trinidad have been considered as doubtfully of Paleozoic age.

In the Isle of Pines, associated with the Gerona marble which is described below, and to some extent interbedded with it, is a great mass of crystalline quartz-mica schist, which rarely reaches the surface except in watercourses, as it is nearly everywhere covered by the Malpais gravel. Wherever it reaches the surface it is deeply weathered to a soft yellowish micaceous sand. In addition to the quartz and mica, some portions of the schist also contain numerous garnets and a thoroughly disseminated black mineral, taken to be manganese. The more siliceous portions of the schist are banded and resemble a gneiss. There are also numerous veins of quartz, from several feet in thickness down to mere stringers. It is evident that these quartz veins and the siliceous bands and grains are the sources of the Malpais gravel and of the extensive deposits of beach sand surrounding the island. Some portions of the schist are highly siliceous, forming essentially a quartzite. In the Cerro Siguanea the rock has been extensively fractured and recemented by iron and quartz, rendering it more resistant and thus causing a series of hills of harder material to stand above the surrounding areas underlain by softer material.

A dark-gray diorite schist has been observed in the Cerro Daguilla and doubtless occurs elsewhere in the island. It is evidently an intrusive basic rock, probably a diorite which has been rendered schistose along with the inclosing formations. It is extremely tough and compact, presenting a high degree of resistance to erosion. Some portions of the rock are rather massive, the schistose structure being most highly developed along the margin of the intrusive mass.

The ridges on either side of Nueva Gerona are composed of crystalline marble which is known as the Gerona marble. It is probable that the same material also forms the Sierra Pequeña, which is parallel to the Sierra Caballos, lying a few miles to the east; and to judge from the topography of the Sierra de Canada, which was seen only at a distance, it is composed of the same formation. This marble is everywhere thoroughly crystalline, retaining no trace, so far as observed, of the organisms it may originally have held. The greater portion is rather coarsely crystalline, although there are some beds of fine white statuary marble. The color varies from pure white to dark gray, and in some places there is strongly marked banding.

Owing to the thoroughly crystalline character of this rock, no evidence was obtained throwing light on its probable age. It can, however, scarcely be younger than Paleozoic. In some beds the impurities of the original limestone have recrystallized to form certain silicate minerals, chiefly fibrous hornblende. This marble was estimated to be not less than 2,000 feet in thickness.

K 10. KLAMATH MOUNTAINS, OREGON.

Diller ²⁸² makes the following statement concerning the Paleozoic rocks of the Klamath Mountains:

The Paleozoic sediments consist of clay slates, dark siliceous, locally banded slates, and greenish slates, interbedded with tuffs and lentils of limestone. Near the contact with granodiorite they are locally metamorphosed into fine-grained mica schist, which usually contains characteristic minerals, such as chialtolite and staurolite. * * *

Measured directly across the strike the area occupied mainly by Paleozoic rocks, both sedimentary and igneous, in the Applegate region has a width of nearly 30 miles, in which there are four more or less clearly defined belts of limestone containing about 50 masses, most of which are located on the accompanying map as quarries or prospects. The largest outcrop is not over one-third of a mile in length and 200 feet in thickness. * * *

The limestones at a number of points are fossiliferous, but the fossils are too poorly preserved to permit definite determination. In two lots * * * corals are abundant, and among them E. M. Kindle recognizes with doubt forms that he compares with *Favosites nitella* and *Cladopora robusta*, as well as a gastropod resembling *Loxonema bella*. * * * A striking feature that occurs locally in some of the limestone ledges of the second belt is the inclosure of vesicular volcanic fragments, which indicates that volcanic eruptions occurred in the region at the time the limestones were forming.

In the third belt of limestone, which outcrops along Kane and Steamboat creeks, the only fossils found were fragments of round crinoid stems; the fourth belt, on Little Applegate River, contains both round and pentagonal crinoid stems well preserved. . The general absence of other fossils from these two belts suggests a difference in age from the Devonian, and it is probable that they are either Carboniferous or Triassic.

K-L 11-12. IDAHO AND SOUTHWESTERN MONTANA.

The area mapped as Paleozoic in Idaho and southwestern Montana covers the mountains on both sides of Salmon River. It is little known geologically. Weed, Lindgren, and Willis have reconnoitered portions of it and furnished the notes on which the outlines are sketched.

K-L 18-19. NEW ENGLAND.

In New England rocks which were formerly regarded as Archean have been shown by the work of B. K. Emerson,³¹⁹ George Otis Smith,⁷⁶⁰ E. S. Bastin,⁶¹ and C. W. Brown to be of Paleozoic age. They are, however, so metamorphosed that separation is difficult, and in the zone here mapped as Paleozoic the distinct systems are not yet certainly correlated with definite periods.

M 9-10, N 8-9. VANCOUVER ISLAND AND QUEEN CHARLOTTE ISLANDS.

For data on Vancouver and Queen Charlotte Islands, Dawson, Webster, Haycock, and Clapp may be consulted. In 1878 Dawson²⁵² explored and mapped geologically the Queen Charlotte Islands, reporting the discovery of fossils which determined the Triassic age of a certain zone of argillites and limestones repeated in many sections along different parts of the coast. But he also states his belief that "from the intimate association of Carboniferous and Triassic rocks in the southern interior of the province, and more particularly from the occurrence of a great mass of rocks largely volcanic in origin and believed to be Carboniferous in age, in the southern part of Vancouver, it is highly probable that rocks of this age may come to the surface in some places."

In 1885 Dawson²⁵⁶ examined the northern part of Vancouver Island and stated:

The geological resemblance between the part of Vancouver Island which is here described and the southern half of the Queen Charlotte Islands is extremely close. This resemblance had previously been reported on by me in general terms and was indeed to be expected, as the Queen Charlotte Islands and Vancouver Island form portions of a single axis of elevation which here constitutes the western member of the Cordillera.

Webster,^{868a} in his report on the west coast of Vancouver, says:

In describing the geology I shall use the late Dr. G. M. Dawson's nomenclature as far as possible. * * * In his description the igneous dark-colored trappean rocks with associated mica schists and gneisses are said to be interbedded with argillites and crystalline limestones, classed as Triassic on the evidence of the fossils discovered in the argillites and named the Vancouver series. On the west coast of Vancouver Island, however, we find the igneous rocks piercing and including fragments and masses of the crystalline limestones, just as the granites at and near their contact with the traps pierce and include the latter. Nowhere did I see clear evidence of the limestones being interbedded with the traps, though in many places at first view there is every appearance of their being so. I therefore look upon the limestones as being older and unconformable.

Haycock ^{415a} adds:

Dr. Dawson's descriptions of the metamorphic rocks of the northern and eastern portions of the island apply with such exactness to this series of the west coast that there can be no reasonable doubt of the latter being a continuation of the former. They may thus be considered as belonging to his Vancouver series and mainly of Triassic but possibly in their lower portions of Carboniferous age.

Clapp has described the topography and geology of the southeastern and southern portions of Vancouver in two articles based on reconnaissance surveys made since 1908. In his earlier report ¹³⁷ he says:

The formations exposed in the southern part of Vancouver Island range from the Devonian period or older, to the Pleistocene and Recent. * * *

The Tertiary sediments of the south coast are the youngest consolidated rocks. Rocks which when unaltered resemble the Coal Measures have along certain belts been metamorphosed. Metamorphic rocks underlie the greater part of the region.

The older metamorphic rocks can not be definitely assigned to any one period. A careful search for fossils was made in the calcareous rocks, now completely crystallized, but without success until the writer's attention was called to the occurrence of fossil corals on the south shore of Cowichan Lake. * * * Although the material has not yet been worked up, the fauna undoubtedly belongs to the Devonian period. * * *

Provisionally, therefore, one can place the great series of old metamorphics in the southeastern part of Vancouver Island as late Middle Paleozoic.

Dawson and other earlier writers classify the old crystallines which underlie the Coal Measures as the Vancouver series and place them in the Triassic period with possibly some Carboniferous members. As the evidence for assigning part of this great series of rocks—especially those in the northern part of the island—to the Triassic is indisputable, and as Dawson suggests that, should this series eventually prove separable into other formations besides the Triassic, the name Vancouver series be retained for the Triassic members, it seems best to restrict the term Vancouver series to Triassic rocks of the northern part of the island, and to introduce a new term for the older rocks. Hence I suggest the term Victoria series as a general name embracing the older metamorphics of the southern part of the island, belonging to the Paleozoic era.

In his later report, on the southern portion of Vancouver, Clapp ¹³⁸ says:

The oldest group of rocks in the southern part of Vancouver Island is the Victoria group. This name was proposed by the writer to include the older metamorphic rocks that occur in the neighborhood of Victoria and which were assigned to the Paleozoic and provisionally, in part, to the Devonian, on the evidence of fossils secured at Cowichan Lake. A later, much more complete collection of fossils from the same locality now shows the fauna to be either Triassic or Jurassic. The correlation of the formations is still doubtful, but it is probable that a large part of the rocks assigned to the Victoria group belongs to an older group of rocks than those in which the above fossils occur, and they are still assigned, provisionally, to the Paleozoic.

In view of the uncertainty of age and correlation of the rocks of these islands, and because the marine Triassic in the Canadian Cordillera, of which these islands are considered a part, is mapped with the Paleozoic undivided, these rocks are shown by the Paleozoic pattern on the present map.

For a description of the Triassic as disclosed in both Vancouver and the Queen Charlotte Islands, the reader is referred to M 9-10 and N 8-9, Chapter XII (pp. 536, 539); for a description of the Lower Cretaceous of the Queen Charlotte group to N 8-9, Chapter XIV (pp. 628-630); and for the Tertiary of Graham Island (of the Queen Charlotte group) to N 8-9, Chapter XVII (p. 834).

M 10-11. WASHINGTON AND BRITISH COLUMBIA.

Umpleby ⁸²⁵ gives the following account of the geology of the Republic district, Washington, which may be regarded as representative of the Paleozoic and later rocks mapped as metamorphic Paleozoic in this region.

The geologic history of the Republic district has as its great features sedimentation in the Paleozoic, erosion with minor volcanism in the Mesozoic, igneous activity and erosion in the Tertiary, and continental glaciation in the Quaternary.

The oldest rocks exposed in the district are the metamorphic equivalents of a great series of shales, sandstones, limestones, and lava flows which are of Paleozoic age and are provisionally assigned to the Carboniferous. After the deposition of this series the area passed through a long period of crustal disturbance which, although not developing sharp folds, metamorphosed the beds and raised the area far above sea level. Either during this period of crustal disturbance or shortly thereafter great batholithic masses of granodiorite were intruded into the Paleozoic series.

From the time of the granodiorite intrusions, which are probably of early or middle Mesozoic age, to middle Tertiary times there was a great period of erosion which may be divided into two parts—a first, during which the entire area was reduced probably to base level (Eocene surface); and a second which was introduced by decided elevation and during which broad valleys at least 2,500 feet deep were developed.

The next rocks in order of formation are of Oligocene age and occupy one of these broad, deep valleys. They are dacite flows, including great quantities of stream gravels. Overlying these, unconformably, are andesite breccias, lake beds, and andesite flows, all of which occur within the old erosion valley. Next in order of age are intrusive latite porphyries with which the ore deposits are thought to be genetically related.

From the time of the latitic intrusions to the Pleistocene erosion was the dominant process, although during this time there was a short period of basaltic eruption. In the Pleistocene period the Cordillera ice sheet covered the entire area.

The oldest known formation exposed in the area is a series of metamorphic rocks including slates, schists, quartzites, marbles, and greenstones. It is most extensively developed southwest of Republic, where about 2 square miles are known. East of the San Poil-Curlew valley * * * are extensive areas where the metamorphic series is the predominating formation. Both areas are so poor in exposures that it is impossible to determine detailed relations.

The Paleozoic rocks are very uniformly but not intensely metamorphosed. True schists are not common, and in many instances the limestone has not been changed to marble. Nevertheless, the series has been so disturbed that a given set of characteristics seldom persists for more than a short distance in any direction. Neither bottom nor top of the series was found.

Black carbonaceous argillite is the predominant rock type, although bluish-gray non-fossiliferous limestones have a wide development. Massive gray quartzites were noted in one exposure southwest of Republic. Porphyries of intermediate and basic composition are found both as dikes and sills, apparently intruded into the series before its metamorphism. The age relations of the various phases of the series are not obvious from studies in the Republic area, but to the north, at Phenix, British Columbia, LeRoy ^a reports a section including all the above types of rocks, which he divides into three parts, with an unconformity between the upper two. His section places the argillites in the upper part, separated from the limestones and tuffs (no tuffs of this age were noted at Republic) by a pronounced unconformity, while the lower member is quartzite with intruded dikes and sills of basic porphyrites. The Paleozoic beds are folded and metamorphosed and are in marked contrast with the overlying Tertiary series, in which folding is less marked and the beds are not metamorphosed.

It is not possible, on the strength of facts now known, to assign this formation to a definite place in the Paleozoic series. Near Republic the formation carries certain fossils, not well

^a Bull. Canada Geol. Survey No. 1072, p. 65.

preserved, but which seem to be crinoid stems. In an exposure of limestone near the top of Buckhorn Mountain, in the northwest part of Republic quadrangle, several fossil crinoid stems were found which are not out of harmony with a provisional assignment to the Carboniferous. These remains, together with the lithologic characteristics of the series, suggest a correlation with the Cache Creek series of Dawson,^a which is of Carboniferous age. On lithologic grounds, however, it is thought that rocks of more than one age are present.

N 10-11 TO Q 7-9. BRITISH COLUMBIA AND YUKON.

The large area mapped as Paleozoic in British Columbia and Yukon is so assigned on the work of the Canadian Geological Survey and chiefly on that of Dr. George M. Dawson. The Cache Creek group is largely represented and is described in Chapter VIII (p. 390). But there are in the region also other terranes which can not be separated, as the country is largely unknown and the geologic relations are intricate.

O-R 2-8. ALASKA.

It is probable that the rocks in Alaska mapped as metamorphic Paleozoic include strata ranging from pre-Cambrian through the Paleozoic column and may possibly include some highly metamorphosed Mesozoic terranes. Adequate differentiation is in part due to limitations imposed by the scale of the map and in part to the absence of detailed field data. According to Brooks^{828 a}—

Four belts of these younger metamorphic rocks are indicated on the map. The first stretches through southeastern Alaska and probably forms the bedrock throughout the greater part of the unexplored St. Elias Range. It has been identified along the lower Copper River valley and in the Chugach Mountains, and then, bending to the southwest, forms the backbone of the Kenai Peninsula of southeastern Alaska. Silurian,^b Devonian, Carboniferous, and Lower Cretaceous^c fossils have been found in these metamorphic rocks of southeastern Alaska.^d The metamorphic rocks of what appears to be the western end of the same belt have thus far yielded no fossils, and they have been variously assigned to the Paleozoic and the Mesozoic.^e The intensely folded rocks of the Chugach Mountains may include some pre-Cambrian sediments, but of this no evidence has yet been found.

A second belt of metamorphic rocks forms the major part of the Alaska Range, and Ordovician^f fossils have been found at a horizon which probably occurs near the base of this series, but it is not impossible that pre-Cambrian sediments are also included.

^f Brooks, A. H., The Mount McKinley region, Alaska: Prof. Paper U. S. Geol. Survey No. 70, 1911, pp. 72-73.

A broad belt of metamorphosed sediments is shown on the map between Yukon and Tanana rivers, and in this are known to be Devonian and Carboniferous and probably Silurian ^a horizons.^b Here, too, pre-Cambrian beds may be included.

Schrader ^c has described a great complex of metamorphic sediments in which Carboniferous fossils have been found near the top of some doubtful Silurian forms in a limestone occurring near the bottom.

Mendenhall,^d in his exploration of the Allen and Kobuk rivers, not attempting to differentiate the semicrystalline rocks which he encountered in his rapid journey, grouped them together under the term "metamorphic complex." In this group are included schists of various types, limestones, quartzites, and greenstones. The lithology is that of the older terranes of other parts of Alaska, but Mendenhall was unable to ascertain the succession within the complex. The group was traced westward to Kotzebue Sound and was regarded by Mendenhall in a broad way as the equivalent of the metamorphic terranes of Seward Peninsula.

In Seward Peninsula the extremely complex structure, the great amount of metamorphism, and the lack of detailed investigations have rendered any definite statement of the stratigraphy impossible. Schists of different mineralogic composition are intricately associated with recrystallized limestones and basic intrusive rocks, all much sheared. In different limestones at widely separated localities fossils of Cambrian, Ordovician, Silurian, and Devonian or Carboniferous age have been found, although most of the limestones have been too thoroughly recrystallized to afford paleontologic evidence. There is strong probability that pre-Cambrian sediments may also be included, but the lack of definite bedding and the known occurrence of continued folds and thrust faults make the projection of dips, and thus the interpretation of sequence, inconclusive.

CHAPTER VIII.

CARBONIFEROUS UNDIVIDED.

Color, light blue, horizontal ruling.

Symbol, 14.

Distribution: Western North America, Arctic region, Newfoundland, and Central America. Subdivided into Mississippian, Pennsylvanian, and Permian in eastern North America.

(See fig. 10.)

Content: Mississippian and Pennsylvanian limestones of the Cordillera including Devonian where present; Mankomen formation and Nabesna limestone of Alaska; Lisburne formation, Alaska; Carboniferous of the Parry Archipelago, Arctic region; Carboniferous of Newfoundland; doubtful Carboniferous or Devonian of Honduras.

Areas mapped as Carboniferous undivided.

E 16. BRITISH HONDURAS.

Sapper⁶⁹⁸ in 1899 compiled the available information concerning the geology of British Honduras, or Belize. The map of that region as furnished by the Mexican Survey in 1906 follows his reconnaissance map of 1899. The Carboniferous and the

^a M 10-11, N 10-11, O 9-10, and P 8-9 in general mapped with Paleozoic undivided.

FIGURE 10.—Sketch map showing the distribution of Carboniferous rocks that are undivided on the geologic map of North America and the key to references in the text.

eruptive rocks constitute the Coxcomb Mountains, which have been crossed by Cockburn, Fowler, Wilson, and Sapper. Sapper's notes contain repeated references to phyllite clay slate and crinoidal limestones. Regarding the latter he says:

Although the crinoidal limestones do not afford definite data for the determination of age, since the crinoids are not specifically determinable, it is nevertheless most likely that the limestone is Carboniferous, since it is only in this terrane that crinoidal limestones have thus far been found in Guatemala.

Crinoids are mentioned also as occurring in a graywacke.

Since the position of these slates and associated limestones within the Carboniferous is not definitely determined, the terrane is mapped as undivided Carboniferous, but it is highly probable that the strata are of the same age as those of adjacent areas in Guatemala, which, as stated in Chapter X (p. 425), are regarded by Girty as not older than lower Pennsylvanian or uppermost Mississippian.

H-I 12. SOUTHERN ARIZONA.

Several isolated sections of Carboniferous strata in southern Arizona are described by Ransome and Lindgren, and in the failure of exact equivalency they are given local formation names: "Globe limestone" of the Globe district (upper part only is Carboniferous), Escabrosa and Naco limestones of the Bisbee district, and Modoc and Tule Spring limestones of the Clifton district.

The "Globe limestone" consists almost exclusively of limestone in beds ranging from 1 to 6 feet in thickness and attains a maximum of 700 feet. It rests without angular unconformity upon the Apache group (Cambrian?), and is cut off at the top by a plane of erosion. Ransome^{657b} states:

It appears from the Pinto Creek sections that the Globe formation includes in its lower part at least 300 feet of Devonian strata and in its upper part at least 500 feet of Upper Carboniferous beds. No unconformity, however, has been found between the beds belonging to these different periods. While future work in the broader region about the Globe quadrangle may result in the discovery of such an interruption of sedimentation and in the consequent splitting up of the Globe limestone, it is believed that no such division is at present practicable within the area covered by this report.^[a]

The case of the Globe limestone recalls that of the Ouray limestone in Colorado, to which Cross has recently called attention. The Ouray limestone, an apparent stratigraphical unit containing characteristic Devonian fossils, was at first referred wholly to that period. Later work, however, has resulted in the discovery of Lower Carboniferous fossils in the upper part of this limestone unit. There is nothing as yet known that precludes the presence of Lower Carboniferous beds in the Globe limestone between the known fossiliferous Upper Carboniferous and the known fossiliferous Devonian. The absence of any recognizable unconformity within the mass of limestone strata is suggestive of uninterrupted deposition from the Devonian to the Upper Carboniferous, and consequently of the presence of some Lower Carboniferous or Mississippian. The paleontological note furnished by Dr. Girty also intimates that the Lower Carboniferous may be represented.

The Escabrosa and Naco formations are Carboniferous limestones of the Bisbee district, Arizona, the former having a thickness of 700 feet and representing the Mississippian series, the latter being 3,000 feet or more thick and equivalent to the Pennsylvanian (Aubrey group and Redwall limestone of northern Arizona in

^a As a result of recent work in the Ray quadrangle, which adjoins the Globe quadrangle, Ransome has separated the Carboniferous from the Devonian. See Min. and Sci. Press, vol. 102, 1911, p. 747.—B. W.

part, according to G. H. Girty). The Escabrosa succeeds the Martin limestone (Devonian) apparently conformably; it is in turn conformably succeeded by the Naco; and the section ends at the top in a surface of pre-Cretaceous erosion.^{658c}

The Modoc limestone (Clifton district) is a remnant of the Mississippian series, about 170 feet thick, which rests conformably upon the Morenci formation (Devonian?), and is limited above by a surface of erosion. The Tule Spring limestone is a representative of both the Mississippian and the Pennsylvanian series.^{541b}

H-I 13. TRANS-PECOS TEXAS.

With reference to the Carboniferous in trans-Pecos Texas Richardson^{668c} states:

The Hueco limestone outcrops in an area of several hundred square miles in trans-Pecos Texas. It underlies the Diablo Plateau, a large area between the El Paso and Van Horn quadrangles, and outcrops in the Sierra Diablo, Finlay, Hueco, and Franklin mountains. The Hueco is a rather homogeneous gray limestone, generally massive, though in places it is thin-bedded. It is comparatively free from chert and differs from the limestones of Silurian and Ordovician age in that it contains little or no magnesia. Although the limestone is prevailing gray, there are local variations in color from light gray to almost black.

In the Franklin and Hueco mountains the Hueco limestone immediately overlies the Fusselman limestone, apparently conformably, in spite of the fact of the great hiatus indicated by their ages. But in the Van Horn region a well-developed basal conglomerate averaging approximately 100 feet in thickness and composed of pebbles of all the pre-Carboniferous formations is present at the base of the limestone, which rests with marked irregularity on the underlying formation. The Hueco limestone generally is overlain by Pleistocene debris, but in a few areas, notably in the Finlay mountains and also 8 miles northwest of Van Horn, it is directly overlain by Cretaceous strata. The total thickness of the Hueco limestone has not yet been determined, but it is more than 3,000 feet.

The Hueco limestone carries an abundant fauna of Pennsylvanian age. * * * According to Dr. Girty, this fauna with some modifications is similar to that found over much of the Cordilleran region, and the Hueco limestone is tentatively correlated with the Aubrey formation and the Weber quartzite.^a

In the Van Horn quadrangle and north of it the bolson plain known as Salt Flat, which is occupied by an unknown depth of unconsolidated Quaternary deposits, lies between the Sierra Diablo on the west and the Guadalupe-Delaware Mountains on the east and completely conceals the relations of the rocks in the two mountains. As has been stated, the Sierra Diablo is made up of the Hueco limestone, the stratigraphic top of which has not been observed, and the Guadalupe-Delaware Mountains are composed of Paleozoic strata, younger than the Pennsylvanian, which contain a fauna not elsewhere known in North America, that Girty has named Guadalupian. This fauna, which has Permian affiliations, is described by Dr. Girty in a paper now in press,^b and it is intended here only to outline the stratigraphy of these rocks, which complete the long Paleozoic sequence of trans-Pecos Texas.

The Delaware Mountain formation includes a varying mass of sandstone and limestone having a maximum thickness of at least 2,300 feet, but the base of the formation is not exposed in Texas and has not been determined. In the northern part of the Guadalupe-Delaware Mountain uplift, the formation is prevailing sandy and contains only thin beds and lenses of limestone. Southward the sandstone decreases and the limestone increases in amount until, in the southern part of the main Delaware Mountains, the formation consists of gray limestone

^a Proc. Washington Acad. Sci., vol. 7, 1905, p. 14.

^b Since published as Prof. Paper U. S. Geol. Survey No. 58, 1908.—B. W.

with only subordinate beds and lenses of sandstone. The sandstone is a massive to thin bedded buff to brownish quartzose rock and the limestone likewise is both thick and thin bedded, of a prevailing gray color, and contains little chert. * * *

In the Guadalupe Mountains, 60 miles north of Van Horn, about 2,200 feet of the Delaware Mountain formation is conformably overlain, in a magnificently exposed section, by 1,800 feet of limestone named the Capitan limestone. The name is taken from El Capitan Peak, which, having an elevation of 8,690 feet, is the highest point in Texas. The Capitan is a light-colored, usually white limestone which, although possessing minor variations, is homogeneous in general appearance. Bedding planes in many places are not apparent and the rock is characteristically massive. Chemically it is of variable composition, some analyses showing the presence of considerable magnesium while others indicate its almost complete absence. Besides its main occurrence in the Guadalupe Mountains the Capitan limestone was determined in 1907 to be present in the southern end of the Delaware Mountains, where it has been faulted down and adjoins the limestone of the Delaware Mountain formation. R. S. Tarr reports,^a in the paper cited above, the presence of 1,000 feet or more of sandstone lying above the Capitan formation, but these rocks have not been studied, so that neither the base nor the top of the strata bearing the Guadalupian fauna has yet been determined. It is expected that these relations can be determined in the northward continuation of the formations in the Sacramento Mountains of New Mexico.

The age of the Guadalupian fauna has been much discussed. Girty tentatively regarded the Guadalupe group as younger than the lower portion of the Kansas Permian, from which alone invertebrate fossils were known. This view was based on the close faunal relationship of the Kansas Permian with the Kansas Pennsylvanian, on the general resemblance to the Pennsylvanian shown by the fauna of the Hueco limestone, which underlies the Guadalupe group, and on the great unlikeness of the Guadalupian fauna both to the fauna of the Hueco limestone and to that of the Pennsylvanian and Permian of Kansas. Subsequent investigations, however, have seemed to indicate, as noted below, that the striking peculiarity of the Guadalupian fauna is only regional. Furthermore, J. W. Beede has reached the conclusion, on stratigraphic and paleontologic evidence not altogether satisfactory, that the lower part of the Capitan limestone, which is the upper formation of the Guadalupe group, is equivalent to the lower part of the Kansas Permian; that the upper part of the Capitan is equivalent to the middle part of the Kansas Permian; and that the upper part of the Kansas Permian (equivalent to the Greer and Quartermaster formations of Oklahoma and Texas) overlies the Capitan limestone. The lower formation of the Guadalupe group (the Delaware Mountain) he correlates with the Pennsylvanian of Kansas, while the still older Hueco limestone is inferentially of early Pennsylvanian (Pottsville?) age.

In 1909 Richardson^{670b} traced the Guadalupe group from the type locality in Texas northward in New Mexico for 50 miles and found that the stratigraphy is varied and that both the Delaware Mountain formation and the Capitan limestone lose their individuality when traced far along the strike. The northward continuation of the group lies between the Pennsylvanian Hueco formation, as developed in the Sacramento Mountains, and the Permian red beds of Pecos Valley. The fossils in the northward continuation of the Guadalupe group, according to Dr. Girty,³⁶⁷ show but little relationship to the typical Guadalupian fauna but

^a Tarr, R. S., Reconnaissance of the Guadalupe Mountains: Bull. Texas Geol. Survey No. 3, 1892.

rather are similar to those of the upper part of the Hueco formation. It seems probable that this difference in the fauna is due to changed environment, which is indicated by the varied lithology. Whether the Guadalupian fauna should be regarded as late Pennsylvanian or Permian is still an open question, but the weight of evidence is in favor of the Permian and that view has been adopted by the United States Geological Survey.

In an earlier report Richardson⁶⁶⁶ described the formations overlying the Guadalupe group, as follows:

The Castile gypsum is a massive white granular variety. It is comparatively pure, and a characteristic sample analyzed qualitatively by Mr. W. T. Schaller shows it to be of no unusual composition. Considering its great extent the Castile gypsum is remarkably homogeneous, yet it varies somewhat. On the surface it is generally disintegrated and earthy. In places it is grayish or dark in color owing to the presence of organic matter, and at other places it is stained red by iron oxide. Locally selenite is abundant. Some sections show occasional thin beds of banded gray limestone in the gypsum. Deposits of native sulphur are also associated with the Castile gypsum. The thickness is not known, but it is considerable. A well at the old sulphur works about 6 miles north of Rustler Spring shows a thickness there of a little over 300 feet, though the base of the gypsum is not known to have been reached.

* * * * *

The Castile gypsum outcrops in a belt between the Delaware Mountains and Rustler Hills, the width of which averages about 15 miles, though at the New Mexico-Texas boundary it is about 30 miles. This gypsum belt begins about 15 miles north of the railroad and extends into New Mexico. Within Texas the gypsum outcrops over 600 square miles. The name of the formation is derived from Castile Spring, which is in the midst of the gypsum about 12 miles south of the State boundary.

The Castile gypsum along its western outcrop lies on little knolls and valleys of the underlying Delaware Mountain formation, indicating an erosional unconformity. Another evidence of unconformity at the base of the gypsum consists in the absence of the Capitan limestone. It appears that either the gypsum was deposited at or near the top of the Delaware Mountain formation as a lens which did not extend westward to intervene between the Delaware Mountain formation and the Capitan limestone in the Guadalupe Mountains, or that erosion removed the former southwestward extension of the limestone (the thickness of which is unknown) before the deposition of the gypsum. The former supposition necessitates the correlation of the Rustler formation, which overlies the gypsum, with the upper part of the Delaware Mountain formation or with the Capitan limestone. But there is little to support this interpretation, and it is tentatively assumed that the Castile gypsum and the Rustler formation were formed after the deposition and erosion of a part of the Capitan limestone.

The Rustler formation consists of a fine-textured white magnesian limestone and less abundant sandstone. The formation occurs in the Rustler Hills, in the dissected southwestern extension of the Rustler Hills between Cottonwood and Hurd's Pass draws, and in a few isolated areas west of the hills.

The formation as here exposed averages about 200 feet in thickness and varies in composition. In the southern outcrops there is no sandstone and the hills are capped by about 150 feet of massive gray limestone, which directly overlies the gypsum. Northward sandstone is present below the limestone. * * *

Recent work⁶⁷⁰ has shown that the Castile gypsum and Rustler formation are parts of the group of red beds of Pecos Valley, which are of Permian age.

I 12. ARIZONA AND NORTHWESTERN NEW MEXICO.

Reagan ^{663a} states in regard to the Carboniferous of the Fort Apache region, in Arizona:

Lower Redwall group.—The first series above the Devonian is from 400 to 1,000 feet of alternating gray limestone and shale. It terminates at the top in a massive to shaly coarse sandrock, often of the millstone grit type. The lime rocks are very fossiliferous from the middle of the series to the top and seem to belong to the lower Carboniferous group; but as yet the writer has not identified fossils enough from the group to verify such a conclusion.

Upper Redwall group.—The writer has included in this group all of the strata superimposed on the millstone grit rock of the group just described, to and including the dark-gray limestone series about 1,000 feet above its base. The series here is very variable, indicating a rapid transformation from west to east. Ripple marks and old shore lines are noticeable and indications of large swamp land areas are exposed on Cibicu Creek and in the vicinity of Fort Apache. As evidence that the country reached the swamp stage the writer found several specimens of *Lepidodendron* and one whole tree of the species *Calamites cannæformis*. The group belongs to the coal-measure series, as is attested by its fossils: *Spirifer cameratus*, *Productus semireticulatus*, *P. costatus*, *Lepidodendron*, *Calamites cannæformis*, etc.

Aubrey group.—The interstream spaces of all the streams in their upper course, as well as the south front of the Mogollon Range and the Cibicu divide, where not covered with later deposits, are capped with 280 feet of calcareous sandstone followed by 500 feet of soft red and gray shales, interrupted by sectile limestone. The Aubrey limestone occurs in one locality—at the headwaters of the Cibicu and Canyon creeks. The rocks of this group are usually non-fossiliferous, but fossils enough were obtained (*Athyris subtilita*, *Productus punctatus*, *Spirifer cameratus*, *Productus*, and *Bellerophon*) to identify it as upper Carboniferous.

The Zuni Plateau lies just north of the thirty-fifth parallel in New Mexico. It is composed largely of Carboniferous strata, which Dutton ^{301b} discusses and compares as follows:

The Carboniferous strata of the plateau country have been divided into two portions, an upper and lower. To the lower portion the local name of the "Redwall group" has been given and the upper portion has been named the "Aubrey group." The Redwall takes its name from the great vertical escarpments which its most massive member presents in the canyons of the Colorado. In the Grand and Marble canyons especially a band of limestone from 800 to 900 feet thick constitutes the face of the principal vertical cliff and becomes the most impressive stratigraphic feature of those great chasms. It has always been spoken of as the Red Wall. Its lower Carboniferous age has been well ascertained. Above and below it are numerous bands of limestone and calcareous sandstones belonging to the same group and always classed with it. While it is always found at the exposures of its proper horizon in the other parts of the plateau country, it is plainly wanting in the district we are about to study, and its absence is certainly a striking fact. It appears to be absent also from the Nacimiento Range, northeast of the Zuni Plateau, where the upper Carboniferous rests on the Archean just as it does here. In the southern and southwestern Colorado, however, it is usually found in its proper place. The conclusion seems obvious that it was never deposited here, and that this locality was a land area in early Carboniferous time.

The upper Carboniferous or Aubrey group is usually subdivided into two portions, an upper and a lower Aubrey. This subdivision is quite proper as well as convenient, for the two portions are strongly contrasted with each other in their lithologic features and in the topography to which their erosion has given origin. The lower Aubrey consists of bright-red sandstones throughout, deposited usually in rather thick and less frequently in moderately thin layers. They are much alike in all outward respects, color, texture, and grouping and in the erosional forms sculptured out of them. They are very fine grained, without traces of conglomerate or coarse shingle or gravels, and, having a calcareous cement, they weather easily

and break down into very fine red sand. Fossils are scarce but may be found here and there in sufficient quantity and distinctness to identify their age. These fossils, so far as I have seen, are the same as those which abound in the beds above them.

The upper Aubrey is composed largely of sandstones, but they have a very different aspect from those below. In color they are yellowish brown and the cement, instead of being calcareous, is siliceous—in fact, a regular chert. * * * These sandstones are conspicuously cross-bedded, and the silicification of the rock has in no way obscured it. * * * There are several bands of these adamantine sandstones, and intercalated with them are three or four thick beds of pure limestone, containing an abundance of fossils of many and characteristic species.

While the Mesozoic strata of this district show some differences in comparison with those north of the Grand Canyon, the upper Aubrey shows none, except in its thickness. Its cliffs in the upper wall of the Grand Canyon and those overlooking the granite of the Zuni Plateau are so similar that it is hardly possible to doubt that their materials came from the same source and were deposited under the same conditions. In the former locality they are thicker in about the ratio of 5 to 3, and this ratio holds good not only for the Aubrey series as a whole but for all its subdivisions and principal members. In the Grand Canyon the thickness of the Aubrey is about 2,000 feet; here it is about 1,200.

I 13. NEW MEXICO.

Lindgren ^{542d} describes the Carboniferous of New Mexico as follows:

The Mississippian, or lower Carboniferous, has been recognized at several places south of latitude 34°. W. T. Lee found limestone of this age in the Ladrones Range and Gordon believes, on the basis of evidence collected by C. L. Herrick, that the lower part of the section in the Magdalena Mountains belongs to this series. Characteristic Mississippian faunas were found by Gordon at Kingston and Hillsboro, and the horizon has for some time been known to be represented at Lake Valley, where a thickness of over 200 feet of limestone has been measured. Rocks of the same age are also present in the Silver City district. Gordon states that at Hillsboro these limestones rest upon the eroded surface of the Devonian calcareous shales, but farther west there is no evidence of unconformity.

The Pennsylvanian, or upper Carboniferous, is deposited with a considerable thickness over the whole Territory and reaches its maximum in the country between Santa Fe and Las Vegas. As far south as the latitude of Socorro the Pennsylvanian consists in large part of sandstones and shales in repeated alternation with some limestone beds. But south of this line the pure limestones prevail and at the same time the total thickness appears to diminish. Everything indicates near-shore conditions in the northern part of the Territory, where some land areas probably existed even at that time.

In northern and central New Mexico there appear to be two divisions of the Pennsylvanian, the upper in certain parts possibly including the Permian. According to W. T. Lee and C. H. Gordon ^a the Pennsylvanian of central New Mexico is divisible into two groups, the lower called the Magdalena group and the upper called the Manzano group. The Manzano consists in fact of the "Red Beds" of Carboniferous age.

The average thickness of the Magdalena group in the vicinity of Socorro is 1,500 feet. This group is subdivided into (1) a lower formation called the Sandia, consisting chiefly of shales, limestones, and sandstones, the first two predominating, with a thickness ranging from 500 to 700 feet; and (2) an upper formation called the Madera limestone, 300 to 500 feet thick, consisting of blue limestone with some shale. Both formations are well exposed in Socorro and Bernalillo counties.

The Manzano group, best exposed on the east side of the Rio Grande near Socorro, consists of 2,000 feet of red and variegated sandstones, shales, limestones, and gypsiferous beds. Its

^a Gordon, C. H., Note on the Pennsylvanian formations in the Rio Grande valley: *Jour. Geology*, vol. 15, 1907, pp. 805-816. Lee, W. T., and Girty, G. H., The Manzano group of the Rio Grande valley, New Mexico: *Bull. U. S. Geol. Survey* No. 389, 1909.

upper part is a bed of blue limestone 300 to 500 feet thick, with Pennsylvanian fossils, which Lee has named the San Andreas limestone. Beneath this is the Yeso formation, consisting of 500 to 1,000 feet of yellow, pink, and white sandstones and shales, with gypsum and some limestone. The basal formation of the Manzano group, to which the name Abo sandstone has been given, is composed of dark-red sandstones interstratified with sandy shales. There are distinct unconformities produced by erosion at the top and the bottom of the Manzano group.

South of Socorro County Lee has traced the red beds of the Manzano group down to Rincon. In the Franklin Mountains, according to G. B. Richardson, the Carboniferous "Red Beds" and in fact all "Red Beds" are absent and the Pennsylvanian is represented by the Hueco limestone, 3,000 feet thick. Still farther east on the boundary line between Texas and New Mexico the Hueco is covered by 2,500 feet of Guadalupian^a sandstone and limestone. Near Silver City and in the southwest corner of the Territory the Pennsylvanian consists almost exclusively of limestones of moderate thickness. The "Red Beds" are absent and Cretaceous rocks carrying Benton fossils rest with distinct unconformity on the eroded Carboniferous formations.

In the Zuni Mountains, according to Dutton, there are 1,650 feet of Pennsylvanian and Permian "Red Beds" resting directly on the pre-Cambrian rocks. In the Mora uplifts there are, according to J. J. Stevenson, 3,276 feet of upper Carboniferous, consisting of sandstones, shales, and limestones in rapid alternation. In the upper Pecos Valley, above Pecos, there is, according to Lindgren, about 4,000 feet of the same series which apparently can not be further divided. At neither place does this series comprise any "Red Beds." Several coal seams, at least one of which is workable, are present. Between Pecos and Glorieta, the relations being especially well exposed in La Cueva Creek, this lower series is covered by a thick mass of "Red Beds" and coarse grits, containing some interbedded limestone, evidently of Paleozoic age. These coarse grits are beyond doubt derived from the pre-Cambrian mass of Thompson and Penacho peaks, just to the northwest, and their extensive development demonstrates the existence of a land area along the Santa Fe Range and probably also an epoch of erosion within Pennsylvanian time. Above these grits and "Red Beds" are similar strata of uncertain age which underlie the Glorieta Mesa and which are capped by a yellow sandstone, outcropping at the edge of the escarpment; the sandstone has been regarded as of Dakota age. The total thickness of the "Red Beds" in the upper Pecos Valley, as measured by Newberry, is 1,350 feet.

I 16. ALABAMA.

Plant remains, probably of Carboniferous age, are recorded by Smith⁷⁴⁷ from the metamorphosed rocks near Moseley (now Erin), in Clay County, Ala., which have been regarded as a part of the Ocoee group of Safford. (See Chapter III, p. 90.)

J 10. SIERRA NEVADA, CALIFORNIA.

On pages 373-376 is given an account of the Carboniferous of northern California. South of the fortieth parallel in the Sierra Nevada occur schists, slates, quartzites, and limestones, which constitute a metamorphic series not usually divisible and which under the name Calaveras formation are assigned to the Carboniferous. In the "Description of the gold belt" included in folios of the Geologic Atlas of the United States relating to the Sierra Nevada⁸¹³ published prior to 1900 occurs the following statement:

The great mass of the Paleozoic sediments of the gold belt consists of quartzite, mica schist, sandstone, and clay slate, with occasional limestone lenses. On the maps of the gold belt these sediments are grouped under two formations:

^aRichardson, G. B., Paleozoic formations in trans-Pecos Texas: *Am. Jour. Sci.*, 4th ser., vol. 25, June, 1908.

The Robinson formation, comprising sediments and trachytic tuffs. This contains fossils showing the age to be upper Carboniferous. The formation is known on the gold belt series of maps only in the Downieville quadrangle, a short distance south of the fortieth parallel.

The Calaveras formation, comprising by far the largest portion of the Paleozoic sediments of the gold belt. Rounded crinoid stems, corals (*Lithostrotion* and *Clisiophyllum*), Foraminifera (*Fusulina*), and bivalves have been found in the limestone lenses and indicate that a considerable portion at least of this formation belongs to the middle or lower Carboniferous. In extensive areas of the Calaveras formation no fossils have, however, been found, and older rocks may be present in these. It is not likely that post-Carboniferous rocks are present in these nonfossiliferous areas.

In the Colfax quadrangle, which lies in the northern-central part of the Sierra Nevada (latitude 39° – $39^{\circ} 30'$, longitude $120^{\circ} 30'$ – 121°), the sedimentary rocks of the "Bedrock series" are divided by Lindgren⁵³⁸ into three "groups," of which the oldest is "the Carboniferous group equivalent to the Calaveras formation of other folios. * * * This group can be subdivided into five formations, lithologically very distinct, though the fossils do not afford data for paleontologic discrimination. These are enumerated from east to west as follows: Blue Canyon formation, Relief quartzite, Cape Horn slates, Delhi formation, and Clipper Gap formation."

According to Lindgren the principal Carboniferous area in the quadrangle is that of his Blue Canyon formation, occupying the southeast corner, adjacent to "Jura-Trias" (Sailor Canyon) rocks, and intruded by granite. The rocks are black fissile clay slates and fine-grained quartzitic sandstones, with one occurrence of fine conglomerate and a few limestone lenses. At two localities these limestones contain fossils (*Lithostrotion*, *Aviculipecten*, a lamellibranch, and *Murchisonia* at one place; *Syringopora*, *Diphyphyllum* or *Lithostrotion*, and crinoid stems at the other). These suffice only to indicate a Paleozoic age.

Lindgren described his Relief formation as a very hard, fine-grained quartzite, alternating with streaks of siliceous clay slates, plainly exhibiting the stratification but unfossiliferous; his Cape Horn formation as consisting of typical clay slates, fissile, almost black, weathering to gray, and containing small limestone lenses which have yielded round crinoid stems of Paleozoic age; and his Delhi formation as composed of a peculiar dark-brown or black hard rock, resembling hornfels (a character probably due to metamorphism of siliceous sediments of a certain kind), with a few lenticular masses of limestone and round crinoid stems.

Lindgren's Clipper Gap formation consists of black clay slates and argillaceous sandstones. Lenticular bodies of limestone are abundant and chert is common. Obscure fossils (*Phillipsastrea* and *Pleurotomaria*) were obtained at one locality, and others (*Clisiophyllum gabbi* Meek, *Lithostrotion whitneyi*, and brachiopod fragments) of lower Carboniferous age were found in a disconnected mass that is probably a fragment of the formation torn loose by a diabase eruption.

J. 11. EASTERN NEVADA.

From Hague's very full account^{391c} of the Carboniferous section at Eureka, Nev., the following extracts are taken:

At Eureka the Carboniferous rocks have been estimated to measure 9,300 feet in thickness, which, however, does not represent the full development of the Carboniferous period, the upper Coal Measures, the top of the Paleozoic system, having suffered a very considerable amount of erosion. This upper limestone is by no means so thick as that found elsewhere.

The Carboniferous rocks have been subdivided into four epochs—first, Diamond Peak quartzite; second, Lower Coal-measure limestone; third, Weber conglomerate; fourth, Upper Coal-measure limestone.

* * * * *

At the base of the [Diamond Peak] horizon fine conglomerates firmly cemented together lie next the argillaceous shale of the White Pine epoch,^a but quickly give place to a more massive, usually vitreous quartzite with a characteristic grayish-brown color and breaking irregularly with a flinty fracture. Intercalated black cherty bands, carrying a more or less ferruginous matter, occur near the middle portion of the horizon. Near the summit the beds pass into thinly laminated green, brown, and chocolate-colored schists and clay shales. The Carboniferous age of the epoch is determined by a narrow belt of blue limestone, which occurs interstratified in the quartzite about 200 feet above its base, in which the widespread species *Productus semireticulatus* occurs associated with an undetermined species of *Athyris*. As the fauna at the top of the black shales foreshadows the coming in of the Carboniferous, the presence of this characteristic *Productus*, with only a Carboniferous fauna higher up in the series, determines without question the geological position of the quartzite between the black shale and Coal-measure limestone.

* * * * *

In the Diamond Range the Lower Coal-measure limestone overlies conformably the Diamond Peak quartzite, the transition beds passing rapidly from siliceous to calcareous sediments. In their lithological character and physical habit they do not differ essentially from the same beds elsewhere, except, perhaps, at their base, where they carry intercalated beds of chert, argillite, and gritty, pebbly limestone, with evidences of shallow-water deposition. They pass rapidly, however, into purer gray and blue limestone, for the most part heavily bedded and distinctly stratified at varying intervals. In broad masses they resemble the Upper Nevada limestone but are rather lighter in color in distinction from the dark blue and black of the latter horizon. No true dolomite beds of any considerable thickness have been recognized, 9.21 per cent being the largest amount of magnesium carbonate obtained in any of the rocks subjected to chemical analysis. Across their broadest development they measure about 3,800 feet in thickness, which is much less than has usually been assigned to this horizon in other mountain uplifts, more especially those lying eastward.

As the term Lower Coal-measure has been employed by most geologists to designate this epoch throughout the Great Basin, it has been thought best to retain the name provisionally, although not exactly applicable, as the epoch includes such a commingling of species from both the Upper and Lower Coal measures that a separation of the beds seems quite impossible.

* * * * *

Three salient features in the life of the Lower Coal measures at Eureka call for special mention, and each is worthy of still further investigation—first, the occurrence near the base of the limestone of a fresh-water fauna; second, the varied development of the lamellibranchiates, a class which has heretofore been but sparingly represented in the collection of Carboniferous fossils from the Cordillera; third, the mingling near the base of the horizon of Devonian, Lower Carboniferous, and Coal measure species in gray limestone directly overlying beds characterized by a purely Coal measure fauna.

* * * * *

Conformably overlying the Lower Coal measures comes the Weber conglomerate [probably of Pottsville age], one of the most persistent and well-defined horizons over wide areas of the Cordillera, stretching westward all the way from the Front Range in Colorado to the Eureka Mountains. It varies in the nature of the sediment with every changing condition, but it is nearly everywhere easily recognized as a siliceous formation between two great masses of Carboniferous limestone. In places it is made up of an admixture of calcareous and sandy beds; in others of fine grits and shales; and again of nearly pure siliceous sediment, varying from fine to coarse grained, dependent largely upon the distance from any land area and depth of

^a Mississippian, according to G. H. Girty (comment on manuscript).

water in which it was deposited. Here at Eureka the material is exceptionally coarse, with abundant evidence of shallow-water deposition and the existence of a land surface not very far removed at the time the beds were laid down.

* * * * *

Beds of the Upper Coal measures are found conformably overlying the Weber conglomerate. * * * The thickness attained by the rocks of this epoch is nowhere exposed in the district, the overlying beds having either suffered removal by the denudation or else been concealed beneath flows of igneous rocks. * * * The beds are estimated at 500 feet. In the northern and central portions of the State of Nevada the Upper Coal measure limestones attain a development of nearly 2,000 feet. * * *

In the field the Upper Coal measures may be distinguished readily from the Lower Coal measures by their lighter color and the greater prevalence of fine-grained beds. These colors are light bluish gray and drab, the latter possessing a conchoidal fracture and compact texture. These compact limestones frequently present forms of erosion quite different from the coarse-grained and granular limestones of the Lower Coal measures. Throughout the horizon the limestones are interstratified with belts of grit and siliceous pebbles, held together by a calcareous cement, in which are intercalated thin beds of purer limestone. One or two prominent beds are apparently made up of quartz pebbles and fragments of an older limestone, carrying such fossils as *Fusilina cylindrica* and *Productus semireticulatus*, as if indicating that they had been derived from the underlying Carboniferous rocks. The fossils, however, which are all Coal measure species, might be derived quite as well from the Upper as from the Lower beds. A chemical examination failed to detect any beds of dolomite in the limestones, the highest amount of magnesium carbonate obtained being 1.33 per cent. This is not without interest, as it is the only limestone horizon in the Paleozoic series at Eureka free from dolomitic strata.

J 12. SOUTHERN UTAH AND NORTHERN ARIZONA.

The eastern margin of the Great Basin in southwestern Utah is mapped according to information supplied by F. B. Weeks.^a The data for the eastern portion of the State, comprising the Green River and Grand River sections and the San Rafael Swell, are derived from McGee's map⁵⁶⁷ and appear to represent observations by Powell and Dutton that are not otherwise recorded.

The later Paleozoic section of northern Arizona comprises the Carboniferous formations known as the Redwall limestone (Mississippian and lower Pennsylvanian), the Aubrey group (upper Pennsylvanian), and the Moencopie formation (Permian?). The Redwall and Aubrey were first described by Gilbert,³⁶⁰ who gives the following generalizations regarding the stratigraphy, beginning at the top with the "Aubrey" limestone (renamed Kaibab limestone by Darton^{246a} in 1910, Aubrey being retained for the group), which in some areas is overlain by Triassic strata and in other areas by the Moencopie formation^{246b} (Permian?):

The Aubrey limestone has a thickness of 820 feet on Kanab Creek, and this is about its maximum. * * * Lithologically the limestone is characterized by a great abundance of chert, which, toward the top, sometimes constitutes half the mass. Near the middle it is, in some places, interrupted by a belt of shale, with gypsum. * * *

The Aubrey sandstone series has a thickness, in the Aubrey Cliffs and along the Grand Canyon, of about 1,000 feet. In every exposure a portion of this body is massive and cross-bedded and another portion soft and gypsiferous, but the order of these parts is not constant. In the Aubrey Cliff the compact rock is at the top and, together with the Aubrey limestone, holds a sheer bluff, at the foot of which the softer portion spreads a broad slope. Along the

^a Personal communication.

Grand Canyon, at Kanab Creek, and near the Uinkaret Mountains the upper sandstone is soft and produces a slope in the profile, while the lower is hard and unites its steep escarpment with that of the Redwall limestone. The sandstones contain no fossils, but an intercalated limestone below the middle of the series at Canyon Creek bears the familiar Coal Measure shells.

The Redwall limestone has, upon fresh fracture, a gray color and shows its red rust only on weather-stained cliffs. In its general character it is heavy bedded to massive. At the top sandstone alternates with the limestone for from 200 to 500 feet. Through its lower half the firm limestone is interrupted by occasional shaly bands, which serve to break its escarpment into a series of narrow terraces, but above them stands a sheer perpendicular face, of from 800 to 1,000 feet. The average total thickness is 2,500 feet.

Accompanying these stratigraphic notes are lists of fossils, according to which the highest beds were referred to the "Permo-Carboniferous" and the upper half of the Redwall to the "Coal Measures" (Pennsylvanian), with a doubtful determination of "Lower Carboniferous" below the middle. Gilbert regarded it as possible that the Redwall extended down to include Devonian.

A recent publication on the stratigraphic succession and age of the rocks of northern Arizona is that by Darton,²⁴⁶ already cited.

J 13. COLORADO.

The Carboniferous terranes of Colorado have been described, compared, and correlated by Girty³⁶² in a monographic work, to which reference should be made for a general treatment of the whole subject.

The following extracts present the general relations:

The lower Carboniferous strata of Colorado are geologically comparatively unimportant by reason of their thinness, but they are widely distributed and form one of the richest metaliferous horizons in the entire rock series. This horizon is everywhere a limestone or a dolomite, sometimes more or less interstratified with shale, but owing to minor differences of lithologic character and circumstances of distribution several local names have been received by it. In central Colorado this limestone is called the Leadville limestone. In the San Juan region it is called the Ouray limestone, and along the Front Range it has received the name of the Millsap limestone. The lower portion almost everywhere contains a distinctive and unmistakable Devonian fauna. At least this fauna has been found at so many and such widely separated points that it may safely be regarded as generally present over the central part of the State wherever the formation is brought to view. In the few fragments of it which are still visible along the Front Range, however, the Devonian fauna seems to be wanting.

* * * * *

Along the eastern margin of the Front Range the Mississippian limestone appears in several places. It is in this tract called the Millsap limestone. The Millsap limestone was first described in the Pikes Peak folio, from which I abstract the following: It consists only of local remnants resting upon the Fremont limestone in Garden Park and along the western line toward Canyon. It is represented by about 30 feet of thinly bedded variegated dolomitic limestone, with a few thin sandstone layers. Chert nodules in the upper limestone layers carry casts of *Spirifer rockymontanus* and *Seminula subtilita*. It is divided from both the formation which preceded and that which followed it by an erosional unconformity.

* * * * *

In the San Juan region Mississippian time is represented by the Ouray limestone, the major portion of the formation, however, containing a Devonian fauna.

The Ouray limestone is defined by Cross and Spencer somewhat as follows: It consists of massive beds of limestone separated by thin intercalations of marl or shale. Certain thin bands are frequently quite coarsely crystalline, but the large mass of the formation is a dense

or semicrystalline limestone. The thickness is about 150 feet. The greater part of this formation appears to be of Devonian age, and it was only comparatively recently that a Mississippian fauna was obtained from its upper portion. The latter is intimately related to the Mississippian faunas at Leadville and Aspen, and also to the Waverly fauna of the Wasatch limestone of Utah, the Madison limestone of Wyoming and Montana, the typical Waverly of Ohio, and the Chouteau limestone of Missouri. The fauna of the Millsap limestone, as we know it from Perry Park and also from Garden Park and Canyon, and that of the Leadville limestone at Leadville present a rather peculiar facies, but even this fauna seems to be related to those of the early Mississippian, and it is somewhat singular that the Leadville fauna is more nearly allied to that of Perry and Garden parks, while lithologically and stratigraphically the Leadville as a formation is especially to be compared with the Leadville of Aspen and of the Crested Butte region. I think we can safely regard these faunas as varying facies of a single widespread and contemporaneous fauna, the differences being due in part to varying environmental conditions and in part to quite a different cause. Our collections from these beds are extremely meager, and to this circumstance can be referred some of the differences at present existing.

* * * * *

It is now fairly certain that the Carboniferous portion of the Leadville, Ouray, and Millsap limestones are of early Mississippian age.

This formation, or, as it has received several names, this horizon, is widely distributed in Colorado. It is known in the Grand River region (the Devonian portion has been recognized on the White River and at Glenwood Springs and the Carboniferous probably on Eagle River), in the Elk Mountain region, in the South Park region, in the northern part of the Sangre de Cristo Range, in the San Juan region, and along the Front Range. It is probably lacking over much of the Front Range and Sangre de Cristo areas, in the Uinta Mountains, and in the valleys of the Dolores and the Grand, and it is concealed over extensive areas by deposits of later geologic age; but it is perhaps the most widespread of all the Paleozoic formations except those belonging to the Pennsylvanian. The remarkable persistency of this horizon as a limestone formation, not only in Colorado but throughout the West, and the widespread distribution of essentially the same fauna would argue extended and uniform marine conditions during Mississippian time.

* * * * *

The Lower Carboniferous period was followed by an epoch of elevation and erosion. At all events none but the early portion of Mississippian time is apparently represented in the Colorado sediments. The chronological point at which this elevation took place is, except in a general way, unknown. It may have occurred soon after the formation of the Leadville limestone, the absence of the upper Mississippian horizons being due not so much to erosion as to nondeposition; but it seems to me rather more probable that this episode was nearly contemporaneous with the elevation in eastern North America at the close of Mississippian time. That the elevation is of wide extent is indicated by the absence over such large areas in our Western States of upper Mississippian faunas. To the erosion which resulted from this elevation the variation in thickness of the Leadville limestone in different sections can often be ascribed. When subsidence again permitted the formation of sediments, the earliest deposits were frequently of a less purely marine character, and shortly a great thickness of sands and conglomerates intermingled with nonpersistent limestone bands began to form over great areas in the State.

The Paleozoic section of central Colorado, by which term I would include the Grand River, Elk Mountain, and South Park areas, is singularly uniform, and this is scarcely less true of the strata of Carboniferous age than of the earlier Paleozoics. Though these are fairly constant in lithologic characters, the nomenclature employed for them has varied somewhat. Thus in the Anthracite-Crested Butte folio the Carboniferous formations are called the Leadville limestone, Weber limestone, and Maroon conglomerate; in the Aspen monograph the Leadville limestone, Weber formation, Maroon formation, and the Triassic; in the Tenmile folio the Leadville limestone, Weber shale, Weber grits, Maroon formation, and Wyoming formation; and in the Leadville monograph the Blue limestone, Weber shale, Weber grits, and Upper Coal Measures.

From special reports the following details are cited:

The Carboniferous of northwestern Colorado south of the fortieth parallel is described in the Anthracite-Crested Butte folio by Eldridge,³⁰⁴ who distinguished the following, in ascending order: Leadville limestone, Weber formation, and Maroon conglomerate.

In the Leadville district, central Colorado, Emmons³²¹ distinguished the following subdivisions of the Carboniferous:

Carboniferous, 3,700 to 4,200 feet:

Upper Coal Measures: Blue and drab limestones and dolomites, with red sandstones and shales.

Mud shales at top. 1,000 to 1,500 feet.

Weber grits: Coarse white sandstones, passing into conglomerates, and siliceous and highly micaceous shales, with occasional beds of black argillite and blue dolomitic limestone.

Weber shales: Calcareous and carbonaceous shales, with quartzite.

Thickness of Weber grits and shales, 2,500 feet.

Blue [Leadville] limestone: Compact, heavy-bedded dark-blue dolomitic limestone. Siliceous concretions at top, in form of black chert. 200 feet.

The Leadville ("Blue") limestone is regarded by Girty as equivalent to the upper part of the Ouray limestone of southwestern Colorado. The "Weber shales" are treated by Emmons^{321a} as a subdivision (150 to 300 feet thick) of the "Weber grits." The siliceous beds of the "Upper Coal Measures" he states^{321b} are "not distinguishable from those of the Weber grits at the base, but pass upward into reddish sandstones, which in their turn are sometimes difficult to distinguish from the overlying red sandstones of the Trias."

This sequence at Leadville is at the north end of the belt of Carboniferous rocks which extends thence southward west of the Colorado Front Range into New Mexico, to the vicinity of Santa Fe. Beyond that point after a brief interruption the strata continue in the upper Rio Grande valley.

In Colorado east of the Front Range the Carboniferous presents a less complete section than that found west of the range at Leadville and thence southward. In the Pikes Peak quadrangle occur the Millsap limestone and the Fountain formation. The Fountain is not very definitely correlated with other Carboniferous formations. The Millsap is a thin-bedded dolomitic limestone, which rests unconformably upon the Fremont limestone (late Ordovician) and which, having been deeply eroded before the close of the Carboniferous, is but 30 feet thick in this locality. It is regarded as approximately equivalent to the Leadville limestone of north-central Colorado. The Fountain is made up of red sandstone and conglomerate and forms a part of the so-called "Red Beds," which were deposited unconformably upon Ordovician and pre-Cambrian and composed in part of detritus from the gneisses and granites. The local thickness is 1,000 feet.

The age of the Fountain formation has been in doubt on account of the scarcity of fossils. It is now regarded by Girty as wholly Pennsylvanian and by Henderson as Mississippian below and Pennsylvanian above. Henderson⁴³⁴ states:

At the northern boundary of Colorado we found a chert concretion zone containing *Spirifer centronatus* Winchell, *Cranæna subelliptica* var. *hardingensis* Girty, and *Spiriferina solidirostris* White, a fauna which is considered Mississippian and is found on the east side of the Front Range at Canyon City and elsewhere. The first-named species and others of like age were long ago reported from that region, but the record had little value because the position in the formation was not given. We traced the chert zone for 8 or 9 miles southward, finding it

everywhere within a few feet of the contact of the conglomerate with the granite and uniformly containing fossils, but found none farther south. The coarse sandstone and conglomerate series in which this fossiliferous zone occurs appears to be stratigraphically continuous with the Fountain formation in the Boulder district as defined by Dr. Fenneman,^a who correlates it with the Fountain of the Colorado Springs region. We have traced the formation in the field the entire distance from the Wyoming line to Boulder and find no reason to doubt that the horizon containing the chert fossils is the equivalent of the base of the Fountain as represented at Boulder, or possibly even much higher than the base as it occurs immediately north of Boulder, where the formation is much thicker than near the Wyoming line.

In limestones at a much higher horizon we found a Pennsylvanian fauna (tentatively considered older than Knight's so-called "Permian" of Wyoming), consisting of *Productus cora* D'Orb., *P. nebrascensis* Owen, *Spirifer rockymontana* Marcou, *Squamularia perplexa* McCh., *Derbya* n. sp.?, *Phillipsia* aff. *major* Shumard, *Myalina swallowi* McC., abundant crinoid stems and others. These limestones were said by Darton^b to pass into the Fountain conglomerates in traveling southward. Of this we are by no means certain without further investigation, but they seem certainly to belong at the very top of the Fountain or base of the overlying Lyons formation of Fenneman's bulletin. These limestones nearly disappear at the Cache la Poudre, and a little work just north of that stream is necessary to determine their exact position. We have traced the contact of the Fountain and Lyons all the way from the northern line of the State to Boulder except 2 or 3 miles between the Cache la Poudre and Owl Canyon, and believe the Tensleep sandstone of Darton's paper to be the stratigraphic equivalent of Fenneman's Lyons.

It seems very clear that all of the Fountain sandstones and conglomerates of northern Colorado are Carboniferous, the base being probably Mississippian (certainly so in the northern portion of the field) and the upper portion possibly as late as Pennsylvanian. It also seems likely that the Lyons is Pennsylvanian.

The fossils were, through the kindness of Dr. T. W. Stanton, of the United States Geological Survey, submitted to Dr. G. H. Girty, whose determinations are followed in this paper.

Girty^c states that he believes the fossiliferous cherts which occur in the Fountain formation to be derived from Mississippian limestone, and he does not think they determine the age of the Fountain. David White^c states that the fossil plants found in the Fountain formation are of Pottsville age.

The San Juan Mountain district of southwestern Colorado has become through the studies of Cross, Spencer, Howe, and others, a standard of reference for the geologic section of that central region of the Rocky Mountains where the Carboniferous is characterized by several very distinct formations and unconformities. The base of the section, the Ouray limestone, has already been described (pp. 367-368). The lower part contains a Devonian fauna, but an upper fossiliferous horizon is of Mississippian age. Cross¹⁹⁴ states:

The erosion in the interval following Mississippian sedimentation removed those strata completely over large areas. As neither the upper Devonian nor the basal Carboniferous horizon is everywhere fossiliferous, it is impossible to decide in many places whether the upper portion of the Ouray limestone ledge is Carboniferous or not.

From the great quantity of Carboniferous chert nodules in the succeeding formation it must be assumed that above the known horizons of the Ouray there once existed in this region a considerable thickness of chert-bearing limestone of Mississippian age. It seems not unlikely

^a Fenneman, N. M., Geology of the Boulder district, Colorado: Bull. U. S. Geol. Survey No. 265, 1905.

^c Notes on the manuscript of this paper.

that somewhere on the slopes of the San Juan Mountains notable remnants of these beds may be found.

From a comprehensive study by G. H. Girty of all Carboniferous invertebrate fossils thus far collected in Colorado, and available to him, the following brief summary concerning the Mississippian of the San Juan region may be made. Thirty-two determinable species have thus far been obtained from the chert pebbles of the Molas formation, which were derived from the eroded beds, and from two localities in the upper zone of the Ouray limestone. This fauna is closely similar to that of the Wasatch limestone of Utah and the Madison limestone of the Yellowstone National Park. It is also similar to the small faunas obtained in Colorado from the Leadville limestone in the Mosquito Range, at Aspen, Crested Butte, and near Salida, and that from the Millsap limestone of the Front Range near Canyon and in Garden and Perry parks. Dr. Girty concludes that the Leadville limestone, which was originally assigned to the Mississippian because of fossils found in its upper part, and the Ouray limestone, which has been considered Devonian on account of the fauna in its lower and middle portions, are equivalent. He thinks that careful search would in many cases show both faunas where only one is now known.

The Pennsylvanian of the San Juan district comprises, from the base up, the Molas, Hermosa, and Rico formations. These are succeeded by the Cutler (Permian?) formation. The sequence is summarized as follows from the Needle Mountains folio, ^{194a} where full descriptions may be found:

Generalized section for the Needle Mountains quadrangle.

Sys-tem.	Se-ries.	Formation.	Thick-ness (feet).	Character and distribution.
Carboniferous.	Permian(?)	Cutler formation.	300±	Complex of bright-red sandstone, lighter-red or pinkish grits, and conglomerate, alternating with sandy shale and earthy or sandy limestone of varying shades of red. Limestone conglomerate fossiliferous.
	Pennsylvanian.	Rico formation.	100±	Dark reddish-brown sandstone and pink grits, with intercalated greenish or reddish shale and sandy fossiliferous limestone.
		Hermosa formation.	2,000	Series of limestone, grits, sandstones, and shales of variable distribution and development. Limestone in thick, massive beds predominates in the middle and upper parts of the section, the lower portion being mainly sandstone and shale, with a few limestone layers. Numerous invertebrate fossils occur in shales and limestones.
		Molas formation.	75±	Red calcareous shale and sandstone, containing pebbles of Mississippian chert and limestone, and limestone lenses with Pennsylvanian fossils.
	Unconformity			
Mississippian.		Ouray limestone.	100-250	Buff limestone, compact above, thin bedded below with shale and quartzitic partings. Mississippian fossils in upper third, Devonian in lower portion.

In southwestern Colorado and southeastern Utah the Carboniferous formations distinguished in the San Juan district have recently been traced and correlated in part with other occurrences in Utah, Arizona, and New Mexico. Fossils collected by Newberry and Powell near the junction of Grand and Green rivers recently compared by Girty with other collections made by Cross and Spencer at Moab,

on Grand River, though within a few miles of one another, appear to show different relations with western and eastern faunas. Cross^{189d} quotes Girty as follows:

Considering the Powell and Newberry collections together it is notable that they contain a considerable number of species which may be called distinctive western types, as compared with the Pennsylvanian fauna of Colorado and of the Mississippi Valley. * * * In some cases nothing at all closely related to the types indicated is known from the region to the east. In other instances there are more or less similar species known which are not yet regarded as identical with western forms, although they may prove to be so.

The collections from Moab consist entirely of typical Pennsylvanian species, lacking the forms specified as characteristic of the far western areas. The distinctly Pennsylvanian forms found at the junction of the Green and Grand occur, however, at Moab. The Sinbad Valley fauna is very closely related to that from Moab.

In view of the fact that none of these collections can be considered as exhaustive for the localities, numerical comparisons are more or less untrustworthy; yet the table brings out certain contrasts or resemblances which seem worthy of note. Out of 42 species represented in the Powell and Newberry collections but 9 have been found at Moab, or in the Sinbad Valley, while out of 43 species obtained in these latter localities 29 are known from the Pennsylvanian rocks of southwestern or central Colorado.

On the basis of the fossil evidence alone there can be no hesitation in considering the Moab and Sinbad Valley sections as belonging to the Hermosa formation rather than to the Aubrey, as represented in the lower Grand River valley.

J-L 13. WYOMING, NORTHERN COLORADO, AND SOUTH DAKOTA.

The stratigraphy of the Carboniferous sequence in the Bighorn Mountains and other ranges of Wyoming, and in the Black Hills has been summed up by Darton:^{237g}

The Lower Carboniferous rocks are exposed principally in the Black Hills and Bighorn uplifts, and a few small areas occur along the foot of the Front Range, in Colorado. It is probable that these rocks extend widely under the Great Plains, but no borings have gone deep enough to reach them, except in eastern Kansas and southeastern Nebraska.

In the Black Hills the Mississippian is represented by two limestone formations, the Englewood and the Pahasapa, both containing an abundance of characteristic fossils, those of the Englewood being equivalent to the lowest Mississippian (Chouteau or Kinderhook) and the Pahasapa equivalent to the Madison limestone of the northwest. Some *Leperditia* in the concretions in red shale at the base of the Minnelusa are of a type characteristic of the Mississippian, especially at about the horizon of the St. Louis limestone. It is possible that considerable of the lower part of the [overlying] Minnelusa is also of Mississippian age, for it appears to be equivalent to the Hartville limestone. The Littlehorn limestone of the Bighorn uplift consists mainly of a representative of the Madison and Pahasapa limestones, and doubtless the Englewood is also included, but the upper limit of rocks of Mississippian age in both uplifts has not yet been ascertained.

Further details concerning the Black Hills are given in another paper by Darton^{232b} as follows:

[The Englewood limestone] appears to extend continuously around the Black Hills, everywhere immediately underlying the Pahasapa limestone. It averages 20 to 30 feet in thickness and presents frequent outcrops in the lower slopes of the limestone escarpment and in numerous canyons. It merges rapidly into the overlying [Pahasapa] limestone, occasionally with a few feet of impure buff limestone intervening. It is usually sharply separated from the [underlying] Deadwood formation, but only by a sudden change in the nature of the materials. The Englewood limestone is usually fossiliferous, containing numerous corals and occasional shells. The

following forms have been reported: *Fenestella*, *Orthothetes* [Schuchertella], *Leptæna*, *Spirifer*, *Chonetes logani*, *Reticularia peculiaris*, *Syringothyris carteri*, and crinoids. It is correlated with the Chouteau or Kinderhook of the Mississippi Valley.

The Pahasapa limestone (Mississippian), directly overlies the Englewood limestone (also Mississippian), into which it merges. It is a massive gray limestone without noteworthy subdivisions, varies in thickness from 225 to 500 feet, and according to Darton contains *Spirifer rockymontanus*, *Seminula dawsoni* (*Athyris subtilita*), *Productus* and *Zaphrentis*.

Darton ^{237b} describes the Minnelusa sandstone as follows:

The Minnelusa formation consists mainly of thick beds of gray, buff, and reddish sandstones, usually fine grained, most of which, in their unweathered condition, contain a considerable proportion of carbonate of lime. Thin sheets of limestone occur in some districts and, less frequently, sandy shales of red or gray color. Some layers are cherty. * * * [The formation] is thickest on the western side [of the Black Hills], where it is fully 750 feet, and it thins gradually to the south and east, being about 400 feet thick in the southeastern portion of the uplift.

On the evidence of "indistinct casts" of *Productus semireticulatus* and *Seminula dawsonii* (*Athyris subtilita*), "recognized with a fair degree of certainty," the upper part of the Minnelusa sandstone is assigned to the Pennsylvanian. The lower part, if correctly correlated with the lower part of the Hartville formation, ^{237f} is Mississippian.

The Minnelusa sandstone is succeeded by the Opeche formation (Permian). (See pp. 495-496.)

The relations of the Carboniferous of the Black Hills to that of the Laramie and Hartville ranges of Wyoming are thus discussed by Darton: ^{237h}

Along the Laramie Range the apparent absence of Lower Carboniferous is an interesting feature, indicating either nondeposition or removal by the very profound later [middle] Carboniferous erosion. A short distance eastward, in the Hartville uplift, there are comprised in the Mississippian the Guernsey formation, 150 feet or more in thickness, and the lower members of the Hartville formation, the two formations being separated by strongly marked erosional unconformity. The basal sediments of the Hartville formation are red sands, and there is strong suggestion that these are of the same age as the red shale at the base of the Minnelusa formation of the Black Hills and base of the Amsden formation in the Bighorns. The representative of the Lower Carboniferous in Colorado appears in the small areas at Perry Park, about Manitou, about Canyon City, and southwest of Pueblo, and is known as the Millsap limestone. This limestone lies unconformably on the Cambrian, Ordovician, and pre-Cambrian and is unconformably overlain by the Fountain [Pottsville age] or lower Wyoming formation, which overlaps directly on the granites in most portions of the area. Its fauna is regarded as moderately early Mississippian.

K 10. KLAMATH MOUNTAINS, CALIFORNIA.

The Klamath Mountain section includes, according to Diller, ^{276e, 279} several Carboniferous terranes—Bragdon formation, basal Mississippian of the region; Baird formation (Mississippian); McCloud limestone and Nosoni formation (includes the "McCloud shales"), Pennsylvanian; and limestones of the Hall City locality, which are Permian.

Of the section on McCloud River, in the northeastern belt of the Klamath Mountains, the original description by J. Perrin Smith⁷⁶² is given below:

Columnar section of the metamorphic series of Shasta County.

Cretaceous.				Shasta-Chico formation.	
Jura.		Bend formation.		Mormon sandstone of Big Bend. Shales and shaly limestones of Big Canyon.	Thickness ?
Trias.	Upper Trias.	Cedar formation.	Hosselkus limestone.	Spiriferina beds, 50 feet siliceous limestone. Atractites beds, 100 feet siliceous limestone. Trachyceras beds, 50 feet soft limestone.	400 feet.
			Swearinger slates.	Halobia slates, 100 feet calcareous slates. Monotis shales, 100 feet argillites and tuffs.	
	Middle Trias.	Pitt formation.	Pitt shales.	Siliceous and calcareous shales and conglomerates, at Silverthorn's ferry and on Squaw Creek, with <i>Trachyceras whitneyi</i> , etc., about 1,500 feet below the Hosselkus limestone. Several hundred feet of shales and conglomerates without fossils.	2,000 feet.
Carboniferous.	Upper Carboniferous.	Pitt formation.	McCloud shales.	Siliceous and calcareous shales and conglomerates, with Upper Carboniferous fauna at the base. Occurs on the McCloud River, about 20 miles north of the United States fisheries.	1,000 feet.
			McCloud formation.	McCloud limestone.	Massive limestones and marbles of the McCloud River; rich in corals and brachiopods.
	Lower Carboniferous.			Baird shales.	Siliceous black shales of the United States fisheries at Baird; very fossiliferous in places.
Devonian.		Sacramento formation.	Kennett limestones and shales.	Limestones and shales near Kennett, on Sacramento River, with Devonian corals.	Thickness ?

The McCloud formation is especially well developed in the region of the McCloud River in Shasta County, and from this it receives its name. The formation consists entirely of Carboniferous strata, the Baird siliceous shales, overlain by the heavily bedded McCloud limestone, with some beds of igneous rock. The thickness is estimated at about 2,500 feet, but this may be far from the true thickness.

* * * * *

The Baird shales consist of about 500 feet of black metamorphic siliceous shales, in places calcareous and occasionally sandy. At the top, too, are beds of diabase and other eruptives, which, however, do not seem to make up any considerable thickness of the rocks. The Baird shales extend from near the junction of the Pitt and the McCloud rivers northward for about 20 miles along the McCloud, but they were studied by the writer only in the neighborhood of the United States fisheries at Baird.

The strata have a general dip to the east, but this is very inconstant; their strike is approximately north and south. What underlies them could not be made out. They certainly are younger than the Kennett limestones, but what the interval between the two formations and whether they are conformable or not could not be ascertained. They are probably overlain

conformably by the McCloud limestone, but the contact could not be observed, and the diabase which separates the two divisions may mark an unconformity.

* * * * *

The list of fossils from the Baird contains a total of 84 species, of which 19 were not specifically identified. Out of the 65 forms specifically determined 26 occur in the Waverly of the Mississippi Valley, although 8 of these also occur in the Upper Carboniferous of that region. Fifteen are known to occur in the Devonian of the Eastern States, but of these 6 also occur in the Waverly; thus there are only 9 forms that in the Mississippi Valley, or east of it, would be considered as decidedly Devonian. Thirty-six are known from the Waverly and Lower Carboniferous of Utah, Nevada, and New Mexico; of these 29 correspond to forms described by Walcott from the Lower Carboniferous of the Eureka district, Nevada. Three species, *Aviculopecten carboniferus*, *Aviculopecten interlineatus*, and *Macrodon tenuistriatus*, have been considered characteristic of Upper Carboniferous.

With this assemblage of species one would not hesitate to place these strata low down in the Carboniferous, but whether they are equivalent to the Waverly is a question not so easily settled. Although about one-half of the species are found in the Waverly and nearly one-fourth in the Devonian of the Mississippi Valley, 29 of these and a large number of others as yet unknown in California, were found in the Eureka district, Nevada, in strata of Lower Carboniferous age but lying 3,000 feet above the Upper Devonian White Pine shale.

We do not know the age of the rocks immediately underlying the Baird shales, but the siliceous shales of the Sacramento River lie some distance below them and are probably in part of Carboniferous age. It thus becomes probable that in California, as in Nevada, the Waverly fauna, with a few Devonian forms, lived on after the corresponding faunas had become extinct in the eastern region. A migration of these survivors into the Lower Carboniferous sea of the Mississippi Valley may explain the supposed colony mentioned by C. R. Keyes from the Burlington of Missouri, and observed in Arkansas by the Geological Survey of Arkansas. In both places, in the midst of the undoubted Lower Carboniferous faunas, there appears a group of fossils that if found alone would be classed as of Waverly age. They are not colonies in the sense in which Barrande used that word but are simply migrations from one faunal region into another, due to shifting of physical barriers; these migrations have taken place during all time and have complicated correlations, until we lose faith not only in the idea of synchronism as proved by fossils, but also in homotaxis, unless we can find the direction of the migration.

In the paleontological sense the Baird shales are homotaxial with the Waverly, while stratigraphically they probably are not but would agree more nearly in position with the higher divisions of the Lower Carboniferous of the Mississippi Valley.

The occurrence of *Productus giganteus* Martin in these strata is very interesting. This is a common Lower Carboniferous fossil in Europe, but in America is not found east of this place, unless *P. latissimus* Sowerby, which F. B. Meek has cited from Montana, on the western slope of the Rocky Mountains, is an equivalent of it. This fact has been used by the writer as evidence that the European Carboniferous species found in America migrated through the ocean that connected on the west the American with the European Carboniferous waters.

Immediately above the Baird shales, and probably conformably with them, lies the McCloud limestone. This series is about 2,000 feet in thickness, uniform in bedding, and very siliceous in places. Some few beds are altered to a crystalline marble, but in the main the series is made up of a fine-grained hard gray limestone, which at the base contains few fossils besides corals, *Clisiophyllum gabbi* Meek, and *Lithostrotion californiense* Meek. But toward the top the beds become more fossiliferous and contain a varied assemblage of species, which, however, do not rival in number those of the Baird shales.

* * * * *

Taken by itself the fauna [of the "McCloud formation"] would not be characteristic of Upper Carboniferous, and indeed it is arbitrary to draw the line at the base of the limestone. Even *Fusulina cylindrica*, which in the region east of the Rocky Mountains seems to be characteristic of Upper Carboniferous, in Nevada is found also in Lower Carboniferous. But the

most decisive proof of the Upper Carboniferous age of these strata is their position so far above the Baird shales, which have been shown in this paper to be equivalent to the Lower Carboniferous of the Eureka district, Nevada, which is known to occur 3,000 feet above the base of the formation.

The McCloud limestone is probably equivalent to the limestone of the Caribou formation of Plumas County. But J. S. Diller thinks that they belong to a lower horizon than that assigned them by the writer. The Robinson beds of the Taylorville section are probably higher up in the section, but nevertheless the McCloud limestone is, in part at least, equivalent to the Coal Measures.

Collections obtained by Diller were subsequently studied by Girty, who finds "little of material importance" to add to the lists made by J. Perrin Smith. "It may be remarked, however," says Girty,^{276f} "that recent collections made in the Carboniferous of Alaska are so suggestive of the fauna of the McCloud shale by way of containing the same or similar species as to indicate the extension of this fauna and, possibly, of the earlier Carboniferous faunas of the California province to that region."

A later article by Diller²⁷⁸ gives detailed descriptions of the Bragdon formation and cites paleontologic evidence of its early Carboniferous age, controverting Hershey's conclusion that it was Jurassic.

The latest description, comprising a summary of all the facts relating to the Carboniferous of the Klamath Mountains, is given by Diller²⁷⁹ in the Redding folio.

(See J 11 (Eureka district), pp. 364-366, and K 12 (Wasatch section), below.)

K 12. WASATCH AND UINTA RANGES.

The stratigraphic relations of the Carboniferous of the Weber Canyon section, Utah, are thus described by King:⁵⁰⁵

Directly and conformably overlying the Ogden quartzite comes the great Wahsatch limestone, which shows continuous outcrops for several miles and is thoroughly exposed from summit to base, making a total single series of limestone of 6,500 to 7,000 feet. The most valuable part of the whole Weber section begins with the bottom of this limestone, which rests on a few thin sheets of olive-colored argillites separating it from the Ogden quartzite below. There seems to be no intercalation whatever of limy material at this point. The quartzite comes up sharply to the argillites, which are here not over 10 or 15 feet thick and give way immediately to impure earthy limestones of a very dark color. Thus far, on this section, the lower 1,200 feet of the Wahsatch have not yielded any fossils, but at the height of from 1,200 to 1,400 feet from the bottom of the limestone, in the neighborhood of Weber station, the hills directly north of the depot are rich in Coal Measure forms.

* * * * *

At Weber station the beds, which are about 1,300 feet stratigraphically above the base of the limestone, * * * are usually of quite pure limestone, and the strata vary in width from extremely thin sheets to heavy tables. So, too, they vary in their lithological condition, some being highly crystalline, others merely granular, and some even very roughly granular.

* * * * *

Passing up the canyon, the series of limestones continues consecutively, without interruption, for 5 or 6 miles, exposing 5,000 to 6,000 feet in thickness above the depot.

* * * * *

About 300 feet from the summit of the series are some extremely dark beds, which emit a fetid odor upon being struck with a hammer and are intercalated with very impure arenaceous limestones. * * *

The limestones at 1,000 feet from the top inclose a series of thinly bedded but heavily blocked quartzites, which contain two or three sheets of small pebbles. These, however, are very thin and localized. The quartzite is more properly indurated sandstone and occupies a belt 150 feet thick. In general, the upper 1,000 or 1,500 feet of this limestone series are made up of thinly bedded rocks, less pure than the strata below and more or less intercalated with siliceous zones. Some of the beds are also considerably argillaceous.

* * * * *

The closing members of the Wahsatch group are arenaceous limestone with a brilliant brick color.

The passage from the Wahsatch limestone into the Weber quartzite is made in perfect conformity and, as the beds clearly evidence, with undisturbed consecutive deposition. Above the reddened and arenaceous summit of the Wahsatch limestone are a few intercalations of siliceous limestone. * * * In this lower zone are sheets of conglomerate, the pebbles of which are usually small and composed of white quartz. The general appearance of the quartzite zone is here that of a coarse, rather gritty sandstone, unevenly compressed into quartzite. The bottom of the series is prevailingly red for about 250 feet and averages coarser than the material above. Over the red is a very finely laminated white and grayish quartzite, quite uniform in texture and with only the most sparing inclosures of pebbles. * * * A mile and a half east from the base of the series there is scarcely any conglomerate at all, and the rock is true quartzite of whitish or greenish hue, developing on many of its weathered surfaces a peculiar dark brown stain which looks like the oxidation of manganese. * * * Conformably overlying the quartzite is a very heavy bed of much altered gray limestone from 600 to 700 feet thick. The bedding planes are often entirely obliterated and the material extremely crystalline, showing traces of great interior disturbance. The lower beds show a true conformity with the underlying quartzite. * * * The average colors of these limestones are cream-grays, inclining often to white in the more crystalline portions. * * * Overlying this main body of 700 feet of limestone is a series of yellow shaly limestones 175 feet thick. * * * Overlying these calcareous shales, as heretofore quite conformable, is a series of sand and mud rocks, all more or less calcareous, varying in color from chocolate to olive, with red argillaceous sandstones, the whole about 225 feet thick. It has the appearance of a comparatively shallow water deposit, made of argillaceous material, limestone, and sand, the thickness of the individual beds being unusually limited. There are very many beds not over an inch thick. On the upper surface of the strata, at several horizons, ripple marks are preserved with unusual distinctness and on a scale of fineness not often seen, the distance between the wave and the trough being frequently not over an inch or an inch and a half. Alternating dark chocolate and olive-colored shales form the lower 200 feet of this group, while the upper 25 or 30 feet are pretty solid sandstone. Over these, still conformable, are 100 feet of yellow and olive calcareous shales, which are so earthy as usually to decompose, yielding a bad outcrop. Above this is a bed of bluish-gray limestone, rather compact, about 150 feet in thickness. Next comes 20 feet of reddish-brown clayey sand, hardly compacted into rock, containing thin stony seams intercalated at intervals in the soft, easily eroded matter. This is immediately followed by 75 feet of a yellowish-gray, brittle, easily decomposed limestone. Next above are 100 feet of light-colored, very thinly bedded limestones, that give way to 100 feet more of dark, siliceous, tough limestone, which breaks under the hammer with great difficulty, yielding an exceedingly rough, ragged fracture.

This section comprises both Mississippian and Pennsylvanian rocks. Weeks,^{873a} describing the Uinta sections, says:

Wherever fossils have been found in the lower and upper members of the Wasatch limestone, they show the former to be of Mississippian age and the latter of Pennsylvanian age. This is also true of the Uinta Range. The precise line of division has not yet been determined. In

the Uinta Range about 600 feet of the 1,070 feet of beds that have been correlated with the Wasatch limestone are certainly of Mississippian age. Powell correlated the beds of the Wasatch limestone with his Grand Canyon section. They correspond in general to the Redwall group

The basal beds of this series are buff, blue, and gray limestones weathering darker in color, and some of them have a decided greenish tinge. They are usually in massive, brecciated beds having a thickness of 150 to 200 feet. Besides the brecciation or fracturing, many small faults occur in them. The succeeding beds, 6 inches to 1 foot thick, are buff-colored crystalline limestones having a total thickness of 300 feet, followed by 25 feet of thinner-bedded dark-blue and purple limestones containing a large amount of dark-colored chert. The fossils found in the above-described beds indicate that they are of Mississippian age.

* * * * * * * *

The Pennsylvanian series comprises the upper part of the Wasatch limestone and the Weber formation. No name is given to the limestones of this series occurring beneath the Weber formation, leaving it for future detailed work to determine the beds which are to be assigned to this formation. In the Wasatch Mountains a similar succession of strata is exposed. In Powell's Grand Canyon section, Lower Aubrey group, and the Yampa sandstone of the Upper Aubrey group correspond to the Pennsylvanian series. The limestones below the Weber formation are to be correlated with the Lower Aubrey limestone and the Weber formation with the Aubrey sandstone of Walcott's section. So far as the faunas are known, they corroborate these correlations.

The strata forming this subdivision are 300 to 500 feet of light-blue and gray limestones containing a considerable amount of light-colored chert, interstratified with fine-grained light-gray sandstones which toward the top contain bands of sandstone weathering brown and resembling in a marked degree the weathered material of the "Uinta" sandstone. These are succeeded by the quartzites of the Weber formation.

The lower part of the Weber formation is a white and gray to greenish quartzite in thin and thick beds, some of which weather brown. In the upper part of the formation are alternating blue and white siliceous limestones and quartzites. The transition to the next series is through blue and reddish limestones and shales. The greatest thickness occurs on the south side of the Weber River, on the north slope of the range. To the east, on this side of the range, the formation is largely covered by Tertiary sediments or glacial débris. On the opposite (south) side of the range the formation is well exposed in all the principal canyons from the Provo River to Green River. This formation, like the "Uinta," is quartzitic in the western and central parts of the range and grades into a rather soft sandstone in the eastern part. No fossils were found in the Weber formation.

The Permo-Carboniferous series of the Uinta Range seems to correspond in position, thickness, and general lithologic characters to the Upper Coal Measure and Permo-Carboniferous formations of the Fortieth Parallel Survey. On similar grounds they may be correlated with the Aubrey limestone [Pennsylvanian] of Walcott's Grand Canyon section. The correlation with Powell's section is less definite. The limestones overlying the Yampa sandstone of the Upper Aubrey group and an undetermined thickness of the shales and soft sandstones of the Shinarump group appear to correspond to the beds under discussion.

The upper beds of the Weber formation are calcareous sandstones and siliceous limestones which weather yellow and grade into thin red shales and red and blue limestones of the upper part of the Permo-Carboniferous series. This series is well exposed on the Duchesne River, Rock Creek, Whiterocks Creek, on the south side of the range, and in the Horseshoe Canyon of Green River, on the north side of the range.

One of the best sections occurs on the east side of the Duchesne River below the mouth of West Fork. There the lower 600 feet of the Permo-Carboniferous are formed of red and purple shales and blue limestones. Above is 1,000 feet of light-gray and white sandstones, with some interbedded limestones in the lower part. In the upper part these sandstones occur in alternating layers of soft and compact beds full of peculiar black points or specks. These are succeeded by 800 to 900 feet of red shales, with a prominent band of light-colored shale at the top.

Girty states that the "Permo-Carboniferous" of the foregoing section is equivalent to Walcott's Permian, not to the Aubrey group of the Grand Canyon section.

Blackwelder ^a states that the Weber Canyon section as described by King is subject to corrections brought out by more recent study. Near the base of the section there are faults which complicate the succession. The quartzite, supposed to be the Ogden quartzite of King (Devonian), is in reality the Middle Cambrian (Brigham quartzite) and the olive-colored argillites are Middle Cambrian shale. The nonfossiliferous lower portion of the Carboniferous limestone may well include beds of Devonian age such as have been found on the borders of Cache Valley farther north. The fossils in the "Wasatch limestone" are typical members of the widespread Madison fauna, which is of early Mississippian age. Upon the weathered and slightly irregular surface of the limestone rests the Morgan formation of Weeks, ^{84a} consisting of brick-red shale and sandstone with a few beds of gray limestone and light-colored sandstones which become bright red on exposure. This passes up conformably into the lower, more or less calcareous portion of the Weber quartzite. The quartzite itself has not been remeasured accurately, but the thickness reported by King is believed to be somewhat excessive. The alternating series of dark limestone and shale with local sandstone beds, which rests upon the Weber quartzite, corresponds to Boutwell's Park City formation. It contains the workable phosphate deposits of the region. There is considerable although not conclusive evidence of an important unconformity between the Weber and Park City formations. A section measured in undisturbed strata near the headwaters of Ogden River is given below for comparison with the Weber Canyon section:

Partial columnar section of Carboniferous beds in the northeastern part of Weber County, Utah.

Pennsylvanian:	Feet.
Park City formation (upper portion concealed or removed by erosion):	
Dark shale with beds of limestone and rock phosphate.....	438
Gray limestone with chert nodules and beds of shale.....	301
Creamy-white sandstone with beds of cherty limestone.....	220
Unconformity?	
Mississippian (perhaps including early Pennsylvanian at the top):	
"Wasatch limestone:"	
Gray crystalline limestone and purplish shale containing nodules of bright-green limestone (abundant fossils— <i>Productus</i> , <i>Spirifer</i> , etc.—tentatively referred by G. H. Girty to the <i>Kaskaskia</i> formation of the Mississippi Valley).....	140+
Dark-gray limestone and dolomite with beds of calcareous sandstone. Fossils rare or poorly preserved.....	795
Black phosphatic shale and cherty limestone.....	126
Limestone, black to gray, with chert nodules only near the top. Abundant fossils, especially in the lower layers, the species being typical of the Madison fauna....	1,015
Gray shale and limestone with poorly preserved marine fossils like those just above.	180
Shale, dolomitic limestone, and sandstone; ripple marks and sun cracks and bright ferruginous bands suggest nonmarine origin. No fossils.....	220
Obscure unconformity.	
Hard siliceous limestone and dolomite, largely concealed. No fossils found in these rocks, but the lower layers may be equivalent to the Devonian limestone of the Bear River Mountains.....	1,100+
	4,535+

^a Personal communication.

The section of Pennsylvanian and Permian beds exposed in Big Cottonwood Canyon, southeast of Salt Lake City, is described in detail by Boutwell,⁹³ who gives the following section:

Columnar section of portion of Carboniferous in Big Cottonwood Canyon, Wasatch Range, Utah.

Series.	Formation.	Thickness (feet).	Character.
Permian.	Ankareh shale.	1,500+	Red shales, locally sandy, with interbedded coarse gray sandstones. Carries in lower portion <i>Aviculipecten weberensis</i> , <i>A. curtcardinalis</i> , <i>A. parvulus</i> , <i>Myalina permiana</i> . No economic importance.
	Thaynes limestone.	1,190	Calcareous with sandstones and shales; "Midred" shale separates more calcareous upper from more arenaceous lower portion. Carries large fauna, with many new fossil species, chiefly pelecypods, including <i>Pentacrinus</i> sp., <i>Myalina permiana</i> , <i>M. aviculoides</i> , <i>Aviculipecten curtcardinalis</i> , <i>A. weberensis</i> , <i>A. parvulus</i> , <i>A. occidentalis</i> , <i>Lingulas</i> , <i>Spirifers</i> , <i>Dentalia</i> . Forms country rock for replacement ore bodies and lodes.
	Woodside shale.	1,180	Red shale, thinly bedded, fine grained. Bears ripple marks, mud cracks, and raindrop imprints. No direct economic importance.
Pennsylvanian.	Park City limestone.	590	Calcareous with interbedded quartzite, sandstones and some shale. Carries <i>Lingulidiscina</i> sp., <i>Productus cora</i> , <i>Productus</i> sp., <i>Plagioglypta canna</i> , <i>Euphemus subpapillosus</i> , <i>Bellerophon</i> sp. Forms country rock for principal bonanza replacement ore bodies.
	Weber quartzite.	1,350+	Gray quartzite, massively bedded, homogeneous, dense. Carries, in Weber Canyon, <i>Lingula</i> sp., <i>Productus subhorridus</i> , <i>Schizodus</i> sp., <i>Plagioglypta canna</i> , <i>Euphemus subpapillosus</i> . Forms wall or walls of lead-silver lodes.

L 11. BLUE MOUNTAINS, OREGON.

Lindgren⁵⁴⁰ refers certain clay slates, siliceous argillites, and limestones of the Blue Mountains in Oregon doubtfully to the Carboniferous:

Rocks referred to the Paleozoic system occupy a large area in the lower Burnt River region, about Pleasant Valley, in the southern Elkhorn Range, and on the headwaters of Burnt River and Granite Creek. Smaller isolated areas of clay slate, inclosed in diorites, diabases, and serpentines, also occur near Susanville, in the Quartzburg district, and near Canyon. There is no clue to the age of these, but they are believed to belong to the * * * Paleozoic series. The prevailing rocks through the whole of this large sedimentary area are dark and very fine grained, ranging from cherts to siliceous argillites and ordinary clay slates. A large proportion of the sediments show no distinct stratification in ordinary outcrops, but in thin sections the carbonaceous streaks which indicate the planes of deposition are readily recognized. In many places, however, the rocks are normal clay slates of fairly fissile character.

* * * * *

The only place where fossils were found is near the Bonanza mine, at Winterville, where round crinoid stems occur in a small mass of crystalline limestone. The other limestone lenses in the series, though carefully examined, yielded no fossils. Round crinoid stems are most common in Paleozoic rocks; taken in consideration with the fact that the series as a whole has a distinctly older appearance than the Triassic of Eagle Creek, from which it is also petrographically very different, we may with some confidence refer it to the Paleozoic and possibly

to the Carboniferous. The series is similar to the Delhi division of the Calaveras formation in the Sierra Nevada,^a which is believed to belong to the Carboniferous.

Well-defined Carboniferous fossils have been found by Prof. Condon in the Crooked River drainage, in the extreme western part of the Blue Mountains.

L 12. WESTERN MONTANA.

The general succession of Carboniferous rocks in the Philipsburg quadrangle, Montana, as stated by F. C. Calkins, in an unpublished manuscript, is as follows:

Pennsylvanian, Quadrant formation:	Feet.
Quartzitic member.....	400
Shaly member.....	600-50
Slight unconformity (?)	
Mississippian, Madison limestone:	
Thick-bedded limestone.....	1,000-300
Shaly black limestone.....	300

Madison limestone.—The Madison limestone in all the Montana sections has basal shaly beds overlain by more massive beds. Although in the Little Belt mines Weed has recognized three lithologic subdivisions, only two are recognizable in the Philipsburg quadrangle. The lower consists mainly of flaggy limestones, black on fresh fracture but weathering to a delicate blue-gray or drab tint. In most places two thin beds of coal-black calcareous shale are intercalated with these limestones, one lying near the base and the other a little below the middle of the lower member. The upper member contains abundant chert. Its lower part is mostly dark blue-gray and in beds of moderate thickness. The upper part is of more massive limestones, mostly white to pale gray and nonmagnesian, their smoothly weathered surfaces and translucence being in contrast to the dull and gritty character of the Jefferson limestone.

Dr. Girty characterizes the abundant fossils collected from the Madison limestone in the Philipsburg quadrangle as referable to the lower Mississippian fauna, which is so widely distributed over the West. He has identified the following forms:

Syringopora surcularia.	Rhipidomella michelini?
Syringopora sp.	Chonetes illinoisensis.
Aulopora geometrica.	Productus lævicosta.
Menophyllum ulrichanum.	Camarotoëchia metallica.
Amplexus sp.	Spirifer centronatus.
Echinocrinus sp.	Composita immatura.
Fenestella 2 sp.	Composita sp.
Schuchertella inflata.	Eumetria marcyi.
Rhipidomella pulchella.	

Apparent unconformity between Pennsylvanian and Mississippian.—The difference of age between the faunas from the Madison and Quadrant indicates the lapse of a considerable time interval between them. Physical evidence of unconformity is given by the sharp lithologic distinction between the uppermost beds of Madison limestone and the lowest part of the Quadrant formation. A further indication of an erosion interval between them is the dwindling of the upper Madison west of Foster Creek in the Flint Creek Range, to about half its normal thickness. Angular unconformity has not been proved.

Quadrant formation.—The two members of the Quadrant are lithologically in strong contrast. The lower, generally not well exposed except where indurated by contact metamorphism, consists of maroon shales containing gray concretions and thin-bedded gray, white, and pink magnesian limestones. The thickest limestone layer observed is about 8 feet thick. The best-exposed section is on the east fork of Rock Creek in the Anaconda Range. Here 125 feet of shale and limestone immediately beneath the quartzite are continuously exposed, and the imperfect exposure below indicates a total thickness of about 500 feet. This is near the maximum, however, and at the place above mentioned where the Madison was observed in

^a Colfax folio (No. 66), Geol. Atlas U. S., U. S. Geol. Survey, 1900.

much less than normal thickness, the Quadrant is only about 50 feet thick. The usual thickness is nearer the maximum than the minimum.

Fossils have been collected from the lower member of the Quadrant formation at two localities in the Philipsburg quadrangle. Two miles south of Georgetown Lake the red shales below the quartzite have yielded the following forms, identified by Dr. Girty:

Archæocidaris sp.	Productus cora.
Fenestella sp.	Spirifer rockymontanus.
Rhombopora sp.	Euomphalus catilloides.
Derbya crassa.	

Dr. Girty considers this faunule referable to the Pennsylvanian.

The upper member of the Quadrant, in the Rock Creek section, is a single massive stratum of pure hard quartzite about 300 feet thick. Almost everywhere else in the quadrangle it comprises (1) a basal stratum of pure vitreous quartzite; (2) a medial stratum, generally not well exposed, of calcareous shale, shaly and cherty limestone, and a peculiar cherty quartzite with irregular limestone concretions; (3) an upper quartzite, less pure than the lower. The aggregate thickness of these is about 400 feet on the little hill just west of the Philipsburg high school.

Fossils collected at this place from the medial calcareous bed (2), were reported by Mr. Weed in 1900.^a Girty referred these to the following forms:

Camarotoechia sappho.	Aviculopecten sp.
C. near C. congregata.	Cyathophyllum sp.
Glyptodesma rectum?	

These fossils, in Girty's opinion, had a Devonian aspect.

In 1906 D. F. MacDonald gathered at the same place a small collection, even less satisfactory than Weed's. This was submitted to E. M. Kindle, who, although unaware of Girty's report, likewise hesitatingly referred the horizon to the Devonian.

In the light of later evidence Girty has further discussed this fauna as follows:^b

"The fauna of lot 1 is with little question the same which Mr. Weed obtained from nearly the same locality and which I reported on in 1900.

"Although when I first encountered this fauna I referred it to the Devonian, I now believe that it is probably Pennsylvanian. The two most significant types are the Camarotoechias and the *Glyptodesma rectum?* Large Rhynchonellas are rare in the typical Pennsylvanian, and none are known having the structure of Camarotoechia, as is the case with these. An exception must be made of Rhynchopora, but that genus has also a punctate shell. It was largely on this account, since Camarotoechia appeared to be restricted to the Devonian and Mississippian, that I was previously led to determine the horizon as Devonian. The force of this evidence holds good to-day, more or less. On the other hand, the *Glyptodesma rectum?*, represented only by one external mold, is probably a Myalina related to *M. deltoidea* Gabb. In view of the facts that there has recently come to hand a large species of Camarotoechia (distinct, however, from the Philipsburg forms) from Utah high in the Pennsylvanian and that the stratigraphic position of lot 1 is above that of lot 12, it now seems probable that the age of the former is, as already stated, really Pennsylvanian. In this event the fauna is unusual and interesting."

H. S. Gale^c in 1910 examined beds belonging to the Quadrant formation in the area south of the Philipsburg quadrangle. He considers the lower and purer quartzite of the quartzite member of the Quadrant equivalent to the Weber quartzite of southern Idaho and Utah, and the portion of the formation above this quartzite as equivalent to the Park City formation of the same regions. This correlation is based on lithologic similarity and the presence of phosphate, which was found at the top of the cherty limestone between the two siliceous strata.

L 19-20. NEW BRUNSWICK.

The Carboniferous of New Brunswick comprises Mississippian, Pennsylvanian, and Permian strata. They have been studied in detail and have been the subject of several reports and discussions. Bailey^{45a} has recently summed up the general facts in an article from which the following extract is taken.

In the reports and maps of the Geological Survey it has been usual to regard this system in New Brunswick as embracing three principal members, somewhat strongly contrasted in lithological characters and conditions of origin, viz, the Lower Carboniferous, the Carboniferous proper or Coal Measures, and the newer or Permo-Carboniferous, the first consisting of reddish sediments, with evidences of a generally marine origin; the second mostly gray or purplish, rarely red beds of marsh or fresh-water origin; and the third again showing a predominance of red tints, though without the marine limestones, gypsums, and salines which distinguish the Lower Carboniferous formation. In the "Acadian geology" of Sir William Dawson (1868) the Carboniferous proper was further subdivided into the "Millstone grit series" and the "Middle coal formation;" while with the marine limestones of the Lower Carboniferous division were associated, under the name of Lower Coal Measures (in addition to some beds resembling the Middle Coal Measures) the bituminous deposits known as the Albert shales.

It has already been stated as regards the peculiar shales last mentioned that there is at present a growing tendency to regard them as of Devonian rather than Carboniferous age, being the equivalents of the fish-bearing and fern-bearing rocks of the Baie des Chaleurs, though very unlike them in their physical aspects. It has also been stated that there are serious objections to this view; but as the question is mainly one of the interpretation of fossils and has little or no bearing upon the main subject of this report, that of the true coal-bearing rocks, it need not be further considered here. The doubtful beds in question being thus eliminated, the rocks which lie above them are very easily and clearly divisible into two great groups, viz, the Lower Carboniferous formation and the Carboniferous proper, or Coal Measures, while another, viz, the Upper or Permo-Carboniferous is less certainly distinguishable. The characters of these several subdivisions may be briefly summarized as follows:

Lower Carboniferous.—The lowest beds of this formation, as here limited, are usually coarse conglomerates, their composition and hence their general appearance varying with the nature of the rocks upon which they rest. They are, however, in almost every instance of a reddish color, varying from a clear rich red to a dark brownish red. They are usually also much harder than similar beds higher in the series, and in places are much stained with oxide of manganese. The cement is always to some extent and often very markedly calcareous. At some points, as at Quaco Head, St. John County, similar conglomerates are underlain by beds of limestone, but the principal limestone strata are situated at the summit rather than at the base of the formation. The conglomerates are usually followed by or interstratified with sandstones, also usually of a reddish color and markedly calcareous. Higher still the beds become finer, embracing shaly and marly deposits, upon which in many instances rest beds of gray flaggy, sometimes bituminous limestone and heavy beds of gypsum. Between these higher beds and the basal rocks of the coal formation (Millstone grit) it is common to find extensive sheets of igneous rocks, sometimes in the form of compact diabase, sometimes as a vesicular or amygdaloidal ash rock, and sometimes as claystone or rhyolite; but such plutonic masses are not confined to the summit of the formation, being sometimes, as at Quaco, near its base. Where igneous rocks are associated, as at Quaco and Hampstead, Queens County, with limestones, the latter have been more or less completely converted into marble.

The thickness of the Lower Carboniferous system varies greatly, but, according to measurements made by Dr. R. W. Ells in Albert and Westmorland, it reaches in those counties about 5,000 feet. Its thickness in the central basin is probably much less. [For "Coal Measures," see Chapter X, p. 473; for "Permo-Carboniferous" see Chapter XI, p. 498.]

L 20. NOVA SCOTIA AND ADJACENT PARTS OF NEW BRUNSWICK.

Writing of the eastern counties of New Brunswick, Ells and Bailey³¹⁷ in 1876 distinguished—

1. Metamorphic rocks of pre-Carboniferous age, with intrusive syenite.
2. Lower Carboniferous formation, including the Albert shales.
3. Millstone grit formation, or lower member of the Carboniferous system.

The Lower Carboniferous rocks * * * lie along the northern flank and at the eastern end of a chain of highlands * * * [and] consist largely of slates, usually either chloritic or talcose in character and of various colors; but with which are associated at some points thick beds of grit and conglomerate, also chloritic or talcose, and, less commonly, beds of pink or flesh-red felsite or petrosilex. Their age has not yet been definitely determined, but from observations made upon the more westerly portions of the same belt in St. John and King's counties, they would appear to belong to what, in previous reports, has been described as the Coastal group, which is believed to be of pre-Silurian and possibly Huronian age.

Along the northern border of the metamorphic belt, and immediately adjacent to the Lower Carboniferous tract * * * chloritic slates are associated with large quantities of reddish and gray syenite, which, in addition to occupying considerable areas, may be seen penetrating the slates in numerous veins and irregular masses of greater or less extent. They are * * * the source from which the materials of the Lower Carboniferous conglomerates have been to a great extent derived.

The Lower Carboniferous rocks * * * form the eastward extension of a considerable area. * * * The red sediments of which it is composed are at several points covered unconformably by isolated areas of gray rocks, having usually a much less inclination and belonging to the Millstone grit series, or the basal portion of the coal measures. * * * Being unconformable alike to the older slates upon which they rest, and to the newer gray rocks which succeed them upon the north, these sediments present in their distribution great irregularity, filling on the one hand depressions and indentations in the underlying formation, while on the other they are themselves often wholly or partially concealed by the deposits of the Millstone grit. * * *

The rocks being greatly disturbed, Ells and Bailey give the following section— as probably representing the true succession, while the thicknesses given are in each case the least assignable to the different groups, allowance being made for their apparent increase by faulting. The order is an ascending one.

	Feet.
1. Basal conglomerate, sometimes wanting; when present usually of a dull greenish color, less coarse than the conglomerates which succeed, and made up mostly of slaty fragments. Thickness unknown.	
2. Calcareo-bituminous shales, from gray to dark brown in color, and including the so-called "Albert shales." At the base these beds are unconformably overlain by brownish-red sandy shale.....	850
3. Gray bituminous and micaceous oil-bearing sandstones and coarse conglomerates, in massive beds of very various composition, usually of a reddish tint; less rubbly and more calcareous than those of division 1.....	700
4. Red and gray calcareous, sandy, and argillaceous beds, in frequent alternations, with thin beds of conglomerate and toward the top heavy beds of fine, rubbly brownish-red shales..	450
5. Red and gray conglomerate, gray flaggy limestone, and gypsum.....	1,950

In his report for 1884 (published in 1886) Ells³⁰⁰ repeats the above section without modification and describes many local sections in New Brunswick and Nova Scotia.

Fletcher³³³ reported on the geology of the northern counties of Nova Scotia (Richmond, Inverness, Guysborough, and Antigonish) in 1879–80, giving many

minutely measured sections, which together with those of other systems are in the report for 1886 generalized and accompanied by details of local sections and distribution.³³⁴ The latest general account of the Carboniferous of Pictou and Colchester counties, which appears to hold in its broader features for the region as a whole, is contained in Fletcher's report for 1887-1891,³³⁵ from which the following notes are taken:

Permian:

Upper red sandstone and shale group, with thin bands of limestone.
Middle gray sandstone and shale group, with small coal seams.
New Glasgow conglomerate.

Carboniferous:

Coal measures.
Millstone grit.
Carboniferous limestone.
Carboniferous conglomerate.

Devonian:

Upper red slate and sandstone group. Red rocks of Union, on the Truro & Pictou Railway.[^a]
Middle gray slate and sandstone group. Riversdale [^a] and McKay Head rocks.[^b]

The lowest Carboniferous is described as a coarse basal conglomerate, which contains pebbles of the underlying rocks from 1 inch to several inches in diameter and which is interstratified with gray and red sandstone. The identification of this formation in distinction to the middle Carboniferous "Millstone grit" is not always certain. The deposit is not everywhere present, the Carboniferous limestone overlapping upon older rocks in many places.

The Carboniferous limestone is a formation "characterized by the occurrence of gypsum, limestone, sandstones, marls, and other soft and friable rocks, apparently everywhere unconformable upon all underlying formations."^{335d}

With reference to these two formations of the "Lower Carboniferous" and the "Millstone grit" Ami^{18b} says in describing the section of the Knoydart (Devonian) of McArras Brook, Antigonish County:

To the north and west of this Devonian area are seen newer measures referable to three distinct horizons of the Carboniferous system as developed in this portion of Nova Scotia. These include—

(a) The so-called "Carboniferous conglomerate" formation described in the above report.^c This series is presumably equivalent to the Bonaventure formation of Gaspé, and is doubtfully referred to it here.

(b) The "Carboniferous limestone" series with its marls, sandstones, and marine limestones and gypsum, designated (in part at least) by the writer as the Hopewell formation.

(c) The so-called "Millstone grit" series, for the most part very flat-lying and undisturbed, showing that the physical disturbances and agencies to which the Silurian and Devonian strata have been subjected which have dislocated and tilted their strata had disappeared previous to the time when these Carboniferous grits were laid down. The so-called "Millstone grit" series, which is very doubtfully the equivalent of the true "Millstone grit" of England, was designated by the writer as the Westville formation, in order to separate it from the other formations in the district.

In 1899 Ami²¹ presented a discussion of facts and opinions relating to the classification of the Carboniferous of eastern Canada and included as "Eo-Carbon-

^a Middle Carboniferous (Pottsville).—B. W.

^b True "Coal Measures" (Allegheny?), Stellarton formation of Pictou, etc.—B. W.

^c Ann. Rept. Geol. Survey Canada for 1886, pp. 71p, 85p, and 124p; idem for 1890-91, p. 173p.

iferous" the two formations known as the Union and Riversdale, which had been classed as Devonian on stratigraphic grounds. He sums up his conclusion in a table as follows:

Formations of the Carboniferous of a portion of Nova Scotia.

Formations.	Northern areas.	Southern areas.	Order.
Neo-Carboniferous	{ Cape John.....	{ Cape John sandstones.....	XII.
	{ Pictou.....	{ Pictou freestones.....	XI.
	{ Smelt Brook.....	{ Smelt Brook shales.....	X.
	{ Small's Brook.....	{ Spirorbis limestones.....	IX.
	{ New Glasgow.....	{ New Glasgow conglomerates.....	VIII.
		Coal Measures.....	VII.
Meso-Carboniferous	{ Unconformity.		
	{ Millstone grit.....	{ Millstone grit.....	VI.
	{	{ Unconformity (?).....	V.
	{	{ Hopewell and Windsor.....	IV.
	{ Unconformity.....		III.
			II.
Eo-Carboniferous	{ Union.....	{ Union.....	I.
	{ Riversdale.....	{ Riversdale.....	

In placing the Union and Riversdale at the base of the Carboniferous Amherst accepted Fletcher's determination of their stratigraphic position below the lower Carboniferous limestone. Subsequent field study led him to recognize the fact that the limestone is overthrust upon these formations and normally belongs below them. He then accepted the evidence of the fossils, which places them in the "Meso-Carboniferous."²² (See pp. 330-331.)

L-M 11-12. WESTERN MONTANA AND NORTHERN WYOMING.

Near the intersection of the forty-ninth parallel with the one hundred and fifteenth meridian, just west of the Flathead Valley, Montana, Carboniferous limestone of St. Louis age was identified by Weller.^{940b} It rests conformably upon a pure quartzite, 25 feet thick, which lies unconformably, though without marked angular discordance, upon pre-Cambrian argillite of the Belt series. The extension of this formation in the McDonald Range of southern Alberta has been noted by Leach⁵²⁶ under the general term "Devono-Carboniferous."

On the headwaters of Teton River, a branch of the Missouri, in latitude 48°, Carboniferous limestone forms the eastern portion of the Rocky Mountains between the Great Plains (Cretaceous) and the central ranges (Belt series, Algonkian).

In the Belt Mountains and other ranges of southwestern Montana and northern Wyoming the Carboniferous is represented, according to Weed and others, by Madison limestone and Quadrant quartzite. The type locality from which they were described by Peale is in the Gallatin Valley near Three Forks, Mont. Peale^{631a} summarized the section. Girty^{393d} has since discussed the fauna and correlation of the Madison limestone under the heading "Lower Carboniferous," as follows:

The Madison limestone has been divided by the geologists of the Survey, upon lithologic characters, into nine beds, ranging from 24 to 32, both inclusive, of their section scheme. The following table, representing in condensed form the stratigraphic succession ascertained in the

Yellowstone National Park, was kindly supplied by Mr. Arnold Hague, geologist in charge of the Yellowstone National Park survey:

Quadrant quartzite.	
Madison limestone.	Feet.
32. Four strata of light-gray, more or less cherty limestone.....	655
31. Gray banded limestone, with abundant fossils.....	400
30. Massive light-gray limestone.....	65
29. Light-gray and brown, very finely crystalline or granular limestone.....	85
28. Limestone, crystalline, light gray, and generally massive.....	200
27. Limestone, dark gray and buff, very argillaceous, thick and thin bedded.....	50
26. 15 feet of quite pure and 60 feet of thin-bedded argillaceous limestone, both containing fossils.....	75
25. Coarsely crystalline dark-gray limestone.....	80
24. Limestone, finely crystalline and massive below, cherty in its upper portion.....	60
Three Forks limestone.	1,670

All the evidence available seems to indicate that the Madison limestone is faunally a unit and can not be subdivided on the basis of its contained fossils.

Having given a table showing the range of species in the Madison limestone and having discussed certain diagnostic species, Girty^{393a} concludes:

(1) The fauna of the Madison limestone can be referred wholly and without question to Carboniferous time; (2) it has a marked Kinderhook facies; (3) it is essentially the same fauna as that described by White, by Hall and Whitfield, and by Meek, and by them referred to the Kinderhook or Waverly; (4) the fauna is not separable into independent units but must be regarded as a whole.

These views regarding the position of the Madison were reaffirmed by Girty^{363a} in 1905:

The fauna of the Madison limestone, which has so wide a distribution in the West, is * * * closely related to the typical Mississippian faunas. In my earlier work I correlated the Madison limestone with the Kinderhook, Burlington, and Keokuk groups of the Mississippi Valley and have seen no reason since to change my views. Nevertheless, it seems to be almost unquestionable that in some areas these western faunas, in their later developments, take on the aspect characteristic of the St. Louis epoch. Nowhere in the West, however, have any Kaskaskia faunas been discovered. One of three hypotheses seems necessary to explain this fact, which is no less striking, even should local areas of Kaskaskia rocks subsequently be discovered. Either no strata equivalent to the Kaskaskia have ever been deposited in this region; or, though deposited, they have since been removed; or else contemporaneously formed sediments supported a fauna which was so unlike the Kaskaskia that its equivalence has failed of recognition. Of these three hypotheses it is probable that the second is the correct one. Unmistakable evidence of unconformity between the Madison limestone (and its correlates) and the overlying beds has been found in so many points in the West that a period of erosion previous to the Pennsylvanian sediments can be hypothesized for all this western country, a generalization which is all the more safe from the widespread evidence of a similar occurrence in the central and eastern United States, and indeed in other parts of the world.

Girty^a states that we now have reason to believe that the Quadrant, from which no fossils were known when the foregoing was written and which was generally supposed to be equivalent to the Weber quartzite (Pennsylvanian), may be in part of upper Mississippian or Kaskaskian age in some areas.

^a Comment on manuscript.

M 11. FRONT RANGE, ROCKY MOUNTAINS OF ALBERTA.

The Banff series, consisting of upper shale, upper limestone, lower shale, and lower limestone, in the order named, constitutes the Carboniferous and possibly Upper Devonian of the eastern range of the Rockies in Alberta. McConnell^{559b} describes the strata as follows:

The Cretaceous is underlain by the Banff limestone, of Lower Carboniferous or Upper Devonian age, and, notwithstanding the complete absence of all the intervening formations, no unconformity was anywhere detected between them, except where faulting is known to have occurred. The apparent conformity is perfect, even in the clearest sections, and the difficulty in drawing an exact line between the two series is further increased by the close lithological resemblance which the upper part of the Banff limestone bears to the lower beds of the Cretaceous.

The Banff limestone series has a total thickness of about 5,100 feet and is divisible into a lower and upper limestone and into lower and upper shales.

The upper shales vary in thickness from 500 to 1,500 feet but are usually in the neighborhood of 700 feet, and where this is much exceeded, as at the mouth of Johnson Creek, there is reason to suspect that some of the Cretaceous beds are included with them. They exhibit great diversity in structure and pass, according to the amount of arenaceous matter present, from finely fissile shales through flaggy and ordinary sandstone into hard quartzite. The quartzites, where present, occupy the lower part of the division and are overlain by the shales, and the two sets of beds in this position can occasionally be traced from one end of the range to the other. In other cases, however, this regularity is wanting and shales constantly pass into quartzites and vice versa. These shales are often calcareous or dolomitic and in places are represented by an impure limestone, and they always contain sufficient iron to give them a reddish color when weathered. They are found on the western slopes of most of the ranges in the eastern part of the chain and also in the bottoms of most of the longitudinal valleys of the same district, as from their relative softness they are one of the valley-making formations of this part of the range, an office which they fill in common with the Cretaceous shales. The Upper Banff shales are underlain by about 3,000 feet of limestone, which may be called the Upper Banff limestone in order to distinguish it from the lower limestones of the same series. This usually occurs as a grayish, purely calcareous and well-crystallized rock but is also found under a number of other forms. It is often dolomitic, and hard, bluish, compact beds are not uncommon, nor are shales and sandstones altogether absent. Its most characteristic features, however, are the abundance of crinoidal remains which it everywhere shows (some of the beds being wholly composed of the broken stems of crinoids) and the cherty concretions which are distributed through it, either irregularly or arranged in lines along the bedding. These concretions are especially abundant in Pilot Mountain and along the western side of the Sawback Range and in both these places are often united into thin irregular beds. They also become more numerous toward the top of the limestone and are occasionally continued on into the shales.

Below these limestones come from 500 to 700 feet of shales and shaly limestone, constituting the Lower Banff shales. The shales are dark colored but usually weather red and are somewhat arenaceous and pass into flaggy sandstone. They are also nearly always calcareous, and in places the series is represented altogether by impure shaly limestones. At a point about 2 miles up a small creek, which joins the Bow River gap, this group is underlain by from 15 to 20 feet of coal-black fissile shales, which rest directly on the massive limestone beds of the underlying formation and are interesting on account of their fossiliferous character. A number of specimens of a *Clymenia*, besides other fossils, were collected here. At one point these black shales bend around a large and well-rounded limestone boulder, belonging apparently to the Castle Mountain group, and looking exactly like an erratic of the glacial drift.

The lowest division of the Banff limestone consists of from 600 to 800 feet of heavily bedded bluish and fairly compact limestone. In composition it is mostly calcareous, but it also contains a certain amount of dolomitic matter distributed in an irregular manner through the beds and

evidently collected together by concretionary action. The dolomite is not visible on a fresh fracture, but, owing to its superior durability, it projects from weathered surfaces, over which it often forms a rough reticulation. This limestone differs from the Upper Banff limestone in being darker, more compact, and in the smaller number of crinoidal fragments and cherty concretions which it contains, although neither of these are altogether absent. * * *

The fossils of the Banff limestone show both Devonian and Carboniferous forms, and include a Rhynchonella like *rockymontana*, another like *R. metallica*, *Atrypa reticularis*, and a Spirifer like *S. whitneyi*; also a species of Athyris, Productus, Lichas, Eridophyllum, and Diphyphyllum. A large number of other species have been obtained, but these have not yet been studied.

The upper shales of this series have yielded some Aviculipectens and Lingulas.

M 21. NEWFOUNDLAND.

The Carboniferous of Newfoundland occurs in the general basin which contains the lower Carboniferous (Mississippian) and upper Carboniferous (Pennsylvanian) of Nova Scotia and New Brunswick. The former is probably represented by divisions *a*, *b*, and *c* of the classification quoted below, and the Pennsylvanian by divisions *d* and *e*. They can not be separated on the geologic map with the information at hand.

Murray ^{608b} in his report for 1873 gave the following account:

By a glance at the geological map of Canada it will immediately be observed that a vast area of the provinces of New Brunswick and Nova Scotia is spread over by members of this series; and further that the geographical position, where similar measures have been recognized in Newfoundland, is suggestive of the latter being the prolongation of a great elliptical-shaped trough extending from the former, the center of which is concealed beneath the waters of the Gulf of St. Lawrence. It may also be perceived that while in New Brunswick the formation extends in a uniform unbroken sheet over the surface, it becomes broken and patched in Nova Scotia and Cape Breton. The symmetry of the ellipse, moreover, will be seen to be broken near its center at the Magdalen Islands, where a part of the lower members of the system come to the surface, indicating the axis of an anticlinal fold bearing in the direction of St. George's Bay. Proceeding from the westward, this fold would thus appear to be the first of a series of disturbances, which increase in frequency farther east and which are intensely developed in Newfoundland. The contemporaneity of the Carboniferous rocks of the latter with those of the mainland is manifested by the same want of conformity with the older and supporting formations and the almost exact resemblance which obtains in mineral, lithological, and fossil characters throughout the stratigraphical sequence, from the base upward; but the accumulation in the island would appear to be in considerably less volume than on the mainland, and so far as our researches will permit the expression of opinion, it seems that it is in the upper members that the Newfoundland series is principally wanting. The southeastern boundary of the formation may be traced from a little way north of Cape Ray along the northwest flank of the Long Range of Laurentian mountains, up to the extreme head of St. George's Bay, where, although concealed from view, it was supposed to cross over, and making a further stretch beneath the marshes to the northward, finally sweeps round in a westerly course and crosses Harry's Brook below Spruce Brook, where it rests upon strata of Lower Silurian age. Its course westward is then interrupted by the protrusion of the Labradorites of the Indian Head Range; but westward from that range the whole of the flat country is supported by Carboniferous rocks, which rest upon the upturned edges of Lower Silurian strata, displayed in the mountains which bound the plain, and on the coast of Port-a-Port Bay. Irregular patches of the formation are then found farther west in Port-a-Port Bay, and a strip is displayed along the outer coast of the Long Point Peninsula of the same, while to the northward it is recognized in the valley of the Coal River.

For convenience in describing the distribution of the series, I have divided it into five members, distinguished by letters, from *a* to *e*, inclusive, the general vertical section of which is given below, in descending order. Corresponding letters will be found on the map.

	Feet.
(e) Green and red sandstones, with brown and black carbonaceous shale, and brown and drab-colored clays. Fossil trees and flora abundant. Coal seams with underclays holding <i>Stigmaria</i> . [Pennsylvanian, "Coal Measures."—David White].....	1,000
(d) Brown and reddish sandstones and conglomerates; brown, blackish, and greenish micaceous and arenaceous shale. False bedding in sandstones and ripple-marked surfaces frequent. Fossil plants, among which <i>Sigillaria</i> and <i>Calamites</i> are frequently met with. Thin seams and nests of coal. [Pottsville?—David White].....	2,000
(c) Variegated red, green, and drab-colored marls; red, green, and brown sandstones, which are frequently calcareous; beds of bluish and gray limestones, some beds apparently magnesian, and many contain a profusion of organic remains, marine shells, etc., carbonized plants in the arenaceous strata. Salt springs frequent. [Mauch Chunk?—David White].	2,000
(b) Great masses of gypsum, with green and brown argillaceous shale; red marly shale; bands of black or dark-gray limestone, and occasionally jet-black shale. [Pocono?—David White].....	150
(a) Very coarse conglomerate composed of great bowlders and pebbles of Laurentian and Silurian rocks, cemented in a matrix of greenish-colored sand; great lenticular intercalations of sandstone with coarse arenaceous shale; large fragments of magnetic iron ore; passes at the top into a brownish-gray flaggy sandstone with brown and greenish shales which underlie the gypsum.....	1,300

M-P 8-11. ROCKY MOUNTAINS OF BRITISH COLUMBIA.

The Cache Creek group of British Columbia is an ill-defined sequence which comprises Carboniferous limestone and various other sedimentary and volcanic rocks. It has been identified more or less surely from the forty-ninth parallel to Alaska in the belt of metamorphic Paleozoic rocks. A comprehensive description is given by Dawson^{261, 262} in his account of the Kamloops area, in British Columbia, from which the following is condensed:

The Cache Creek formation, as shown on the present map and as now understood, must therefore be regarded as including a very thick series of Paleozoic rocks, of which the greater part is definitely referable to the Carboniferous period by means of its fossils but of which it is scarcely probable that the upper and lower limits agree precisely with those of the typical Carboniferous. It may very possibly be found at the base, particularly, to transgress these limits and to include beds older than those of the system.

In attempting a brief general description of this formation, it must in the first place be observed that the extremely broken and disturbed character of the rocks almost everywhere renders it next to impossible to learn much about their attitude or sequence in any one locality. It is very generally impossible to determine whether the dip of the beds is normal or has been overturned. It is thus only by following the general association of the rocks from place to place and by piecing together facts observed at many different places that it becomes practicable to outline the salient features of the whole.

The western part of the Kamloops sheet, between the Thompson and Bonaparte rivers on one side and the Fraser on the other, is the typical area for the Cache Creek formation, and the most definite feature which can be traced throughout is the belt of massive * * * and whitish limestones, sometimes marbles. * * *

Practically the entire mass of the Marble Mountain Range is composed of these limestones, as well as the whole eastern part of the Pavilion Mountains. They include comparatively insignificant intercalations of argillite, cherty quartzite, and materials of volcanic origin. Farther south, in the region to the east of Hat Creek, such materials become more abundant and form thick beds among the limestones, particularly the cherty quartzites and the greenstones. In this region it is probable that the lower part of the great limestone series is most prominently displayed and that the higher beds are more characteristic in the north, particularly in the Marble and Pavilion mountains. The earlier stages of the great period of limestone deposition appear to have been marked by frequent interruptions, during which argillaceous

and volcanic products were laid down; while in its later stages the deposition of the limestone must have been almost unbroken. The interlocking of the different classes of materials is such, however, as to show the close connection which obtains between the Marble Canyon limestones and the lower parts of the Cache Creek formation. * * *

The extremely unsatisfactory condition of the rocks of the Cache Creek series for all purposes of measurement [is such that] in endeavoring to give some idea of the total volume of the formation, no even approximately correct data can be quoted. The subjoined summarized section is therefore merely an attempt to indicate the general order of succession, and to some extent the importance of the formation, in the western part of the area of the [Kamloops] map. The order is descending.

	Feet.
1. Massive limestones (Marble Canyon limestone), with some minor intercalations of volcanic rocks, argillites, and cherty quartzites. At least 1,000 feet seen in some single exposures. Total thickness probably at least.....	3,000
2. Volcanic materials and limestones, with some argillites, cherty quartzites, etc. Minimum thickness about.....	2,000
3. Cherty quartzites, argillites, volcanic materials, and serpentines, with some limestone. The thickness of these beds, or of a part of them, was roughly estimated in two places as between 4,000 and 5,000 feet. Minimum total thickness say	4,500
	9,500
* * * * *	*

Thus, the entire volume of the rocks of the Cache Creek formation as this is now defined, may be assumed to be about 10,000 feet as a minimum, while I am inclined to believe that it really exceeds 15,000 feet.

* * * * *

A few characteristic fossils have been obtained in a number of places beyond the limits of the present map. At Stuart Lake (latitude 54° 30'), Dease River (latitude 59° 15'), Frances River (latitude 60° 30'), and on Tagish Lake (latitude 60°), fusuline limestones have been observed.

To the westward of the Coast Ranges (in which it is probable that numerous infolds of Paleozoic rocks will yet be found) a formation known from its fossils to be of Carboniferous age is again well represented. This has, so far, not been very minutely examined or reported in detail, but it is known to comprise thick beds of limestones, argillites, and volcanic materials, the latter being even more characteristic and in greater development than in the region here specially dealt with.

In the Rocky Mountains proper, or eastern member of the Cordilleran system, the section which must now be regarded as the typical one for these latitudes is that worked out by Mr. R. G. McConnell. In this section the Carboniferous period is represented by the Banff lime series, which, including two shaly zones, has a thickness of 5,100 feet. This has yielded a number of fossils and these show that the series as a whole represents the lower part of the Carboniferous, passing below into the Devonian-Carboniferous. The later part of the Carboniferous period seems either to be unrepresented, or, if represented at all, to find but a partial equivalent in the upper shales. It is thus very probable that before the close of the Carboniferous the present position of the Rocky Mountains formed part of a land area.

* * * * *

It has already been noted that the lower portions of the Cache Creek formation may be older than the Carboniferous period. The very general blending of the Carboniferous and Devonian systems in the West shows that no well-marked line need be anticipated at the base of the Carboniferous. The separation of any beds of Devonian age can only be made in the event of the future discovery of characteristic fossils. The same may be said respecting the possible existence of Silurian or Cambro-Silurian beds.

Reference is made to the occurrence of limestone of the Cache Creek group on Atlin Lake, British Columbia, where it is present on both sides of Taku Arm,^{389a} in latitude 59° 30'; and 10° farther south dolomites, argillites, serpentine, and

greenstone, probably belonging to the Cache Creek group, have been noted.⁹⁹ In studying the Boundary Creek district, in British Columbia, adjoining the State of Washington, Brock¹⁰⁰ again distinguished the Cache Creek group among the metamorphic rocks of the region. He says:

On Observation Mountain near Grand Forks and on the rounded hill a little south of west of this and some of the hillsides on Newby's ranch are crystalline mica and hornblende schist with a few bands of crystalline limestone. These highly altered rocks resemble lithologically those of the Shuswap series (Archean) but may only be the argillites and limestones found elsewhere, in a more metamorphosed form.

The argillites, in places altered to schists and hornfels, limestone, usually crystalline, often highly so, quartzite, the latter occurring only sparingly, together with serpentine, which occurs in many portions of the districts associated with these, form a group which closely resembles the Cache Creek series described by Dr. Dawson and assigned by him to the Carboniferous. In the Boundary Creek sedimentary rocks no fossils have been found, but they are probably of about the same age as similar rocks occurring to the north and west and may, on this ground, be provisionally classed as Carboniferous.

N-O 8-9. SOUTHEASTERN ALASKA.

At Freshwater Bay, in the northeastern part of Chichagof Island, in latitude 58°, occur limestones about 1,500 feet thick, which carry a lower Carboniferous fauna that is related to the Mississippian of the interior of the continent but is of a different facies. Kindle^{496b} correlates the formation with the lower Carboniferous of the upper Yukon and of the Cape Lisburne section.

An upper Carboniferous fauna characterizes a limestone 600 feet thick which occurs about Pybus Bay, Admiralty Island, in latitude 58°. Kindle gives the following section:

The oldest Carboniferous fauna which has been found in southeastern Alaska was obtained at Freshwater Bay, in the northeastern part of Chichagof Island. This fauna was submitted to Dr. George H. Girty, who states, in a report furnished the writer, that, "while not unlike the American Lower Carboniferous or Mississippian, it resembles and probably should be correlated with the Russian Lower Carboniferous or *Productus giganteus* zone or Mountain limestone." Freshwater Bay is the only locality visited where the Lower Carboniferous fauna has been found in southeastern Alaska. This locality is important also because the stratigraphic relation of the Lower Carboniferous to the older rocks may be observed.

On the northeastern side of the bay, and opposite the Silurian and Devonian limestones already described, the Carboniferous limestones form a low, narrow peninsula. * * * The thickness of the several divisions of the limestones which are exposed along the north shore of this peninsula is indicated approximately in the following section; which begins about one-half mile above (northwest of) North Passage Point:

	Feet.
(e) Breccia of large gray limestone fragments.....	100
(d) Hard gray limestone, much fractured by numerous irregular joints and breaking into small irregular fragments on weathering. Large productoids common. Dip 30° to 90° toward southwest; strike N. 40° W.....	90
(c) Gray limestone with frequent bands of black chert. Fossils scarce. Strike N. 10° to 20° W.; dip 80° to 90° NE.....	275
(b) Dark-gray limestone with black chert bands. Fossils abundant near upper and lower limits. Average strike N. 30° E.; dip 70° to 80° NW.....	250
(a) Limestone similar to b. Corals common.....	275
	990

Exposures on the north side of the bay and just west of the peninsula, which are lower but not continuous with this section, would add, if included in it, several hundred feet to its thickness. The total thickness of the Lower Carboniferous section is probably not less than 1,500 feet.

* * * * *

The Lower Carboniferous in southeast Alaska, while representing a different facies from that of the Mississippi Valley, is still much more closely allied to the interior continental faunas than is the Upper Carboniferous fauna of this region. The Lower Carboniferous fauna is widely distributed in Alaska. It has been recognized as far north as Cape Lisburne, on the Arctic coast, and it occurs at numerous points on the Yukon and Porcupine rivers in eastern Alaska.

Concerning the interval between the Upper and Lower Carboniferous faunas in this region we have but few data. No fauna representing it has been found.

The younger of the two Carboniferous faunas of southeastern Alaska is well represented in the limestones about Pybus Bay, on the southeast side of Admiralty Island, where they outcrop extensively along both arms of the bay. The limestones characterized by this Upper Carboniferous fauna have a thickness of about 600 feet at Pybus Bay. These Upper Carboniferous limestones are generally heavy-bedded or massive. * * * The Lower Carboniferous limestones where observed have thinner bedding and are darker colored than those of the higher horizon.

The following section, taken along the west shore of the east arm of the bay, indicates the character of the Carboniferous limestone (*c* of the section) and the associated beds:

[Mesozoic:]	Feet.
(<i>g</i>) Black to dark-gray argillaceous slates.....	300
(<i>f</i>) Covered interval.....	100
(<i>e</i>) Massive or heavy-bedded gray limestone with conchoidal fracture.....	40
[Carboniferous:]	
(<i>d</i>) Light-gray limestone full of small angular cherty masses.....	80
(<i>c</i>) Light-gray cherty limestone in 10 to 30 inch bands, fossils abundant.....	600
[Age undetermined:]	
(<i>b</i>) Red chert in 6 to 20 inch bands.....	300
(<i>a</i>) Black chert in 4 to 10 inch bands, with rarely a brown or red band.....	550
	1,970

The Mesozoic beds are represented by the two divisions *e* and *g* of the section.

The faunal relations of this limestone are considered by Girty to be rather with the Gschelstufe of Russia, which underlies the Russian Permian, than with that Permian itself. The horizon is, however, the same as that of those formations of Alaska which have been assigned to the Permian. The fauna is unlike any of the faunas of the Mississippi Valley but resembles that of the McCloud limestone of California. (See K 10, p. 376.) Kindle says:

The fauna of the Pybus limestone is the same which has been previously referred to the Permian in Alaska. Dr. George H. Girty, to whom the writer is indebted for the determination of the horizons represented by the Carboniferous collections, states, however, that he finds "that a greater resemblance exists with the Gschelian stage of the Russian section than with the Russian Permian. Provisionally, therefore, I will correlate this horizon with the Gschelstufe, in which occur a great number of equivalent or identical species. This fauna is entirely unlike anything in the Mississippian province of the United States, but some of our western faunas resemble it."

Fossils are usually abundant and well preserved wherever the Upper Carboniferous limestone is found. The character of this fauna is shown by the list of the species collected at Pybus Bay, which has been furnished by Dr. Girty.

* * * * *

In the faunas of the Halleck Harbor section Dr. Girty reports both the upper and lower series of the Gschelstufe or upper Carboniferous faunas to be represented. This section, which is located on the north side of Saginaw Bay, Kuik Island, follows:

	Feet.
(b) Light-gray limestone, locally cherty; fossils abundant.....	450±
(a) Black carbonaceous shales, with interbedded dark calcareous sandstones, arranged in belts, in which shales and sandstones alternately predominate.....	125+

At one point the shales and sandstones of division *a* are seen to pass along the bedding directly into cherts similar to those of Pybus Bay. The fauna of this lower division of the section comprises [many species which have been determined by Girty.]

**P 6-7. NORTHERN BASE OF THE ST. ELIAS RANGE AND WHITE RIVER BASIN, ALASKA
AND YUKON TERRITORY.**

Moffit and Knopf⁶⁰⁰ describe the Carboniferous of the Nabesna-White River region as follows:

Upper Carboniferous deposits are represented in the headwater region of Copper River by the Mankomen formation.^a This formation is a series of sediments, between 6,000 and 7,000 feet thick, composed of sandstones, shales, limestones, and tuffaceous beds with included lava flows and intruded sheets. These beds were originally described as Permian but should be correlated, on both structural and fossil evidence, with the beds along White River and would now be called upper Carboniferous. The Mankomen formation, as described by Mendenhall, "falls naturally into two divisions—an upper, prevailingly calcareous division, which includes somewhat more than half the total thickness, and a lower, prevailingly arenaceous and tuffaceous division, over 2,000 feet thick." Two principal limestones are present in the upper part of the Mankomen formation. The lower, a white massive limestone about 500 feet thick, is separated from the upper, which is about 600 feet thick, by several hundred feet of shale. This upper limestone is made up of thin beds and is highly fossiliferous, much more so than any other parts of the section examined. Fossils were collected at several horizons from the base to the top of the Mankomen section, and the correlation with the White River section is made on their evidence. The Mankomen resembles the Nabesna-White Carboniferous section in the presence of much volcanic material, in which respect both differ from the corresponding Yukon Carboniferous.

A massive limestone, having a maximum thickness of more than 2,000 feet, is found in the Chitina Valley and reaches its greatest development on Chitistone River, which heads near Skolai Pass. This formation is known as the Chitistone limestone and was correlated by Schrader and Spencer in their report in 1901 on the geology of the Chitina Valley^b with the Carboniferous limestone of White River. They found no determinable fossils in the Chitistone limestone, and the correlation was based on stratigraphic evidence and lithologic similarity. After studying the Carboniferous formations of the Upper Copper River valley, Mendenhall^c questioned this correlation, his objections being based on the seeming absence of fossils in the Chitistone limestone, on its conformable relation to the overlying Triassic sediments, and on its freedom from basic intrusives, all of these features being contrary to the character of the Carboniferous sediments of the Mankomen formation. Later work,^d however, proved the Chitistone limestone to be of Triassic age, but it is suggested that the Nikolai greenstone, which conformably underlies the Chitistone limestone in the Chitina Valley, may probably

be the equivalent of some of the upper lava flows referred to the Carboniferous in White River valley. Proof for this correlation is lacking and will remain so until the upper limit of the Carboniferous is determined, but the seeming transition, without interruption, from Carboniferous to Triassic deposits in the Yukon Valley suggests the possibility of such a condition holding at the head of White River and that an unconformity between Carboniferous and Triassic deposition may not occur there. Whether the volcanic beds occurring between the massive limestones of the White and Chitina valleys should be referred to the Carboniferous or Triassic may be difficult if not impossible to determine.

Q 3. SEWARD PENINSULA, ALASKA.

Carboniferous limestone has been recognized in Seward Peninsula at Cape Mountain, near York;^a at Baldy Mountain, in the Kougarok mining district;^b at Cape Deceit, in Kotzebue Sound;^c and at Black Mountain, on the lower part of Fish River^d—in other words, at widely separated localities throughout the peninsula.¹⁶⁶ There is strong reason for believing that in addition to these known mapped localities some of the areas of limestone in the “unclassified Paleozoic” of Seward Peninsula may be of Carboniferous age. In 1909 fossils of either Devonian or Carboniferous age were found by Smith and Eakin⁷⁶⁸ in dark-colored limestones on the eastern flanks of the Darby Range at several places. Other limestones associated with schists having characters similar to those of the known Carboniferous areas apparently occur in many places in northeastern Seward Peninsula. In 1908 a very poorly preserved fossil from the large limestone area west of Casadepaga River suggested possible correlation with the Carboniferous.

From the wide distribution of Carboniferous rocks in the peninsula it is probable that many infolded and infaulted remnants occur in such relations to the other members that the structural relations are obscure and involved. All of the known Carboniferous has been subjected to deformation, and in some places it has been intruded by igneous rocks of the granite family, so that under ordinary circumstances fossils are lacking and the original characters are more or less obliterated by secondary structures.

Q 7. UPPER YUKON AND PORCUPINE RIVERS, ALASKA.

Brooks and Kindle,¹⁰² who examined the Porcupine-Yukon section in 1906, distinguish the following section as Carboniferous:

	Feet.
Limestone (youngest Carboniferous).....	200
Shales, sandstones, and conglomerates, with a basal member of chert conglomerate.....	1,600
Probable unconformity by erosion.	
Thin-bedded limestone and shale, containing Carboniferous fossils.....	1,000
Black shale, classed as upper Devonian but comprising the transition to Carboniferous.....	1,300

The Carboniferous strata are said to embrace about 2,800 feet of sediment, usually not associated with contemporaneous igneous rocks and thus distinguished from the Devonian.

Details of the sections on Porcupine River are given by Kindle,^{497a} who quotes determinations of faunas by Girty and floras by White. They conclude

^a Collections made by A. J. Collier.
^b Collections made by A. J. Collier and E. M. Kindle.
^c Collections made by E. M. Kindle.
^d Collections made by W. C. Mendenhall, F. L. Hess, E. M. Kindle, and P. S. Smith.

that collections obtained from the Porcupine below the Upper Ramparts, including both faunas and floras, indicate an early or basal Mississippian horizon, and Girty regards it as possible that the whole of Mississippian time is represented. In the Upper Ramparts, 40 miles east of the lower stations, is a belt of Carboniferous rocks which Girty regards as upper Carboniferous (Pennsylvanian).

R 3. CAPE LISBURNE AND CAPE THOMPSON, NORTHWESTERN ALASKA.

The Lisburne formation, once considered to be Devonian, has been shown to be Carboniferous by Collier,¹⁶⁵ who collected fossils and measured the following section:

Section of Paleozoic rocks in Cape Lisburne region, Alaska.

Age.	Formation.	Contact relations.	Thickness (feet).	Lithologic character.
Lower Carboniferous, Mississippian.	Lisburne.	Conformity.....	3,000+	Massive limestones, interstratified with white cherts. Extensive coral and bryozoan fauna.
		Conformity.....	1,000+	Thinly bedded shales, slates, cherts, and limestones. Fauna includes brachiopods, trilobites, cephalopods, and lamellibranchs.
		Conformity?	500+	Thinly bedded black shales, slates, and limestones. Several coral beds. Lower Carboniferous flora. Brachiopod and coral fauna.
Devonian (?).			2,000+	Calcareous sandstones and slates. No fossils found.

Probably the oldest formation of the region consists of heavy calcareous sandstones and interbedded calcareous slates, which occur on the west side of the Lisburne Hills, where they form the sea cliffs for about 15 miles north of Marryat Inlet, and are exposed for about 10 miles along Kukpuk River. The heavy sandstones range in thickness from 1 to 10 feet each, while the slaty beds are usually thinner. The massive members often present schistose phases and contain secondary mica. The total thickness has not been determined, though it is certainly not less than 1,000 feet. * * *

The age of the formation is inferred from its relations to the Carboniferous beds which overlie it with apparent conformity, though no direct paleontologic evidence could be obtained. It is certainly older than the Lower Carboniferous and is tentatively placed in the Devonian. * * *

The Carboniferous rocks lie east of the area of sandstones and slates just described and constitute the mass of the Lisburne Hills. * * *

The contact of these rocks with the supposed Devonian sandstones and slates has been observed at three localities. In two of these localities situated north and south the relation seems to be conformable, while in the third, 2 miles farther south of Cape Dyer, the contact is a well-defined thrust fault, with the sandstone overlying.

* * * The general area of undifferentiated Carboniferous * * * includes a diversity of rocks. Along the coast, where the observations were in more detail, three formations are differentiated, as follows: (1) A lower formation, consisting of slates, shales, and limestones, containing several coal beds and yielding Paleozoic fossil plants. (2) Overlying the coal-bearing beds are black cherts, slates, shales, and cherty limestones containing corals and bivalve fossils, the most common being several species of *Aviculopecten*. (3) Above these beds is a great thickness of massive limestones, largely made up of coral interbedded with massive white cherts.

The shaly members of the series are usually intensely crumpled, while the more massive beds present broad, open folds complicated by frequent thrust faults, which make the stratigraphy difficult to decipher.

The coal-bearing formation, which is the lowest, * * * is distinguished from the overlying formation by the presence of coal beds and of fossil plants in some of the black shales and clays. It is, therefore, essentially a fresh-water deposit. In one instance marine invertebrates have been found in such position as to suggest a possible interbedding of marine sediments with the fresh-water deposits, but as this relation may be due to the infolding of some of the overlying formations it can not be accepted as conclusive evidence. The beds are usually thin and the formation as a whole is softer than the overlying rocks. * * *

The middle formation of the Carboniferous series * * * consists of thinly bedded black slates, shales, cherts, and cherty limestones and is distinguished from the lower formation, which it resembles in general appearance, by the absence of coal beds or fossil flora of any kind, and from the upper formation of the series, first by its lithologic character and second by its fauna, which consists principally of brachiopods and mollusks, while that of the upper consists principally of corals. * * *

The upper member of this series [Lisburne formation] consists of massive thick-bedded limestones, massive white cherts, and occasional thinner beds of black slate or shale and is distinguished from the underlying Carboniferous formations by its lithologic character and its fauna, which consists mainly of corals. The contact relation of the upper to the middle formation of the series is conformable in an exposure south of Cape Lewis, * * * but in most of the other places where the contact is exposed faulting has occurred. The thickness exposed at Cape Lewis and also south at Cape Lisburne can not be regarded as less than 2,000 feet and may be much greater.

Girty^a states regarding the age of the Lisburne formation:

The Pennsylvanian probably occurs there, but the greater part of the beds appear to be Mississippian. The Lisburne formation is in the main to be correlated, with little doubt, with the Mountain limestone of Europe and the upper Mississippian of the middle United States. There appears to be an older series, however, which correlates with the lower Mississippian. We have from it a few invertebrates suggesting this conclusion, among them *Leptæna rhomboidalis*, which is not known above the Burlington limestone, of the Mississippian.

The section exposed along the coast south of Cape Thompson was examined by Kindle,⁵⁰⁰ who says:

The lowest beds exposed at Cape Thompson outcrop along the beach immediately north of the cliffs. The rocks exposed in these beach outcrops and the accessible or northern portions of the cape cliffs are indicated by the following section:

Section at Cape Thompson.

	Feet.
(d) Light-buff or cream-colored limestone with numerous fossils. Strike about north-south, dip variable, mostly E. 25° to 90°, complicated toward the south.....	500+
(c) Black and buff thin-bedded limestone, the former predominating. Productus and large crinoid stems abundant.....	330
(b) Bluish-gray to black fissile shale with abundant plant fragments. Dip E. 80° to 90°, strike N. 15° W.....	280
(a) Very thin bedded lead-gray sandstone, with occasional bands of brown ferruginous chert and films of coal. Plant fragments abundant. Strike N. 15° W., dip E. 86° to 90°....	140

The lower 400 feet of the section appears to contain no invertebrate fossils. All or nearly all of these beds represent nonmarine sediments. Plant remains in various stages of maceration occur through most of the shales and sandstones below the limestone. Plant fossils were obtained from both *a* and *b* of the section and numbered respectively lots 5289 and 5290. These were submitted to Dr. David White, whose report follows.

^a Letter of June 20, 1909, from the field.

"Lot 5289. This lot consists of three fragments of coarse gray sandstone bearing carbonized impressions of pieces of partially decorticated stems. The characters of the very imperfect impressions point toward a close affinity with *Lepidodendron corrugatum*.

"Lot 5290. This lot includes two small packages of wavy, black carbonaceous shale splitting in thin laminæ. This shale contains many fragments of leaves of *Lepidodendron*, and unidentifiable, decorticated stem fragments of several kinds, together with several imperfect remains in a better state of preservation. The latter represent *Sphenopteris frigida* Heer, twigs of *Lepidodendron veltheimianum* as generally identified in the European and Arctic floras, with a cone fragment possibly belonging to the same species, and portions of a *Lepidophyllum* very close to *Lepidophyllum fuisseense* Vaff. There are also present several fragments of a cyclopterid type; these are so incomplete that it is not really possible to decide whether they represent (a) rachial pinnules of *Neuropteris*; (b) some large, broad pinnuled *Aneimites*; or, (c) pinnules of *Cardiopteris*. I am inclined to refer them to the latter genus.

"The plant remains from Cape Thompson are so fragmentary and meager as to determinable species as not to permit a close determination of the age of the beds. They appear to be Mississippian and probably represent a stage in the lower part of this division. They may even come from the basal member thereof."

These plants evidently belong to the same horizon as that from which Collier obtained Carboniferous plants at Cape Lisburne. Concerning the Cape Lisburne plants, Dr. White's report^a contains the following statement relative to their age:

"These fossil plants are evidently of Carboniferous age. Owing to the marked scarcity of flicate elements the testimony of the collection is less direct as to precise age than might otherwise be the case. However, from the evidence in hand I am forced to conclude that the plant-bearing terrane is Mississippian, and it appears probable that it is referable to the lower portion of the Mississippian. The flora * * * is very closely related to that from Bell Sound and Klass-Billen Bay in Spitzbergen. It seems to be slightly younger than the *Ursa* flora."

Above the plant-bearing beds only marine fossils are seen. The limestones which follow the sandstone and shales carry an abundant fauna. Corals are quite abundant in the upper division of the limestone series.

Dr. Girty furnished a list of fossils from these beds, on which Kindle comments as follows:

While some of the collections are much less numerous than others, it is probably safe to refer them to a single fauna, which is without much question of lower Carboniferous or Mississippian age. It is true that some of the forms appear to be allied to species in the Burlington and Keokuk of the Mississippian section, but I believe that the beds furnishing these fossils should correlate only with the upper Mississippian. Indeed, the faunas are especially suggestive of the well-known fauna of Spergen Hill, which is known to have been rather extensively distributed toward the northwest.

I have long been of the opinion that our upper Mississippian correlates in a general way with the Mississippian limestone of Europe and Asia, but the evidence has been more or less indirect and general in character. The present faunas are especially interesting, because they seem to show to some extent a mingling of the two faunas. The Mountain limestone element is represented by the abundance of *Lithostroton*, and other features could probably be pointed out by one familiar with the European faunas. The coral fauna of the Mountain limestone is already known in Alaska, especially at Cape Lisburne, but it has not there, so far as known, the admixture of Mississippian types.

In connection with the interesting resemblance of the Cape Thompson fauna to the Spergen Hill fauna pointed out by Dr. Girty, reference may be made to the minute character of many

^a Collier, A. J., Geology and coal resources of the Cape Lisburne region, Alaska: Bull. U. S. Geol. Survey No. 278, 1906, p. 22.

of the brachiopods. * * * In this feature the fauna strikingly resembles the depauperate Spergen Hill fauna. The presence in the fauna of a small specimen of *Pentremites* or a closely allied genus is also worthy of note in this connection. Although extremely abundant in the Mississippi Valley, this blastoid has been recognized at but two localities in the Rocky Mountains, and in both of these occurrences it is associated with a fauna closely resembling the Spergen Hill fauna.

R 5. ENDICOTT RANGE, ALASKA.

The Fickett "series," a very thick sequence of strata comprising a great variety of sedimentary rocks, was observed by Schrader in traversing the Endicott Range, longitude 150°–155° west. Lower Carboniferous fossils occur in pebbles found in gravels derived from it. Brooks^{101f} summarizes the observations as follows:

During his exploration of the Anaktuvuk, in northern Alaska, Schrader traversed a belt of phyllites, chloritic schists, limestones, slate, sandstone, quartzite, grit, and conglomerates about 50 miles in width. In spite of the heterogeneity of these rocks and the uncertainty of their interrelations, the hasty character of the field observation made it necessary to group them in one formation, the Fickett series. The only fossils encountered were in the stream gravels and were evidently derived from beds in this series, and on this evidence the entire succession was provisionally assigned to the Lower Carboniferous. The Fickett overlies the Skajit (Silurian?) on the south by an unconformable overlap, and on the north it is cut off by a fault from the Lisburne (Carboniferous). Schrader states that the Fickett and Lisburne series bear an unconformable relation.

The Fickett series, which may have a thickness of 8,000 to 10,000 feet, has a basal member made up of shale, slate, and limestone, succeeded by quartzite, grit, and conglomerate, and then by slate and micaceous sandstone. It is in this part of the section that the limestone is supposed to occur which yielded the Carboniferous fossils of the stream gravels. A still higher member includes sandstone, limestone, quartzite, schists, slate, and conglomerate, succeeded by quartz schists and green chloritic schists, the latter often cut by quartz veins. It is not made clear why the most highly altered members should occur at the top of the series, for while it is true that these metamorphosed rocks lie near one of the axes of intense folding, it would be expected that the same metamorphic effect would have been noted at the northern limit of the section, where another locus of extreme deformation was observed.

S-T 10-14, T 15, AND U 17-20. BARING (OR BANKS) LAND, PARRY ISLANDS, ELLESMERE LAND, AND GRINNELL LAND.

Haughton's description of the Arctic Carboniferous is quoted by Low^{550g} as comprising the principal known facts regarding the Parry Islands:

The southern boundary of the Carboniferous sandstones with their included coal seams crosses the southern part of Banks Island in a north-northeast direction, and they consequently cover the northern two-thirds of that island, while the extreme northwest portion of Victoria Island is also occupied by these rocks. The western Parry Islands, on the north side of Melville Sound, are almost wholly formed of these rocks, whose southern boundary strikes northeast across the northern half of Cornwallis Island. They are found again in Grinnell Peninsula, the northwest portion of North Devon, and again on the western side of Ellesmere, in the vicinity of Store Bjornekap, being probably largely developed in the northeast part of that great island.

These rocks are described as follows by Prof. Haughton:

"The Upper Silurian limestones, already described, are succeeded by a most remarkable series of close-grained white sandstone, containing numerous beds of highly bituminous coal and but few marine fossils. In fact, the only fossil shell found in these beds, as far as I know, in any part of the Arctic Archipelago, is a species of ribbed *Atrypa*, which I believe to be identical with the *Atrypa fallax* of the Carboniferous slate of Ireland. These sandstone beds are succeeded by a series of blue limestone beds containing an abundance of marine shells, commonly found in

all parts of the world where the Carboniferous deposits are at all developed. The line of junction of these deposits with the Silurian on which they rest is northeast to east-northeast (true). Like the former, they occur in low, flat beds, sometimes rising into cliffs, but never reaching the elevation attained by the Silurian rocks in Lancaster Sound."

In regard to Ellesmere Land, Low ^{550h} quotes Schei ⁷⁰⁶ as follows:

The Carboniferous rocks of western Ellesmere appear to be isolated areas resting upon the underlying Devonian and in turn covered by Mesozoic rocks. Schei describes the area at Store Bjernekap as consisting in its lowest part of beds of brownish-gray hard fossiliferous limestone; higher up, of a white pure limestone, flinty limestone, and pure flint strata, richly fossiliferous, among the fossils being *Lithostrotion* sp., *Fenestella* sp., *Streptorhynchus crenistria*, *Rhynchonella* (*Pugnax*) sp., *Spirifer* cfr. *ovalis*, *cuspidatus*, *mosquensis*, *Productus* cfr. *semireticulatus*, *costatus*, *punctatus*, *cora*, etc.

Lists of the fossils collected by various expeditions up to 1860 are given by Houghton ⁴⁴⁴ and republished in the "Arctic manual," 1875, edited by T. Rupert Jones. ⁴⁷²

The lower division of the Arctic Carboniferous, which consists of sandstones and shales, has furnished a few plants from localities in Melville and Bathurst islands. Heer assigned the formation to the Ursa stage and correlated it with similar deposits in Bear Island and Spitzbergen. David White, however, regards the typical Ursa as Devonian at latest, and reports that the plants from the Arctic Archipelago represent the lower Carboniferous. The formation is probably related to the Mississippian of the section at Cape Lisburne, Alaska.

The upper division of the Carboniferous in the Arctic is the limestone from which the marine invertebrate fossils have been obtained. Girty has examined the literature and has furnished the following statement:

The most extensive fauna reported was obtained at Depot Point in Grinnell Land. In it have been identified *Fusulina hyperborea*, *Stylastræa inconferta*, *Lithostrotion basaltiforme*, *Zaphrentis ovibos*, *Clisiophyllum tumulus*, *Syringopora aulopora*, *Fenestella arctica*, *Productus semireticulatus* var. *frigidus*, and *Spirifer keilhavii*.

This fauna, composed as it is largely of corals, is difficult to correlate satisfactorily. A suggestion is found in the fact that Tschernyschew states that the fossil cited by Houghton under the name *Spirifer keilhavii* undoubtedly belongs to *Spiriferella saranæ*, which is a species of the Gschelian fauna of Russia. Some of the other Arctic brachiopods show similar alliances and this is also conspicuously the case with certain of the Alaskan faunas. It seems highly probable, therefore, that the Gschelian fauna was distributed over this region.

Some of the species cited from Depot Point have been found also at other stations, one or two at a time. In addition the following have been identified apparently from the same limestone in the Parry Islands: *Syringopora geniculata*, *Productus cora*, *Productus sulcatus* var. *borealis*, and *Spirifer arcticus*.

Still another Carboniferous formation with invertebrate fossils is found in Ellesmere Land. In the preliminary notice Schei refers his fauna to the upper Carboniferous and if his identification of *Spirifer mosquensis*, a leading fossil of the upper Carboniferous of Russia, is to be trusted, the horizon is possibly the Mosquensis zone of the Russian section, which comes in at the base of the upper Carboniferous. The position of the Ellesmere occurrence would then be below the horizon of the Carboniferous limestone of the Parry Islands and above the phytiferous beds. Whether the *Spirifer mosquensis* horizon occurs in the Parry Islands can not be determined from the fragmentary paleontologic evidence thus far obtained. There is yet no clear suggestion of two distinct faunas in the species cited from the Parry Islands and from Grinnell Land, nor does the fauna from those areas present any close similarity with that from Ellesmere Land.

CHAPTER IX.

MISSISSIPPIAN.

Color, light French blue.

Symbol, 13.

Distribution: Guatemala; eastern North America from Oklahoma to Nova Scotia; present but included in the "Carboniferous undivided" (14) in the Cordillera, Arctic region, and Newfoundland.

Content: "Lower Carboniferous" limestones and their equivalents where they are separated on the map from Pennsylvanian coal measures. In Guatemala the Santa Rosa formation.

I 16. ALABAMA AND TENNESSEE.

In their southern extension into Tennessee and northern Alabama the Mississippian strata were described by Safford ^{687a} as the "Siliceous group" (regarded by him as equivalent to Burlington, Keokuk, and St. Louis) and the "Mountain limestone" (regarded by him as equivalent to Chester), and these terms were used in Alabama. The latest classification for western Tennessee is that given by Hayes and Ulrich ^{431b} in the Columbia folio, as follows:

Mississippian formations in western Tennessee.

Generalized time scale for central North America.		Mappable lithologic equivalents in the Columbia quadrangle.	Safford and Killebrew (Elements of geology of Tennessee, 1900). Middle Tennessee.	Safford (Geology of Tennessee, 1869). Middle Tennessee.	
Carboniferous (Mississippian).	Chester.	(Not present.)	Mountain limestone.	Mountain limestone.	
	St. Louis.	St. Louis limestone.	St. Louis limestone.	Lithostrotion bed or St. Louis limestone.	
	Keokuk.				Sili- ceous group.
	Burlington.	Tullahoma formation.	Tullahoma formation.	Lower or Protean member.	
	Kinderhook.				

FIGURE 11.—Sketch map showing the distribution of Mississippian rocks that are separately represented on the geologic map of North America and the key to references in the text.

The strata are thus described:

Tullahoma formation.—This formation consists chiefly of siliceous shales and limestones, but the lowest member is a calcareous shale, generally a grayish green or pale blue but occasionally dark, varying from nothing to perhaps 30 feet in thickness. * * * The fossils, though chiefly of undescribed species of Ostracoda, indicate very early Mississippian age. * * *

A strongly siliceous and argillaceous limestone that weathers into a cherty, shale-like material occurs stratigraphically above the calcareous shale but usually constitutes the ordinary base of the formation. Similar strata, in one place more shaly, in another more calcareous, and generally with heavier chert, continue to the top of the formation, which has a maximum thickness of about 250 feet. Usually it is much less, especially in the southeastern quarter of the quadrangle. * * *

Excepting in the basal shales, specifically recognizable fossils are extremely few in this formation. Here and there the heavier chert blocks contain large crinoid stems in abundance, and occasionally a brachiopod cast, indicating the Burlington or Keokuk horizon of Iowa and Illinois.

St. Louis limestone.—This, the latest or youngest formation exposed in the quadrangle, consists in the main of a thick bed of limestone, gray to blue in color, and associated with considerable chert. * * * The fossils are mostly small and consist mainly of Bryozoa and brachiopods more or less characteristic of the "Warsaw horizons" of Illinois, Indiana, and Kentucky, which have been referred to various ages. Above these heavy layers come the more characteristic St. Louis fossils, like *Melonites* and *Lonsdaleia*, or as the latter is generally called, *Lithostrotion canadense*.

In 1894 the Alabama section of the Mississippian was thus classified by Smith⁷⁴⁶:

Mountain limestone:

- (a) Bangor limestone and Hartselle sandstone.
- (b) Oxmoor shale and sandstone.
(Chester.)

Fort Payne:

- (a) Tusculumbia (St. Louis).
- (b) Lauderdale (Keokuk, etc.).

This classification has since been revised and modified. The latest statement is by Butts,^{107b} as follows:

Overlying the Devonian black shale unconformably are rocks of Mississippian or lower Carboniferous age. At the base of the Mississippian rocks, throughout the whole region, is the Fort Payne chert; this is succeeded in Brown and Murphrees valleys by the Bangor limestone, with the included Hartselle sandstone member, and by an overlying shale which is correlated on stratigraphic and lithologic grounds with the Pennington shale to the north. At the southern end and along the east side of Blount Mountain, and along the east side of Shades Valley, the Pennington shale is overlain by shales and sandstones to which the name Parkwood formation is here given. South of Boyles Gap in Opossum Valley and south of Oxmoor in Shades Valley the Bangor limestone runs out and is replaced by black and gray shales similar to the Floyd shale to the northeast. Because of its stratigraphic position and lithologic similarity this shale will be called Floyd shale in this report. South of Boyles Gap and Oxmoor, therefore, the Mississippian rocks above the Fort Payne chert consist of the Floyd shale (including the Hartselle sandstone, which persists after the thinning out of the Bangor limestone and thus locally becomes a member of the Floyd shale) and the Parkwood formation above the Floyd. The Floyd shale is thus the equivalent of the Bangor limestone and the Pennington shale. In reports of the Alabama Geological Survey the Floyd shale and the rocks comprising the Parkwood formation have been treated together as the "Oxmoor or shale and sandstone phase" of the upper part of the lower Carboniferous rocks, and the Bangor limestone has been called the "Bangor or limestone phase" of the same rocks, the two phases being regarded as contemporaneous.

As a result of the writer's study of the geology of the region, however, the conclusion has been reached that only the Floyd shale and the rocks included by the Alabama Survey in the "Bangor or limestone phase" are contemporaneous. The Parkwood formation of Shades Valley and Blount Mountain is absent from the section in Murphrees and Brown valleys, having been eroded west of Birmingham Valley before the deposition of the Pottsville or "Coal Measures," so that they rest unconformably on the Pennington shale.

The variations in the stratigraphy of the Mississippian formations above the Fort Payne chert are shown in the sections below:

Section of Mississippian rocks above the Fort Payne chert in Brown and Murphrees valleys.

Pottsville formation.	Feet.
Pennington shale.....	100
Bangor limestone:	
Limestone.....	350
Shale.....	30
Sandstone (Hartselle member).....	100
Shale.....	50
Limestone.....	160
Fort Payne chert.	790

Section of Mississippian rocks above the Fort Payne chert near Irondale.

Pottsville formation.	Feet.
Parkwood formation, shale and sandstone.....	2,000
Pennington shale, dark, calcareous (?).....	292
Bangor limestone:	
Limestone.....	317
Shale, soft, dark, calcareous (?).....	39
Sandstone (Hartselle member).....	117
Shale, dark, calcareous (?).....	97
Limestone.....	88
Fort Payne chert.	2,950

Still farther south, in the vicinity of Readers Gap, borings show only dark shale, probably calcareous, in the 500 feet immediately over the Fort Payne chert. The well logs are corroborated in the main by all that can be seen of the formation. South of Boyles Gap and Oxmoor good sections and accurate measurements of the rocks under discussion are not obtainable. A compiled section for the region south of Oxmoor, probably a close approximation, is as follows:

Pottsville formation.	Feet.
Parkwood formation, shale and sandstone.....	2,000
Floyd shale:	
Shale, some calcareous, sandstone, and limestone lenses.....	700
Sandstone (Hartselle member).....	100
Shale, dark, calcareous.....	200
Fort Payne chert.	3,000

Sections of rocks below the coal measures.

A. In Murphrees and northern part of Birmingham valleys.

System.	Formation.	Thickness (feet).	General character.
Carboniferous (Mississippian series).	Parkwood formation.	Knife-edge to 2,000.	Prevailingly gray shale and sandstone; no calcareous beds. Fossils very scarce.
	Pennington shale.	60-300	Gray, green, and red shale, with a little chert and some sandstone and conglomerate. Highly fossiliferous.
	Bangor limestone.	700	Prevailingly thick-bedded light-gray crystalline limestone. Hartselle sandstone member and shale in midst. Merges through sparingly cherty limestone into Fort Payne chert below. Highly fossiliferous. (Prevailingly fine-grained firm sandstone, locally coarse and friable.)
	(Hartselle sandstone member).	(100)	
	Fort Payne chert.	200	Mostly thin-bedded chert; locally thick bedded at bottom. Generally fragile. Fossiliferous.
Unconformity			
Devonian.	Chattanooga shale and Frog Mountain sandstone.		Black carbonaceous shale, locally sandstone below, with phosphate nodules and fossils.
	Unconformity.		

B. In southern part of Birmingham and Shades valleys.

[Section below Floyd shale is same as in A.]

Formation.	Thickness (feet).	General character.
Parkwood formation.	1,500-2,000	Same description as in A.
Floyd shale.	1,000	Gray, dark, and black shale, calcareous at horizons. Contains beds of sandstone and lenses of limestone. Highly fossiliferous throughout. Equivalent to the Bangor and Pennington formations. Hartselle sandstone member.
Fort Payne chert.	200±	

Stevenson^{794e} comments on the fact that the formations represented in Alabama are recognizable far to the north and northeast, although they undergo very material lithologic changes, and he thus sums up the relations:

Beginning at the south, on the western outcrop, one finds, ascending, the Tuscumbia, limestone and markedly siliceous; the Hartselle, sandstone with shales and limestones; and the Bangor, limestones more or less argillaceous. These three divisions retain their characteristics across Tennessee into Kentucky, the Bangor meanwhile becoming more argillaceous in northern Tennessee, where its upper portion has been identified with the Pennington shale. In Kentucky the Tuscumbia and Hartselle are taken together as the St. Louis, but they retain the Tennessee features, one of the Hartselle sandstones being persistent. The Bangor becomes very shaly and, like the Tuscumbia, thins out northward more rapidly than the Hartselle, so that the last alone is present in central Ohio, where Prof. Andrews called it the Maxville.

Along the eastern outcrop one finds greater variation, for outlying areas toward the south-east reveal something of the conditions existing along the old shore line. But those areas may be neglected in this connection. Following the border of the principal areas, one finds the Tuscumbia, Hartselle, and Bangor sharply defined in Alabama, with the same features as on the western side. In Tennessee the Tuscumbia is easily recognized in the upper portion of Mr. Hayes's Fort Payne, while at least one of the Hartselle sandstones is persistent in southern Virginia; but the Bangor, the upper portion of Mr. Hayes's Bangor limestone, becomes increasingly argillaceous northward, so that frequent reference is made to its tendency to weather into shale. Toward the Virginia line it becomes almost wholly shale and sandstone, while it increases greatly in thickness, so that Mr. Campbell has separated the Pennington shale from the limestone which he calls Newman. The enormous increase in thickness of the section, due to increase of land detritus, renders exact tracing difficult for a little way in southwest Virginia, the more so since detailed descriptions have not been published. The Bangor evidently becomes wholly shale and sandstone before New and Greenbrier rivers are reached, where Fontaine and Campbell found so great a mass of shales with insignificant streaks of limestone. The persistence of the Hartselle sandstone at the bottom of the shales or near the top of the limestone is shown by many of the oil records and along the outcrops almost into Pennsylvania. The upper limestone of Virginia, Maryland, and Pennsylvania is the Hartselle. The Tuscumbia retains its siliceous character throughout, though losing its chert in Virginia and becoming merely a siliceous limestone; this feature, along with a curiously current-bedded structure and a peculiar whiteness when crushed, characterizes it thence into Pennsylvania, where by several of the geologists it was termed the Siliceous limestone.

The correlation seems to be:

Shenango [shale].—Bangor of McCalley in Alabama; upper portion of Bangor of Hayes in Tennessee; upper portion of Safford's Mountain limestone in Tennessee; Chester of Kentucky geologists (Second Survey); Pennington and top of Newman of Campbell in Tennessee and southwest Virginia; Umbral shales of Fontaine; Canaan shales of Darton; Greenbrier shale of W. B. Rogers; Mauch Chunk shale of Maryland; Mauch Chunk of Pennsylvania in part; absent from most of Ohio; Shenango shale of I. C. White in northeast Ohio and northwest Pennsylvania.

Maxville.—Hartselle of Alabama; greater part of Bangor in Tennessee; lower part of Mountain limestone in Tennessee; greater part of upper Newman and of upper Greenbrier in Virginia; upper Umbral and upper Mauch Chunk limestones in Pennsylvania; Maxville of Ohio; upper St. Louis of Kentucky.

Tuscumbia.—Tuscumbia of McCalley in Alabama; Lithostrotion of Safford in Tennessee; upper part of Fort Payne in Tennessee; lower part of St. Louis in Kentucky; lower Newman and Greenbrier in Virginia; lower [part] of Greenbrier in Maryland; Siliceous limestone of Pennsylvania; absent in Ohio except at Kentucky border.

The term *Shenango* is the earliest applied definitely to the latest division. Though Dr. White's *Shenango* shales have been spoken of as representing the whole of the Mauch Chunk sedimentation, it will be shown in the next chapter that they represent practically only the sedimentation of the closing epoch. The name *Maxville* was given by Prof. Andrews in 1870

and therefore antedates Hartselle by many years. Tuscumbia, being a geographical term, will have to replace the much older Lithostrotion of Prof. Safford.

The fossils from the Shenango appear to be those characteristic of the Chester of the Mississippi basin. Forms belonging to that epoch have been collected in Pennsylvania, Virginia, Kentucky, and elsewhere. Fossils collected by Andrews in 1869 from the Maxville localities in Ohio and by Stevenson in 1870 from the same limestone in West Virginia were submitted to Mr. F. B. Meek, who pronounced them distinctly Chester. Prof. R. P. Whitfield afterward figured and described the Ohio forms, referring them practically to the same horizon. Still later, in 1901, Stevenson collected carefully at a locality in Fayette County of Pennsylvania and submitted the specimens to Mr. Weller, who found that the fauna contains some St. Louis as well as the Chester forms. There is, however, practically no change in the fauna from the bottom to the top of this locality, the same forms, with two or three exceptions, being found throughout. The Chester forms predominate, and of those belonging to the St. Louis some lived on into the Chester at typical localities within the Mississippi basin. The same fauna occurs in Randolph County of east-central West Virginia and in Washington County of Virginia at the Tennessee border. In Tennessee and Alabama the Maxville (Hartselle) is clearly Chester. The Kentucky geologists of the Second Survey make the Maxville the upper part of their St. Louis, but it overlies the Lithostrotion bed, the lower part of their St. Louis. No list is given of the fossils which lead to classification of the limestone as St. Louis.

The Tuscumbia is practically nonfossiliferous at most localities in Pennsylvania. In Tennessee and Alabama, as well as in Kentucky, *Lithostrotion canadensis* is the characteristic fossil, and it is associated with other forms belonging to the St. Louis.

Girty^a comments on the correlation which Stevenson thus suggests as follows:

In the correlations quoted from Stevenson there appears to be an error. Stevenson there places the Shenango above the Maxville and the Tuscumbia, whereas on page 42 he assigns the Shenango to the horizon of the Burlington and Keokuk and correlates it with the Logan which underlies the Maxville in the Ohio section. It seems almost certain that in the former case he is speaking of the Shenango shale of White and in the latter of the underlying Shenango sandstone of the same author. There can hardly be a doubt that the Shenango sandstone is the same in part at least as the "Logan group" of Ohio (now the Blackhand and Logan formations). The correlation of the Shenango sandstone with the Blackhand and of the Logan with the Shenango shale is suggested by the lithologic sequences. Professor Stevenson, however, appears to consider the Shenango shale as occupying a much higher position. He places it equivalent to the upper Mauch Chunk and above rather than below the Maxville. If this is so, there must be an important interval between the Shenango shale and the Shenango sandstone representing the lower and middle Mauch Chunk, so that it would be inadvisable to include the shale and sandstone under the same formation name. If Stevenson is right, the sandstone alone should be called Shenango.

Some doubt also is involved in the use of the name Tuscumbia for the lowest of these three formations, with which he aligns the Fort Payne of Tennessee. I have good faunas of both the Fort Payne of Alabama and the overlying Hartselle of the same area and I also have a collection from the limestone at Tuscumbia, Ala., which is without much question the Tuscumbia limestone. The Tuscumbia fauna is decidedly different from either the Fort Payne or Hartselle faunas and much more closely allied to that of the overlying Bangor.

J-K 15. IOWA, ILLINOIS, MISSOURI, ARKANSAS, AND OKLAHOMA.

The region here comprised is that in which the Mississippian is typically developed as a great limestone, which is divided locally into several formations according to the nature of the strata, and these are grouped according to their fossil contents.

^a Comment on manuscript.

In originally defining the Mississippian Williams⁹³² discussed previous attempts at correlation and proposed the following classification:

Recent studies of the fossils, their original grouping into local faunas, and their association in other parts of the province have led me to recognize three fairly well differentiated faunas in the Mississippian series, the subdivisions of which are believed to be local and therefore very unsatisfactory for purposes of correlation.

The following table sets forth the proposed classification and nomenclature:

	Structure scale.		Time scale.
Mississippian series.	{	Chester stage.....	}..... Genevieve age.
		St. Louis stage....	
		Warsaw stage.....	
	{	Keokuk stage....	}..... Osage age.
		Burlington stage..	
{	Kinderhook stage,	}..... Chouteau age.	
	including.....		
	Chouteau limestone.....		
		Vernicular shale and sandstone..	
		Lithographic limestone.....	

The Chouteau age is the age of the Chouteau group of Broadhead. The Osage age is the age of the fauna of the Burlington and Keokuk formations, which are locally distinguishable but in the sections on the northwestern, western, and southwestern flanks of the Ozark uplift are so blended that it seems impracticable in most cases to differentiate them. The name is suggested by the fact that the Osage River drains the region in which this confusion of the two faunas is clearly exhibited. The Genevieve age is the age of the fauna of the Archimedes group of Shumard.

The name is suggested by the fact that Shumard first called attention to the union of the several formations in which the common fauna prevails in his description of the geology of Ste. Genevieve County, Mo. The name he applied was Archimedes group, but this is not a satisfactory name, and in the county of Ste. Genevieve and on the eastern and northeastern margins of the Ozark uplift, above and below this county, are found the typical outcrops of the individual formations included in the group.

The term Mississippian is now generally used for the lower Carboniferous in North American stratigraphy, but the definition of its limits and the classification of its subdivisions have been subjects of continued research and discussion. Chamberlin and Salisbury¹³⁴ give the following list of divisions in the Mississippian province, together with those of other sections of the eastern interior:

Subdivisions of Mississippian series.

Mississippi River States. ^a	Ohio. ^b	Pennsylvania. ^c	Maryland. ^d	
4. Kaskaskia or Chester.	{	2. Mauch Chunk.	3. Mauch Chunk.	
3. St. Louis.			} 4. Cuyahoga.	2. Greenbrier. ^e
2. Osage or Augusta (including the Burlington, Keokuk and Warsaw).				3. Sunbury.
1. Kinderhook or Chouteau.				2. Berea grit.
				1. Bedford.

^a Williams, Bull. U. S. Geol. Survey, No. 80, p. 169. St. Genevieve was the term applied by Williams to the upper part of the Mississippi system.

^b Prosser, Jour. Geology, vol. 9, p. 215; vol. 11, p. 520. See also Am. Geologist, vol. 34, p. 335.

^c Pennsylvania Repts. and folios of U. S. Geol. Survey.

^d O'Harra, Maryland Geol. Survey, Allegany County, pp. 109-113.

^e The Greenbrier is absent in eastern Pennsylvania. It comes in as a lentil of limestone farther west, and thickens southward, becoming an important formation in Virginia, largely replacing the Mauch Chunk shale. See Brownsville-Connellsville folio, U. S. Geol. Survey (Campbell).

The latest statement on the Mississippian is by Weller,⁸⁸⁶ whose full discussion may be abstracted as follows:

Weller distinguishes (1) a "southern Kinderhook or Chouteau fauna," partly derived from the Devonian (showing relationships to the Hamilton fauna) and partly composed of "a new element from some unknown region." "The return of this fauna into the Mississippi Valley basin marks the opening of the Kinderhook epoch and the Mississippian period." This southern fauna is well developed in southern Indiana and Illinois, in the Rockford limestone of the Indiana State reports.

(2) A northern Kinderhook fauna, differing markedly from the southern, typified by the "Chonopectus" sandstone and developed in Iowa and northern Illinois, north of the "Kankakee peninsula." This northern fauna is related to the Chemung faunas of the eastern upper Devonian. The southern and northern Kinderhook faunas, though apparently contemporaneous within comparatively narrow limits, occupied distinct faunal provinces as regards invertebrate life. A fish, *Ptyctodus calceolus*, was common to both.

During the progress of Kinderhook time the sea was encroaching from both the north and the south, until before the close of the epoch free communication was established between the earlier separated provinces, and the fauna of the southern province became the dominant type throughout the entire Mississippi Valley basin. * * * It is evident that the arrangement of the Kinderhook formations into three successive divisions, the Louisiana, Hannibal, and Chouteau, as has usually been done, does not express the proper relationships of the faunas. The Chouteau fauna, in some of its expressions, is without doubt as old as the Louisiana fauna, and it is as impracticable to make one continuous section to contain all of the Kinderhook formations as it would be to make a standard Devonian section to include the formations of New York and Iowa.

East of the Cincinnati arch the early Mississippian formation (Bedford shale) carries a fauna which resembles that of the southern Kinderhook. The succeeding formations of the Waverly group in Ohio are similarly related, but in the north occur forms (*Paraphorhynchus*) which suggest connection with the northern Kinderhook also.

West of the Cincinnati axis the union of the northern and southern provinces gave rise to an extended sea and conditions favorable to the deposition of limestones (Burlington and Keokuk) forming the Osage group, characterized by its crinoids. Succeeding formations in the Mississippi Valley basin constitute the Warsaw, Salem [Spergen], St. Louis, and Ste. Genevieve limestones. Unconformities follow the Salem [Spergen], and more extensively the Ste. Genevieve, over the northern part of the Mississippi Valley basin. Southern Illinois, where the Ste. Genevieve comprises the Fredonia limestone, Rosiclare sandstone, and Ohara limestone members, was the northern limit of continuous deposition. On the other hand, faunal relations with the faunas of the far West indicate marine connections, of which that established during the Ste. Genevieve was one of the most extensive.

The closing epoch of the Mississippian in the typical province, the Mississippi Valley basin, was that of the Chester group.

Comparing the classification of the formations of the Appalachian Basin (east of the Cincinnati arch)—that is, those of the Waverly group—with the divisions of the typical Mississippian, Weller accepts Stevenson's conclusion^a that only the upper part of the Pocono is of Mississippian age and that this upper part is stratigraphically continuous with the Waverly. "The most definite point of faunal contact between this basin and the Mississippi Valley basin is found in the Maxville limestone, whose fauna is to be correlated essentially with the Ste. Genevieve of southern Illinois and Missouri."

The Iowa section of the Mississippian as compiled by Chamberlin and Salisbury^{134c} from the reports of the Iowa State Survey is as follows:

Mississippian formations in Iowa.

	Formation.	Thickness (feet).	Characteristics.
Mississippian.	Unconformity. St. Louis limestone.	100	Light ash-colored limestones and marls, with thin beds of sandstone. Good building stone.
	Osage (Augusta) formation.	200-300	Buff limestone and shales, underlain by coarse-grained encrinital limestone; basal portion usually ferruginous; prominent chert beds.
	Kinderhook formation.	150-200	Bluish or greenish clay shales, fine grained; buff, compact, more or less argillaceous limestones; sandstones.
Devonian.	Lime Creek formation.	80	Dark-colored argillaceous shales, highly fossiliferous, and locally calcareous.

In northern and central Iowa, owing to the effects of elevation and erosion during the later part of the Mississippian epoch, the higher divisions of the series are unrepresented; they are restricted to the southern portion of the State and the Kinderhook alone extends across it.⁷⁰¹

On each side of Mississippi River between Burlington, Iowa, and southern Illinois occur the typical sections of the Mississippian. The deposits are chiefly limestone, but in both the lower and the upper portions occur shales and sandstones, which mark the advance and retreat of the Mississippian sea. The basal formations (Kinderhook group) are irregular in occurrence, varying lithologically and faunally, and there are unconformities by erosion, particularly at the base of the Kaskaskia.^{490, 492, 881}

In southwestern Missouri and northern Arkansas, on the southwestern shore of the Ozark land, the Mississippian formations are, according to Adams and Ulrich,^{5a} as follows:

^a "The lower portion of the Pennsylvania Pocono * * * decreased rapidly in the southwestern part of the State [Virginia] until it disappeared or was merged into the Grainger [Devonian] shales of M. R. Campbell." Stevenson, J. J., *The Lower Carboniferous of the Appalachian Basin*: Bull. Geol. Soc. America, vol. 14, 1903, p. 35.

"His [White's] Shenango shales, Shenango sandstone, and Meadville shales, down to and including the upper Meadville limestone, are undoubtedly Lower Carboniferous, while the underlying divisions—the lower part of the Meadville shales, the Sharpville sandstones, the Orangeville shales, and the Oil Lake group—are evidently later Devonian." *Idem*, p. 40.

Correlation table of the Paleozoic formations in northern Arkansas [in part].

A standard time scale of the Ohioan province.				Mappable lithologic equivalents in northern Arkansas.	
Carboniferous.	Mississippian.	Chester.	Kaskaskia.	Birdsville.	Pitkin limestone.
					Wedington sandstone.
				Tribune.	Fayetteville formation.
			Cypress.	Batesville sandstone.	
			Ste. Genevieve.		
		Meramec.	St. Louis.	Moorefield shale (including Spring Creek limestone).	
			Spergen Hill.	(Wanting.)	
			Warsaw.		
		Osage.	Keokuk.	Boone limestone.	Cherty limestone.
			Burlington.		Gray subcrystalline limestone. St. Joe limestone.
			Kinderhook.	Noel shale.	

Adams ⁵ describes these formations as follows:

The Noel shale [now called the Chattanooga shale] has been previously described by the Arkansas State Survey under the name of the "Eureka shale;" but this name is preoccupied by the Eureka quartzite of Nevada, and accordingly it has been renamed, from the town of Noel, in southeastern Missouri, where it has been studied and at which place it is typically exposed. It consists of a bed varying from a few feet, and in some cases a few inches, up to 70 feet in thickness. Usually it averages from 15 to 30 feet. Its color is often black, although not infrequently it has a greenish and sometimes a yellowish appearance, according to the conditions of weathering or the amount of carbonaceous material contained in it.

* * * * *

The Noel shale is succeeded by the Boone formation, which appears to be conformable with it and represents merely a change in the character of sedimentation. Over a large area its basal member is an even-bedded limestone, free from chert and showing in a distinct ledge, sometimes shelly and thin bedded. It is known as the St. Joe limestone member. Its thickness in northern Arkansas varies from a few feet up to 50 feet. * * *

The remaining portion of the Boone formation consists of beds of cherty limestone and beds of chert, which vary in their lateral and vertical extent in such a way that it has been impossible to divide this part of the formation into members which can be generally recognized. The thickness of the formation is about 325 feet.

The limestones of the upper portion of the Boone formation are often coarsely crystalline and have usually a light-gray color. They contain numerous well-preserved fossils, but crinoid stems are perhaps the most conspicuous.

Generally the upper portion of the formation is heavily bedded, and the lower portion contains a large amount of flint. The line separating the St. Joe member from the remaining portion, although not marked by any very evident stratigraphic break, has been drawn at the point where the chert appears and is at a definite horizon.

In the vicinity of Batesville there is a bed of shale lying upon the Boone limestone and chert. It is well exposed around Moorefield, from which place it is named. In that locality it has a thickness of from 50 to 75 feet. To the west, at Marshall, it is not over 35 feet thick, and evidently it does not extend much farther westward. The shale has a light-grayish or bluish color, and is very friable. In places it is sandy.

The Moorefield shale is succeeded at Batesville by sandstones with some interbedded shale. In certain localities to the west the formation contains interstratified limestones, which,

where they are weathered, appear sandy. Where the Moorefield shale is absent this formation rests directly on the Boone formation and is usually found in this position between Marshall and Fayetteville. The thickness of the formation in the Yellville quadrangle is about 75 feet. The conspicuous portion of it is an even-bedded yellowish-brown sandstone.

The conspicuous portion of the Fayetteville shale is a bed of black carbonaceous shale, which is usually thinly laminated. It frequently exhibits a jointed structure and upon disintegration falls into small fragments. Its thickness varies from about 50 feet up to 200 feet. It is named from exposures around Fayetteville, where it is conspicuous in the valley of the West Fork of White River. This formation rests upon the Batesville sandstone or, where that formation is absent, upon the Boone formation. The lower portion of the black shale in the Fayetteville formation contains lenses of dark-blue siliceous limestones at some places.

Southeast of Fayetteville and westward to the State line the Fayetteville shale is succeeded by a sandstone formation varying in importance but usually having a thickness of between 50 and 150 feet. It is thin bedded and heavy bedded and carries some interstratified shale.

Succeeding the Fayetteville formation in the lead and zinc region there is nearly everywhere a bed of limestone. It is not always conspicuous, since it frequently occurs on slopes and is covered with débris of sandstones and shales from the higher formation. Its thickness where well developed is usually from 10 to 40 feet. In exceptional cases it is thicker. It sometimes has associated with it sandstone beds which contain the same fossils found in the limestone. The Pitkin limestone has been called the "Archimedes limestone" by the Arkansas Survey, because of the presence of this easily recognized bryozoan, the screwlike stems of which are seen in the weathered surface of the rock. In the northwestern part of the State, around Fayetteville, the limestone thins out to a pebbly stratum and disappears from the section. Along the north front of the Boston Mountains, however, it is a very persistent ledge, and the beds are frequently massive and give rise to an escarpment, a bench being developed on its upper surface. This formation is regarded as the highest one of the Mississippian series. It is probable that the thinning to the north and west is due to shore conditions, and its absence in some cases may be due to erosion previous to the deposition of the Pennsylvanian series which succeeds it.

J-K 16. KENTUCKY AND INDIANA.

Along the west side of the Cincinnati axis the Mississippian presents a section similar to that of the series along Mississippi River. At the base the strata lie conformably upon the Devonian and are somewhat sandy and shaly. The bulk of the deposit is limestone. The top part, which includes sandstone, is limited above by an unconformity. The local section for Indiana, as given by Blatchley and Ashley⁸⁶ and substantially quoted by Chamberlin and Salisbury,^{134b} is as follows:

Generalized section for Indiana.

	Formation.	Thickness (feet).	Characteristics.
Mississippian.	Unconformity.		
	Kaskaskia or Chester group.....	120	Sandstone and limestone.
	Mitchell limestone.....	0-250	Massive impure limestones and calcareous shales.
	Bedford oolitic limestone.....	20-80	Excellent building stone.
	Harrodsburg limestone.....	60-90	Limestones and shales.
Mississippian.	Knobstone formation.....	40-600	Arenaceous shales and sandstones. Not included in Knobstone by Blatchley and Ashley.
	Rockford goniatite limestone.....		Thin bed of limestone and calcareous shale.
	Devonian.		
	New Albany black shale.....	70-120	

The detailed stratigraphy of the foregoing section has been described by Hopkins and Siebenthal,⁴⁶⁴ Ashley,³⁸ and Newsom,⁶¹⁵ and the faunal relations have been discussed by Kindle.⁴⁹³

The Mississippian of Kentucky has been classified by Ulrich⁸²⁴ in a manner differing in several respects from any arrangement previously published. It is as follows:

Formations in the Kentucky-Illinois fluorite district.

		Names of formations and members used in this work.		Synonyms and equivalent formations in the Mississippi and lower Ohio valleys. ^a	
Carboniferous.	Pennsylvanian.	Pottsville group.	Mansfield sandstone.	Mansfield sandstone of Indiana. Coal Measures conglomerate of western Kentucky.	
		Tennesseean.	Chester group.	Kaskaskia limestone.	Birdsville formation.
	Tribune limestone.				
	Cypress sandstone.			Aux Vases sandstone of Keyes. Probably also Big Clifty sandstone of Norwood.	
	Ste. Genevieve limestone.		Ohara limestone. Rosiclare sandstone. Fredonia oolitic limestone.	Two upper members referred to as lower Chester by Worthen and Engelmann. Entire formation referred to as St. Louis by Norwood.	
	Mississippian.	Meramec group.	St. Louis limestone.		St. Louis limestone of most authors, but not of Engelmann, Shumard, and Swallow, who do not include two lower formations in the St. Louis limestone. The two upper formations equal, respectively, the Mitchell limestone and the Bedford oolitic limestone of recent Indiana reports.
			Spergen limestone.		
			Warsaw formation, lacking.		
	Waverlyan.	Ossage group.	Tullahoma formation.	Keokuk limestone. Burlington limestone.	Harrodsburg limestone (typical) and Knobstone of Indiana.
		Kinderhook group.		Various formations of the Kinderhook group.	
Devonian.	Chenung group.	Ohio shale.		New Albany shale of Indiana reports. Chattanooga shale. Grassy Creek shale of Keyes.	

^a The matter in this column is generalized and incomplete. It will be given in greater detail in a work on the Paleozoic section in the Mississippi Valley soon to be published by the writer.

J-K 17. OHIO AND EASTERN KENTUCKY.

The Mississippian series on the east side of the Cincinnati arch consists chiefly of argillaceous and sandy deposits which are in contrast to the limestones of the west (Indiana) side. They have been described under the name Waverly since 1838 (Briggs) and 1869 (Newberry), but with various classifications. Above these strata occurs a thin limestone which also belongs to the Mississippian and upon which the Pottsville (Pennsylvanian) was laid down unconformably. Prosser^{645, 649} has recently reviewed the literature and sequence of formations and his arrangement has been in general followed by Chamberlin and Salisbury^{134a} in the following table, but Prosser called the Logan exclusive of the Blackhand a formation, and not a group, the old "Logan group" including both the Logan formation and the Blackhand.

Generalized section for Ohio.^a

Formation.		Thickness (feet).	Characteristics.	
Mississippian.	Unconformity. Maxville limestone.....	25±	Fossiliferous limestone often brecciated.	
	Waverly series.	Logan group.....	100-150	Sandstone, massive conglomerate and shale.
		Blackhand conglomerate.	50-500	Sandstone and fine conglomerate.
		Cuyahoga shale.....	150-300	Light-colored argillaceous shales, with thin beds of sandstone. Shales characterized by ferruginous nodules.
		Sunbury shale.....	5-30	Black bituminous shale.
		Berea grit.....	5-175	Sandstone, used for building stone and for grindstones; locally carries oil, gas, and brine.
Bedford shale.....	50-150	Thin-bedded shales; occasional thin beds of sandstone.		
Devonian.	Ohio shale.....	300-2,600	Mainly black or dark-brown shale.	

^a Prosser, Jour. Geology, vol. 11, 1903, pp. 520, 521. Geol. Survey Ohio, vols. 6, 7; Bull. No. 7, 4th ser., 1905.

The correlation of this section with that of the typical Mississippian section and the Appalachian equivalents on the east is discussed by Girty as follows:³⁶¹

In 1900 an effort was made to trace eastward into Pennsylvania the members of Newberry's Waverly section in northern Ohio. The Berea grit of the Waverly group was found to be the equivalent of the Cussewago sandstone of northwestern Pennsylvania. The Orangeville shale of that region is the basal third of the Cuyahoga shale, in part equivalent to Orton's Berea shale. The Sharpsville sandstone, representing the middle portion of the Cuyahoga, is probably the stratum producing the lower falls at the village of Cuyahoga Falls. The Meadville shale can with little doubt be correlated with the upper portion of the Cuyahoga, and it seems probable that the Shenango sandstone and shale are the equivalents of the Logan group. It is doubtful if the Corry sandstone is represented in Ohio, while the Bedford and Cleveland shales probably die out before reaching the Pennsylvania line.

The relations of the Waverly to the clastic formations of Pennsylvania and West Virginia have been traced by Stevenson,^{794a} who uses the term Logan in the sense given to it by Orton, rather than as restricted by Andrews and Prosser. "Logan" in the following quotation thus comprises the original Logan formation and the Blackhand formation.

The Shenango sandstone has been followed by Dr. White into Trumbull County of Ohio, where it is about 15 feet thick and rests on 80 feet of Meadville shales. Prof. Orton regards the Logan sandstone of Ohio as the Shenango sandstone but includes also in the equivalence the overlying Shenango shales of White, which, as will appear in the second chapter, must be considered with the Mauch Chunk.

The Logan, in Ohio, is double, sandstone above and conglomerate below, at the typical localities. Followed into Ohio from Pennsylvania the rock becomes finer, the sandstone becoming shale and the conglomerate sandstone. In the counties of Knox, Holmes, Richland, and Coshocton the sandstone is represented by the Olive shales of M. C. Read, which are upward of 200 feet thick, but farther south the mass becomes a fawn-colored even-bedded fine-grained sandstone. The conglomerate gains in coarseness westward and southward, being a coarse rock in Wayne, Holmes, Coshocton, Knox, Licking, Fairfield, Hocking, Vinton, and Ross counties, which, as Prof. Orton observes, mark "the northwestern arc of the sea boundary in Sub-Carboniferous time." The conglomerate is not always continuous, there being usually, as Prof. C. L. Herrick has shown, two beds of conglomerate separated by layers of fine sandstone or even of shale. The pebbles are usually flat, small, and of practically uniform size. Southward from Ross County, along the western outcrop, the rock is less coarse and it ceases to be conglomerate before reaching the Ohio River, where it is the upper portion of the Kentucky Knobstone. The Logan rests upon the Cuyahoga shales of Orton, varying from 150 to 400 feet, with the Buena Vista sandstone at the base, a persistent bed, identified with the Sharpsville of White and continuous from the Pennsylvania line around the outcrop to the Ohio River at Buena Vista. Below this is the Berea shale, regarded as the equivalent of White's Orangeville, and at the base is the Berea grit, continuous from Lake Erie to the Ohio River, 50 to 75 feet thick, a fine sandstone at the north but somewhat argillaceous at the south. This ripple-marked sandstone is thought by Prof. Orton to be equivalent to the upper part of White's Oil Lake group.^a This rests on the Bedford shales. Herrick has shown that the Logan does not extend so far northward as do the Cuyahoga shales.

At this point may be inserted a table of approximate correlations worked out by Stevenson,^{794b} between the Appalachian Basin and the Mississippian section of the Mississippi Valley:

Lower Carboniferous:		
Shenango and Upper Meadville.....	Northwestern Pennsylvania.....	} Keokuk, Burlington, and Kinderhook.
Logan, including Waverly shales.....	Ohio.....

The Waverly group of Ohio has recently been traced across Ohio River into Kentucky and certain variations of stratigraphy have been described by Morse and Foerste,⁶⁰⁵ who recognize the formations distinguished in Ohio (Bedford, Berea, Sunbury, Cuyahoga, Blackhand, and Logan, in ascending order) but find that the strata below the Cuyahoga thin out toward the south and west and also lose such arenaceous partings as they had at the Ohio. The littoral formations of the Waverly

^a Orton, E., Ohio Survey Repts., vol. 7, 1893, pp. 28 et seq.

gulf thus diminish southward toward the Mississippian sea. A typical section at Vanceburg, Ky., is stated by Morse and Foerste as follows:

Section of Alum Rock, Vanceburg.

	Ft.	in.	Feet.
5. Cuyahoga formation.....			39
Interval covered except a thick layer of argillaceous sandstone at the top. The sandstone contains Taonurus. Small phosphatic nodules are found in the basal part of the interval.			
4. Sunbury shale, total thickness.....			15½
Black fissile carbonaceous shales, which can not be distinguished lithologically from the Ohio shale.			
3. Berea grit, total thickness.....			22¼
Thick layer of gray sandstone.....	2	6	
Heavy layer of rather coarse grained gray sandstone, the upper surface excellently ripple marked.....		3	
Medium to thick bedded, rather coarse grained gray sandstones, beautifully ripple marked.....		15	
Arenaceous shales.....		1	
Layer of fairly coarse grained gray sandstone.....		9	
2. Bedford formation, total thickness.....			95½
Blue arenaceous shales and shaly sandstones; lower part slightly covered.....	35		
Arenaceous shales with thin sandstone partings.....	7		
Layer of thick-bedded gray sandstone.....	1	8	
Arenaceous shales with two layers of sandstone.....	6	9	
Heavy layer of gray sandstone, with lower surface contorted.....	2	4	
Arenaceous shales with two layers of gray sandstone.....	6	6	
Layer of thick-bedded buff sandstone.....	1	9	
Medium-bedded gray sandstones with shaly partings.....	2	10	
Arenaceous pink shales with sandstone partings.....	2	6	
Covered interval.....	5		
Layer of thick-bedded buff sandstone.....	2		
Practically covered interval with some argillaceous shales.....	22	6	
1. Ohio shale.....			242
Black fissile carbonaceous shales. About 10 feet from the top one or two linguloid shells occur. Near the central part the shales become softer and lighter in color and resemble a similar zone in the Ohio at Columbus (Ohio). The interval (242 feet) is mostly exposed and extends to the level of the Chesapeake & Ohio Railway. At "Slate Point," however, the top and bottom contacts are shown and the total thickness is 301¼ feet.			

At Petersville, Ky., southwest of Vanceburg, the Bedford and Berea are, according to Morse and Foerste, no longer separable and have together a thickness of 46½ feet only. Several successive sections are cited by them. At Irvine, Ky., southwest of Petersville, they measured the following:

Section of Minerva Mountain, Irvine.

	Ft.	in.	Feet.
6. Subcarboniferous limestone.....			1
Yellowish sandy-like limestone, lying at the extreme top of the hill.			
5. Upper Waverly series, not divided.....			344
Covered interval.....	60	6	
Thin-bedded buff argillaceous sandstones, which weather to thin shaly pieces; Taonurus.....		17	
Layers of massive buff argillaceous sandstone, Taonurus abundant.....		24	
Buff argillaceous sandstones, weathering to shales; Taonurus.....		17	
Covered interval.....	225	6	
4. Cuyahoga formation, top not determined.....			144
Brownish ferruginous and calcareous nodular layer of sandstone.....		6	
Indurated bluish to pinkish argillaceous shales with ferruginous nodular layers.	69	6	
Soft bluish argillaceous shale with ferruginous nodular layers, slightly covered (top of Linietta clay).....		63	6
Layer of brownish argillaceous sandstone, which breaks up into shaly layers....		2	
Soft bluish to pinkish argillaceous shales and small phosphatic nodules.....	8	6	

	Ft. in.	Feet.
3. Sunbury shale, total thickness.....		3
Black fissile carbonaceous shales.		
2. Bedford-Berea, total thickness.....		1½
Argillaceous shales with phosphatic nodules.....	2	
Black fissile carbonaceous shales.....	3	
Dark argillaceous shales, with some carbonaceous material.....	6	
Gray calcareous and argillaceous shales, slightly fossiliferous.....	2	
Yellowish calcareous and argillaceous shales, the upper part very fossiliferous...	5	
1. Ohio shale.....		94½
Black fissile carbonaceous shales, with an occasional softer argillaceous layer.		
Practically all exposed to the highway.		

In the Irvine section the Bedford and Berea are stated to be represented by 1½ feet of fossiliferous shale and the Sunbury by but 3 feet of black carbonaceous shale. Morse and Foerste conclude:

The Bedford and Berea formations thin rapidly southwestward from the Ohio River and this horizon, even after it has been reduced to a thickness of only a few inches, can be traced to near the crossing of the Cincinnati geanticline by the Waverly series.

The Sunbury shale, on the contrary, suffers but little decline, at least until Indian Fields is reached.

The Ohio black shale of the Kentucky reports or the Chattanooga shale of United States reports, south of Petersville, is not of Devonian age alone but of Devonian and Carboniferous—that is, is composed of both the Ohio and Sunbury shales and a thin zone representing the Bedford and Berea.

The sandstones which are extensively quarried about Rockville station belong to the Buena Vista member of the Cuyahoga formation rather than to the Berea grit.

The Buena Vista sandstones begin to disappear from Olympian Springs southwestward except a single layer which, if not always the same, at least occupied the position of the lowest and which persists as far south as Stanton if not to Irvine.

The Linietta clays belong to the lower part of the Cuyahoga formation.

The so-called Waverly of at least the Richmond folio includes only the upper part of the Waverly, beginning with the base of the Cuyahoga.

J-K 17-18. PENNSYLVANIA, MARYLAND, WEST VIRGINIA, AND VIRGINIA.

The area considered under the above heading covers that restricted part of the ancient bay of New York and Pennsylvania which was occupied by the sea at intervals during the Mississippian epoch and within which were laid down the coarse clastic sediments of the Pocono, at the base of the series, and subsequently the shaly, sandy Mauch Chunk formation. The Pocono is commonly a sandstone which includes also strata of conglomerate shale, and thin coal beds. Its thickness is 1,800 feet in West Virginia and 2,000 feet in a section on the Susquehanna. It thins out to the north and south, to 500 feet in the Wyoming anthracite field, Pennsylvania, and to 100 feet or less in West Virginia. In western Pennsylvania, Ohio, Kentucky, and Tennessee its equivalents are shales and sandstones whose precise stratigraphic and faunal relations are still matters of doubt; but they, together with the Pocono, are referred in general terms to the position of the Kinderhook, Burlington, and Keokuk of the Mississippi River section.⁷⁹⁴

The lower part of the Pocono is regarded as Devonian by Stevenson.

The Mauch Chunk formation is dominantly a red sandy shale, which in Pennsylvania is chiefly a subaerial flood-plain deposit, according to Barrell.⁵⁶

It attains a maximum thickness of 3,000 feet in the southern anthracite fields and thins away toward the north, west, and south, as shown by Barrell and Stevenson. In southern Pennsylvania, Maryland, and West Virginia the lower part of the shales gives way to the sandy Greenbrier limestone. Stevenson^{794d} sums up the stratigraphic relations and nomenclature as follows:

The Mauch Chunk is represented only by shales, or by shales and sandstones, along the northerly border in Pennsylvania, but southward limestone is found with shale above and below it. This limestone, in the Allegheny Mountain region, reaches to within 30 miles of the northern outcrop, while traces of it are present still farther north in the anthracite region. In southern Pennsylvania it is double, with a siliceous division below and a more or less argillaceous division above. The former is the more persistent at the north and in the central part of the basin, but it is wanting in Ohio except in the extreme southeast. Both divisions persist in Virginia, Tennessee, and Alabama, as well as in the greater part of West Virginia and Kentucky. The lower shales become indefinite southward and the upper shales extend as shales little beyond the northern line of Tennessee.

The whole series has been termed Mauch Chunk in Pennsylvania, and no special geographical term has been applied there to any of the subdivisions except in the northwestern part of the State, where Dr. I. C. White gave the name Shenango to the shale which there is the sole representative of the Mauch Chunk. In Maryland the upper shales have been termed Mauch Chunk and the limestone Greenbrier; in Virginia Prof. W. B. Rogers used the names Greenbrier shale and limestone; the United States geologists in that State have applied the names Canaan and Pennington to the shales, Greenbrier and Newman to the limestone; Prof. Safford in Tennessee divided the limestone into Mountain limestone above and the Siliceous group below, the latter into the Lithostrotion and the Protean, of which the former belongs to the Mauch Chunk; to Prof. Safford's divisions Mr. Hayes applies the designations Bangor and Fort Payne, with, in the southeastern areas, Floyd as equivalent to the lower portion of the Bangor; in Alabama the limestone is divided by Smith and McCalley into Bangor, Hartselle, and Tuscomb; in Kentucky the divisions are Chester and St. Louis; and in Ohio Andrews termed it Maxville.

Regarding the Mississippian of the Meadow Branch Mountains area of West Virginia, adjacent to the Potomac, Stose⁸⁰³ points out that these rocks are structurally the southeasternmost occurrence of Carboniferous rocks in the northern Appalachians, outside of the anthracite region. They are widely separated from the main body of Mississippian sediments in western Maryland and Pennsylvania, and the formations which he maps have not been positively correlated with those of the broader area. These formations, which he regards as subdivisions of the Pocono group, comprise the Rockwell formation, Purslane sandstone, Hedges shale, Myers shale, and Pinkerton sandstone.

Stose describes the Rockwell formation—the basal Carboniferous deposit—as composed of coarse arkosic sandstone, fine conglomerate, and buff shale, with some dark shale containing locally thin coal beds, and gives a section of this formation as seen at Sideling Hill, on the north bank of the Potomac, showing a thickness of $541 \pm$ feet.

The Purslane sandstone he describes as the ridge-making rock of the Meadow Branch Mountains, Sideling Hill, Spring Gap Mountain, and the higher parts of Town Hill, and as composed largely of heavy-bedded coarse white sandstone with bands of quartz conglomerate and some soft white sandstones containing locally thin coal seams. Sections of the Purslane sandstone show that the thickness varies from 180 to 310 feet.

The Hedges shale is described as a dark coal-bearing shale overlying the Purslane sandstone in the Meadow Branch syncline. Because of its soft and unresistant character it is exposed in but few places. The best estimate of its thickness, obtained from a section south of Devils Nose, is 170 feet.

The Myers shale is distinguished by its bright-red color. The basal 60 feet is composed of cross-bedded reddish-gray gritty arkosic sandstone. At the top thin reddish-stained sandstone merges into the overlying Pinkerton sandstone. The thickness is estimated at 800 to 900 feet.

The Pinkerton sandstone appears in only two small areas, one at Pinkerton Knob and the other in the northern part of Third Hill Mountain. At the base are gray platy sandstone and white quartz conglomerate, with soft crumbly sandstone above. The upper layers, however, are very massive cross-bedded coarse white sandstone. The thickness of the formation on Pinkerton Knob is given as about 125 feet.

Plant remains found in the Rockwell formation, the Purslane sandstone, and the Hedges shale are definitely referred by White to the Pocono group of the Carboniferous, and the few fragments from the Pinkerton sandstone are tentatively regarded by White as of the same age, certainly not younger than the Mississippian.

No fossils were found in the Myers shale, but as it lies below the Pinkerton sandstone, it is older than that formation.

Stose quotes from Stevenson, Ashburner, and I. C. White four sections of the Pocono and arranges them geographically from west to east, in comparison with a composite section in the Meadow Branch syncline in the Hancock quadrangle, as follows:

Summarized sections of the Pocono group.

	Riddlesburg (I. C. White).	Shoups Run (I. C. White).	Juniata River (Stevenson).	Sideling Hill tunnel (Ashburner).	Meadow Branch Mountains (Stose).
	<i>Feet.</i>	<i>Feet.</i>	<i>Feet.</i>	<i>Feet.</i>	<i>Feet.</i>
Massive and flaggy sandstone and shale, some red..	609	730	620	610	825
Dark shale containing thin coal seams in massive and thin-bedded sandstone.....	50	100	70	313	170
Massive sandstone and conglomerate generally cross-bedded.....	85	55	45	380	310
Red to green or gray shale and flaggy sandstone....	698	495	630	830	541
	1, 442	1, 380	1, 365	2, 133	1, 846

All the above sections show in general the following fourfold divisions; a lower group of shales and soft sandstones, generally reddish in color where weathered; a middle heavy sandstone and conglomerate, usually cross bedded; a variable thickness of black shale with thin coal seams and sandstone; and an upper series of shales, usually red, and thick sandstones. The thicknesses in the first three columns of the table correspond rather closely, the total thickness varying from 1,365 to 1,442 feet. The Sideling Hill tunnel section is much thicker, all the members except the top sharing in the increase. * * *

It is concluded from the above comparison that all the Carboniferous strata now remaining in the Meadow Branch Mountains are Pocono in age and correspond to the rocks in the Broad Top coal field below the Mauch Chunk. * * *

As pointed out by Stevenson, the thickening of the Pocono eastward is progressive. From 300 feet in Laurel Ridge, Fayette County, the Pocono increases to 1,030 feet in the southeastern

part of Cambria County, to 1,400 feet in the western side of the Broad Top syncline, and to 2,133 feet in Sideling Hill, Pa. If these measurements are correct, it apparently reaches its culmination in Sideling Hill and decreases eastward to 1,850 feet in the Meadow Branch Mountains.

K-L 16-17. MICHIGAN.

According to Lane ^{519a} the Carboniferous of Michigan consists of the formations tabulated as follows:

Carboniferous formations of Michigan.

System.	Series.	Formation.	Thickness (feet).	Character of rock.
Possibly later.	Conemaugh.	Woodville.	0-110	Light-reddish sandstone and sandy shales.
Carboniferous.	Pennsylvanian (Upper Pottsville).	Saginaw.	400	White sandstone, coal seams, black and white shales; then bands of limestone and of siderite rare, rarely broken up and found in fragments of the sandstone.
		Parma.	0-170	White sandstone and conglomerates, of small white quartz pebbles; brine and sulphates.
	Mississippian.	Bayport or Maxville. Upper Grand Rapids. Upper St. Louis.	50-235	Limestones, light and bluish, cherty; also calcareous sandstones.
		Michigan. Lower Grand Rapids. Lower St. Louis. Osage or Augusta.	0-300	Dark or bluish limestones and dolomites with gypsum and blue or black shales; rarely reddish or greenish shales and dark or red sandstones.
		Napoleon. Upper Marshall.	260-560	White sandstone, often pyritic; brine or fresh water; sulphates low.
		Lower Marshall.		White and red sandstones, peanut conglomerates, sandy shales, whetstones and blue shales, much carbonate of iron and mica in the formation; generally a red shale at the top and bottom.
		Coldwater. Buena Vista.	800-1,000	Blue shale, with nodules of carbonate of iron, especially at the top; sandstone; very subordinate streaks of fine-grained limestone, especially on the west side; black shales at the base.
	Sunbury or Berea.			
Berea.		White sandstone; brine and salt even near the surface.		
Devonian.	Neo-Devonian.	Bedford. Antrim (Senecan).	140+480	Shale, mainly black and always at the base, with huge round balls of calcite; toward the top, blue and black shales.

The formations are deeply covered by drift and are known chiefly by drill records. Lane comments on the sequence according to the sections drilled in many localities.

The base of the Carboniferous in Michigan is usually drawn in practice at the top of the Antrim shale, between it and the overlying Berea sandstone, although it is theoretically drawn in the Antrim shale itself, so as to separate from it a portion equivalent to the Bedford shale of Ohio, regarded as the lowest Carboniferous of that State. Ulrich would draw the line below the Antrim, removing that formation entirely from the Devonian to the Carboniferous. Where the Berea sandstone is not present the Antrim shale is succeeded by the Coldwater shale (Carboniferous) and a practical distinction is not possible.

With reference to the line between Devonian and Carboniferous, G. H. Girty has prepared the following discussion ^a for this paper:

In northwestern Pennsylvania I have discriminated a group of rocks between the Berea ("Corry") sandstone and the top of the typical Chemung under the name "Bradfordian." In Ohio I am tentatively assigning to this group the Bedford shale, the Cleveland shale, and the Chagrin ("Erie") shale, or at least the upper portion of the Chagrin shale, from which our fossil faunas are obtained. Because the "Bradfordian" faunas were very different from the Waverly faunas (inclusive of the Berea sandstone but exclusive of the Bedford shale), I originally assigned the "Bradfordian" without hesitation to the Devonian. After comparing the "Bradfordian" faunas with the typical Chemung, however, I find that there exists a difference, almost equally marked, and feel somewhat doubtful whether the "Bradfordian" would not better be placed in the Carboniferous.

In northern Ohio the most convenient horizon at which to draw the base of the Carboniferous would doubtless be immediately below the Berea sandstone. If the Bedford shale is included in the Carboniferous, so must also be the Cleveland. A more or less conspicuous change of fauna occurs in passing from the Chagrin into the Bedford.

If the Berea sandstone is taken as the earliest formation of the Carboniferous in Ohio, then in Michigan the Devonian would naturally close with the top of the Antrim. If the Bedford and the Cleveland of Ohio are included in the Carboniferous, then probably a corresponding portion at the top of the Antrim would have to be taken out of the Devonian. If the entire "Bradfordian" is assigned to the Carboniferous (on the assumption that that term includes in Ohio the whole of the Chagrin shale), then more or possibly all of the Antrim would have to be placed in the Carboniferous.

Regarding the Berea sandstone, Lane ^{519b} states:

This is an Ohio formation and has never been seen at the surface in Michigan, but may be traced very well along the flanks of the Cincinnati anticlinal, from near Adrian north. Westward it seems soon to disappear and to be spotty in occurrence. Eastward it is persistent in Ohio, but thin, about 50 feet or less.

It continues to the northeast and north, as determined in wells at several points cited by Lane.

Its thickness is usually about 100 feet and, as is well shown in Huron County, it thickens gradually from about 40 feet until it is thickest near its western margin (over 200 feet), where it disappears suddenly * * *. It is generally fine grained, micaceous, a grindstone, and overlain by a black shale (the Berea or Sunbury shale).

The Coldwater shale of Michigan directly overlies the Berea sandstone where that formation is present; elsewhere it succeeds the Antrim shale. The base of the

^a Notes, December, 1910.

Coldwater is the black shale which Lane refers to in the above quotation as the equivalent of the Sunbury. The Coldwater comprises further the representative of the Cuyahoga shale and possibly that of the Blackhand formation.^{519c} Lane cites the following section from Huron County:

	Feet.
Blue and sandy shales.....	172
Light House Point conglomerate.....	4
Blue shales with carbonate of iron, with <i>Chonetes scitulus</i> cf. <i>pulchella</i> common throughout...	720
Black shale (Sunbury), with <i>Lingula melie</i> and <i>Orbiculoidea newberryi</i> in Ohio.....	103
	1,000±

The Coldwater shale thus represented and as originally defined covers the interval between the Berea sandstone below and the Marshall formation above. Among the subdivisions, the conglomerate in the above section is tentatively correlated by Lane with the Blackhand of Ohio, and beneath it should come the representative of the Cuyahoga shale. Lane gives a number of well sections showing variations in color, composition, or thickness of the several subdivisions, and the strata have also been described by earlier writers.

The Coldwater shale is succeeded by the Marshall formation, into which it passes by increasing sandiness without distinct plane of division.

The Marshall formation as known in Huron County comprises, according to Lane,^{519d} the following beds:

	Feet.
Napoleon (Upper Marshall) sandstone.....	300
Lower Marshall (original Marshall):	
Hardwood Point shales and sandy flags, fossiliferous ("typical Marshall" fauna).....	85
Port Austin sandstone.....	23
Sandy shale.....	68
Point aux Barques sandstone.....	18
Shales and flags with <i>Romingerina julia</i>	41
Grindstones with bands of peanut conglomerate and broken goniatite shells.....	25
	560

Lane comments:

The facies with the battered shells, chip pebbles (now coal), Solens, and lamellibranchs is a real shore facies. As we go toward the center of the basin the sandy facies of the Lower Marshall seems to disappear, especially the clear white sandstone, nor is the upper sandstone so thick.

The Michigan formation, a sequence that carries brine and gypsum and is of smaller extent, succeeds the Marshall. Lane regards it as the deposit of an inclosed sea, like the Caspian. Its thickness is generally about 200 feet. At Mount Pleasant, where it is thickest, the section is as follows:^{519f}

	Feet.
Shale.....	5
Sandstone.....	20
Dolomite and shale.....	75
Anhydrite and dolomite.....	100
Anhydrite.....	45
Dolomite, shale, and anhydrite.....	103
Sandstone.....	8
Shale.....	5
Sandstone.....	4
Shale.....	15
	380

The shales are dark or even black and the dolomites blue or dark and impure. The general association of dolomite and gypsum is like that in the Salina, but the deposits contain more clastic mud in proportion to the lime salts.

According to Lane the deposition of the Michigan formation went on until "a depression to the west opened connection with the wide ocean at the time of the Maxville limestone of Ohio." Deposition appears to have gone on continuously with change to the formation of limestone.

The Bayport (Maxville?) limestone succeeds the Michigan formation, the two formations composing the Grand Rapids group. The Bayport is a hard light-colored limestone with chert. It was deeply eroded before the deposition of the overlying Parma sandstone, of Pottsville age. The thickness remaining is usually only 50 to 75 feet, but in the well at Mount Pleasant Lane^{519g} recognizes as Maxville (Bayport):

	Feet.
Shale and red limestone (weathered?).....	30
White limestone.....	30
White sandstone, very salt water.....	120
White limestone.....	55
	235

The erosion of the Bayport limestone was general and at some points is complete. The formation is taken as the plane of division between the Mississippian and Pennsylvanian.

L 20. NOVA SCOTIA AND ADJACENT NEW BRUNSWICK.

For discussion of this area by Ells and Bailey see Chapter VIII, pages 384-386.

M 20. BONAVENTURE COUNTY, QUEBEC.

The "Lower Carboniferous" (Mississippian) is represented by the Bonaventure conglomerate along the north shore of Chaleur Bay and the extremity of the Gaspé Peninsula. The Bonaventure, as described by Logan,^{544v} is a basal conglomerate, in places remarkably coarse, composed of pebbles, bowlders, and blocks derived from the underlying Silurian limestones and igneous rocks intrusive in them; all embedded in a red sandstone, which constitutes also an upper and more continuous member. Ells^{307a} distinguishes between the basal conglomerate and the upper red sandstone, more particularly on the south shore, near Restigouche Harbor, where the lower conglomerates are interstratified "with gray beds containing Psilophyton and other Devonian fossils," and are unconformably overlain by the upper beds.

The relations of the Bonaventure conglomerate in the eastern exposures of Gaspé Peninsula have recently been studied by Clarke,^{157d} who describes them as follows:

Over the tops of the broken and decapitated folds of sand, limestone and conglomerate in Gaspé County lies a mantle of coarse clastic material, partly sand but chiefly jasper and limestone conglomerates. These strata do not appear north of Gaspé Bay and are chiefly confined to the mountains about Perce and to Bonaventure Island. Sandstones and conglomerates together may attain an elevation of 1,500 feet represented by the Perce Mountain and they have a gentle and apparently uniform dip to the north, not often exceeding 10° and generally less. These constitute the Bonaventure formation of Logan and were regarded by him as of early Carbonic age.

At places, as south of the Robin beach at Perce, the lower beds are fine feldspathic red, green, or gray sandstones, but even these carry pebbles, and the prevailing character of the formation is conglomeratic. South of this region under immediate consideration, sweeping along all the country on the north shore of Chaleurs Bay and into New Brunswick, these deposits are widespread.

It is by no means easy, with present knowledge, to determine the true age of these deposits. In considering the commonly accepted view of Logan and his successors expressed above, we are confronted by phenomena at Perce and thence north to Point St. Peter, which seem to us to render this conclusion less secure than the observation of the more southerly outcrops would induce. Strata of conglomerates composed of pebbles carrying Siluric and Devonian fossils from the beds beneath and included by Logan in the Gaspé sandstone group, are found at various inclinations from Chien Blanc, on Gaspé Bay, all the way around Malbay to the Grande Coupe at Perce; at places these beds are nearly horizontal; from Cannes de Roche to Corner of the Beach, on the south shore of Malbay, they are nearly vertical and their color varies from red to ashen gray. In lithologic composition, the nature of the component pebbles, and in the general aspect of this northern series there is no distinction from that comprising Perce Mountain and Bonaventure Island. This latter, the typical expression and section of the Bonaventure conglomerates, stands with abrupt and sheer escarpments on the east and north, telling, like the Catskills, of a widespread further extension. The stratigraphic distinction between these higher Bonaventure conglomerates and the lower conglomerates of Malbay is only the apparent unconformity between the two. The gently sloping higher mass of Perce Mountain seems to lie directly on the vertical conglomerates of Cannes de Roche, and it is the indication of this sharp unconformity that has been regarded as evidence of the distinction in age in the two parts of this great homogeneous mass of conglomerates. My examination of the sea wall from the Murailles at Perce to Corner of the Beach leads me to the impression that the erect conglomerates at the latter place, cut off as they are, to a narrow shore belt by the Siluric limestones behind, have been downthrown from their normal position along the zone of great disturbance which has involved the Murailles, Cape Barre, the sea floor outside the North Beach, and Perce Rock. No fact impresses the casual observer more forcibly than the apparent presence of extensive unconformity between these Bonaventure beds and the lower conglomerates, but the appearance is, I am confident, illusive and the Bonaventure conglomerates seem to represent a southern slightly undulated part of the same conglomerate mantle which appears more highly faulted in the anticlines farther north. Such an interruption involves several important conceptions.

1. These conglomerates were certainly laid down unconformably on the vertical edges of the Devonian and Siluric strata about Perce.

2. As the Gaspé sandstones of the Gaspé Basin have been folded up together with the Devonian limestones of the Forillon, either the Gaspé sandstones of the north are older than the entire series of conglomerates or the folding at the south, which involves the Devonian limestones and the Siluric strata together, was earlier than the upturning of the Devonian limestones at the north with which the older strata were not involved; or both conclusions are probable.

3. While the sandstones constituting the lower part of the "Gaspé sandstone series" and their presence in the higher beds are indicative of barachois or lagoon conditions, the conglomerates themselves are clearly open coast deposits formed under such circumstances as prevail to-day wherever these very rocks are exposed to the play of the sea.

4. That the Bonaventure conglomerates of this typical section, either in whole or in part, are of Carboniferous age is probably only in a sense that their formation began in late Devonian time and continued without effectual interruption into that of the subsequent era, in the same sense perhaps as the upper beds of the Catskill group of New York seem to be of a post-Devonian age.

These strata constitute the latest of the rock deposits in Gaspé.

CHAPTER X.
PENNSYLVANIAN.

Color, dark gray.

Symbol, 12.

Distribution: Guatemala, central and eastern United States, New Brunswick, and Nova Scotia. Present though not distinguished from Mississippian throughout the Cordillera, the Arctic region, and Newfoundland.

Content: "Coal Measures" (Pottsville to Monongahela inclusive) of eastern North America and their equivalents where distinguished; Carboniferous limestone of Guatemala. Mapped elsewhere with Carboniferous undivided.

Pennsylvanian areas.

D 15-16. GUATEMALA AND CHIAPAS.

The Carboniferous of Guatemala and Chiapas was recognized by geologists who preceded Sapper, but has been more accurately determined by him. He has described it in two works.^{694, 695} From the later one we quote:

In Alta Verapaz one may distinguish two series or formations—a lower, which consists of quartz, conglomerates, sandstones, clay slates, and graywacke, which has been called the Santa Rosa terrane by Dolfus and Mont-Serrat, and an upper series of limestones, dolomites, and conglomerates or breccias, which consists of both these rocks. These limestones and dolomites are both of very dark color and often strongly bituminous. The graphitic limestone occurs near Tucuru.

In the older rocks of the Santa Rosa terrane are quartz conglomerates and puddingstones. They rest directly upon the Archean. In many places they contain pebbles of crystalline schists as large as nuts. The higher beds consist of sandstones, slate, shales, and graywackes which are sometimes interbedded and also show gradual transitions and even pass through coarse sandstones into conglomerates. The Santa Rosa strata also include limestones which contain crinoids and also *Fusulina granum avenæ*. [Sapper mentions local occurrences of gypsum, yellow shales and slates and clay slate, and other rocks.]

The age of the Santa Rosa terrane is definitely fixed by the discovery of typical Carboniferous fossils which were determined by Stolley under the direction of Zittel. They are *Syncladia biserialis* Swallow, *Lonsdaleia floriformis* Fleming, *Fenestella* sp., *Nucula* cf. *ventricosa*, *Leda* sp. n., *Natica* sp. [lower Pennsylvanian or possibly upper Mississippian—G. H. Girty].

The fossils have been found only in the upper horizons of the Santa Rosa and consequently the age of the lower horizons is not fixed. The thickness of the Santa Rosa in some places rises to as much as 200 or 300 meters but is very different in different localities.

The upper terrane of the Carboniferous formations has a thickness of 600 to 800 meters and is shown by abundant fossils to belong to the upper Carboniferous [Pennsylvanian—Girty]. The fossils are *Fusulina granum avenæ* Roemer, *Bellerophon* cf. *costatus* Sow., *Athyris ambigua*, *Athyris sublamellosa* Hall, *Productus semireticulatus* Martin. In the vicinity of Senahu the rocks are chiefly dark-gray dolomites which readily decompose into a sand and show no traces of

FIGURE 12.—Sketch map showing the distribution of Pennsylvanian rocks that are separately represented on the geologic map of North America and the key to references in the text.

fossils. In the western part of Alta Verapaz these dolomites are, it is true, not entirely wanting, but limestones, limestone conglomerate, and breccia greatly predominate. The limestones rest conformably upon the Santa Rosa terrane.

Complete lists of the Carboniferous fossils identified for Sapper by Stolley are given in an earlier paper by Sapper.⁶⁹⁷

H 14. CENTRAL TEXAS.

The following notes are selected from the forthcoming Llano-Burnet folio and from a bulletin⁶²⁶ on the mineral resources of the region, both by Paige:

The Carboniferous of the Llano-Burnet district is represented by limestone and shale formations of lower Pennsylvanian age. The limestone forms the lower portion of the system and has been mapped as the Marble Falls limestone. The shale, in which are included sandstone lentils, overlies the limestone and is mapped as the Smithwick shale.

The Marble Falls limestone is separated from the underlying Ellenburger limestone (Cambrian and Ordovician), by a thin limestone conglomerate, though in one place a very coarse angular conglomerate or breccia was observed. There are some localities, however, where little or no discordance could be noted, as, for example, in the small basin 5 miles northeast of Blufton. The boundary at the top of the formation is sharp, and the Smithwick shale succeeds with perfect accordance in dip.

The Marble Falls limestone is believed to be not more than 450 feet in thickness. It is composed of alternating beds of dark and light gray, dove-colored, and dark blue to black limestone. Many beds carry an abundance of cherty nodules, largely of a decidedly dark or black color. The color of this chert is diagnostic in distinguishing this formation from the underlying Ellenburger limestone, in which the chert is of a decidedly lighter color. The formation usually may also be distinguished by the petroliferous odor which it emits on being struck a sharp blow with a hammer. The Marble Falls limestone is confined largely to the southeast quarter of the Burnet quadrangle, but a small patch occurs northeast of Blufton and there are considerable areas in Riley Mountain.

The two following sections will illustrate the lithology of the formation:

Section of Marble Falls limestone in Riley Mountain, in stream 7½ miles north of south edge and 4 miles west of east edge of Llano quadrangle.

Very hard, compact, nearly black limestone; some chert; nonfossiliferous.	Feet.
Thin, dark, very hard limestone; conchoidal fracture; weathers buff; platy and considerable black chert.....	10
Rather massive gray limestone; some black chert.....	10
Thin-bedded, very fine grained black slaty limestone.....	20
Rather massive dove-colored limestone.....	20
Thin-bedded slates or slaty limestone, black or dark gray; weathers yellow; apparently no fossils.....	35
Massive, coarse brown limestone.....	5
Thin-bedded limestone with cherts, gray-browns; marly in some places; weathers light yellowish; few fossils noted in talus slopes.....	50
Crystalline grayish-brown limestone; some fossil fragments.....	12
Massive brown limestone with large amount of chert.....	7
Coarse-grained brown limestone containing considerable light chert; weathers into a slope of talus.....	9
Irregular limestone, gray to brown, fine grained, nonfossiliferous.....	32
Thin-bedded, very dark fine-grained limestones with a large quantity of black chert; a few fossils.	
Irregularly bedded fine-grained brown and gray limestone; very fossiliferous at base; bituminous odor strong; some parts of base are mostly Productus remains.....	22
Mostly thin-bedded fine to coarse grained brown and dark-gray limestone, highly fossiliferous..	8
Thin-bedded hackly limestone, brownish, sugary; bituminous odor.....	6½
Conglomeratic limestone containing pebbles of white chert and fine-grained light limestone....	2
Ellenburger limestone (Cambrian and Ordovician).	248

Section of Marble Falls limestone along north bank of Colorado River from dam to point above bridge at Marble Falls.

	Feet.
Smithwick shale.....	20
Thin-bedded black limestone.....	15
Fine-grained dark-gray limestone.....	30
Thin-bedded and massive black limestone.....	30
Brownish-gray subvitreous to crystalline limestone.....	4
Thin-bedded dark-gray or black fossiliferous limestone with <i>Productus</i> and crinoids.....	4
Fine-grained crystalline gray limestone.....	20
Fine-grained gray limestone with molluscan fossils.....	2
Dense black or dark-gray limestone.....	5
Light and dark gray mottled limestone with chert nodules.....	5
Mottled gray limestones with crinoid stems 26 inches long.....	1
Limestone conglomerate.....	2
Gray limestone without chert.....	8
Gray cherty limestone.....	8
Black limestone with cherty layers.....	9
Black, evenly bedded limestone with cherty layers.....	8
Massive gray crystalline limestone.....	25
Gray cherty limestone.....	6
Gray crystalline limestone.....

Dark cherty limestone.....	7
Dove-colored limestone with black bands and lenses.....	40
Conglomerate.....	20
Ellenburger limestone (Cambrian and Ordovician).....	

368

The Smithwick shale consists of a soft, very dark to nearly black carbonaceous shale in which are included a number of sandstone lentils. Because of its soft nature the formation was not observed in such attitude as would permit its measurement. Moreover, its top is overlapped by Cretaceous sediments. Probably the beds exposed in Burnet County do not exceed 400 feet in thickness. The basal boundary of the formation is always sharp, the change to limestone occurring very abruptly. The formation represents the youngest Paleozoic sedimentation in the region and the erosion surface, represented by its beveled beds, marks the great unconformity between Paleozoic and Cretaceous sedimentation. The formation is confined to the southeast portion of the Burnet quadrangle and to a small area in Riley Mountain, in the Llano quadrangle.

I 14. NORTHERN TEXAS.

Northern Texas is geologically almost completely separated from the areas to the north by the uplift of the Arbuckle Mountains. There is a possible connection around the west end of this uplift by "Red Beds" strata as yet unclassified. The stratigraphy of the Pennsylvanian of northern Texas was summed up by Taff⁸⁰⁷ as follows:

The north Texas coal field extends from the south side of the Colorado River valley between Lampasas and Concho counties northward to Red River in Montague County. It is nearly 250 miles in length, with an average width of about 45 miles, and has, therefore, an approximate area of 15,000 square miles. * * *

The north Texas coal field is limited on the east by the Cretaceous rocks, which rest unconformably upon Coal Measures. At the south end of the field the Coal Measures lie unconformably upon the Mississippian (Lower Carboniferous) and are in part concealed by Cretaceous strata. Upon the west and northwest sides the Coal Measures are bounded and succeeded stratigraphically by the Permian. * * *

The Coal Measures of north Texas were separated by Mr. Cummins^a into five divisions or groups, as follows, in descending order: Albany, Cisco, Canyon, Strawn, Millsap.

Millsap division.—This group of strata has not been recognized south of northern Erath County, though, according to the structure of the rocks, it should occur in the basin of Leon River in Comanche County. According to the Texas Survey it thins southward and does not occur in the Colorado River valley. North of Trinity River valley in Wise County it is concealed by the overlap of Cretaceous rocks. The top of the formation includes coal bed No. 1, whose outcrop is located upon the map and which is mined at Thurber, Gordon, Rock Creek, and Bridgeport. The strata of this group occur at the surface between the coal outcrop referred to above and the Cretaceous border. The base is not exposed, and much of the section, which has a thickness of about 1,000 feet, is concealed. The complete section was obtained by diamond drill, penetrating the strata at Thurber.

It is composed of blue and black shale, interstratified with occasional limestone and sandstone strata.

The deep wells at Gordon and Thurber produce gas and salt, but no coals were encountered below coal No. 1.

Strawn division.—This is composed of nineteen separate members of sandstone and shale, making an aggregate thickness of 3,700 feet in the southern part of the field, where the members of the group rest unconformably upon the massive shale and limestone of the Mississippian, and in many cases are unconformable with regard to each other.

In the northern part of the field the aggregate thickness decreases to 950 feet. Coal is not known to occur in this division.

Canyon division.—This group is composed chiefly of limestone and shale, with local beds of sandstone and conglomerate. The thicker beds of limestone occur near the base and in the upper part of the series. The limestones are generally thick or massive and hard, making escarpments or outcropping in prominent ledges. In the northern part of the field the group contains twelve separate members of limestone and shale and one conglomerate, making an aggregate in all of 800 feet of strata. Unlike the Strawn, this division increases in thickness northward. In the northern part of the field it contains 930 feet of strata. No coal is reported to occur in these rocks.

Cisco division.—There are nineteen different members of this group, each of which is found to be variable in lithologic nature. Some of the members contain limestone, shale, coal, and sandstone, and several contain conglomerate, while a few are composed almost entirely of limestone and shale. Throughout the section there are not fewer than twenty separate beds of limestone, which are usually thin. The shale as a whole is much thicker than all the other strata together, and the whole group aggregates about 800 feet from end to end of the field.

Several of the members which contain conglomerate rest upon eroded surfaces of lower beds and in some instances have been found to overlap and displace beds of coal. The heterogeneous nature of this group of strata indicates many repeated changes in sedimentation. Several thin beds of coal have been recognized near the top and in the lower middle part of the group, besides two beds of workable thickness. These workable beds occur 200 and 300 feet above the base of the division.

Albany division.—The class of sediments making this group is generally a repetition of that found in the Canyon division. They are thick beds of limestone generally separated by shaly members.

According to Mr. Cummins's report the Albany division thins northward from 1,180 feet at the south end of the field to zero on the Brazos River.

It contains two shaly members which bear thin coal strata, none of which, however, have been found to exceed a few inches in thickness.

This group is succeeded by the Permian, which overlaps upon the Cisco division between Brazos and Red rivers.

^a Cummins, W. F., Report on the geology of northwestern Texas: Second Ann. Rept. Texas Geol. Survey, 1890.

According to Cummins,¹⁹⁹ later studies have shown that the beds to which the name "Albany" formation was applied are the same as the Wichita formation, with which they are stratigraphically continuous, the "Albany" being simply deposits in deeper water.

I 16. ALABAMA.

Plant remains, probably of Pennsylvanian age, are recorded by Smith⁷⁴⁷ from the metamorphosed rocks near Moseley (now Erin), Clay County, Ala., which have heretofore been regarded as a part of the Ocoee group of Safford. (See Chapter III, p. 88.)

I-J 16, J-K 17-18. APPALACHIAN COAL FIELD.

The following statement on the Appalachian coal field was prepared for this work in 1910 by David White:

GENERAL FEATURES OF THE PENNSYLVANIAN IN THE APPALACHIAN PROVINCE.

Conditions of deposition.—The Pennsylvanian (upper Carboniferous) rocks of the Appalachian trough or province lie unconformably upon a portion of the eroded and somewhat warped Mississippian surface. The initial invasion of the old basin by the Pennsylvanian sea formed a relatively narrow and elongated estuary extending from the southern anthracite field in Pennsylvania southwestward along or near the eastern margin of the central and southern Appalachian coal fields⁸⁹⁸ to the Gulf region in southern Tennessee or northern Alabama, where, becoming confluent with the eastern interior lobe, it opened into the broader sea to the southwest.

Later the basin expanded both to the north and the west, broadening out in these directions to and beyond the limits of the present coal fields. There was, therefore, encroachment of the sea on the land and overlapping of the terranes during at least the earlier divisions of Pennsylvanian time. Nearly everywhere the Pennsylvanian-Mississippian contact exhibits sharply contrasting sediments, though at a few points, such as the Bluestone section¹²³ in southwestern Virginia, there is an absence of conglomerates and a less abrupt change in the rock-forming material. Along the eastern portion of the basin the Pennsylvanian deposits lie on the Mauch Chunk formation (regarded as of Chester age); but farther northwest they are found resting basetwise on rocks nearly if not quite as old as the Pocono. Farther along the western margin of the bituminous coal field they come into contact with the Cuyahoga shale, Logan formation, Blackhand formation, and Maxville limestone.^{39e} Yet there is a remarkable absence of local topographic relief, the Mississippian floor having been apparently a base-level coastal plain over most of the area.

Character of sediments.—The rock-forming materials are mainly terrigenous, brought down by rivers chiefly from eastward lands, which were probably the site of nearly continuous though variable epeirogenic action. Consequently the formations are in general thicker and more arenaceous toward the east side of the basin. The greatest thickening is toward the southeast, where at the edge of the Cretaceous overlap in Alabama the Pottsville, or lower division, probably exceeded 7,500 feet. Marine or brackish-water faunas, extending over wide areas, occur at numerous stages except in the later Pennsylvanian, thus showing frequent accessibility to marine life, though the conditions of sedimentation in the Appalachian trough were generally less favorable for open-water marine Mollusca than in the eastern interior arm. The subsidence kept, on the whole, relatively close pace with loading, so that, though the warping was unequal, there is slight evidence of the contemporaneous formation of new basins as the result of the orogenic changes.

General structure.—In the western portion of the basin the beds lie nearly horizontal, but toward the eastern margin—that is, the eastern escarpment—of the bituminous regions, open folds with more marked anticlines were developed, from some of which the Pennsylvanian

is largely or wholly eroded, and still farther east the folding was closer, with concomitant faulting, usually overthrusting, as in the anthracite and eastern Alabama regions. The folds dating from the great post-Paleozoic movement conform in system to those in the older rocks to the east and the principal faults are similarly northwestward overthrusts. The high elevation and consequent erosion of large areas of the closer folded basins, in the northern portion of the trough, resulted in the isolation of the anthracite and Broad Top fields in Pennsylvania and the Potomac and upper Cheat basins of Maryland and West Virginia. Similar detachments are seen in the southern Appalachian region.

DIVISIONS OF THE PENNSYLVANIAN IN THE APPALACHIAN TROUGH.

Pottsville group.—The Pennsylvanian of the Appalachian trough is, as a whole, divided into subdivisions which in practical application have the value of groups, although in the northwestern areas they are mapped as formations. Of these the Pottsville, or lower group, occupies the early narrow estuary, but the later divisions extend over the greater part of the Pennsylvanian overlap. The Pottsville, like the succeeding formations, is composed of sandstones, shales, and clays (including fire clays, coals, and limestones), but it contains a larger proportion of sandstones and arenaceous shales than the later formations. This is a natural result of the conditions of encroachment and rapid filling under which it was laid down. The Pottsville is thickest in the southern exposures, where, near the eastern outcrops, it probably exceeds 7,500 feet. In the northwestern bituminous area, partly as the result of less voluminous sediment, partly by reason of the absence of all but the latest members of the group, it measures locally less than 200 feet. The older divisions of the Pottsville—that is, those within the earlier limits of the Pennsylvanian sea—occur only (1) in the southern Appalachian area, (2) along the eastern border of the coal field in the central Appalachian region, and (3) in the southern and middle anthracite fields of Pennsylvania.

Marine conditions, attested by the presence of marine Mollusca, were present at a number of stages in Pottsville time, particularly in the central and southern Appalachian regions, though limestone is extremely rare except in the upper Pottsville of the central Appalachian region, and in the Mercer shale member, in the upper part of the Pottsville in the northern bituminous areas. The Pottsville contains all the workable coals south of the Kentucky-Tennessee State line. Subdivisions of the Pottsville and their characters will be cited on a later page in connection with the discussion of the map units.

Allegheny formation.—The Allegheny, next succeeding the Pottsville, is a thin formation characterized by a larger proportion of coal, shale, limestone, and iron ore. Like those of the Pottsville, its sediments are generally grayish or whitish, though they are more apt to be somewhat ferruginous. Red beds are absent except possibly in northeastern Kentucky. Its limestones, several in number, are distinctly marine, though relatively thin, and may be traced continuously over large areas. In the bituminous districts, where it is sometimes known as the "Lower Productive Coal Measures" ("XIII"), the Allegheny ranges generally between 250 and 350 feet in thickness near the northern outcrop, though it thins southwestward to 160 feet in northeastern Kentucky. It is also greatly thinned in the bottom of the broad syncline of the main coal field. The Allegheny appears to have been completely eroded from the region south of the Kentucky-Tennessee line, but it is possible that the sandstones tipping the summits of several of the highest mountains in the coal field of northern Tennessee may represent its basal terranes.

Conemaugh formation.—The Conemaugh, which succeeds the Allegheny, is generally marked at its base by sandstone or conglomerate. It is especially characterized by sandstones, shales, and limestones, intermingled, particularly in the western area, with red and green shales, clays, and sandstones. It contains less coal than any of the other Pennsylvanian formations of the Appalachian trough, and in most of the earlier reports of the Pennsylvania and Virginia State surveys it was consequently known as the "Lower Barren Measures" ("XIV"). A thin limestone known as the Ames (or "Crinoidal") limestone member, which occurs near the middle of the Conemaugh formation, is locally present over large portions of the field, and

was formerly supposed to contain the last representatives of distinctly marine Mollusca in the Appalachian trough, but recent discoveries indicate marine conditions at a level somewhat higher. Not far from the horizon of the Ames member there have been found reptilian bones allied to early representatives of the group characteristic in general of the Permian. They may be regarded as forerunners of the Permian fauna.

All sediments of Conemaugh or later age appear to have been removed from the portion of the Appalachian trough south of northeastern Kentucky, though the presence of the marine Mollusca implies continuity of these sediments down the basin to connect with the open sea.

Monongahela formation.—The Monongahela is distinguished by its relatively large proportion of coal and limestone, the latter composing over one-third of the sediments in some districts. The formation, as stratigraphically recognized in Pennsylvania, Ohio, western Maryland, and West Virginia, averages about 325 feet or less in thickness. Its coals, including the great Pittsburg coal at its base, are of notable thickness and value. As with the Conemaugh, red sediments become more prominent toward the south and its limestones, generally blue and in places containing "fresh-water" Mollusca, thin and disappear in the same direction.

The Monongahela and the Conemaugh are not fully differentiated in the anthracite regions.

Dunkard group.—The Dunkard group, which succeeds the Monongahela and which in lithologic characters and mineral content does not differ notably from that formation, is discussed in Chapter XI (pp. 492–494). The reference of its lower portion (below the Washington coal) to the Permian is not wholly beyond question.

DETAILED DISCUSSION OF FORMATIONS.

The composition and stratigraphy of the several formations of the Appalachian trough will now be considered. In order to give precedence to the series and regions more thoroughly known, the geographic order of treatment will be from north to south. Proceeding thus, we shall begin at the northwest border of the Pennsylvanian trough, encountering first the younger formations in the regions of late Pottsville overlap. Subsequently, working eastward and southward, we shall reach the thicker developments of the formations and the minor areas of the oldest formations lying along or near the earlier axis of the basin.

OHIO AND PENNSYLVANIA.

General features.—Map sections K 17 and K 18 include the north end of the great bituminous coal field in Ohio and Pennsylvania, several small isolated residual areas to the northeast, the Broad Top field, and the anthracite region. With the exception of the anthracite fields the coal measures of this strip are a unit not only in the classification applied but also as to essential continuity and parallelism of the strata.

The great bituminous coal field of these States forms a part of a plateau correlated with the Cretaceous or later base-leveling and subsequent elevation. Toward the north and west the strata, rising more rapidly than the plateau surface, outcrop diagonally and are cut by erosion into an intricate fringe of irregular lobes, tongues, and isolated patches that it is impracticable to indicate on the map scale. The eastern border of the plateau coal field is defined by the stronger anticlines to which reference has already been made.

The Broad Top coal field in Huntingdon, Fulton, and Bedford counties, in southern Pennsylvania, is a small remnant in a deep compound fold, in the region of close plication. In general the alteration of the coals increases toward the regions of greater thrust pressure; and so from ordinary domestic and gas fuels we pass through coking and steam coals to semi-bituminous coals at the eastern escarpment (Allegheny Front) of the great plateau field and in the Broad Top field. Small residual areas of semianthracite in Wyoming and Sullivan counties survive in other very shallow folds between the plateau and anthracite regions.

The anthracite fields, three in number, in eastern Pennsylvania, consist of a group of residual troughs lying in northeast-southwest synclines. The structure is very complex, the strata being locally overturned, especially toward the southern edge of the region, while subordinate folds connect many of the synclines in varying degrees.^{795c}

It will be seen that the eastward-increasing amplitude of the folds results in erosion of the Pennsylvanian from a number of the anticlines within the plateau region. The most prominent of these are known as the Deer Park, Laurel Hill, and Chestnut Ridge anticlines. The intervening folds have been described as First, Second, and Third bituminous basins, etc., or synonymously designated by geographic terms.^a

A radius from the border of the plateau coal field to the southwest corner of Pennsylvania spans a section extending from a point at or near the base of the upper Pottsville to the top of the Pennsylvanian as at present somewhat conventionally drawn. The middle and lower Pottsville are not encountered, as the entire upper Carboniferous area of Pennsylvania, outside of the anthracite fields, together with the whole of the Ohio Pennsylvanian, falls in the region of extension and overlap of the later Pottsville sea. The lower divisions are, however, present at the type locality, Pottsville, in the southern anthracite field.

The terranes of the several sections throughout Ohio and Pennsylvania have received careful consideration and correlation by E. V. d'Inwilliers^{285b} and J. J. Stevenson,^{795a} who give full details or citations. The original data relating to the bituminous area will for the most part be found in the "Geology of Pennsylvania," by H. D. Rogers, 1858; in the county reports of the Second Geological Survey of Pennsylvania; in the reports of the Ohio Survey (especially volume 6 and Bulletin 9); in the following folios issued by the United States Geological Survey: Warren, Foxburg-Clarion, Beaver, Kittanning, Rural Valley, Elders Ridge, Indiana, Latrobe, Ebensburg, Johnstown, Amity, Sewickley, Brownsville-Connellsville, Rogersville, Waynesburg, Masontown-Uniontown, and Huntington; in United States Geological Survey Bulletins 65, 279, 304, 318, and 349; and in the report of the Topographic and Geological Survey Commission of Pennsylvania for 1906-1908.

Pottsville group.—The Pottsville group, earlier known as "Conglomerate series," "Pottsville conglomerate" ("XII"), and "New River series," forms the lowest division of the Pennsylvanian. As the basal and conglomeratic stage of the "Seral," the last of the ideal time divisions proposed by the brothers Rogers⁶⁷⁴ for the Paleozoic in America, it was earlier called the "Seral conglomerate." It has sometimes been roughly correlated with the Millstone grit of Great Britain, though on the paleobotanic evidence it appears that the upper Pottsville is to be correlated with the middle Coal Measures of the United Kingdom.

The Pottsville as a whole is the most natural of the Appalachian upper Carboniferous subdivisions, for it represents the first or main epoch of sea transgression in the cycle of Pennsylvanian sedimentation. In his characterization of the Pottsville I. C. White^{905c} points out the strong contrast which it presents to the red and greenish softer sediments below it, and to the softer, generally more argillaceous, terranes above it.

"The series as a whole possesses a large amount of hard white or grayish sandstone, much of which is conglomeratic. The sandstones are harder, more compact, and siliceous; than any of the lower coal series above. Boulders of this sandstone take a smooth polish when rolled along river beds, but this is not the case with most sandrocks above this."

On account not only of the highly variable thickness of the different component terranes but also of the absence of one or more of them in different regions it is difficult to give a generalized section of much value. The following regional section in Mercer County, Pa., near the Ohio line, prepared by I. C. White,⁹⁰⁴ is fairly typical of the upper Pottsville in Ohio, Maryland, and western Pennsylvania; and though of unusual thickness (301 feet) it is especially important on account of its location at or near the type localities for most of its members. The bracketed matter is added by the present writer.

^a For description of structure, anticlines, and basins, see Summary Final Rept. Second Geol. Survey Pennsylvania, vol. 3; Bull. U. S. Geol. Survey No. 65; Ohio Geol. Survey, Rept. V; West Virginia Geol. Survey, vols. 2 and 2A; Maryland Geol. Survey, vol. 5, p. 260. For the anthracite regions see Second Geol. Survey Pennsylvania, mine maps in Atlas of anthracite region, and Reports of progress A and AA; also Rogers, H. D., Geology of Pennsylvania, 2 vols., 1858.

Section in Mercer County, Pa.

	Feet.
1. Homewood sandstone ["Tionesta," "Johnson Run," and "Piedmont"].....	50
2. Shales.....	5
3. Iron ore [in western Pennsylvania and across the southeru Ohio line into northeastern Kentucky].....	2
4. Mercer upper limestone [marine fossils].....	2½
5. Mercer upper coal [place of Mount Savage coal and fire clays in Pennsylvania and Maryland].....	2½
6. Shales [locally in northern Pennsylvania inclosing a "Middle Alton" coal].....	25
7. Iron ore [somewhat more persistent than No. 3, over much the same areas].....	2
8. Mercer lower limestone [marine Mollusca; more persistent than the Upper Mercer limestone but disappearing eastward].....	2½
9. Shales.....	10
10. Mercer lower coal.....	2½
11. Shales.....	10
12. Iron ore.....	1
13. Shales.....	5
14. Connoquenessing upper sandstone ["Massillon" sandstone in part; present in nearly all sections].....	40
15. Shales with iron ore.....	10
16. Quakertown coal [generally recognized].....	2
17. Shales [in places lacking].....	40
18. Connoquenessing lower sandstone [lacking in portions of the Allegheny Valley, locally along the Allegheny Front, and in some of the small northeastern residual areas; "Massillon" sandstone in part].....	30
19. Sharon iron shales [locally including a thin "Upper Sharon" coal].....	30
20. Sharon coal.....	4
21. Fire clay and shales.....	5
22. Sharon conglomerate [usually conglomerate, at least in part, and extremely variable in thickness or absent entirely; perhaps equals the Olean conglomerate of McKean and Warren counties, Pa.; usually lacking together with Nos. 19 to 21, where No. 18 is deficient].....	20
Contact with Mississippian.....	301

The average thickness of this part of the Pottsville in the bituminous regions of K 17 and K 18 is less than 250 feet. As might be expected in a region of encroachment and overlap, the lower members are in places lacking. This lack is especially noticeable along portions of the northern border of the field in Ohio and Pennsylvania; but it is also evident locally in the interior regions, especially in the areas east of Allegheny River, in the Allegheny Front, and in the Broad Top field. It is not recognized beneath the deeper portions of the main basal syncline.

The Homewood sandstone member, like the others, is highly variable, being in some places represented only by a few feet of shales. The limestones and coals are likewise subject to disappearance, the limestones being rarely represented near the eastern escarpment. The coals are all workable at one point or another.

For the upper Pottsville in the region under consideration, as described above, I. C. White^{907a} has recently revived Lesley's term Beaver River group, though excluding therefrom the Sharon conglomerate member, which was shown by Chance and D'Invilliers to be of Pennsylvanian age.

Allegheny formation.—The Allegheny, as differentiated in 1875^a by Franklin Platt,⁶³⁷ is a formation whose limitation is largely dictated by convenience. It embraces the softer sediments of more quiescent waters intervening between the arenaceous invading Pottsville and the Mahoning and other sandstone and shale members of the overlying Conemaugh formation, or "Lower Barren Measures." It is remarkable for its good coals, on account of which it was for a time known as the "Lower Productive Measures," No. XIII of Lesley. As compared with the Pottsville the members of the Allegheny are relatively regular and continuous, and the occurrence in them of marine Mollusca is comparatively common.

The principal members of the Allegheny formation, which in the bituminous regions does not usually exceed 300 feet in thickness, are as follows:

^a For other earlier and abandoned classifications see Stevenson, J. J., Bull. Geol. Soc. America, vol. 17, 1906, pp. 65-69.

1. Upper Freeport coal; persistent over most of the area of the formation and workable in many districts.
2. Upper Freeport limestone member; thin but widely persistent with fossils reported as "fresh-water" in some areas, "marine" in others; accompanied, especially in portions of Westmoreland and Fayette counties, in western Pennsylvania, and in Jefferson and Muskingum counties, Ohio, by the Bolivar clay member.
3. Butler ("Upper Freeport") sandstone member; highly variable in thickness, or even lacking, being replaced by shales.
4. Lower Freeport coal; widely persistent and locally very valuable.
5. Lower Freeport limestone member; usually thin and more or less earthy, with fossils regarded as indicating fresh-water conditions; here and there associated with iron deposits.
6. Freeport sandstone member ("Lower Freeport sandstone"); white and in places conglomeratic, usually 30 to 50 feet or more in thickness; locally a sandy shale.
7. Upper Kittanning coal (Cement coal); usually present, though variable, and of little importance except in the eastern portion of plateau; rarely recognized in Ohio; carries local cannel near Redbank Creek and in Beaver, Clearfield, and Indiana counties, Pa.
8. Johnstown limestone member; 1 to 8 feet, magnesian limestone lying 2 to 5 feet beneath the preceding coal, but not found in the western tier of Pennsylvania counties or in Ohio.
9. Middle Kittanning coal; important as the "Hocking Valley" coal of Ohio, where it is locally roofed by black shale with marine fossils; widespread, with rare cannel, in Pennsylvania, but unimportant except near the Ohio line.
10. Lower Kittanning coal; very persistent, nearly everywhere; valuable, especially toward the Allegheny Front, also workable in parts of Ohio.
11. Lower Kittanning clay; valuable, 5 to 15 feet thick west of Allegheny River and passing through Ohio, where it touches the Vanport limestone member; locally, especially at the east, replaced by thick shales or sandstones.
12. Kittanning sandstone member ("Lower Kittanning sandstone"); local only, chiefly in Butler County, Pa., where it is massive and conglomeratic; 50 feet or more in thickness.
13. Buhrstone iron ore; 6 inches to 20 feet thick, highly variable, usually cherty at base, underlain by Vanport limestone member; important in southern Ohio but less regular and persistent east of western counties of Pennsylvania.
14. Vanport limestone member; familiar as the "Ferriferous limestone;" marine, with rich fauna,⁹⁰³ unknown in the First and Second bituminous basins (east of the Chestnut Ridge anticline) in Pennsylvania; 5 to 20 feet thick in western counties north of Kiskiminitas River; locally present in Ohio, especially toward the south, where it is fairly persistent.
15. Clarion coal; generally unimportant and less persistent; apparently lacking in considerable areas; a supposed split of this coal, the "Scrubgrass" or "Upper Clarion" coal, occurs about 10 to 15 feet higher and less than 10 feet below the limestone in portions of western Pennsylvania and over much of Ohio.
16. Clarion sandstone member; locally massive and thick, especially in southern Ohio, and fairly persistent, though usually insignificant.
17. Brookville coal; very persistent; recognized in many deep borings beneath the Monongahela formation; usually separated only by its underclay from the Homewood sandstone member of the Pottsville formation; in portions of Ohio a thin marine limestone, known in the Ohio State reports as the Putnam Hill limestone, overlies a coal correlated by Orton⁶²¹ and Stevenson^{796c} with the Brookville, but it is probable that both limestone and coal are of Mercer age (Pottsville).^{39d}

Considering the large territory covered, the members of the Allegheny are more regular and persistent than those of either of the contiguous formations. I. C. White,⁹⁰⁶ confirming the conclusions of the late Edward Orton, State geologist of Ohio, remarks that "all of the main strata in the Allegheny series of western Pennsylvania can be traced bodily across that State [Ohio] from where they enter it in Columbiana County to where they leave it to enter Kentucky from Lawrence County, 250 miles from the Ohio-Pennsylvania boundary. In this intervening distance some of the coal beds may change in thickness or disappear entirely over areas of considerable size, but they ultimately come into the section again, so that the integrity of the persistent beds of the Allegheny series in Pennsylvania is maintained entirely across the State, and this is true, not only of the coal beds, but also of the limestones, sandstones, fire clays, and even the iron ores, so that a section in Lawrence County is practically a duplicate of one in Columbiana."

The Allegheny, which in northern Pennsylvania reaches a maximum thickness of a little over 300 feet and is in few places less than 250 feet, is thinner in the Broad Top field and thins to less than 250 feet in southwestern Ohio, while in the Kenova quadrangle, in northeastern Kentucky, it declines to about 170 feet. Several of its members are attenuated or lacking beneath the higher formations in the axis of the broad bituminous syncline. The local details given with great care in the Ohio and Pennsylvania county reports, cited in the general description (p. 431), are summarized in the final report of the Second Pennsylvania Geological

Survey,^{285a} and the identifications of the members have been critically reviewed and revised by I. C. White^{905e} and J. J. Stevenson.^{796a} The variation in the sections and the introduction of local coals are discussed by Ashley.³⁹⁰ The correlations in the Broad Top field are fully considered by Stevenson.^{796f}

Conemaugh formation.—The Conemaugh as defined by Franklin Platt,⁶³⁷ in the Conemaugh River section of Pennsylvania, includes a series, generally less than 600 feet in thickness, lying between the Allegheny or “Lower Productive Coal Measures” (“XIII”), and the Monongahela, or “Upper Productive Coal Measures” (“XV”). On account of its relative deficiency in coals and economic limestones or iron ores it has been known as or included in the “Lower Barren Measures” also called “Elk River series”^{905b} and “No. XIV.”^{796b}

The numerous sections given in the Ohio and Pennsylvania reports, or cited by I. C. White^{905c} and G. H. Ashley,³⁹ show a lack of regularity far exceeding that of the members of the Pottsville. Not only do the component terranes vary greatly in thickness but in many places they are absent; yet several of the individual members are of great persistence. The principal members of the Conemaugh formation which have been described from different areas^{607, 736} are, in descending order:

1. *Upper Pittsburg limestone member*; just under Pittsburg coal; one to several thin, in places brecciated limestones, containing minute univalve mollusks in a variable interval averaging about 25 feet; in Fayette County, Pa., locally replaced by iron ores.
2. *Little Pittsburg coal*; a widespread coal-bearing zone, rather than a single coal, 20 to 60 feet below the top of the formation; locally associated with two limestones, one (“Upper Pittsburg limestone”) 3 to 5 feet thick, above, and the other (Lower Pittsburg limestone member) 8 to 10 feet thick, below the coal horizon.
3. *Connellsville sandstone member*; massive, conglomeratic, about 20 feet or more in thickness, largely confined to the Connellsville region of Pennsylvania and the Potomac basin of Maryland and West Virginia.
4. *Little Clarksburg coal*; 100 to 130 feet below the top of the formation; confined to southern Pennsylvania and northwestern West Virginia; directly underlain in latter region by the Clarksburg limestone member, which is impure, with ostracods and fish, and attains a local thickness of 20 to 30 feet.
5. *Morgantown sandstone member*; yellowish-gray mealy sandstone, 20 to 100 feet thick, locally conglomeratic or brecciated; 200 feet below top of Conemaugh at Morgantown, W. Va.; generally persistent in Pennsylvania, Maryland, and West Virginia.
6. *Elk Lick coal*; close under No. 5, widely persistent and usually present in Pennsylvania, Maryland, Ohio, and northern West Virginia, and locally workable to the east; surmounts the Elk Lick limestone member, 12 feet thick, in Somerset County, Pa.
7. *Ames (“Crinoidal”) limestone member*; very thin bed nearly midway in Conemaugh, generally 275 to 300 feet below top in most of Pennsylvania, 200 feet below on the Ohio at Wellsburg, the interval decreasing westward to 140 feet, though swelling to 300 feet at the southern outcrop in Ohio,^{905d} dark-bluish or greenish-gray tough siliceous granular limestone, usually 3 to 5 feet thick; present or represented by marine calcareous shell-bearing shales nearly everywhere except in northeastern portion of the Plateau region; a series of red clays, sandstones, and marls, the “Washington Reds,” of variable thickness and color, lies above it; the limestone is rich in marine brachiopods and pelecypods; “its common fossils are *Productus nebrascensis*, *P. prattenianus*, *P. longispinus*, *P. semireticulatus*, *Hemipronites crassus*, *Spirifera camerata*, *S. plano-conveza*, *Athyris subtilita*, *Lophophyllum proliferum*, *Zearcinus mucrospinus*, together with undetermined plates and stems of crinoids.”
8. *Harlem (“Friendsville” or “Crinoidal”) coal*; thin and less persistent, immediately under Ames limestone member; present in most of outcrops in Ohio and western Pennsylvania, but rare near Allegheny Front.
9. “Pittsburg Reds;” mainly soft or variegated shale and marly clays in thick variable series under No. 8; less in evidence toward the northeastern and northwestern borders of the Conemaugh area; incloses a bluish fossiliferous limestone (the Ewing limestone of Ohio State reports) over much of the Ohio area.
10. *Saltsburg sandstone member*; massive (20 to 60 feet); in places absent; probably same as Cow Run sand of southeastern Ohio; underlain by thin shale and local dark or gray limestone.
11. *Bakerstown coal*; “Tyson” coal of Maryland, correlated by Stevenson with the Barton coal; fairly persistent in southern Pennsylvania but rarely identified in Ohio; locally important in Maryland and West Virginia.
12. *Upper Cambridge (“Pine Creek”) limestone member*; typical in Noble County and southward in Ohio; thin and local in southwestern Pennsylvania.
13. *Anderson coal*; unimportant; fairly persistent through Ohio and northern West Virginia but disappearing a short distance east of the Pennsylvania State line.
14. *Buffalo sandstone member*; correlated with the Saltsburg by Stevenson; locally a conglomerate, 60 feet thick on Kiskiminitas River; generally persistent, 30 to 50 feet thick, though thinner on northern and eastern sides of basin; less important though locally coarse on west through Ohio.
15. *Lower Cambridge (“Brush Creek”) limestone member*; thin, black, fossiliferous, 30 to 60 feet below No. 13; generally present in Pennsylvania but disappears to west and south in Ohio.

16. Brush Creek coal; Masontown coal in part; unusually persistent though generally unimportant in Broad Top field, through Pennsylvania, and largely in outcrops through Ohio; "Gallitzin" coal of the eastern side; multiple in division, with interbedded limestones.^{39b}

17. Mahoning limestone member; developed in eastern part of plateau field and locally associated with iron ore (Johnstown iron ore).

18. Mahoning sandstone member. Includes: (a) Upper sandstone, in places massive and conglomeratic; said to be fairly persistent through much of Conemaugh exposure on east side of basin, but generally lacking on west; separated from lower sandstone of the Mahoning member by highly variable shale interval with coal. (b) Mahoning coal; locally present with clays in western Pennsylvania. (c) Lower sandstone; generally persistent through Conemaugh area, and in places conglomeratic though locally obscure or lacking; is here and there the basal member of the formation, resting directly on the Upper Freeport coal, the topmost member of the Allegheny formation.

19. Uffington shale member; thin, local only, and crowded with marine invertebrates near Morgantown, W. Va. (Contact with Upper Freeport coal.)

The Conemaugh formation occupies, naturally, a relatively small area. It reaches a thickness of over 700 feet near Monongahela River and in Maryland. Along the northerly outcrop it averages not over 600 feet, and to the west and south in Ohio it falls off to 300 feet or less. Coals in unusual number and thickness were developed in the Castleman basin, in southern Somerset County, Pa., and in Maryland.

Broadly viewed, the Conemaugh is an arbitrarily limited and highly variable formation, largely sandstone or even conglomeratic in its lower portion, with much red and green clay material and marls in its middle, and more sandstones, locally conglomeratic, in the upper part, which was locally eroded before the deposition of the succeeding Monongahela formation.

The last, so far as at present known, of the strictly marine invertebrate faunas occurs not far above the Ames limestone member (No. 7 of preceding list), perhaps the most widely extended of the distinctly marine members.^a According to the fossil floras, the writer is inclined to draw the Westphalian-Stephanian boundary provisionally at or close above the top of the Allegheny formation, the Mahoning sandstone member being interpreted as showing the beginning of a more pronounced orogenic movement which seems gradually to have brought about the final exclusion of the sea. On the other hand, I. C. White,^{907j} citing (1) the discovery by Dr. P. E. Raymond, in the "Pittsburg Reds" (No. 9 of list) at Pitcairn, Pa., of the reptilian genera *Eryops*, *Desmatodon*, and *Naosaurus*, closely allied to types regarded as Permian,¹³⁰ (2) a fossil obtained near the horizon of the Ames limestone member near Salt Lick Bridge in Braxton County, W. Va., regarded as the tibia of a large reptile; (3) the Permian aspect, according to Scudder, of the insects from about the same horizon near Steubenville, Ohio; and (4) the introduction of red sediments,^b argues for the reference of all the beds above the Buffalo sandstone member (No. 15) to the Permian. The evidence both of plants and of mollusks is distinctly contrary to this proposed correlation. The upper boundary of the Conemaugh is not yet drawn in the anthracite regions.

Monongahela formation.—The Monongahela formation, or "Upper Productive Coal Measures" (XV of Rogers), is the highest of the Pennsylvanian formations in the Appalachian trough. In K 17 and K 18 it occupies a small area in the bituminous regions, being for the most part confined to the deeper portion of the basin^{285c} in southwestern Pennsylvania and eastern Ohio.^c East of the Chestnut Ridge anticline in Westmoreland County, Pa., it appears only in very small residual areas in the Ligonier Valley and it is represented partly also in the Broad Top and Castleman basins. It is fully present in minor areas in the Potomac basin of Maryland and West Virginia.

The Monongahela as defined by I. C. White⁹⁰⁵ begins with the great Pittsburg coal and extends to the roof of the Waynesburg coal, comprising another somewhat arbitrarily differentiated division of the Pennsylvanian. The upper part of the Waynesburg coal contains *Tæniopteris*, *Equisetites*, *Baiera*, and *Saportæa*, of Permian relations, while, as stated in the

^a At several points local deposits of red material occur as low as the top of the lower sandstone of the Mahoning member.

^b Red beds are stated by Dr. J. J. Stevenson^{796e} to be present in the upper part of the Allegheny in northeastern Kentucky. See also Phalen, W. C., Bull. U. S. Geol. Survey No. 349, 1908.

^c For areas of formations and individual coals see Geol. Survey Ohio, Repts. V and VI, Bull. No. 9, 4th ser.

description of the Dunkard group in Chapter XI (pp. 492-494), the beds of the Dunkard above the Washington coal carry plants undoubtedly indicative of lower Permian age. I. C. White⁹⁰⁷ⁱ regards the earlier Monongahela, together with the upper half of the Conemaugh, as representing the closing stage of the Permo-Carboniferous, connecting the latter with the base of the true Permian. No paleobotanic or invertebrate evidence justifying a reference of the Monongahela to the Permian has yet been found. It is regarded by the writer^{4a, 899, 897} as of Stephanian age. The black shales of the Monongahela contain fish fragments, largely unstudied, while the limestones present abundant Cyprian and Estherian types, generally regarded as of fresh-water origin.

In the vicinity of Carnegie, Pa., a local unconformity occurs at the base of the formation, the topmost Conemaugh being eroded.^{39a} The formation, which is variable in character, contains much limestone and coal. The section at the Lambert shaft in Fayette County, Pa., was found by I. C. White^{907c} to contain 44 feet of carbonaceous shale and coals and 202 feet of limestone, out of a total thickness of 388 feet for the entire series. There is relatively little red material in areas K 17 and K 18, though the limestones turn to shale and sandstone with great increase of red and green sediments in passing southward into J 17. The Monongahela reaches its greatest thickness, over 400 feet, in central West Virginia, averages about 380 feet along Monongahela River in southwestern Pennsylvania, is 240 to 270 feet in the Maryland district, is incomplete in the Broad Top field, and thins to about 260 feet along the Ohio River boundary and to about 140 feet at its farthest northwest occurrence in Jefferson County, Ohio. Its composition in the type district is indicated by the following general section in Fayette and Westmoreland counties, Pa., compiled by J. J. Stevenson.^{793, 905a} The annotations in brackets are taken chiefly from another paper by Stevenson.⁷⁹⁷

Section of Monongahela formation in Fayette and Westmoreland counties, Pa.

	Feet.
1. Waynesburg coal [fairly persistent in northern part of great bituminous field and on west, but locally absent in south and east; sometimes replaced by limestone breccia or iron].....	6
2. Sandy shale or sandstone [Browntown sandstone]; hard, gray, massive, in Harrison County, W. Va.....	20
3. Little Waynesburg coal [thin, apparently confined to southwestern Pennsylvania and northern West Virginia].....	2
4. Waynesburg limestone [recognized generally in the Monongahela River valley of southwestern Pennsylvania and possibly in Broad Top field, but rarely in Ohio; usually over 8 feet thick, but fades entirely to the south in West Virginia].....	20
5. Uniontown sandstone [coarse, gray, locally occupying interval in southwestern Pennsylvania, massive and conglomeratic in portions of the West Virginia area, shale in other regions].....	50
6. Uniontown coal [unusually persistent as coal or black shale, in Maryland, southwestern Pennsylvania, and West Virginia, even in deeper bore holes, though apparently patchy northward in Ohio; near type locality, Fayette County, it underlies a thin limestone with pelecypods].....	3
7. Uniontown limestone [generally persistent, 2 to 12 feet thick, in Pennsylvania and most of Ohio and West Virginia, though not noted in some drillings on west side of basin; 160 feet above Pittsburg coal in Salisbury basin (Somerset County, Pa.)].....	12
8. Sandstone [interval appears to change to "Tyler red beds" and "Ritchie red beds" of northwestern West Virginia].....	30
9. Great limestone [later designated Benwood limestone; thin along northern outcrop, lacking in portions of southwestern Pennsylvania; thickest (60 to 90 feet) in parts of Fayette and Westmoreland counties; replaced by shale and sandstone locally; patchy and broken by partings in northern part of Ohio area, fading to sandstone and shale to south in Ohio and West Virginia; includes Bulger and Dinsmore limestones].....	80
10. Sewickley sandstone [local, though massive or even double].....	30
11. Sewickley coal [Meigs Creek of Ohio; important and widely persistent, about 100 feet above base of series, in Maryland, Pennsylvania, Ohio, and most of West Virginia].....	3
12. Fishpot limestone [same as "Sewickley" limestone of Stevenson; gray limestone, variable to 30 feet in thickness; absent east and south of area in southwestern Pennsylvania, northern Ohio, and northern West Virginia, as well as from much of deep interior of basin; fades to shale and sandstone to south; has "fresh-water" shells].....	25
13. Shale or shaly sandstone.....	20

	Feet.
14. Redstone coal ["Pomeroy" coal of Ohio; very persistent, 50 to 70 feet below Sewickley coal; 30 to 80 feet above base of series in Maryland and nearly everywhere throughout basin except around southwestern part of outcrop area, where not always recognized].....	4
15. Redstone limestone; apparently only in southern Pennsylvania and adjoining region of West Virginia and Ohio, 10 to 20 feet thick, with minute "fresh-water" fossils; thins rapidly southward in West Virginia and Ohio.....	10
16. Pittsburg sandstone (sandstone or shale) [variable, coarse, in places pebbly, generally present about borders of the basin, though abruptly disappearing locally in shale and sandstone, the Redstone limestone (No. 15) being apt to vanish where the sandstone is well developed; in many localities lies directly on the Pittsburg coal (No. 17)].....	40
17. Pittsburgh coal [most important coal; very persistent and regular; correlated in Broad Top field, the Potomac basin of Maryland, through southern Pennsylvania, the northeastern counties in West Virginia, and the northern portion of the basin in Ohio, but becoming patchy, irregular, or absent around the southwestern part of the basin in Ohio ^a and West Virginia, and apparently absent in a portion of the south-central interior of the deep basin; yet fairly regular and workable over an area of 7,000-8,000 square miles].....	12

ANTHRACITE REGION.

General features.—The position of the anthracite fields and their general relations to the Appalachian folding in eastern Pennsylvania have already been indicated (pp. 430-431). The Pennsylvanian synclines are relatively small, their combined area being about 650 square miles, of which the area of workable coal approximates but 484 square miles.^{745a} The anthracite fields have been treated with great detail and thoroughness in an elaborate series of publications for each field,^b as well as in several special reports,^c published by the Second Geological Survey of the State. The whole has been admirably condensed by A. D. W. Smith.⁷⁴⁵ More recently the general geologic relations and stratigraphy have been briefly discussed by J. J. Stevenson;^{796h} and the stratigraphic paleobotany of the southern anthracite field has been treated in an advance publication giving correlations by the writer.⁸⁹⁵

In the anthracite region the greatest thickness of the Pennsylvanian, 2,500 feet, is in the southern field; the sections do not reach to horizons as high in the middle fields. In the northern field the deepest syncline contains 1,800 feet of Pennsylvanian strata.

The Pennsylvanian of the anthracite region is divided only into the Pottsville ("Seral conglomerate") and the "Coal Measures." The latter are grouped according to "white ash" or "red ash" coals, but these divisions are local and highly variable. The paleontologic correlation of the post-Pottsville beds is incomplete and without attempt to draw definite boundaries.

The strata in the anthracite region are in general much more arenaceous than those of the bituminous series in any other part of the northern Appalachian coal field, the arenaceous character being more and more predominant as the southeastern border of the region is approached. Conversely, limestone seems to be unknown except in the northern field. The series is moderately coal bearing, there being as many as 25 coals, 20 of which are of workable thickness, in the southern anthracite field, about 15 in the western middle field, and 16 in the northern anthracite field. In the eastern end of the southern anthracite field the Mammoth bed attains the remarkable thickness of 114 feet, of which 105 feet is coal.

Pottsville group.—The Pottsville as a whole is most fully developed in the southern anthracite field. It was somewhat arbitrarily defined by the Lesley Survey as extending from the Buck Mountain coal bed, the lowest stratum of the "Coal Measures," to the top of the Mauch Chunk shale (Mississippian). In the type section, the Sharp Mountain gap at Pottsville, in which the "Twin" coal is regarded as equivalent to the Buck Mountain, the thickness as published by the writer^{895g} is very nearly 1,200 feet, though the Broad Mountain section to the

^c Repts. Progress A and AA, see also Ann. Repts. 1885, 1886, and 1887.

northwest appears to be rather thicker. The group is overwhelmingly conglomeratic, the lower beds consisting of poorly assorted, locally subangular detrital material, which varies in size not only at different localities but at a single locality,^{895a} and is interstratified with some mud beds and coals. The higher conglomerates are more exclusively quartzitic, the pebbles less variable and generally better rounded, and the top portion of the column consists of a plexus of most massive, fairly regular, well-assorted quartzose conglomeratic material, in which occur several thin coals. The group is underlain at Pottsville by 400 feet or more of irregular, poorly assorted puddingstone conglomerates, locally unconformable on brownish-red and olive-green muds, which by some authors are included in the Pottsville and which no doubt belong to the Pennsylvanian. This transitional series, which technically lies beneath the topmost stratum of red shale, the arbitrary lower boundary of the Pennsylvanian, quickly disappears in passing north. The lowermost Pennsylvanian in the southern portion of the anthracite regions (not deposited in the eastern middle and northern anthracite fields) bears some evidence of fluviatile deposition. The beds are, in general, unusually variable in thickness, and the stratigraphy of the coals shows a lack not only of parallelism but, to a certain extent, of synchronism. Consequently the correlation of the coals is far from complete or satisfactory. Little progress has been made in correlating the coals of the northern anthracite field with those of the basins to the south.

The fossil plants of the Pottsville in the type region exhibit a rapid development and series of modifications which are of high stratigraphic value. With the exception of the species from the topmost beds, the ferns are, in general, readily distinguished specifically from those at the base of the "Lower Coal Measures,"^a or Allegheny formation, as recognized in the northern United States, while the floras of the lower portions of the section are found, in passing downward, to bear still less resemblance to those of the "Lower Coal Measures." On the paleobotanic basis the type section is parted into four divisions, as follows:

1. A lower division, 700 feet in thickness, called the "Lower Lykens division"^{895b} because it includes (paleontologically) the lower group of Lykens coals (Nos. 4-6 and "0") as mined in the western portion of the field. This, the older Pottsville, includes two zones—(a) the *Neuropteris pocahontas* zone, including Lykens coals Nos. 5, 6, and "0," and contemporaneous with the Pocahontas formation (basal Pottsville) of the southwestern Virginia region^{123, 124, 126} (J 17), and (b) the *Mariopteris pottsvillea* zone, probably contemporaneous with the Quinimont formation^b of the central Appalachian region. Both are included in the time interval covered by the Lee formation, which to the south is represented, according to the fossil plants, by the Lookout sandstone and a part of the Walden sandstone in Tennessee and Alabama and which constitutes the lower Pottsville.

2. Above the "Lower Lykens division" is a relatively barren series, about 130 feet in thickness, which the writer^{895c} for temporary convenience called the "Lower Intermediate division." It contains a mixed flora and is regarded as lying at or near the horizon of the Raleigh sandstone, the topmost division of the lower Pottsville in the Virginian region, as will be explained farther on.

3. A zone of about 200 feet, extending, roughly, from 370 to 570 feet below the top of the formation, contains the floras characteristic of Lykens coals Nos. 2 and 3, farther west, and has therefore been termed by the writer^{895d} the "Upper Lykens division." It is provisionally referred to the middle Pottsville, which embraces the Sewell formation, or New River group of I. C. White,^{907a} as recently proposed by him. The latter term, as restricted, is conducive to confusion, not only because of the economic development of the lower Pottsville coals along New River, but also on account of its former application to the Pocono coals (basal Mississippian), which are likewise commercially exploited along New River.

^a "Lower Coal Measures" as sometimes applied in the anthracite fields of Pennsylvania; not the series of that name in Canada or Europe.

^b See Raleigh, Pocahontas, Tazewell, Bristol, Estillville, and Briceville folios, Geol. Atlas U. S.

4. The upper portion of the section, extending down for about 370 feet, contains for the first 200 feet some mingling of "Coal Measures" plants with species found in the "Upper Lykens division" of the Pottsville, and was therefore provisionally termed by the writer ^{895a} the "Upper Intermediate division." This division, which includes Lykens coal No. 1, belongs to the upper Pottsville or Beaver River formation.^a It will be recalled that this is the only part of the Pottsville found throughout the bituminous coal regions of K 17 and K 18, all of which falls within the region of later Pottsville overlap. In the Virginian region this upper Pottsville expands tremendously to the southeast, probably exceeding 1,500 feet in thickness and including the greater part, if not all, of the Kanawha formation in West Virginia. The paleobotanic data seem to indicate the Pottsville-Allegheny line of the bituminous fields at a coaly streak about 100 feet below the conventional top of the Pottsville in the type section, the paleobotanic boundary being inclosed in the upper part of the great plexus of conglomerates. In the more northern anthracite areas the upper conglomerate has waned and the boundary as drawn on the sheets of the Geologic Atlas generally falls on or near a coal which, so far as determined paleontologically, belongs to the Brookville-Clarion coal group.

From a thickness of over 1,400 feet in the Pottsville region of the southern anthracite field, the Pottsville, in passing to the north, thins to about 850 feet in the Mahanoy region, in the western middle field, about 400 feet in the Silver Creek basin, only a few miles to the north, in the eastern middle field; 300 feet in the vicinity of Hazleton, in the same field; and from about 250 to 163 feet, averaging about 225 feet, in the northern anthracite field.^{745b, 795d} In the western part of the western middle field the lower Pottsville^b is partly represented, though the remaining coals have thinned. It is not recognized and is probably not present in the eastern middle field, where the upper part of the middle Pottsville is thought to have a thin representative. Only the upper Pottsville ("Upper Intermediate division") appears to be present, incomplete in some sections, in the northern anthracite field, where the lowest fossiliferous stratum, at points just above the Mississippian, is not older than the Sharon shale member of the bituminous districts. Pottsville coals, such as the Dunmore coal group (Mercer age in part), are few in the northern area though workable at a number of points (Boston mine, near Pittston, etc.), where they are included in a lower "red-ash group." Only the upper Pottsville is present in the small residual areas in Wyoming and Sullivan counties. At Bernice it presents not over 125 feet, missing the lower portion of the Beaver River formation; at Mehoopany, the lowest bed, a conglomerate on the red shale, is perhaps not older than the lower sandstone of the Connoquenessing member. In other words, the basal portion of the Beaver River formation ("Upper Intermediate division" of the Pottsville type section) appears not to have been deposited in portions of the overlap area north of the anthracite fields, nor locally along the Allegheny Front or in certain other parts of the bituminous regions of K 17 and K 18. The subsidence and overlap of sediments is thus seen to have been most rapid and strongly marked in the anthracite regions.

The axis of the lower Pottsville estuary doubtless extended southwestward across the eroded region to the south of the Broad Top field, which contains no Pennsylvanian older than the Beaver River formation or upper Pottsville. The early series is not seen again until, following the eastern edge of the coal field, we begin, in the Cheat Mountain region of central West Virginia, to pick up lower beds, as the present border of the Pennsylvanian gradually passes diagonally downward into the deeper portions of the smaller basin of the early deposition. Not till we reach the Pocahontas district do we meet beds as old as the lowest of the lower Pottsville in the type section of the southern anthracite field. The Pottsville expansions have been described and illustrated elsewhere by the writer.^{898b}

The "Coal Measures" or post-Pottsville in the Pennsylvanian anthracite region.—The variability of intervals and the consequent difficulties of correlation of the individual members

^a See remarks on application of the name, pp. 433-434.

^b I. C. White ^{907a} has applied the name Pocahontas group to the lower part of the lower Pottsville.

between the northern anthracite region and the regions to the south have already been mentioned. Between the southern and middle fields numerous correlations have been made by the State survey of the anthracite regions, as shown on the mine maps and in the "Summary final report." Others affecting in particular the northern field have been proposed by Stevenson,⁷⁰⁶ⁱ who inclines to the belief that the post-Pottsville beds also thin to the north and that the deep part of the northern anthracite field in the Wilkes-Barre and Nanticoke region may contain beds younger than the topmost in the southern anthracite field. Of this there is, however, little proof. The inclusion of the Mammoth coal bed in the Allegheny formation has been indicated by the writer,⁸⁰⁹ who is disposed to place the Allegheny-Conemaugh line as high as the Holmes coal bed in the southern areas, or as the Baltimore or Checker coal bed in the northern anthracite field. Harmonious with this is Stevenson's conclusion ^{706j} that the marine fossils of the Mill Creek limestone of the Second Pennsylvania Survey reports, 688 feet above the Baltimore coal bed, are as old as Conemaugh and may be older. These fossils, as reported by Heilprin⁴³² and Girty,³⁶⁵ comprise a distinctly marine invertebrate fauna, with *Chonetes*, *Eumicrotis*, etc. Three other thin limestones occur in the interval covering 320 feet below the limestone to which the name Mill Creek was applied by the Second Pennsylvania Survey, and a black shale with a marine fauna lies about 250 feet above that limestone. The occurrence of these marine limestones in the northern anthracite field is especially interesting, as is also the apparent absence, so far as yet reported, of typical marine faunas from any horizon in the southern field. The Oliphant coal bed, the supposed equivalent of the Hillman coal bed, would seem from the paleobotanic evidence to be older than the Monongahela formation.

In the southern anthracite field the higher coals have furnished plants regarded by the writer as of Monongahela age, but no beds of Permian age have yet been recognized in the anthracite regions.

CENTRAL APPALACHIAN REGION.

General features.—To the south, in the next section of the Appalachian trough, the Pennsylvanian strip in J 17 and the southeast corner of J 16 becomes narrow gradually in West Virginia and rapidly in eastern Kentucky. We have here only the southward continuation of the great plateau (bituminous) field, which merges into the Cumberland Plateau. Except for the Frostburg-Potomac and Cheat Mountain basins, which are isolated along the eastern margin of the coal field, the separating anticlines being eroded, the eastern margin of the Pennsylvanian is fairly parallel to the general direction of the Appalachian folding. For portions of its extent the boundary is an overthrust fault, as, for example, St. Paul, Va., where the Cambrian is thrust on the Pottsville. Other important overthrusts which have caused the exposure of older beds in the interior of the field are those along Pine Mountain, in eastern Kentucky and Tennessee, and the Sequatchie Valley, in eastern Tennessee. Aside from the folds mentioned above or in the previous section the Pennsylvanian of J 17 and J 16 is relatively horizontal.

The higher formations of the Pennsylvanian continue southward from K 17 and K 18 in greatly reduced area and markedly changed character, though the general sequence of the members is essentially the same. The principal changes pertain to composition of the beds as well as to thickness.

Monongahela formation.—The Monongahela territory practically falls within a scalene triangle whose southeast and west sides roughly conform to lines drawn from Cumberland, Md., and Cambridge, Ohio, to Big Sandy River in Lawrence County, Ky. In Maryland the formation measures 240 to 270 feet;⁵⁷² it is considerably thinner on its western outcrop in Ohio and it reaches its greatest thickness—400 feet—in north-central West Virginia. It is thin in the deeper portion of the broad syncline, farthest from the old shore lines. It is notable that the limestones, which form so large a part of the formation in southwestern Pennsylvania, disappear soon after entering West Virginia, being replaced by red and green shales and sandstones. The Sewickley coal enters farther into the basin than the Pittsburg, but the Uniontown is the only one which appears to traverse the entire deeper part of the basin.^{707a}

Conemaugh formation.—The Conemaugh formation has naturally a much larger area than the Monongahela and extends closer to the anticlines near the West Virginia and Maryland line. From a thickness of 700 to 800 feet in southwestern Pennsylvania it thins to the northern and western outcrops (about 300 feet in Ohio), but on the east, in one of the sections of western Maryland, it exceeds 625 feet. In the Piedmont folio ²²⁸ the equivalent of that part of the Conemaugh above the Bakerstown coal is mapped as the Fairfax formation and the equivalent of the lower Conemaugh is included in the Bayard formation. Toward the southwest the Conemaugh thins again, so that the formation is limited to a very narrow strip, hardly more than a county in width, on entering Kentucky, where it measures about 550 feet, and, though its distribution is not fully worked out, it probably does not extend southwest of Morgan County, Ky. The fossil floras of the formations show that neither the Monongahela nor the Conemaugh is now represented in all that portion of the Appalachian trough lying to the south of this district. Like the Monongahela, the Conemaugh is notable for the diminution of the calcareous matter toward the south; the red sediments increase in passing diagonally downward through the formation, which also becomes more conglomeratic toward its eastern outcrop.

Allegheny formation.—The lower limit of the Conemaugh along its southern outcrop has recently been so radically changed as the result of a revolution in the classification of the older Pennsylvanian in the southern region that only in the latest contributions by Stevenson ^{799g} and I. C. White ⁹⁰⁷ is it even approximately located.

The Allegheny formation, which in K 17 and K 18 approaches so near the margin of the Pennsylvanian as to be nearly everywhere indistinguishable on small-scale maps, except in the southern and western middle anthracite fields, keeps the same relative position along the western outcrop for some distance beyond Ohio River; but on the east side it retreats westward as the thicker and successively lower Pottsville strata are developed along the Pennsylvanian outcrop; so that at the Kentucky line its connected areas are confined to a short belt lying in the western half of the field, though isolated patches cap the high ridges and tallest mountain tops far to the east.

The formation measures 260 to 350 feet in western Maryland,⁵⁷² where that portion below the Middle Kittanning coal is described by Darton and Taff²²⁸ as the Savage formation, the upper part being included in the Bayard formation. Deep-well records show it to be much thinner beneath the Monongahela area, though it approaches 300 feet in thickness at some places on its western outcrop in Ohio. Toward the south, however, it thins remarkably, so that in the Kenova quadrangle, in northeastern Kentucky, it falls under 170 feet, though several of its limestones are there present. Remarkably enough, in consonance with the downward diagonal trend of the red material noted in the overlying formations, we find records^{635a, 796d} of red shales in the upper part of the Allegheny at several points on the southeastern and southwestern borders of the basin. This feature is, however, attributed by I. C. White⁹⁰⁷ⁱ to weathering.

Formerly it was supposed that the Allegheny formation was very much thickened to the southeast and included what had been described¹²⁷ as the Kanawha formation, which attains a thickness of over 1,200 feet in southern West Virginia. A later review of the stratigraphy by Stevenson^{795, 796a} more than confirmed the very conservative changes first proposed by the writer⁸⁹⁶ after the study of the fossil plants. Subsequent conclusions reached as the paleobotanic studies progressed have been met by the results of the stratigraphic work of the State Survey, so that the classification given by I. C. White in a recent report of the West Virginia Geological Survey is in nearly all important points in agreement with the preliminary correlations drawn by the present writer. The Stockton coal, the topmost coal of the Kanawha formation, which was previously^{906a} placed in the Upper Freeport position and regarded as the topmost bed of the Allegheny, is now put at a horizon beneath that of the Homewood sandstone member, being regarded as representing an Upper Mercer horizon. Similarly the "Roaring Creek" sandstone member, so well developed in the Tygart Valley and in the Buckhannon quadrangle, though formerly regarded as "Upper Freeport," is now placed by Stevenson and I. C. White at the level of the Homewood sandstone, the top member of the Pottsville, a corre-

Pennsylvanian formations in the Raleigh, Charleston, and Huntington quadrangles.

[From folios of the Geologic Atlas of the United States, by M. R. Campbell.]

Raleigh quadrangle, West Virginia (folio 77, 1902).	Charleston quadrangle, West Virginia (folio 72, 1901).	Huntington quadrangle, West Virginia-Ohio (folio 69, 1900).
[Eroded.]	Braxton formation, 800+ feet (chiefly red and green shales and green sandstone, with beds of coarse sandstone and conglomerate at intervals).	Braxton formation, 800+ feet (chiefly red and green shales and green sandstone, with beds of coarse sandstone and conglomerate at intervals).
Charleston sandstone, 500+ feet (coarse sandstone with several thick seams of coal). [Partly eroded. Extends down to the "Black Flint."]	Charleston sandstone, 250-400 feet (coarse sandstone or conglomerate, with occasional bands of shale and beds of coal).	Charleston sandstone, 200-300 feet (coarse sandstone or conglomerate, with occasional bands of shale and beds of coal).
Kanawha formation, 1,000± feet (sandy and argillaceous shales and soft sandstone with numerous beds of coal).	Kanawha formation, 650-1,000 feet (shale and sandstone with many coal beds).	Kanawha formation, 400+ feet (shale and sandstone with many coal seams).
Sewell formation, 600-625 feet (sandy and argillaceous shale and sandstone): Nuttall sandstone lentil, 0-200 feet (massive sandstone or conglomerate). [Equivalent to the Fayette sandstone.] Harvey conglomerate lentil, 0-50 feet (massive conglomerate). Guyandot sandstone lentil, 0-100 feet (coarse sandstone or conglomerate).	Sewell formation, 100+ feet (sandstone, conglomerate, and shale, the latter containing several beds of workable coal). [290 feet to Mississippian at Winfield.]	[Older formations lacking over part of quadrangle.]
Raleigh sandstone, 75-150 feet (coarse sandstone or massive conglomerate).		
Quinnimont shale, at north 180-200 feet; at south 200-225 feet (sandy shale; Beckley coal at top; Quinnimont coal at base).	[Probably lacking.]	
At north. Thurmond formation, 450-550 feet (sandstone and shale).	At south. Clark formation, 350-375 feet. Pocahontas formation, 250-325 feet.	[Lacking.]

The Pottsville formations up to and including the Raleigh sandstone compose the lower Pottsville as here treated and are collectively correlated by both the writer and Stevenson with the Lee formation of the quadrangles farther south, though the writer is inclined to believe that in some sections the lower beds of the Sewell formation may have been included in the Lee. In general, however, the correlation is accepted, and the term Lee is preferred as a geographic term to designate the lower Pottsville, that is, the beds extending to the top of the Raleigh sandstone. Paleobotanically these beds are correlated ^{895f} with the "Lower Lykens division" and the "Lower Intermediate division" of the Pottsville type section in the anthracite region (see p. 440), the "Lower Lykens division," including Lykens coal No. 5 and underlying beds, being correlated with the Pocahontas formation or possibly the whole Thurmond formation, and the higher zone, including the Lykens No. 4 coal, being referred to the Quinnimont formation.

The Sewell formation constitutes the middle Pottsville and paleobotanically corresponds approximately to the "Upper Lykens division" of the type section of the anthracite region (see p. 440), which contains the floras characteristic of Lykens coals Nos. 2 and 3. It is made by Campbell, Stevenson, and I. C. White to include at the top the Nuttall conglomerate member (equivalent to the Fayette sandstone), which is correlated with the Sharon conglomerate member by the two geologists last named. The present writer, regarding the Nuttall as the initial sea-expansion member of the upper Pottsville subcycle of deposition, would prefer to separate it from the Sewell; and, while provisionally correlating it with the Sharon conglomerate member,^{898d} would restore the latter to its old place in the base of the Beaver River formation, thus conforming to the early establishment of that division by Chance¹³⁵ and D'Invilliers.²⁸⁵ Chance shows that the initial omission of the Sharon conglomerate member in the definition given by Lesley in the preface to I. C. White's Report Q (p. 65) was due to the misapprehension that the sandstone was Mississippian.

The Kanawha formation is upper Pottsville and on the paleobotanic evidence corresponds roughly to the "Upper Intermediate division" of the type section of the anthracite region. (See p. 441.) Together with the underlying Nuttall sandstone member and the sandstone which is just above the overlying black flint and which corresponds to the Homewood sandstone member, it is correlated by the writer with the Beaver River formation as already described for the northern strip (p. 441).

The Charleston sandstone covers the entire Allegheny, here about 120 feet in thickness,^{907h} together with a portion of the Conemaugh and the heavy sandstone ("Roaring Creek" or Homewood) at the top of the upper Pottsville. Most of the Allegheny coals are thin or lacking in the Charleston and Huntington quadrangles.

The Braxton formation represents the balance of the Conemaugh with so much (a small thickness) of the Monongahela as caps a few summits in the northwestern portion of the area.

The remarkable reduction in the thickness of the Pottsville toward the northwest is due both to thinning of the divisions and to the disappearance of the older terranes as the section passes beyond the older and smaller early basin. At the same time the absence of paleontologic material from the drill holes makes it more difficult to determine the precise limits of the several divisions. The lower Pottsville, which appears to attain a thickness of over 1,200 feet in the vicinity of Norton, Va., in the Estillville quadrangle, is said to measure 1,080 feet on Barrenshe Creek, McDowell County, W. Va., in the Tazewell quadrangle; 815 feet at Wolf Gap,^{907b} Wyoming County, W. Va.; and 736 feet at Grand View, in the Raleigh quadrangle. Apparently it was not deposited in the Charleston quadrangle. It is less difficult, however, to distinguish the upper Pottsville in many of the sections in which the two lower divisions are not clearly differentiated. Thus, at Powelton, Fayette County, W. Va., the Kanawha is reported by I. C. White^{907g} at 1,295 feet and the middle and lower Pottsville at 812 feet; at Hernshaw, a few miles south of Charleston, the upper is 890 feet and the middle and lower 787 feet; at Charleston the upper is 600 feet and the middle and lower 660 feet; 5 miles farther west the upper measures 490 feet and the two lower divisions 480 feet; at Winfield, in the same quadrangle, the upper is 365 feet and the middle and lower combined 275 feet; whereas in the well at Letart, to the northwest, on Ohio River, the entire Pottsville measures but 360 feet, of which the lower 60 feet is perhaps referable to the middle Pottsville. The direction of most rapid thickening is somewhat east of south. At Naugatuck, on Tug River, in Mingo County, W. Va., the upper Kanawha is said by I. C. White^{907f} to measure 2,116 feet, a thickness that is possibly equaled in the Estillville quadrangle.

The determination of the northernmost outcrop of beds of middle Pottsville age along the western border of the coal field is subject to differences of opinion. Stevenson^{795e} interprets the Jackson shaft coal, in Jackson County, Ohio, as just beneath the Sharon conglomerate member, and, placing the Sciotoville fire clays and coal at the same horizon, is inclined to regard the highest of the middle Pottsville terranes as a thin veneer extending as far north, at least, as Ohio River, with local developments of an underlying conglomerate (vicinity of Jackson, Ohio)

which he correlates with Campbell's Rockcastle conglomerate lentil. But in the Kenova quadrangle the writer does not recognize pre-Sharon sandstones farther north than the south-east corner of the quadrangle. It is certain, however, that the middle Pottsville beds outcrop at the western border of the coal field not far south of the Kenova quadrangle and that successively lower beds are encountered in passing south through Kentucky; for in the folio on the Richmond quadrangle Campbell reports a thickness of 250 to 300 feet of Pottsville [part of which is erroneously included as Lee] below a 90-foot conglomerate (Corbin conglomerate lentil), which is correlated by Stevenson with the Sharon conglomerate member. This underlying series of beds includes the Rockcastle conglomerate member, a transgression deposit, to which reference will again be made.

In the London quadrangle, next south of the Richmond, including portions of Rockcastle, Jackson, Laurel, and Pulaski counties, Ky., Campbell finds beneath the Corbin 500 to 1,000 feet of shales and sandstones that he maps as Lee, with the Rockcastle conglomerate member (0-150 feet), which probably forms the top of the true Lee, near the middle of the thick sections.^a It is thus shown that in these quadrangles the western border of the coal field has been eroded far enough eastward to cut into the region of the middle Pottsville encroachment of the sea. The Rockcastle appears to represent the western extension of the Raleigh sandstone of southern West Virginia. From the London region southward erosion seems to have narrowed the field so that it lies wholly within the limits of the Raleigh-Rockcastle water level—that is, within the lower Pottsville basin. In the southern part of the Standingstone quadrangle, Tennessee, which lies in the second tier of quadrangles to the south of the London quadrangle, the Bonair conglomerate member, a sandstone over 200 feet below the Rockcastle conglomerate member (top of the lower Pottsville in Tennessee), outcrops along the western border. Farther south the Sewanee conglomerate of Safford and Killebrew is found to lie above the Mississippian and at some places nearly in contact with it.^{898c} This conglomerate, long supposed to be continuous with the Bonair conglomerate member, has been shown by Butts to lie about 200 feet below the Bonair in the Crossville special quadrangle, Tennessee. The "Sewanee," which forms the top of Hayes's Lookout sandstone, constitutes an important early invasion or transgression member in the old Pottsville basin.

In the northern part of the Standingstone quadrangle the Rockcastle conglomerate member, 100 to 200 feet thick, is underlain by 100 to 300 feet of sandstone and shales belonging to the Walden portion of the Lee. In the south half of the quadrangle the Bonair conglomerate member, 125 feet below the Rockcastle and 100 to 200 feet thick, locally rests on the eroded Mississippian. The Rockcastle, which in this western region originates at the north as a remarkable gravel wash filling a river valley but a few miles in width, is blended toward the south with a sandstone of wide extent, which, according to Stevenson, is recognizable in nearly all the sufficiently complete sections of Tennessee and Kentucky.

From the Standingstone quadrangle the coal field is mapped in consecutive quadrangles extending across the coal field from west to east near the southern boundary line of J 16 and also reaching southward to the Alabama line.

Before referring again to the thick eastern sections the western border will be briefly reviewed. In the southern and eastern of these border quadrangles, whose study by Hayes antedates Campbell's work, just cited, the important sandstone designated by Safford and Killebrew as the Main Sewanee conglomerate was made the top member of the Lookout sandstone. Toward the northeast the Bonair conglomerate member, which for a time was, on paleobotanic grounds, considered possibly as young as the Raleigh, was made the top of the Lookout. However, as already noted, the Bonair is, according to Butts, the second sandstone above the Sewanee conglomerate of Safford and Killebrew, and the Sewanee is more than 600 feet below the top of the Lee formation in the Briceville quadrangle and the corresponding sandstone in the Kingston quadrangle. Accordingly the Lookout sandstone, which ends in the Sewanee conglomerate, represents but about one-half (the lower) of the Lee in this district. The beds above the Look-

^aThe Corbin conglomerate member (0-150 feet) is overlain by 500 feet of the Breathitt formation, which is said by Stevenson to extend a little above the limits of the upper Pottsville.

out in the southern quadrangles are mapped as Walden sandstone, the lower portion of which, including the Rockcastle conglomerate member, is accordingly represented in the Lee of the eastern quadrangles, as has just been shown.

In the McMinnville quadrangle the Walden is reported as 250 feet thick, not thick enough to reach the middle Pottsville; while the Lookout, 200 to 300 feet thick, is here extended to cover the Bonair. Coals are present at the base and just beneath the Bonair ledge. In the Pikeville quadrangle, next eastward, 400 to 650 feet of Walden strata, but slightly surmounting the Rockcastle, remain. These beds include several coals, the most important, near the base, being the Sewanee and Soddy coals. The Lookout, which attains a thickness of 650 feet, has several coals distributed through its section.⁶³⁶ Walden beds, to a thickness of 500 feet, remain in the Sewanee quadrangle, which reaches nearly to the Alabama line. In this quadrangle the Lookout expands from 120 feet on the west to 510 feet on the east. The Upper Sewanee conglomerate of Safford, about 250 feet above his Main Sewanee conglomerate, in the Sewanee quadrangle, has been referred by Stevenson to the Rockcastle horizon.

Even more than in the northern regions the terranes of the Pottsville of the southern Appalachian area are highly variable, both in character and in thickness, and are in some places lacking, so that it is difficult to follow many of the horizons, even when the work is continuous. Thin limestones or calcareous shales are present, especially in the lower Kanawha, and sediments with marine Mollusca are found here and there in each of the major divisions, but none of the marine faunas has yet been followed over a great area in the central and southern sections of the coal fields. For these reasons it was found most expedient by the United States Geological Survey in mapping the generally isolated areas of the southern Appalachian region to use for the Pennsylvanian subdivisions local formational names, which were applied to divisions differing as to lithologic characters or, in many cases, arbitrarily segregated for convenience in mapping. The detailed sections of the early publications, which unfortunately are very much scattered and which are generally either deficient in or erroneous as to broader correlations, have been well digested and thoroughly reviewed in a correlative way by Stevenson, who cites nearly all the fragmentary literature.^a It may be noted that in most of the literature antedating the publication of the Federal folios the upper beds of the sections, though of Pottsville age, are frequently referred to horizons as high as the Mahoning sandstone member of the Conemaugh formation or even the Monongahela formation. The data now available are not sufficient to correlate with accuracy the subdivisions described in the detached areas covered by the folios, but the further study of the paleobotanic material already assembled will doubtless settle many of the points now in question.

In the Tazewell quadrangle, to the west of the Pocahontas, several of the key rocks of the Raleigh quadrangle are missing. Campbell describes the following formations:

- Tellona formation, 500 feet (incomplete), sandstones, shales, and coals.
- Sequoyah formation, 450 feet, shales and sandstones with coals.
- Dotson sandstone, 120 feet of sandstone overlying 60 feet of shales.
- Bearwallow formation, 60 feet, conglomerate.
- Dismal formation, 490 feet, shales, coals, and sandstone, including a conglomerate lentil.
- Raleigh sandstone, 100 feet, conglomeratic.
- Welch formation, 700 feet, shales, sandstones, and numerous coals.
- Pocahontas formation, 360 feet, shales, sandstones, and coals, up to coal "No. 3."

^a For eastern Kentucky see Crandall, A. R., Eastern Kentucky coal field: Geol. Survey Kentucky, vol. C, 1884; Moore, P. M., Geol. Survey Kentucky, new ser., vol. 1; Lesley, James, Geol. Survey Kentucky, vol. 4, 1861; Crandall, A. R., Geol. Survey Kentucky, new ser., vol. 6; Hodge, J. M., Preliminary reports on the southeast Kentucky coal field, 1887; Sullivan, G. M., Geology of parts of Jackson and Rockcastle counties, 1891; Loughridge, R. H., Geology of Clinton County, 1890; Norwood, C. J., Ninth Ann. Rept. Inspector of Mines, 1893, and Tenth Rept., 1894.

For Tennessee see Safford, J. M., Geology of Tennessee, 1869; Bradley, F. H., in Killebrew and Safford, Resources of Tennessee, 1874.

For Virginia see Rogers, W. B., Geology of the Virginias, and other State reports; Watson, T. L., Mineral resources of Virginia; Stevenson, J. J., Geological reconnaissance of parts of Lee, Wise, Scott, and Washington counties, Va.: Proc. Am. Philos. Soc., vol. 19, 1881; Hodge, J. M., The Big Stone Gap coal field: Trans. Am. Inst. Min. Eng., 1893; White, I. C., Geol. Survey West Virginia, vols. 2 and 2A; and Stone, R. W., Bull. U. S. Geol. Survey No. 316, 1907, pp. 42, 55, 68.

Of these the last three are lower Pottsville (equivalent to the Lee); and the Dotson sandstone is correlated by both I. C. White and the present writer with the Nuttall sandstone. The 60 feet of shales in the lower part of the Dotson, together with the Bearwallow and Dismal, therefore represent the Sewell, that is, the middle Pottsville. The Dotson sandstone, supposed to correspond to the Sharon conglomerate member, goes, along with the Sequoyah and Tellowa, which represent the Kanawha, into the upper Pottsville, the Sequoyah being in the lower half of that formation.

In the two contiguous quadrangles, Bristol and Estillville, lying in the Big Stone Gap field, the Pennsylvanian syncline between the Pine Mountain fault and the eastern edge of the coal field contains, according to Campbell, the following:

Harlan sandstone, 880 feet, sandstones, conglomerates and coals. [Not present in the Bristol quadrangle.]

Wise formation, 1,260 feet, shales, sandstones, and coals, with several thin marine limestones. [Only 100 feet present in Bristol quadrangle, the rest of the formation being eroded away.]

Gladeville sandstone, 100-120 feet, conglomeratic sandstones, between coals.

Norton formation, 1,200-1,270 feet, shales, sandstones, and important coals.

Lee formation, 1,240-1,530 feet, sandstones, conglomerates, shales, and few coals.

In this region, and on to the Tennessee line, the coals of the lower Pottsville are so unimportant and the sandstones so dominant that all are mapped in one formation, the Lee, which includes everything to the top of the Raleigh sandstone of the Tazewell quadrangle.^a

Stevenson⁷⁹⁵¹ places the horizon of the Sharon conglomerate member and of its supposed southern representative, the Nuttall sandstone, in the Norton formation, at 800 or 900 feet below the Gladeville sandstone, the latter being identified by him as the sandstone just under the Upper Mercer coal on the west side of the coal field and therefore near the top of the upper Pottsville. On the other hand, the writer would place the Gladeville at or very little above the horizon of the Nuttall sandstone, making the Norton formation essentially equivalent to the Sewell—that is, the middle Pottsville—while the Gladeville itself, followed by the Wise and over 300 feet of the Harlan, which are found to contain Kanawha floras, are regarded by him as upper Pottsville. The horizon of the Homewood sandstone member, the top member of the upper Pottsville, is not yet fixed in the Harlan sandstone. The topmost beds in the "Flatwoods" of the region near Elkhorn, Ky., are put by the writer in the Harlan, the Flatwoods coal itself being of Kanawha age instead of representing the Pittsburg bed, as was formerly believed.

The greater part of the Cumberland field, to the southwest of the Big Stone Gap coal field, has been studied by Ashley and Glenn,⁴¹ whose work unfortunately fails to join with completeness Campbell's work, just cited, or Keith's, farther south. The formations described are as follows, those above the Lee being differentiated so as most satisfactorily to map the coal groups:

Bryson formation, 300 feet, sandstones, shales, and thin coals above Red Spring coal.

Hignite formation, 440-450 feet, sandstones, shales, and coals, down to lower Hignite coal.

Catron formation, 280-450 feet, shales, sandstones, local conglomerates, and numerous coals above Poplar Lick coal.

Mingo formation, 950 feet, shales, sandstones, and good coals above the Bennett's Fork coal.

Hance formation, 600 feet, shales, sandstones, and numerous thin coals.

Lee sandstone, 1,200-1,500 feet conglomerates and sandstones, with thin shales and coals.

The lower Pottsville (Lee) appears to continue in unity from the Estillville quadrangle; the Hance and about half of the Mingo represent the Sewell, the Gladeville being provisionally placed by both Ashley and White^{41b, b} in the region of the Slater and Puckett sandstone members, a little above the middle of the Mingo formation. The Catron and Hignite formations, which contain Kanawha floras, together probably with the upper part of the Mingo and certainly with the basal portion of the Bryson, are included by the writer in the upper Pottsville. The Bryson which, capping the highest knobs and ridges is present only in the deepest synclines, is there equal in part to the Harlan of the Big Stone Gap region.

^a For information concerning the intervening area see Stone, R. W., Bull. U. S. Geol. Survey No. 316, 1907, pp. 42, 55; Bull. 348, 1908.

^b See same paper also for correlations with other regions.

The area in Tennessee mapped by Keith begins not far beyond the region mentioned and joins, on the south, the district studied by Hayes. It includes the Briceville and Wartburg quadrangles,^a which present a complete cross section of the coal field. The formations, distinguished on lithologic grounds, are as follows:

Pennsylvanian formations in Briceville and Wartburg quadrangles, Tennessee.

	Briceville.	Wartburg.
	<i>Feet.</i>	<i>Feet.</i>
Anderson sandstone: Shales, sandstones, conglomerates, and coals. [Eroded.].....	1,000+	500+
Scott shale: Sandy shales, sandstones, and coals.....	650-500	600-500
Wartburg sandstone: Sandstones, shales, and coals.....	650-500	600-500
Briceville shale: Shales, sandstones, and coals.....	650-250	400-250
Lee formation: Sandstones, conglomerates, and thin coals.....	1,500-500	900-375

It is suspected that the maximum Lee here may extend one sandstone higher than in the regions to the northeast, though the Big Creek Gap outcrop of the Lee, near the eastern margin of the Briceville quadrangle, is given by the writer ^{41a} as about 1,250 feet thick. In general, however, the Lee is doubtless essentially equivalent to the division under the same name farther east, the variations being probably local. The inclusion of middle Pottsville terranes in the "Lee" of the Richmond and London quadrangles in Kentucky has already been mentioned. The Sewell age of the Briceville shale is agreed on, and the horizon of the Corbin (equivalent to the Nuttall sandstone) is placed by Stevenson ^{795h} in the bottom of the Wartburg sandstone. The Scott shale, together with the upper part of the Wartburg and the lower part of the Anderson sandstone are correlated, on the paleobotanic evidence, with the Kanawha, and therefore placed in the upper Pottsville. The lack of prospecting and exposures of the soft beds on the tops of the mountains have rendered the acquisition of fossil plants very difficult, and the Allegheny-Pottsville boundary is still undetermined. However, the Anderson of these quadrangles, the Bryson of the Cumberland basin, and the Harlan of the Big Stone Gap field are paleobotanically shown to be in part contemporaneous, each seeming to reach up into the post-Pottsville. It is probable that the highest beds of these formations, occurring only on the top of a few of the highest mountains of these regions and, in Tennessee, limited to these two quadrangles, comprise the last and only Allegheny Pennsylvanian remaining in all this southern region of the coal fields.

For comparison the section given by Campbell for the southern half of the Standingstone quadrangle, west of the Wartburg, is repeated:

Lee formation:

Rockcastle conglomerate lentic; 100-180 feet, sandstone and conglomerate.

Shale and sandstone, 125 feet.

Bonair conglomerate lentic, 100-200 feet, conglomerate, sandstone, with inclosed or underlying coals, resting on the Mississippian.

The total of these divisions, about 375 feet ^b at the western outcrop in this quadrangle, agrees with the western outcrop measurements of the eastern Lee, given by Keith as 375 feet in the Wartburg quadrangle to the south. Stevenson's correlation of Campbell's Rockcastle of the western region with the top conglomerate of the true Lee as mapped along the eastern margin of the coal field appears to be well established.

The Sewanee conglomerate of Safford and Killebrew, which along the western margin of the coal field in this region, this being the region of "Sewanee" transgression, locally rests

^a The Cumberland basin terminates on the southwest in a faulted cross anticline, along Fork Mountain, in the Briceville quadrangle.

^b The total, including the Rockcastle and underlying Pennsylvanian beds in the northern half of the Standingstone quadrangle, is given by Campbell as 200 to 400 feet.

almost directly on the Mississippian, or is even absent, is, over most of the area, continuous as the upper member of the Lookout of Hayes.

The section of the Tennessee coal field lying south of the Briceville tier of quadrangles is included in the area mapped by Hayes at an early date in the work of the United States Geological Survey and is practically covered by the Kingston, Pikeville, McMinnville, Chattanooga, and Sewanee quadrangles. The measurements of the Pottsville formations are as follows, from east to west:

Thickness, in feet, of Pottsville formations in southeastern Tennessee.

	Kingston quadrangle.	Chattanooga quadrangle.	Pikeville quadrangle.	Sewanee quadrangle.	McMinnville quadrangle.
Walden sandstone: Shales, sandstones, conglomerates, and numerous coals, the most important being two in the first 100 feet above the base of the formation.	1,300+	600-700+ (with two or more conglomerates).	400-650+	300-500+	250+
Lookout sandstone: Sandstones, conglomerates, and workable coals; the Main Sewanee conglomerate of Safford at the top.	260-510 (with coals at various points below the top conglomerate member).	450-550	90-650 (made to include the Bonair conglomerate member in northwest corner of quadrangle).	120-510	200-350

Some uncertainty exists as to the identification of Safford and Killebrew's Sewanee conglomerate in the vicinity of Chattanooga. Stevenson,^{795g} reviewing the details published by Safford^{687b} and Colton,⁵⁵⁵ concludes that the top of that terrane is 215 feet higher at the Whiteside (old Etna) mines, 235 feet higher at Daisy, and 234 feet higher at Rathbun than the position assigned it by Hayes at these points, though at Graysville and other points to the northeast in the Kingston quadrangle, there is agreement. The Upper Sewanee conglomerate of Safford, in the Walden 240 feet above his Main Sewanee conglomerate (long regarded as equivalent to the Bonair) at Tracy City, in the Sewanee quadrangle, is questionably correlated by Stevenson with the Rockcastle, the top of the Lee, and regarded as probably equivalent to the Raleigh. The flora of the Sewanee coal, about 50 feet above the Lookout at Tracy City, is somewhat like that of the Sewell coal in West Virginia and was therefore made the basis of one of the writer's earliest preliminary correlations in the southern Appalachian region, the underlying conglomerate being then correlated by him with the Raleigh. However, from his later paleobotanic and stratigraphic work it appears that if the sandstone at the top of the Lookout in the Kingston quadrangle is correctly identified with the "Main Sewanee conglomerate" as developed at Tracy City, as appears to be true, a thickness of over 600 feet intervenes between the top of the Lookout and the top of Keith's Lee in the Emory Gap region of the Briceville and Kingston quadrangles, where the upper massive Rockcastle conglomerate member, 100 feet thick, about 500 feet above the "Sewanee," is the same as Safford's and Killebrew's Emory sandstone,⁶⁹⁰ forming the top of the Lee in Emory Gap, near the south border of the Briceville quadrangle.

The correlation as Corbin (equivalent to Nuttall) by Stevenson of a conglomerate member only 100 feet above the supposed Rockcastle conglomerate member in the Pikeville quadrangle would seem to assume a too rapid thinning of the middle Pottsville in passing from the Briceville quadrangle across to Clifty Creek.

In the Kingston and Chattanooga quadrangles the lower Pottsville seems neither to expand so rapidly eastward nor to exhibit so great a thickness as is found in the eastern basins of Virginia and Alabama.

SOUTHERN APPALACHIAN REGION.

The southern portion of the Appalachian coal field falls in the geographic unit I 16, and lies mostly in Alabama, though it cuts the northwest corner of Georgia. At the northern line, opposite Chattanooga, the residual area of the Pennsylvanian is less than 30 miles wide. From this it expands to a width of 85 miles along its southern exposure. On the east, where the longitudinal folding, locally accompanied by overthrusting, is stronger, the coal field is gashed by several anticlinal valleys, while farther east several synclinal areas are wholly detached. The three most important of the latter are the lightly elevated Lookout Mountain syncline, extending south from Chattanooga; the deeply set Coosa field, a complex synclinorium south of Lookout Mountain, lying farthest east of the three; and the Cahaba syncline, ranging through nearly the same latitude, about midway between the Coosa and the main Warrior field on the west. Overthrust faulting, not uncommon along the eastern margins of the synclines, is especially notable along the eastern border of the Cahaba field and the Warrior field south of Birmingham, where Cambrian strata are thrust on beds of the middle Pottsville. The Walden Plateau, east of the Sequatchie Valley, extends into Alabama as Raccoon Mountain, and the Cumberland Plateau, continuing as a plateau though ruptured by several anticlines, is called Sand Mountain in northern Alabama. Subordinate folds produce oblique lobes or branches of the eastern synclines.

In passing westward the folds die out and the beds rise gradually northwestward to fringe the main field with irregular lobes and isolated patches, comparable to those along the western and northern borders of the great Appalachian basin; but to the south and west in Alabama the Pennsylvanian disappears beneath a Cretaceous mantle in the great Gulf embayment. How far the coal measures extend beneath this southward-thickening cover has not been ascertained. It is nearly certain that on the west they blend with the Pennsylvanian of the eastern interior lobe. It is probable that at the stage of Kanawha (upper Pottsville) encroachment union with that lobe occurred in Tennessee or perhaps in Kentucky.

We have seen that in southern Tennessee the lower Pottsville, perhaps slightly thinner than it is farther north, appears not to expand eastward as rapidly as the middle Pottsville, but in Alabama we find a marked southeastern expansion of the lower as well as of the middle division.

The general characters of the Pennsylvanian in the greatly elevated and much eroded northern region are shown in the Ringgold and Stevenson quadrangles, geologically mapped by Hayes, and in the Gadsden quadrangle, which, lying southwest of the Stevenson, cuts three of the eastern synclines, including the south end of Lookout Mountain.

Thickness, in feet, of Pottsville formations in northwestern Georgia and northeastern Alabama.

	Ringgold quadrangle.	Stevenson quadrangle.	Gadsden quadrangle.
Walden sandstone: Coarse sandstones, sandy shales, good coals, and clays.	930 [eroded]	500+	500+
Lookout sandstone: Sandstones, conglomerates, sandy shales, and interbedded coals; has heavy cliff, usually conglomerate, at top.	200-550	300-400	60-570

It will be noted that the Gadsden quadrangle is nearly "in strike" with the Ringgold, which explains the similarity in the thickness of the Lookout. The highest fossils collected in the Lookout Mountain syncline, from beds reported as about 600 feet above the Lookout, suggest the basal horizon of the middle Pottsville. It is therefore very doubtful if any upper Pottsville is present in these quadrangles, which contain the highest beds in this northern section of the State.^a

^a For detailed sections outside of the folios cited, see McCallie, S. M., The coal deposits of Georgia: Geol. Survey Georgia, 1906; McCalley, H. B., Coal measures of the Plateau region: Alabama Geol. Survey, 1891; Spencer, J. W., Paleozoic group: Geol. Survey Georgia, 1893; Hayes, C. W., Twenty-second Ann. Rept. U. S. Geol. Survey, pt. 3, 1902, Pl. XIV. For discussions of sections see Stevenson, J. J., Bull. Geol. Soc. America, vol. 15, p. 126.

The Blount Mountain synclinal lobe, southwest of the Gadsden quadrangle, appears to be intermediate to the Warrior field. The stratigraphy as described by A. M. Gibson presents an enlarged number of divisions which show a marked expansion, notably in the lower Pottsville. Though not paleontologically correlated, they appear to be stratigraphically referable to the divisions in the Warrior basin next beyond.

In the Warrior field the downward pitch of the synclines on passing from the Plateau (northern) district permits the retention of a great thickness, over 3,000 feet, of strata. At the same time the divisions, particularly the lower Pottsville, appear greatly thickened. In McCalley's detailed studies of this field⁵⁵⁶ the individual coals have been traced with great success over the greater portion of the area. In the following summary of the divisions of this field the sections above the lowest important coal, the Black Creek coal, are given (in averages) for the eastern border of the field, the Warrior River section, and the edge of the Cretaceous overlap on the west. The series below the Black Creek coal is continued by McCalley's average section for Jefferson County,⁵⁵⁴ which is placed in the middle column.

Thickness, in feet, of Pottsville strata in the Warrior basin region of Alabama.

	Eastern border.	Along Warrior River.	Western border of exposed "Coal Measures."

14. Interval of sandstones, conglomerates, shales, and coals, from top of "upper conglomerate" of Tennessee to top of "lower conglomerate" of Tennessee.....		100	
15. Interval of conglomerates, shales, and coals, from top of "lower conglomerate" ("Millstone grit") to Mississippian.....		90	

According to the preliminary correlations by the writer, based on the incomplete study of the Pottsville floras, the sandstones of the Lookout become greatly broken up and parted, with expanded intervals of varying materials, while at the same time earlier beds of lower Pottsville age are assumed to underlie those in contact with the Mississippian at the Tennessee line. He correlates the entire lower part of the section, including the conglomerate and sandstone interval (No. 11) above the Black Creek coal group (the whole averaging about 1,575 feet), with the Lookout. The Horse Creek coal group and its overlying conglomerate series, making when added to the other about 1,900 feet, is provisionally placed, on the fossil plant evidence, in the lower Pottsville, No. 9 of the section being tentatively correlated with the Raleigh sandstone of the central Appalachian sections. The Horse Creek coal group (Mary Lee) and No. 9, taken together, may be found to represent the recognized difference between the top of the Lookout on the east side of the Tennessee strip and the top of the Lee farther north.

The Pratt and Cobb coal groups are middle Pottsville, in which the Gwin also belongs, making a total of about 670 feet, and a part of No. 2 should probably also be included. It is thought, however, that the study of the Brookwood (No. 2) plants may show them to be of upper Pottsville age.

The Cahaba coal field, a few miles east of the Warrior field, occupies a deep-set and compound syncline about 40 miles long and 3 to 6 miles in width. A part of its western margin is overturned, and older Paleozoic rocks are thrust on the coals along the eastern border. This

field was studied and mapped in detail by Joseph Squire ⁷⁷³ and the greater portion of it has recently been reexamined by Charles Butts.^{107, 113}

Squire divides the section, calculated to average 5,525 feet, into four parts, which, in descending order, are as follows:

"Conglomerate group," 475 feet, four coals intercalated with conglomerates, and extending from the Montevallo coal to the top of the section.

"Productive group," 2,200 feet, sandstones, shales, and 28 coals, including the Helena coal at 240 feet, a conglomerate (called Thompson) at 310 feet, and the Little Pittsburg coal at 655 feet below the top of the "group;" the Adkins coal, 790 feet lower; and the Wadsworth coal, 500 feet lower, or about 240 feet above the base of the "group."

"Micaceous group," 1,055 feet, micaceous gray and coarse pink sandstones and grits, with seven coals intercalated; the Harkness coal, 160 feet below the top, underlain by 275 feet of sandstones and grits; the Nunnally coal 165 feet above the base.

"Millstone Grit group," 1,795 feet, conglomerates, sandstones, and six coals; the main sandstone masses at the top (360 feet), in the middle (650 feet), and just below the latter (340 feet); the Gould coals in the basal portion.

The section given by Butts agrees in most points with that abstracted above, though indicating an average total thickness of over 6,100 feet in the regions studied. It seems probable that the deeper southeastern portion of the field will ultimately be found to have a depth of 7,000 feet or more. The "Millstone Grit group" is correlated by Butts with the Lookout sandstone. On the fossil plant evidence at present available, the writer is disposed to include the Nunnally and Harkness coals (in the lower part of the "Micaceous group") also in the Lookout. At least they are of lower Pottsville age. The paleobotany of the Wadsworth coal group, which is thought to be as old as the Horse Creek coal group of the Warrior field, will probably be found to place this division also within the limits of the lower Pottsville, the Little Pittsburg-Helena coal group belonging to the middle Pottsville. Fossils of upper Pottsville age have not yet been recognized in the Cahaba field. These preliminary correlations indicate both a very great thickness and a tremendous expansion of the terranes to the southeast in Alabama.

The Coosa field, a short distance east of the Cahaba field, is about 40 miles long and 4 to 10 miles broad. The coal measures are overlain by overthrust Lower Cambrian on the east. Though this field was the scene of the first coal mining in the State, at least 12 workable coals being reported by the Alabama geologists, its deformation has been so violent and the folds are so complicated and the exposures of the soft beds so meager that little successful development has been accomplished, even in the north end of the field. Very little detailed geologic work has been done in the basin. A report on the field by A. M. Gibson ³⁵⁹ shows a section which exceeds 5,000 feet and which appears to be stratigraphically similar to that of the Cahaba field, though there is said to be further eastward expansion of the groups. The greater part of the reported thickness apparently belongs to the lower Pottsville. The basin lies low and, like the Cahaba, passes under the Cretaceous to the south. No paleontologic studies of the Pennsylvanian of this basin have been made.

I-K 14-15. WESTERN INTERIOR COAL REGION.

The following statement was prepared for this volume by G. H. Ashley in 1909:

GENERAL FEATURES.

The Pennsylvanian of the western interior coal region covers a large area in Iowa, Missouri, Nebraska, Kansas, Arkansas, Oklahoma, and Texas, the area exposed being a part, possibly only a small part, of that originally covered. The area of exposure has been much reduced on the southeast by folding and faulting, on most of the eastern edge by erosion, and along all of the west and southeast sides by the deposition of a mantle of later rocks. In central Arkansas the southeastern edge of the outcrop passes beneath a cover of Tertiary rocks. Farther west and south the Pennsylvanian is hidden by Cretaceous and Permian rocks. The extension to the west in Iowa and most of Kansas is concealed by Cretaceous rocks; across Kansas, Oklahoma, and Texas by Permian rocks. Deep drilling for oil and gas indicates a continuance to the west of the Pennsylvanian rocks, so far as the series is reached by such drilling, but they may be assumed as extending indefinitely beyond.

The older Pennsylvanian deposits are confined to the southeastern part of the region, in Arkansas and Oklahoma, and correspondingly in that region is found the greatest thickness of rocks. Later a series spread northwestward and westward over Kansas, Missouri, Nebraska, and Iowa. The Pennsylvanian of northeastern Missouri and southeastern Iowa would seem to have been at one time connected with the "Coal Measures" of Illinois. Whether the series in Arkansas has extended southeastward to join with the Appalachian field in Alabama is uncertain.

SUBDIVISIONS.

For purposes of study the region may readily be divided into four subareas. The Kansas-Missouri-Iowa area is characterized by rocks nearly all of which are of post-Pottsville age, that are easily divisible into the "Upper Coal Measures" and "Lower Coal Measures," by common elements in their stratigraphy, and by simple monoclinical and basin structure. The Pennsylvanian of Oklahoma and Arkansas may be divided into two subareas by a great fault or fault zone, extending from Atoka to the northeast and east, crossing Arkansas River about 40 miles above Little Rock. The area north and east of this fault, which may be called the Arkansas Valley field, differs from the Kansas-Missouri-Iowa area in structure and in stratigraphy, there being a great thickening of the series from Kansas to the southwest, where the strata are underlain by older Pennsylvanian rocks. In the main this area is gently folded and faulted. The area south of the great fault, which may be known as the Ouachita region, differs from the area last mentioned in its stratigraphy, notably in the presence of a great series of shale and sandstone not found outside of this area, and in structure, its rocks having been closely folded and markedly faulted, and possibly overthrust upon the rocks to the north. The northern Texas area is cut off from the areas to the north by the Arbuckle uplift. It is plainly a continuation of the northern Arkansas-Oklahoma area, though differing greatly in its stratigraphic details.

IOWA-MISSOURI-KANSAS AREA.

The Pennsylvanian in Iowa, Missouri, and Kansas outcrops over an area of 63,000 square miles, distributed, according to Bain,⁵⁰ as follows: Iowa, 20,000; Missouri, 23,000; Kansas, 20,000. Bain^{50a} describes the "Coal Measures" in these States as follows:

"The Coal Measures of the western interior field * * * rest unconformably upon the rocks of the Lower Carboniferous or Mississippian series. They are covered in Kansas and Nebraska by the Permo-Carboniferous beds, which are conformable with them. In Iowa Cretaceous deposits rest unconformably on them, and in Iowa, Nebraska, northern Missouri, and northeastern Kansas the drift and associated deposits of the Pleistocene cover the coal-bearing strata.

"The Coal Measures of this field include limestones, sandstones, shales, fire clays, and the coal beds proper. Limestones are probably least abundant, and shales in their various phases—argillaceous, bituminous, calcareous, and arenaceous—most abundant. In the northern portion of the field limestones and calcareous shales are notably more abundant in the upper or barren portion, and less so in the lower or productive portion. In Kansas the distinction between the two divisions is not so well preserved, and in the adjacent southwestern field it quite loses value. In a general way there is a prevailing dip to the west of 10 to 20 feet per mile. In detail the dip is south to southwest in Iowa, west to northwest in Missouri, and predominantly northwest in Kansas.

"The Coal Measures of this field increase in thickness westward from their outcrop. There is also a gradual increase in maximum thickness from north to south. In Iowa the maximum thickness measured is 1,060 feet.^a In Missouri Winslow has estimated the total thickness at 2,000 feet.^b In Kansas Haworth gives 3,000 feet as the thickness.^c

"On the maps accompanying this report two divisions of the Coal Measures are represented. These are the Upper and Lower Coal Measures. In Iowa and Missouri the terms

^a Norton, W. H., Iowa Geol. Survey, vol. 6, p. 333.

^b Missouri Geol. Survey, vol. 1, Preliminary report on coal, p. 24.

^c Univ. Geol. Survey, vol. 3, p. 20.

Des Moines and Missourian, respectively, are used for the two divisions. In Kansas these terms have not been used, although essentially the same division is recognized. The basis of the division is largely lithologic and economic. The Coal Measures in this field belong to one series and represent a continuous sequence of deposition. The faunal change at the dividing line is slight, but the division is none the less valid and important. The Lower Coal Measures include the bulk of the productive coal beds throughout the field. From 93 to 98 per cent of the coal mined comes from them. These beds are relatively thick, are notably irregular, and show a patchy distribution. They are associated with thick sandstones, thick bodies of shale, particularly of bituminous and argillaceous types, and with thin and unimportant limestones. The Upper Coal Measures include a few very thin beds of coal of great regularity and extent. They are associated with little sandstone, and with shale usually calcareous or argillaceous in type. The measures also include a notable number of thick and persistent limestones. As already stated, these differences are not pronounced to the south, though even here the general relations are as stated above. The dividing line is drawn at the base of an important limestone, 40 to 80 feet thick, known variously as the Winterset, Bethany, or Erie. The general equivalence of these three terms is well recognized, though there is as yet some doubt as to the exact correlation of this and other minor divisions.^a Subdivisions of both the Upper and Lower Coal Measures have been systematically recognized and mapped in Kansas by Haworth and his associates.^b In Missouri corresponding divisions have been recognized and partially mapped by Keyes^c and Marbut.^d In Iowa divisions of the Lower Coal Measures have been recognized^e but have not been mapped except in Appanoose County.^f

“The divisions recognized in each State and their approximate correlation are shown in the following table. Keyes has suggested more exact nomenclature and correlation.^c His suggestions have not as yet been followed in mapping.

Divisions of the Lower Coal Measures.

Kansas (Haworth).	Missouri (Keyes).	Iowa (Geol. Survey).
Pleasanton Altamont Pawnee... Labette... Fort Scott. Cherokee.....	Marmaton..... {Marais des Cygnes..... Henrietta..... Cherokee.....	Pleasanton. Appanoose and equivalents. Cherokee.

“It will be seen that the Lower or Productive Coal Measures are made up of three divisions. The uppermost, the Pleasanton shales, including the Altamont limestones, attain a thickness in Kansas of 200 feet. To the north they thin, until in central Iowa they are hardly to be separated from the next lower member. In Kansas they have been grouped with this middle division by Haworth under the name Marmaton formation.^g The middle member passes under various names in different parts of the field. In Kansas it includes the Pawnee and Fort Scott limestones, with the intercalated Labette shales, and has an approximate thickness of 150 feet, a thickness which it maintains well to the north. In southwestern Missouri the shale member of the sequence is unimportant, and the limestones, the Henrietta formation of Keyes,^h form a single escarpment, which may be seen near Hume, in Bates County. In northern Missouri and southern Iowa the formation includes a number of thin limestones separated by shales and carrying thin coal seams. This is the phase of the formation which has been called the Appa-

noose. In central Iowa there are beds equivalent to the Henrietta, but the sequence of strata is different.

"The lowest member of the measures is the Cherokee shale, which outcrops in a crescent-shaped area following the outer lines of the outcrop of the Coal Measures from Kansas to north-central Iowa. The shales vary in thickness from 200 to 600 feet along the outcrop of the next higher formation and thin to nothing at their own outcrop. The formation is made up largely of shale and sandstone and carries numerous important coal beds. The individual strata vary in character and thickness from point to point, so that it is impossible to construct a general section of more than local value. In the southwest, especially in southeastern Kansas and the adjacent portions of Missouri, the beds are apparently more regular than elsewhere, and the irregularities found farther north serve to mark this as an exceptional portion of the field."

The persistent limestones of the "Upper Coal Measures," as well as the intervening shales, have all been named in Kansas. In many reports these have been considered as separate formations. In other reports they have been treated as members of somewhat more inclusive formations. Later work has shown that the earlier correlations of some of the limestones at different points were erroneous. Again, some of the earlier names used have later been found to be preoccupied by use for some other formation elsewhere. These facts have led to many changes in the nomenclature of the Pennsylvanian of Kansas.

In the table opposite is presented the stratigraphy of the Pennsylvanian of Kansas, as contained in several recent reports. Bulletin 211 of the United States Geological Survey gives the synonymy of the several formations listed, with the fauna of each formation or member. Bulletins 238 and 296 show the groupings and treatment of the rocks at still later dates, and the latest is that quoted from volume 9 of the State report.

ARKANSAS VALLEY AREA.

The area of Pennsylvanian strata of Kansas, Missouri, and Iowa is, in large measure, cut off from the Arkansas Valley area on the south by the Ozark uplift. The two areas are connected by a relatively narrow belt of outcropping rocks running southwestward through eastern Oklahoma. In this narrow area, which has not been studied as much as the regions to the north and south, there is a notable thickening of the formations toward the south; a running out of the limestones, so characteristic of the formations of Kansas, and the introduction of sandy beds; and a downward transgression of the red clay, which to the north is characteristic of the Permian beds but which in this region extends downward into the upper part of the Pennsylvanian. As a result of these changes the stratigraphy of the Pennsylvanian in central Arkansas and eastern Oklahoma is very different from that in Kansas. In part the increased thickness is due to the appearance of older Pennsylvanian strata at the bottom of the series.

The second table opposite shows the stratigraphic nomenclature, with the thickness of some of the strata, as given in the reports of the more important studies made in this field, in addition to a correlation with the Pennsylvanian to the east, based entirely on the work of David White.

For comparison, Purdue's section^{655a} in western Arkansas (Pike, Howard, and Sevier counties) and an abbreviated section from Kansas are also given. The Mississippian formations underlying the Pennsylvanian in these sections are included in the table to show the character of the contact at different points and as bearing on the stratigraphy of the Ouachita region.

OUACHITA AREA.

As already stated, the Ouachita area is cut off from the Arkansas Valley area by a great fault or fault belt extending from Atoka northeastward and eastward. South of this fault the rocks are closely folded or overturned as well as faulted. The result of this faulting and folding has been to greatly shorten the north-south extent of the area covered by the Pennsylvanian. The writer³⁵ has estimated that in the southern part of this area a section along Cossatat River, now 24 miles long, was originally 35 miles long, and a section on Antoine Creek, now 20 miles long, was originally also 35 miles long. As this estimate does not make any allowance for overthrust faulting, and

Stratigraphy of the Pennsylvanian of Kansas, as interpreted by different authors.

Pennsylvanian and Mississippian as given in the reports cited.

as the Ouachita area as a whole has a width of about 70 miles, it is evident that the total shortening has been very considerable. The rocks appear to have been pushed from south to north.

Stratigraphically the upper part of the series of rocks is similar to the series in the Arkansas River valley, from the Caney shale upward. The lower part of the series differs from the adjoining rocks in the Arkansas area in the presence of a great thickness of sandstone and shale resting on the Ordovician rocks and belonging beneath the Caney shale and apparently above the Woodford chert. These have been estimated by Ulrich to have a thickness of 14,000 feet on Little Missouri River. This series was named by Taff⁸⁰⁶ the Standley (now spelled Stanley) shale and Jackfork sandstone. At the west is the Caney shale, supposed to be later than the Jackfork. To the east the Caney shale has not been recognized, and the Atoka formation overlies the Jackfork. In the Atoka folio Taff gives the Jackfork sandstone and the Stanley shale a thickness of 5,000 feet each. Branner⁹⁶ gave these beds, including the Atoka, a thickness of 18,480 feet in the area west of Little Rock. Purdue,^{655a} in a paper on the Arkansas slate area, gives the thickness of the Atoka, Jackfork, and Stanley as 6,000, 6,600, and 6,000 feet, respectively, or a total of 18,600 feet, in substantial agreement with the earlier estimate of Branner.

The age of the Jackfork sandstone and Stanley shale is still a matter of some doubt. They are either late Mississippian or early Pennsylvanian, possibly passing from the one over into the other.

The proper correlation of the Caney shale is also a matter of some doubt. In folios 74, 79, and 98 of the Geologic Atlas of the United States the Caney was assigned first to the "Carboniferous and probably Devonian" and later, on the evidence of fossils which were thought by Girty to indicate a late Mississippian age, to the Mississippian. Two years later (1905) Girty^{363c} placed the Caney in the Pennsylvanian because, inasmuch as it was underlain by 10,000 feet of Carboniferous strata, there was reasonable doubt of its Mississippian age. In 1909 the same author³⁶⁶ published a description of the Caney fauna in which, after citing the inconclusive paleobotanic evidence, he summed up the faunal evidence as follows:

"The faunal evidence furnished by the Caney is much more extensive than that of the fossil plants referred to above. The Caney fauna has a facies widely different from that of the typical upper Mississippian faunas, and it would be difficult to determine its position in the time scale were it not that it is closely related to certain faunas in Arkansas which contain more of the typical upper Mississippian species and which have long been regarded as belonging to that period. When I originally determined the Caney as neo-Mississippian, I did so because its fauna was so closely allied with that of the Moorefield shale of Arkansas. If, upon returning to the subject with a presentation of one side of the evidence upon which this conclusion was based, it were possible to say that the preliminary opinion had been erroneous, it would afford me real satisfaction as opening a way out of the present difficulties. But a more detailed study of the one fauna and a hasty review of the other have only added to the weight of the evidence. A large number, and those in many cases the most striking and typical of the Caney species, occur also in the Moorefield shale. * * *

"The ordinary inference from these facts, one which I should draw without hesitation were it not for the bearing of the plant evidence found in the Standley, is that the Caney and the Moorefield-Fayetteville beds were contemporaneous in a geologic sense.^a But this, it may be urged, does not necessarily entail the Mississippian age of the Caney without carrying the inquiry one stage further. Careful consideration has been given the hypothesis that the Moorefield-Fayetteville beds may be not Mississippian but Pottsville in age. While some circumstances lend a color of probability to such an hypothesis, the negative evidence seems at present to warrant its rejection.

"If, then, the Caney correlates with the Moorefield, if the Moorefield is of Mississippian age, if the Caney rests on the Jackfork sandstone, and if the evidence furnished by the Standley flora halts between upper Mississippian and Pottsville, the conclusion that the Standley is upper Mississippian and that the sedimentation of that period was peculiar and excessive in the

^a The White Pine shale of Nevada, which is also a black shale formation, likewise contains a fauna similar in many respects to that of the Caney.

Ouachita region seems to involve the fewest inconsistencies. This conclusion is tentative and unsatisfactory but seems to accord best with the evidence known to me. Future discoveries may prove it wrong."

The Pennsylvanian shales, limestones, and sandstones of Oklahoma have been studied by Gould and his associates,³⁷⁵ who have classified them as follows:

The rocks in the area under discussion consist of a thickness of from 10,000 to 12,000 feet of sediments of Pennsylvanian age extending from the Mississippian to the Permian. In general these rocks consist of alternating layers of shale and sandstone. The shales greatly predominate, making up approximately three-fourths or possibly nine-tenths of the entire thickness of the strata. In the northern part of the State there is a number of ledges of limestone, but even in this region shales constitute more than three-fourths of the strata, the remainder being about equally divided between sandstone and limestone. Farther north, in east-central Kansas, the limestone ledges are not only more numerous (no fewer than twenty distinct ledges having been recognized) but they are thicker, while sandstones make up a relatively small per cent of the entire series.

In Kansas it has been noted that on passing from the center of the State to the Oklahoma line the various limestone ledges frequently thin out and some of them disappear before the line is reached. Others pass for several miles into Oklahoma before disappearing, but, except in eastern Kay County, comparatively few limestones reach the Arkansas River. Of the half dozen or more which persist south of that stream only one ledge, so far as known, exceeds 10 feet in thickness.

It has also been found that as the limestones thin out to the south and finally disappear, sandstones often come in, usually either just above or just below the limestone. In other cases the ledges become more arenaceous to the south, until finally the ledge which was a limestone has become a sandstone. It frequently happens, also, that additional sandstone ledges come in, first as mere arenaceous bands in the shales, then as thin lenses which thicken to the south and finally become ledges of hard sandstone 20 to 50 feet thick, which resist erosion and give rise to pronounced escarpments. In a number of instances, however, the thinning out of the limestone ledges is to the north. This fact is particularly well exemplified in the case of several limestone ledges in the region about Bartlesville, and between that city and Arkansas River above Tulsa. Here at least two heavy ledges of limestone disappear to the north. Many of the ledges, both limestone and sandstone, when traced for any considerable distance are found to be local lenses. The general rule throughout the area is, however, that limestones "finger out" to the south and sandstones to the north, while the intervening shales coalesce.

Another factor which complicates the difficulty of the situation is the gradual thickening of the entire series to the south, particularly near their base. For instance, the basal group, to be hereinafter described as the Muskogee group, is about 450 feet thick at the Kansas-Oklahoma line, but in the region north of the Choctaw fault, in the eastern part of the State, the same group has an approximate thickness of 9,000 feet. Part of the apparent thickening in this instance is probably caused by unconformity by overlap on the Mississippian, but much of it is doubtless caused by normal thickening of strata southward. The thickening of other groups from north to south, while not so conspicuous as in the case mentioned, is nevertheless often obvious.

From what has preceded, it will be evident that the problem of the proper division and correlation of the various beds is, in the absence of paleontological data, at best difficult. In rare cases only may any single ledge of either limestone or sandstone be traced from Kansas line southward for any considerable distance. As has been stated, many of the sandstones and a few of the limestones are lenticular and have but a comparatively limited areal extent. These conditions have already given rise to considerable confusion in folio and economic mapping, and it is feared that, as this work progresses, the complications may be augmented. It is with the hope of lessening the possibility of confusion in the application of stratigraphic terms and the needless multiplication of names in the future that this article has been prepared.

PROPOSED SOLUTION.

The authors are convinced that the problem of the future division and correlation of the various beds may be greatly simplified by dividing all the rocks in the region into a few general groups, the limits of which may be demarked by certain conspicuous ledges of limestone and sandstone which extend southward from the Kansas line. After studying the region in considerable detail, it has been found that there are at least four of these ledges of sufficient importance and linear extent along the line of outcrop to serve as adequate group markers, which groups must, of course, be confirmed by paleontological evidence. Beginning on the east, these ledges are as follows:

1. The Claremore formation, the approximate equivalent of the Fort Scott limestone of Kansas, which is correlated with the Calvin sandstone in the Coalgate folio.
2. The Lenapah limestone, which lies at the approximate horizon of the Upper Parsons or Coffeyville limestone of Kansas.
3. The Pawhuska formation, which is believed to be the equivalent of the Deer Creek and Hartford limestones of Kansas.
4. The Wreford limestone, which, south of the Cimarron River, gives way to the Payne sandstone.

From the study of the map it will be seen that these four formations trend approximately parallel northeast and southwest, from the Kansas line toward the region of the Arbuckle Mountains. The southern extension of none of them has been definitely located, but it is believed that accurate field studies will fix the position of each formation.

PROPOSED GROUPS.

It is therefore proposed to demark the limits of four general groups of the Pennsylvanian rocks of eastern Oklahoma as follows:

1. The Muskogee group, including all the rocks from the base of the Pennsylvanian series to the base of the Claremore formation. The name proposed is that of Muskogee County, which lies near the center of the area occupied by the group.
2. The Tulsa group, including everything from the base of the Claremore formation to the base of the Lenapah limestone. The name is from Tulsa County, in the eastern part of which the rocks of the group are well exposed.
3. The Sapulpa group, including the rocks between the base of the Lenapah limestone and the base of the Pawhuska formation. The name is from Sapulpa, the county seat of Creek County.
4. The Ralston group, including everything from the base of the Pawhuska to the base of the Wreford, which has usually been considered the base of the Permian. The name here proposed is from the town of Ralston, in northern Pawnee County.

In proposing these groups the authors do not wish to be understood as attempting to fix definitely the nomenclature of the region. The purpose is merely to provide a comprehensive yet simple scheme of classification which may be followed in future mapping. The classification is made entirely upon stratigraphic and lithologic data.

DESCRIPTION OF GROUPS.

MUSKOGEE GROUP.

Area.—The Muskogee group includes a series of rocks, chiefly sandstones and shales, extending from an unconformity at the top of the Mississippian series on the east to the base of the Claremore formation^a and its approximate southern equivalent, the Calvin sandstone, on the west. In the northern part of the State it includes the approximate area occupied by the southern continuation of the Cherokee shales of Kansas; in the southern extension it includes the great coal region of Oklahoma. The area included in this group in Oklahoma is bounded on

^a This formation includes the Fort Scott limestone of Kansas and some of the upper part of the Cherokee shale. At the south boundary of the Claremore quadrangle as much as 100 feet of the Cherokee is included.—C. D. Smith, comment on manuscript.

the north by the Kansas line, and on the northeast by the areas occupied by Mississippian rocks. On the east the Arkansas line is the boundary. The Choctaw fault, the Cretaceous overlap in Atoka County, and the Arbuckle Mountains demark the southern limit. It includes all or part of the following counties in Oklahoma: Ottawa, Craig, Mayes, Rogers, Wagoner, Cherokee, Okmulgee, Muskogee, Sequoyah, Le Flore, Haskell, McIntosh, Okfuskee, Hughes, Latimer, Pittsburg, Coal, Pontotoc, and Atoka.

Stratigraphy.—Near the Kansas line, in which State the name Cherokee shales has been applied to the rocks of the group, the approximate thickness of the strata is 450 feet and consists largely of shales, with local beds of sandstone and limestone and several thin beds of coal. The following section from Pryor Creek to Claremore made by Messrs. Ohern and Wolf will give a fairly comprehensive idea of the stratigraphy at that place.

Section from Pryor Creek to Claremore.

	Feet.

4. Massive medium-grained sandstone.....	37
3. Shaly sandstone.....	8
2. Massive medium-grained sandstone.....	14
1. Bluish shale, weathering to light yellow, and a few interstratified sandstones.....	550
	960

In the Muskogee folio Mr. Taff describes two formations, the Boggy and the Winslow, the latter being the equivalent of the Hartshorne, McAlester, and Savanna formations as exposed in the coal fields farther south. The formations above the Boggy have not been described in Muskogee, Okmulgee, and McIntosh counties.

The stratigraphy of the southern part of the Muskogee group is better understood than that of any other part of the Pennsylvanian series in Oklahoma. Numerous reports and folios bearing upon the subject, chiefly from the pen of Mr. Taff, whose work in the region continued almost without interruption from 1895 to 1908, have given us a very comprehensive idea of the stratigraphy, structure, and economic resources of the coal fields of the State. The general sequence of the formations with their approximate thickness as shown in Coal and Hughes counties is here given, the oldest below:

	Feet.
Calvin sandstones.....	200
Senora formation.....	500
Stuart shale.....	250
Thurman sandstone.....	200
Boggy shale.....	2,000
Savanna sandstone.....	1,200
McAlester shales.....	2,000
Hartshorne sandstone.....	200
Atoka formation.....	3,000
	9,550

This entire series of strata is coal bearing. In Arkansas beds of considerable thickness occur in the Atoka formation, but in Oklahoma these beds are usually thin and inconspicuous. The McAlester formation contains four beds of workable coal and a number which may eventually be developed. The Savanna contains at least three and the Boggy formation two workable beds. Several occur in the higher formations of the series, particularly one in the upper part of the Senora which is mined at Henryetta, Schuller, and Morris. In the southeastern part of the area occupied by rocks of the Muskogee group the strata have been extensively folded and

in certain places faulted. A series of anticlines and synclines have their axes extending northeast-southwest.

It is not the purpose in this connection to discuss the problem of the cause of the thickening of the various beds of the Muskogee group to the south, or what amounts to the same thing, the thinning of the beds to the north. It has usually been assumed that the change in the thickness is due largely to unconformity by overlap. While in the present state of our knowledge, particularly in the absence of complete paleontological evidence, it would be extremely unwise to say that this cause did not obtain, at least in part, still in the light of accumulating evidence it seems very probable that we must look elsewhere for reasons to account for a considerable part of the southern thickening of the beds.

TULSA GROUP.

Area.—This group includes all the rocks lying between the base of the Calvin-Claremore formation and the base of the ledge which in Kansas has been known as the Upper Parsons or Coffeyville limestone, but which in a paper by Ohern, now in press, is designated as the Lenapah limestone. The rocks of the group outcrop on the surface as a band, averaging 20 miles in width, and extending from the Kansas line south to the region of the Arbuckle Mountains. The Lenapah limestone^a has not been certainly located south of the North Canadian River, although there is reason for believing that it will eventually be correlated with a limestone in the upper part of the Holdenville formation, which outcrops not far from the town of Holdenville, in Hughes County, and which probably extends nearly to Ada. The rocks of the Tulsa group occupy all or part of the following counties: Craig, Nowata, Rogers, Tulsa, Wagoner, Okmulgee, Okfuskee, Coal, Hughes, and Pontotoc.

Stratigraphy.—The rocks of the Tulsa group, as exposed in the northern part of the State, include formations which in Kansas have been described under the names Fort Scott limestone, Labette shales, Pawnee limestone, Bandera shales, Altamont limestone, and Walnut shales. The combined thickness of these rocks at the Kansas line is about 250 feet; farther south this thickness is much greater.

The Fort Scott limestone, known to the oil drillers of Kansas and Oklahoma as the Oswego lime, was first described in Kansas, where it consists typically of two limestone members and an intervening shale member. Ohern, however, finds that in northern Oklahoma a third limestone member comes in below the Fort Scott of Kansas and persists at least as far south as the Arkansas River. For this formation, consisting of three limestones with two intervening shale beds, each containing coal, in a paper now in press, he is proposing to use the name Claremore.

The Labette shales, named and described in Kansas, extend from the Kansas line southward across Oklahoma, finally, on the disappearance of the higher limestones, coalescing with other shales. The Pawnee and Altamont (Lower Parsons) limestone, which at the Kansas line are separated by the Bandera shales, come together in southern Nowata County and form a single ledge, the Oologah, the "Big lime" of the drillers. The ledge extends southward, crosses the Arkansas River near Broken Arrow, and disappears in the vicinity of the Concharty Mountains.

From the Arkansas River south the rocks of the Tulsa group consist of sandstones and shales with an occasional lentil of limestone. In the Coalgate folio Mr. Taff has described the following formations beginning with the Calvin:

	Feet.
Seminole conglomerate	150
Holdenville shale	250
Wewoka formation.....	700
Wetumpka shale.....	120
Calvin sandstone.....	200

If, in the above section, the Tulsa group includes the Calvin, Wetumpka, and Wewoka formations, and probably 200 feet or more of the Holdenville formation, this would indicate that

^a This formation is not recognizable south of Watora, in Nowata County, Okla. The Dawson coal, however, which occupies practically the same horizon, extends southward beyond Kansas River.—C. D. Smith, comment on manuscript.

the rocks of the group as exposed in the region south of the Canadian River reach a thickness of approximately 1,200 feet.

SAPULPA GROUP.

Area.—The rocks which constitute the Sapulpa group include everything from the base of the Lenapah limestone to the base of the Pawhuska formation (as that term was used by J. P. Smith) as these formations are exposed in the northern part of the State. Neither the Lenapah nor the Pawhuska has been definitely located south of the North Canadian River and for that reason the southern limits of the group can not now be accurately demarked.

The area included in the group averages 35 miles in width, extending from the Kansas line south to the vicinity of the Arbuckle Mountains. It includes all or part of Nowata, Washington, Osage, Pawnee, Creek, Tulsa, Okmulgee, Payne, Lincoln, Okfuskee, Pottawatomie, Seminole, Pontotoc, and probably McClain, Garvin, and Murray counties.

Stratigraphy.—Included in the Sapulpa group in Oklahoma are rocks which in Kansas have been described under the following formation names: Coffeyville limestone, Pleasanton shales, Bethany Falls limestone, Ladore shales, Mound Valley limestone, Galesburg shales, Dennis limestone, Cherryvale shales, Drum limestone, Chanute shales, Iola limestone, Lane shales, Stanton limestone, LeRoy shales, Kickapoo limestone, Lawrence shales, Oread limestone, Kanwaka shales.

The approximate combined thickness of these rocks as exposed in southern Kansas is 1,000 feet. In Oklahoma the thickness of the group gradually increases until at the Arkansas River it is probably 1,200 feet or more.

So far as known, with the exception of the Lenapah, none of the limestone ledges exposed in Kansas persist as far south as the Arkansas River. The Drum limestone splits near the Kansas line, and the lower member, which Ohern calls the Hogshocter, disappears some 20 miles north of Tulsa. The upper member of the Drum disappears soon after crossing the State line. Two limestone lentils, the Dewey and Avant, come in not far from Bartlesville and persist beyond the Arkansas River, where they also disappear. As the limestones disappear near the Kansas line, sandstones become prominent and farther south increase in thickness until they make up a considerable part of the rocks of the group, although, as in other parts of the general region occupied by Pennsylvanian deposits, shales are the predominating rock.

No accurate section has ever been made across the southern part of the region occupied by rocks of the Sapulpa group, and for that reason it is impossible to do more than to approximate the thickness of the group along the Canadian River, but it is probable that in this region it is somewhere between 1,500 and 2,000 feet.

In its southwestern extension the Sapulpa group passes into and includes the eastern part of the Oklahoma Red beds, being part of the so-called Chandler beds. * * *

RALSTON GROUP.

Area.—The Ralston group includes the rocks in the upper part of the Pennsylvanian series, beginning at the base of the Pawhuska formation and extending to the base of the Wreford limestone and its southern continuation, the Payne sandstone, which has usually been considered the base of the Permian.^a The group is exposed as a band averaging 30 miles in width extending parallel to the other groups described in this paper, from the Kansas line south toward the Arbuckle Mountains.

Neither the Pawhuska formation nor the Payne sandstone has been definitely located as far south as the North Canadian River and consequently the limits of the southern part of the Ralston group, which is exposed in Lincoln, Oklahoma, Pottawatomie, Cleveland, McClain, and Garvin counties, can not be accurately demarked. In the northern part of the State this group is exposed in Osage, Kay, Pawnee, Payne, and Lincoln counties.

Stratigraphy.—The equivalents of the following formations in Kansas, the combined thickness of which is approximately 800 feet, are included in the Ralston group as the latter is exposed in northern Oklahoma: Lecompton limestone, Tecumseh shales, Deer Creek lime-

^a Beede now considers the Elmdale as the provisional base of the Permian.

stone, Calhoun shales, Topeka limestone, Severy shales, Howard limestone, Scranton shales, Burlingame limestone, Willard shales, Emporia limestone, Admire shales, Americus limestone, Elmdale formation, Neva limestone, Eskridge shales, Cottonwood limestone, Florena shales, Neosho formation.

These formations are exposed along the Flint Hills in southern Kansas, but near the Oklahoma line most of the limestone members thin out and disappear, while sandstones come in and thicken to the south. No accurate section across the group has been made in Oklahoma, but it is probable that the group does not thicken to the south as rapidly as do the groups heretofore described. In fact, there is some evidence which indicates that in Lincoln, Pottawatomie, and Cleveland counties the rocks representing the southern extension of the Ralston group are not so thick as they are farther north.

In southern Pawnee and northern Payne counties the color of the rocks in the Ralston group changes and becomes a deep brick-red and so continues to the southern limits. This area includes the greater part of the so-called Chandler beds mentioned above.

HIGHER ROCKS.

Above the Ralston group the sequence of limestones and shales with occasional sandstones continues uninterrupted for several hundred feet. The Kansas geologists have described these rocks under the following names, the oldest below:

Wellington shales.
 Marion formation.
 Winfield limestone.
 Doyle shales.
 Fort Riley limestone.
 Florence flint.
 Matfield shales.
 Wreford limestone.

The limestones contain much flint, which, being resistant, withstands erosion, giving rise to a series of pronounced escarpments, which, in southern Kansas, constitute the Flint Hills. The rocks of the Marion are less resistant and form few pronounced escarpments. The Wellington shales are all soft rocks and weather into a flat plain.

In Oklahoma, all these formations pass into the Red beds along the line indicated on the map. Several of the limestones, particularly the Wreford, the Florence, and the Fort Riley, extend several miles into the Red beds before finally losing their color and merging with red sandstones and shales.

This peculiarity of relations is represented on the map in Kay and adjoining counties, where there is exposed an area of non-red Permian rocks, triangular in shape, bounded by the Kansas line, the Wreford limestone, and the eastern margin of the Red beds.

The Pennsylvanian terranes of Iowa are described as the Missouri and Des Moines groups. Smith⁷⁵³ has the following note on the Missouri:

The Missouri of southwestern Iowa is composed of shales, limestones, and limited amounts of sandstone. The shales, which comprise much the greater part of the strata, are generally calcareous—so much so that even those in immediate contact with the coals effervesce readily with acid. The limestones occur in layers from an inch or two in thickness to ledges 20 feet thick. Usually the limestones are highly fossiliferous. In all the Coal Measures exposures of Adams, Montgomery, Page, and Taylor counties not a single sandstone is to be found. Deep drillings also show a total absence of sandstone in the Missouri in these counties.

The Des Moines is described by Lees⁵³¹ as follows:

The beds of the Des Moines stage are usually divided in a broad way into three general divisions. These, as indicated in the section, are, from above downward, the Pleasanton, the Appanoose, with its equivalent beds farther northwest, and the Cherokee. Of these three the lower division, the Cherokee, is the most important, in Iowa as well as in Missouri and Kansas.

* * * It will be seen from the section that shales are the preponderating element in this

division, while sandstones are also quite important. Coal beds and fire clays play a minor part, although economically the former are exceedingly important. All these beds are wonderfully irregular in distribution. They thicken and thin with amazing rapidity and grade from one to another horizontally as well as vertically. * * * The beds of coal vary in thickness up to 7 feet, with an average of about 4 feet. Their areal extent is usually not above a few hundred acres and many of them are much below this maximum. Many of them lie in depressions in the St. Louis limestone, and their limits are determined by this formation. The Cherokee beds form the eastern line of outcrop of the Lower Coal Measures from Van Buren to Webster counties. Their maximum thickness will probably average 500 feet, although over most of their area they are considerably thinner. * * *

The Appanoose formation is typically developed in Appanoose and neighboring counties, as well as across the State line in Missouri. The beds composing this division are much more regular in structure than those underlying them, and the coals, while thinner, are more continuous and dependable. The most important of these coals is the Mystic seam, which underlies an area of about 1,500 square miles in the two States. * * *

Accompanying this coal seam are several relatively thin limestone beds marked, like the coal, by great continuity and uniformity of character. Some shales and a conglomerate are also present. * * *

The upper division of the Des Moines, the Pleasanton, is not of great importance in Iowa. While in Kansas these beds attain a thickness of about 200 feet and carry some important coal seams, they thin to the north and in Iowa are characteristically barren of coal and scarcely distinguishable from the next lower division. They thin rapidly in Guthrie County and probably do not extend beyond the northern limit of this county.

It is not to be understood that these three divisions are sharply set off one from the other, for they are for the most part conformable each to each, and hence there are no clear dividing lines. The divisions are made because each phase exhibits certain well-marked features which set it off in a general way from the others.

J-K 15-16. EASTERN INTERIOR COAL REGION.

The following statement on the eastern interior coal region was prepared for this volume by G. H. Ashley:

The Pennsylvanian of the eastern interior coal region consists of about 2,000 feet of rocks, occupying a simple structural basin that includes most of Illinois, southwestern Indiana, and part of western Kentucky, an area of about 50,000 square miles. The rocks consist of shales, sandstones, coals, clays, and limestones, usually in members of small thickness, many times repeated. Soft shales and sandstones predominate. Coals up to 13 feet thick, usually underlain by stigmarial clays, occur at about forty horizons, and limestones up to 20 feet thick are fully as numerous.

The basin, while mainly structural, was enlarged and extended by pre-Pennsylvanian erosion in the underlying Carboniferous rocks. To the north especially erosion removed successively the several Mississippian formations, and in part of northern Illinois the Pennsylvanian rests on Ordovician rocks.³⁴⁶

The oldest Pennsylvanian rocks of the region correspond in age with the Pottsville of the Appalachian region and are confined to the central and southeastern parts of the basin in southern Illinois³⁰⁰ and probably southern Indiana and the eastern part of this region in Kentucky, this basin probably having been for a time connected with the northern Appalachian field. These rocks are predominately sandy, with shale, clay, thin coals, and in many places conglomerate. The sandstone is massive and resistant and now forms a belt of rugged hills along the whole eastern and southern margin. The oldest of these rocks are probably of lower Pottsville age, and the top not older than Sharon, the basal member of the upper Pottsville. Unconformably above these in southern Indiana are 100 feet or less of rocks of later Pottsville age, more shaly in character and containing workable coals in small basins, as well as valuable

clays. These rocks may have had an original extent equal to or greater than the underlying sandstones.

Above the rocks just described are about 300 feet of rocks approximately corresponding in age with the Allegheny formation of Pennsylvania. These rocks are predominantly shaly. They contain at least sixteen coal beds, several of which are widely workable, forming the productive part of the Pennsylvanian. The coals are usually underlain by clays and overlain by shales. Most of the shales are either light colored and contain fragments of land plants or a marine or brackish-water fauna, or they are black and highly bituminous and contain an open-sea fauna. As a rule marine limestones closely overlie the roof shales, and at several horizons such limestones underlie the underclays. The beds of this part of the section are very persistent, many coal beds, clays, and limestones having been traced more or less continuously over large parts of the field. The geology of the basin has been described in several State and Federal reports.^a

The coals have been variously designated by numbers and letters. In Illinois the coals of this part of the series have been called Nos. 2 to 7. In Indiana they are known as coals II to VII, some of which correspond to coals of similar number in Illinois, and for the smaller intermediate coals small letters have been added. Numerals also have been used in Kentucky, where 9, 11, and 12 correspond to V, VI, and VII of Indiana and Illinois.^{40, 268, 952}

The upper 1,000 feet of the series is characterized by more limestones, some of them widely persistent, by thinner and fewer coals, and by more sandstone.

In the early reports the Pennsylvanian of this basin was divided into (1) Basal sandstone or Millstone grit, (2) Lower or Productive Coal Measures, and (3) Upper or Barren Coal Measures,⁹⁵¹ the line between the "Upper Coal Measures" and the "Lower Coal Measures" being drawn at a limestone variously known in the reports of different regions as the Shoal Creek, Curlew, Carthage (?), Carlinville, New Haven, and Somerville limestone, local names being also given to some of the other more persistent limestones and sandstones of the coal measures. In 1898 the present writer³⁶ divided the coal measures of Indiana into "divisions" on the basis of the principal coals, an arrangement continued in his supplemental revised report published in 1909.⁴⁰ The sandstone of Pottsville age in Indiana had previously been designated the Mansfield sandstone by Hopkins.⁴⁶² In 1900 the series was divided by the writer³⁷ into the Mansfield, Wabash, and Merom groups, corresponding respectively to (1) the Mansfield sandstone and associated rocks; (2) the rocks between the nonconformities above the Mansfield sandstone and below the Merom sandstone; and (3) the Merom sandstone and overlying rocks. In 1902 and 1903, for cartographic purposes, Fuller and Ashley^{347, 348} divided the series above coal VII into the Wabash, Inglefield, Ditney, Somerville, and Millersburg formations, and the upper part of the series, below coal VII, into the Petersburg and Brazil formations.

In view of the probable difficulty of carrying the bounding lines of these formations over all the basin, the names have not been retained in recent work. Since 1906 White and Weller have done considerable paleontologic work in all parts of the basin, in addition to the stratigraphic work in Illinois by DeWolf and in Indiana by the writer. (See references above.) As a result, the Pennsylvanian of the eastern interior basin has been divided into three formations, the first, or Pottsville, extending from the bottom of the series up to the top of the underclay of coal II in Indiana and coal No. 2 in Illinois; the second, or Carbondale formation, extending from that horizon up to and including coal No. 6; and the third, or McLeansboro formation, from the top of coal No. 6 to the top of the series. It is possible that future work may show that the limestone which in the Illinois State reports has been called Shoal Creek limestone can be traced over all of the basin, and that it may again be used as a line of division between the upper and lower parts of the McLeansboro formation. Coal V of Indiana, which appears to be the same as coal No. 5 of Illinois and coal 9 of Kentucky, may be developed throughout most of the coal field. If future tracing shows that it is, it may possibly be used

^a Illinois State Geol. Survey, vols. 1-7, 1866-1890; Bulls. 3, 4, 6, 8, 1906. Indiana Dept. Geol. and Nat. Hist., vols. 1-14; vol. 23, pp. 1-1573, containing a detailed report; vol. 33, containing a revised supplement to the report in vol. 23. Kentucky Geol. Survey, vols. 1-4; vols. 1-5, new series; reprints A, C, D; Bulls. 3, 4. U. S. Geol. Survey, folios 67, 84, 105, Geol. Atlas U. S.; Twenty-second Ann. Rept., pt. 3, 1902, pp. 272-303.

as the dividing line between two formations in the middle member. Again, future work may show it possible to divide the beds of Pottsville age into at least two formations, the upper one including the more shaly portion unconformably overlying the Mansfield sandstone.

The table opposite shows the subdivisions of the Pennsylvanian that have been made in the several fields of this region, with their known or probable correlations.

K 16. MICHIGAN.

The Michigan section of the Pennsylvanian is discussed by Lane⁵¹⁹ in a paper recently published. It comprises the Parma sandstone and Saginaw formation and is wholly of Pottsville age.

The Parma is a sandstone with small white pebbles of the size of split peas. According to Lane it may be regarded as the basal shore phase which was deposited earlier in the deeper and later in the marginal portions of the basin. It is thus synchronous in part with the Saginaw. The thickness assigned to the Parma in a well at Saginaw is 60 feet.

The Saginaw formation is described by Lane^{519h} as a succession of white shales or sandstones, black shales and coal, and blue shales, with a few thin bands of black-band iron ore and nodules of siderite containing zinc blende and iron pyrites. Limestones with marine fossils occur but are rare. *Lingula carbonaria* or *mytiloides* is found in the black shales. It appears to mark the horizon of the Upper Verne coal, which in places lies close above the Lower Verne coal, separated from it by a limestone.

The flora of the Verne coals, which Lane lists, is assigned by David White to the horizon of the Mercer coal, or upper Pottsville. Nothing younger than Pottsville is known, and it is probable that the earliest Pottsville is not represented in Michigan, even in the center of the basin.

To the account of the coal measures for this volume G. H. Ashley has contributed the following notes regarding Michigan:

The Pennsylvanian of Michigan is nearly everywhere deeply buried beneath glacial drift, so that our knowledge of its thickness, distribution, and stratigraphy depends almost altogether on drillings. Including the Parma sandstone at the base, it covers an area of about 11,000 square miles, of which the coal-bearing part of the series covers possibly 6,500 square miles.^{519a} This area is situated in about the center of the Southern Peninsula. The structure is that of a "very flat, gentle synclorium, whose longest axis is perhaps from northeast to southwest. This is modified by minor undulations."^{515a} The Pennsylvanian has a thickness of 700 feet or more, including the Parma sandstone at the base. This sandstone is about 100 feet thick, though measurements up to 145 feet are reported and measurements below 100 feet are common. In places the sandstone is absent.¹⁷¹

For the rocks above the Parma sandstone the name Saginaw formation has been used.⁵¹⁴ This formation consists of sandstone and shale, with coal, clay, limestone, and iron carbonate in nodules or thin beds. Coal occurs at twelve or more horizons.^{171a} The coals appear to lie on floors of irregular surface, varying in thickness to correspond—that is, the coal is thicker in the low places or "swamps" and thinner in the higher places. Many of the low places have the shape of a trough. The coals may range in thickness up to 5 feet; most of the merchantable coal is less than 4 feet, and some less than 2 feet. Under the coal is usually clay, and over it black shale, with blue shale and limestone above. Cannel coal or cannel-like coal is associated with many of the Michigan coal beds, usually at the top of the bed. Sandstones are abundant in the Saginaw formation, many of them as thick beds of white sandstone, in places grading into red at the top.⁵¹⁵ They do not occur at any constant horizon in the formation.

A comparison of the dip of the higher members of the Saginaw with that of the underlying strata and the stratigraphic sections in various parts of the basin indicates that at least part of

the earlier Pennsylvanian was confined to the center of the basin, the strata of later age extending outward by overlap to the present limits of the coal field and beyond.⁵¹⁵

The Pennsylvanian of Michigan appears to be all of Pottsville age.⁵¹⁶ From a study of the plants David White has suggested that the Verne coals, near the top of the series, may come at about the horizon of the Mercer coals of Pennsylvania. The basal sandstone, or Parma sandstone, may be of the age of the Sharon conglomerate member of the Pottsville of Ohio and Pennsylvania.

K 19. RHODE ISLAND AND EASTERN MASSACHUSETTS.

The Carboniferous strata in Rhode Island occupy the Narragansett Basin, which has been described by Shaler, Woodworth, and Foerste. From fossil plants obtained in these beds Lesquereux considered them equivalent to beds of the upper Carboniferous (Pennsylvanian) in Pennsylvania. Woodworth⁷³² tabulates the strata as follows:

Tabular view of the strata in the Narragansett Basin.

Group.	Northern field.		Southern field.		Remarks.
	Local areas.	Characters.	Local areas.	Characters.	
Dighton (1,000-1,500 feet).	Rocky Woods conglomerate. Seekonk conglomerate.	Coarse quartzite and granitic pebble conglomerates, with finer conglomerates and sandstone.	Purgatory conglomerate.	Coarse quartzite pebbles, usually much elongated and indented.	Probably though not certainly identical in all parts of the field, lying in synclines above the Coal Measures.
Rhode Island Coal Measures (10,000 feet).	Westville shales and Seekonk sandstones. Tenmile River beds. Mansfield beds. Cranston beds. Sockanasset sandstones. Pawtucket shales.	Alternations of fine and medium quartz, quartzite and granitic pebble conglomerates, with pebbly sandstones, sandstones (graywacke), shales, and coal beds, becoming metamorphic southward. Colors, black, blue, green, gray, locally red. <i>Odontopteris</i> flora and insect beds.	Aquidneck shales of Dr. Foerste. Kingstown series of Dr. Foerste.	Mainly shales with coal beds. Mainly sandstones and conglomerates with coal shales; usually metamorphic.	Both the Aquidneck and Kingstown series of Dr. Foerste, when traced northward, appear to form equivalent sections beneath the Dighton group, one on the eastern, the other on the western side of Narragansett Bay, and both extend downward to the basal beds in this typical area.
Wamsutta (1,000 feet).	Wamsutta { Slates and shales. Attleboro sandstone. Wamsutta conglomerates.	Beds of quartz, quartzite, felsites, felsite breccias, and felsite conglomerates, sandstones, arkose, and shales. Colors, red, locally brown, and green. Calamites.			The Wamsutta beds are not traceable south of Providence; probably represented by lower strata of Dr. Foerste's Kingstown series. In the vicinity of Pawtucket the Coal Measures underlie the Wamsutta.
Pondville (100 feet).	Millers River conglomerates, arkose beds.	Quartz conglomerates. Coarse, white, granitic waste or arkose.	Basal beds.	Quartzose conglomerates and arkose.	Essentially similar products of decayed granitic land surface in all parts of basin.
Unconformity.	Widespread erosion interval, representing all of Silurian and Devonian time and probably upper Cambrian.				
Pre-Carboniferous.	Broad exposures of granite intruded into lower and middle Cambrian and pre-Cambrian sediments.		Same as in northern field.		Pre-Carboniferous strata not definitely determined; Cambrian or pre-Cambrian.

Sayles and La Forge⁷⁰⁵ have published a note on faceted and striated pebbles from the Roxbury conglomerate, from which they conclude that the conglomerate is in part at least of glacial origin. They say:

The tillite occupies the upper portion of what has been known as the Roxbury conglomerate and at Squantum is from 500 to 600 feet thick and is overlain by about 60 feet of stratified conglomerate, sandstone, and interbedded slate, which make the top of the Roxbury and form a transition to the overlying Cambridge slate. The possible glacial origin of the Roxbury conglomerate has been suggested by the late N. S. Shaler and others, but these are the first known discoveries in that formation of definite evidence of glacial action or of the existence of glacially deposited beds.

They conclude that the Roxbury conglomerate and Cambridge slate are probably of Permian age.

The Boston Basin of eastern Massachusetts contains terranes which have been assigned to the Carboniferous, in part on physical and in part on paleontologic evidence, and which consist of arkose, conglomerate, sandstone, and slate. The rocks were described by Crosby¹⁸² and have been made the subject of a very detailed study by Mansfield,⁵⁷⁰ who has given special attention to the origin and distinguishing characteristics of the conglomerates. He describes them under the headings "Roxbury series," "Norfolk Basin series," "Narragansett Basin series," and "Harvard conglomerate." These distinctions are areal rather than stratigraphic and are made because in the absence of fossils and under the conditions of occurrence exact stratigraphic correlation among the small areas of outcrop was not practicable. Mansfield^{570a} concludes that—

The evidence adduced in the preceding paragraphs as to origin is largely negative and unsatisfactory. The bedding and texture of the sediments, though attaining a fair degree of regularity, do not display these features in so high a degree of development as might be expected in true marine strata. The apparent gradation upward from coarse to fine texture in the Boston Basin, suggestive of marine transgression, is offset by the occurrence in the Narragansett Basin of a gradation in the opposite direction, suggestive of nonmarine deposition. The fossils thus far found in the Narragansett and Norfolk basins are indicative of nonmarine rather than of marine origin. Similar evidence is borne by the irregularities of bedding and of texture. The lithological similarity of the Roxbury conglomerate to the rocks of the Norfolk and Narragansett basins makes it probable that all are of like origin and that the entire Carboniferous series of this region is nonmarine. More than one process, however, was concerned in the formation of the series. The more regular and even-bedded portions are suggestive of quiet fluvial or lacustrine origin, while the more irregular and tumultuous portions of the deposit indicate torrent action. The great quantity of large pebbles of relatively fresh granite and the abundance of feldspathic material in the sandstones and in the matrices of the conglomerates suggest that much material was furnished to the streams of that time by glaciers of which no direct evidence now exists.

In describing the geology of Worcester and vicinity, Perry and Emerson,⁶³⁴ after giving an account of local occurrences, summarize the facts relating to the Carboniferous as follows:

Starting at Worcester, as a center, we find first and uppermost the Worcester phyllite. This rock underlies the central part of the city and may be traced southwesterly and northeasterly across the State. It presents varying stages of metamorphism, from a true argillite to a well-defined mica schist, and contains in different places minerals resulting from metamorphism, as garnets, chiastolite, graphite, staurolite, and anthracite. The laminæ of the phyllite are frequently highly crumpled, producing folds almost infinitesimal in size and infinite

in number. In some places these fine folds have been so compressed and flattened that they constitute the beginning of folia of a new structure across the old. In one place, also, this rock exhibits the development of a new structure by the rotation in sections of the laminae between fault planes.

That the phyllite is really uppermost in position with reference to the other rocks of sedimentary origin found in Worcester is shown by its superposition in anticlines. In deciding as to its position in the geologic series—that is, its age—we rely on the specimens of *Lepidodendron acuminatum* found at the so-called coal mine here in Worcester, and we assign it to the Carboniferous. It probably belongs to an early part of that period.

On the east this phyllite blends into a rusty, fibrolitic, graphitic mica schist which is found in small, detached patches within the Bolton gneiss area. These are probably remnants, indicating the former greater extension of this schist formation.

The second and lower formation in Worcester is a micaceous quartzite of a brownish-gray color. This is associated with the phyllite in the latter's extent across the State and occurs in bands east and west, sometimes also in the midst, of the phyllite.

Because of the close relationship which these two formations bear to each other, the micaceous quartzite is also assigned to the Carboniferous period. They have been folded together on a large scale in the Oakdale-Millstone Hill anticline, the phyllite above and the quartzite beneath, and they have been crumpled together on a small scale in many places, as may be seen in the rocks of the deep cuts of the Boston & Albany and Boston & Maine railroads here in Worcester. These two formations appear, as far as can be seen in the midst of such severe folding, to be conformable.

Like the phyllite, the quartzite also shows the development of a new or secondary structure across the old or original structure; and in the case of the rock of Wigwam Hill the new structure was formed by the compression of small folds in the micaceous part of the quartzite, so that these compressed folds have become the folia of the schist as it is at the present time. This quartzite is in a few places conglomeratic, and the pebbles show deformation by pressure, being more or less flattened in the plane of the laminae.

Penetrating the Carboniferous phyllite and quartzite are granite bosses, of which Millstone Hill is typical. These granites are later than the Carboniferous. That of Millstone Hill contains inclusions of both the phyllite and quartzite. The structure of the adjoining Carboniferous quartzite wraps around this granite, sometimes with the original bedding and sometimes across it. The rocks in the immediate vicinity of the granite have been greatly shattered and now frequently appear as breccias or made up of small angular blocks cemented together by fine quartz veins. Even the phyllite included in the granite is brecciated, indicating that the pressure was not excessive when this was included in the molten granite, hence that this granite did not solidify at a very great depth beneath the surface of the earth. * * *

The Carboniferous quartzite, traced to the east, blends into a coarser-grained, more highly metamorphosed quartzose mica schist, frequently containing alternating hornblendic bands. Between the laminae of this schist there has been forced, by parallel injection, much coarse granite. This schist and granite afford many minerals, both original and secondary, as enumerated in the study of the quarry near Quinsigamond. The alternation of schist and granite is very gneissoid in appearance and often presents a close resemblance to a metamorphic conglomerate. From this appearance, and from the fact that it extends through the town of Bolton and there contains the well-known limestone mineral locality, this phase of the Carboniferous quartzite is called the Bolton gneiss.

It is upon this Bolton gneiss that are spread the patches of the rusty, fibrolitic, graphitic mica schist phase of the Carboniferous phyllite already referred to as indicating the former greater extension of that formation.

Within this Bolton gneiss are also small areas of crystalline limestone in the towns of Boxboro, Bolton, Northboro, Millbury, and Webster. These crystalline limestones abound in minerals formed during the metamorphism, and the Bolton and Boxboro limestones have long been noted for the scapolite and other minerals they afford. * * *

The Bolton gneiss may be traced northeasterly, easterly and southeasterly from Worcester and is found underlying Oxford, Millbury, Grafton, Shrewsbury, Northboro, Berlin, Bolton, Boxboro, and other towns to the northeast. It is seen from this that the Bolton gneiss makes up a large portion of the eastern part of the plateau of central Massachusetts. * * *

It is well for us, therefore, in tracing the Bolton gneiss, to follow a southeasterly direction through the town of Millbury into the town of Sutton. * * * In this direction we find that the Bolton gneiss extends from Worcester through Millbury and the northwestern part of Sutton; then as we go still farther to the southwest, in the vicinity of West Sutton, we become aware that the rock beneath is quite different. This change from one formation to another may be nicely seen about three-fourths of a mile southwest of West Sutton.

This more ancient formation consists, generally, of a light-colored, nearly white, finely grained, sugary quartzite, which is at times actinolitic. It constitutes a comparatively narrow band extending through the towns of Webster, Oxford, Sutton, Grafton, and Westboro and is called the Westboro quartzite. As it dips beneath the Bolton gneiss on the western side of a large anticline, the quartzite is considered older than the gneiss. In appearance this quartzite reminds one of the Cambrian quartzite of western Massachusetts, though there is nothing in this eastern rock to definitely fix its geological age. * * *

We have now briefly considered the rocks from Worcester to the eastern and southeastern border of the plateau of central Massachusetts, bringing out the relation of each to the succeeding one, as far as we can. Let us next start from Worcester, and, in like manner, trace the rocks westerly. Passing over the phyllite, which is found underlying the central part of Worcester and which has already been considered, we find in the western part of the city the Carboniferous micaceous quartzite, identical with that found east and in the midst of the Carboniferous phyllite. This arrangement of these two formations is due to folding and subsequent erosion, by which the lower one is revealed alongside of the upper.

On following this micaceous quartzite in the extreme western part of Worcester the rock becomes coarser in grain and abounds in parallelly injected granite, giving an appearance that frequently simulates a metamorphic conglomerate. This western and more highly metamorphosed phase of the Carboniferous quartzite has been called the Paxton schist, from its occurrence in that town, just as the similar gneissoid extension of the same quartzite on the east is called the Bolton gneiss. The Paxton schist is less gneissoid than the Bolton gneiss because of a smaller proportion of injected granite.

Lying above the Paxton schist, as is shown by its upper position in an anticline in the northwestern part of Worcester, is a rusty, graphitic, fibrolitic mica schist identical with the rusty, graphitic, fibrolitic mica schist found in patches within the area of the Bolton gneiss. This rusty schist has been crumpled into almost innumerable folds, both large and small, and contains much injected granite. Lying as it does above the Paxton schist, which is a more highly metamorphosed phase of the Carboniferous quartzite, this rusty schist bears the same relation to the Paxton schist that the Worcester phyllite bears to the Carboniferous quartzite; also on the east side of Worcester there is, in a small area, a transition from the phyllite into a like rusty, graphitic, fibrolitic schist; this rusty schist in the western part of Worcester, called the Brimfield schist, is then, a more highly metamorphosed or more coarsely crystallized phase of the Worcester phyllite and belongs to the Carboniferous period. This Brimfield schist, in addition to making up large areas, also occurs in limited patches within broad areas of the Paxton schist. These patches probably indicate the former extension of this upper Brimfield schist and are remnants that have escaped in the profound erosion by which the rock surface of this plateau has been formed. These two rocks, the Paxton and Brimfield schists, together with their included eruptives, make up the plateau of central Massachusetts westerly from Worcester to the boundary as already defined.

But these Carboniferous rocks have even a greater extension to the south and north and may be traced far into Connecticut on the one hand and beyond the Massachusetts boundary into New Hampshire on the other.

L 19-20. NEW BRUNSWICK.

The Carboniferous of New Brunswick comprises Mississippian, Pennsylvanian, and Permian strata. Bailey has summed up the general facts in an article, quoted at some length in Chapter VIII, from which the following ^{46b} regarding the "Coal Measures" is taken:

The contrast between the above-described rocks [lower Carboniferous] and those of the coal formation is, in the central counties, usually very marked, the bright-red color so characteristic of the one being replaced by an equally characteristic gray color in the other, while at the same time the strata cease to be calcareous. The basal beds of the coal formation are especially noticeable as being very light colored and almost entirely made up of well-rounded pebbles of white quartz. Conglomerates which are somewhat less coarse occur also higher in the series, but with them are beds of coarse sandstone and thinner beds of shale, with, in places, thin seams of coal. Upon the shore of the Baie des Chaleurs about 50 feet of fine shales, gray, green, or red in color, with limestone nodules, extend for several miles in the coastal cliffs about New Brandon, resting upon gray sandstones, but over the larger part of the central coal field the absence of fine sediments is a noticeable and unpromising feature.

Though gray is the prevailing color in the rocks of the coal formation, it is necessary to add that it is not unfrequently replaced by a dark purple tint. Occasionally also the beds are reddish, but where this is the case it is always a question whether the rocks so colored are not of the next division, viz, the newer coal formation or Permo-Carboniferous.

The only data available with regard to the thickness of the coal formation in the Central Basin is that to be derived from borings, particulars of which will be given later. The greatest attained at Grand Lake was 400 feet. At Dunsinane, in Kings County, a depth of 1,200 feet was reached, apparently all in the Carboniferous. In Westmoreland County north of Moncton a depth of 700 feet has been reached in apparently Carboniferous strata. In Albert, where the strata are more highly tilted, the Carboniferous rocks alternate, by displacement, with lower Carboniferous beds, but never attain any considerable thickness.

CHAPTER XI.

PERMIAN.

Color, light gray.

Symbol, 11.

Distribution: Southwestern United States; West Virginia, Ohio, and Pennsylvania; New Brunswick and Nova Scotia. Elsewhere mapped with "Carboniferous undivided." (See fig. 13.)

Content: Permian limestone and red beds, Kansas to Texas; Permian red beds, New Mexico; Opeche and Minnekahta formations, Black Hills; Dunkard group of the northern Appalachians; red and gray sandstones and subjacent New Glasgow conglomerate of New Brunswick, Nova Scotia, and Prince Edward Island. Includes some Triassic red beds in mapping.

Permian areas.

H-I 13-14. TEXAS AND NEW MEXICO.

The strata assigned to the Permian in trans-Pecos Texas and adjacent parts of New Mexico comprise the Delaware Mountain formation, the Capitan limestone, the overlying unnamed sandstones and limestones on the eastern flanks of the Guadalupe Mountains, and the red beds of Pecos Valley, which include the Castile gypsum and the Rustler dolomite. These formations outcrop in the areas colored as Carboniferous undivided, and Richardson's descriptions of them are given in Chapter VIII (p. 360).

The Delaware Mountain formation and the Capitan limestone contain a unique fauna, named the Guadalupian, which has been described in detail by Girty,^{364,367} who tentatively assigned it to the Permian. (See p. 359, Chapter VIII.)

The Capitan limestone, the uppermost formation known to contain the Guadalupian fauna, on the eastern flanks of the Guadalupe Mountains, southwest of Carlsbad, N. Mex., is overlain by a few thousand feet of sandstone and limestone to which formation names have not yet been given. These in turn are overlain by the red beds of Pecos Valley, which, according to Richardson^{670a}—

consist of a group of varicolored sandstone and shale, red predominating, interstratified with beds of magnesian limestone and gypsum. In detailed study it is desirable to divide these rocks

FIGURE 13.—Sketch map showing the distribution of Permian rocks that are separately represented on the geologic map of North America and the key to references in the text.

into a number of formations of comparatively limited extent similar to the Castile gypsum and the Rustler formation, which when traced for a number of miles beyond the area in which they were named lose their individual character and become difficult to recognize as such. The formations of the red-bed group are characteristically lenticular. * * *

The red beds of Pecos Valley are delimited above, as Cummins and Drake determined a number of years ago, by an erosional unconformity, which separates them from the overlying Dockum formation, of Triassic age. The lower limit of the red beds of Pecos Valley, defined as the lowest occurrence of either red strata or of gypsum, is variable and is not a definite horizon but rather forms a zigzag line extending diagonally across the strike of the rocks. * * * [In central New Mexico] almost the entire Carboniferous section is composed of red beds.

Fossils are of rare occurrence in these red rocks, although at a few localities shells have been obtained from the interbedded limestones, and fragments of fossil wood also have been found. Dr. Girty does not feel justified in saying anything definite as to the age of the fossils collected from the red beds either by Mr. Fisher or by myself. These include *Schizodus ovatus* and *Pleurophorus* aff. *subcostatus* from 7 miles northwest of Roswell, N. Mex., and a *Schizodus* having the general shape of *S. harei*, and a form suggesting by its shape a small *Myalina* from the Rustler Hills, El Paso County, Tex. Nevertheless the stratigraphy indicates that the red beds of the Pecos Valley are to be correlated with part of the Permian red beds of Oklahoma and northwest Texas, for they were connected by tracing around the northern border of the Staked Plains, by W. F. Cummins in 1891. * * * Cummins's work has been confirmed by C. N. Gould, who has mapped the Greer and Quartermaster formations, which are part of the Permian red beds of Texas and Oklahoma, across several counties in the panhandle of Texas, and along the Canadian River as far as the Texas-New Mexico boundary.

This stratigraphic correlation is in agreement with paleontologic data recently obtained by Dr. J. W. Beede, * * * who found fossils in a limestone in the red beds south of Lake-wood, N. Mex., which he correlates with the Whitehorse-Quartermaster fauna.

The Permian of northern Texas is continuous with that of Oklahoma in area and stratigraphy. It comprises red beds, which grade southward into blue clays and limestones, just as the red beds of Oklahoma change northeastward into similar rocks. Cummins¹⁹⁸ says:

In previous discussions of the Permian formation in Texas ^a I have separated the strata into three divisions, naming them Wichita, Clear Fork, and Double Mountain, the Wichita being the lowest in the series. In my description of the Coal Measures in Texas I separated the strata into five divisions, giving to the upper division the name of Albany and the one immediately below that the name of Cisco. * * *

The Wichita division was described as extending southward as far as the Salt Fork of the Brazos River. It is represented as resting on the top of the Cisco division of the Coal Measures, along its entire eastern border, and as being overlain by the Clear Fork division along its entire western border.

The Albany division of the Coal Measures was described as beginning on the north at the Salt Fork of the Brazos River and extending southward to the southern limits of the Coal Measures in the State, resting directly upon the Cisco division and overlain on the west by the Clear Fork division of the Permian. It will therefore be seen that the Wichita and Albany divisions were made to occupy the same stratigraphic position.

At the time these divisions were first described the relationship between them could not be determined from the facts then in my possession. The area of the Wichita division was known to be Permian and had been somewhat described prior to my giving it the present designation. It was embraced in the area known as the "Red Beds" of Texas. In it the invertebrate fossils were partly those known to occur in the Upper Coal Measures, and partly those that were char-

^a See Ann. Repts. Geol. Survey Texas, 1889 to 1892.

acteristic of the Permian in Europe. The vertebrate fossils, which had been found quite abundantly in the area, were forms peculiar to the Permian. The area was therefore assigned to the Permian without any hesitancy.

The fossils that had been taken from the area assigned to the Albany division were only such invertebrate fossils as had been found in the Upper Coal Measures, and no vertebrate fossils had been found.

Instead of the strata being composed of red clay beds and sandstones, as was the case in the Wichita division, they were principally limestones and yellowish and bluish clays. In view of these dissimilarities it was thought best to describe the two areas under different names, although it was thought at the time that it was more than probable that the Wichita and Albany divisions were but different facies of the same beds. * * *

During my recent examinations the true stratigraphic relation between the two divisions has been brought out, and I can now say with absolute certainty that they are the same in time and belong to the Permian.

The Wichita division is now admitted by everyone to be Permian. This conclusion is based chiefly on the fossils that have been taken from the area and which have been described and determined by different specialists.

Prof. E. D. Cope described the vertebrate fossils collected from this division, a list of which was published in the second annual report of the Geological Survey of Texas. These fossils show the Permian age of the beds as plainly as any one kind of life can show the age of any formation.

The invertebrate fossils were partly described by Dr. C. A. White, and a list of his determinations was published in the second annual report of the Texas Geological Survey. The evidence from this source strongly corroborates the conclusion reached by a study of the vertebrates, showing the Permian age of the division.

Part of the flora collected from the division was described by Dr. I. C. White, and the evidence thus obtained also corroborated the conclusion of the Permian age of the strata.

Williston^a dissents from this statement and cites Case,¹³¹ who summed up the evidence as follows:

The evidence for the Permian character of the beds rests, then, on the presence of a single genus, *Naosaurus*, common to the Permian of North America and Europe, and on the community of many very primitive characters and numerous more specialized ones, which, however, reach either down into the Carboniferous below or up into the Triassic above.

Cummins continues:

The Permian age of this division being admitted, it follows that if the Albany division is but a different facies of the same bed it also must be Permian. This fact has been abundantly shown by the stratigraphic work done during the past season by myself and party.

In previous years I made and published complete sections, by instrumental measurement, across the area of the Albany and Wichita divisions at right angles with the strike, and gave descriptions of the different beds composing the divisions, with a partial list of the fossils collected from them. The lines of these sections were about 70 miles apart. The section across the Albany division began at Albany and ran thence in a northwestern direction, crossing the Clear Fork of the Brazos River at the mouth of Fish Creek. The section across the Wichita division began at a point 8 miles north of the town of Seymour and ran thence to Wichita Falls.

During the past year (1894) I have traced prominent beds found in each of these divisions across the country between these two sections, and have found them to be continuous from one to the other. By this means I was enabled to see the gradual change in the beds and to understand that they were the same in time of deposition.

^a Personal communication.

The panhandle of Texas has been surveyed by Gould,³⁷⁴ who gives the following section and description of the gypsiferous red beds and sandstones below the Cretaceous:

Geologic formations of the Texas panhandle.

System.	Formation.		Characteristics.
Triassic.	Dockum group.	Trujillo.	Red shales. Red to gray sandstone and conglomerate (upper sandstone). Red shales. Red to gray cross-bedded sandstone and conglomerate (middle sandstone). Red shales. Massive to cross-bedded sandstone (lower sandstone).
		Tecovas.	Dark-red or magenta shales and soft sandstones. Variegated shales and soft sandstones.
Carboniferous (Permian).	Quartermaster.		Red clay. Massive white dolomite (Alibates lentil). Red clays. Massive white gypsum (Saddlehorse lentil). Red shales.
	Greer.		Massive white gypsum in ledges interstratified with red shales.

By far the greater part of these rocks are of Permian, Triassic, or Tertiary age. The Permian and Triassic rocks are generally spoken of as red beds, owing to the predominating color of the clay which forms a large proportion of these deposits.

Farther east in Texas and particularly in Oklahoma the Permian red beds are well exposed and have been divided into five formations—the Enid, Blaine, Woodward, Greer, and Quartermaster. In the region here described only the two upper formations of the Permian red beds occur, and these are found in the deep canyons, where erosion has cut through the overlying Triassic and Tertiary formations. The Triassic red beds are exposed along the edge of the Llano Estacado in Texas and New Mexico, as well as in the canyons cut by the various streams that rise in the southern part of the High Plains.

The formations are described and correlated in detail in the report by Gould, and references to earlier work are given.

In a recent article on the Wichita formation of northern Texas, Gordon³⁷¹ submits results of investigations made in connection with a study of the underground-water conditions of that area. The invertebrate fossils are discussed by Girty and the plant material by David White. In regard to the correlation and classification, Gordon has the following to say:

That the limestone series of Baylor County is the equivalent of the "Albany" formation of the southern area is fully established by both the stratigraphic and the faunal evidence. The beds in the northern area, which include the limestones, shales, and sandstones of Baylor County and the sandstones and shales of Archer and Wichita counties, constitute the Wichita formation. Our investigations therefore fully support the conclusions of Cummins and Adams as to the equivalency of the "Albany" and Wichita formations. * * *

The Permian age of the beds to which the name Wichita was originally applied has been accepted quite generally, though there are not wanting those who regard the evidence as unsatisfactory. It was based chiefly upon the vertebrate and plant remains. In the southward or

"Albany" area the beds are wholly marine and destitute of both plants and vertebrates, though abounding in the remains of invertebrates. The Pennsylvanian aspect of this fauna has strongly impressed some investigators, including the author of this paper, and doubt was entertained as to whether the plane of separation between the Pennsylvanian and the Permian should be drawn at the base or at the top of the formation. The studies of David White, Beede, and others have contributed much in recent years to a knowledge of the Permian in America and in the main support the view of the Permian age of the Wichita formation. In a recent paper Beede has ably discussed the Permian of Kansas, with which he correlates the "Red Beds" of Texas. Cummins correlates the beds of eastern Baylor County which he regards as the top of the Wichita formation with the Fort Riley limestone of the Chase group of Kansas. * * * The top boundary of the Wichita formation was drawn by Cummins at the top of a stratum of red clay overlain by thin beds of limestone and blue shales at a point on the Big Wichita 4 miles west of the east boundary of Baylor County. However, as we have shown, beds which are undoubtedly the same as those which appear at Seymour and southward in Throckmorton County appear in the banks of the Big Wichita River some 8 to 10 miles west of this point. The thickness of the strata included here, which overlies Cummins's topmost beds and are here included with them in the Wichita formation, is estimated to be 250 to 300 feet. The whole limestone and shale series of Baylor County thus included as the upper division of the Wichita formation is provisionally placed at 450 to 500 feet and consists, as shown elsewhere, of limestone beds of varying thicknesses separated by varying but usually great thicknesses of shale.

How much of this is to be correlated with the Fort Riley limestones can be determined only by more detailed stratigraphic and paleontologic studies. Cummins evidently intended to include the lower beds only in his correlation. It may be that further studies will show that the overlying beds of the Winfield limestones of Kansas are represented here.

In regard to the fauna Girty says:

Not until recently, it seems to me, has adequate evidence been adduced either for distinguishing the Permian of Kansas and that of Texas sharply from the underlying Pennsylvanian or for correlating them with the Permian of Europe. C. A. White found the Wichita fauna to have essentially a Pennsylvanian ("Coal Measures") facies, in which, however, certain characteristic Permian ammonites occur. A similar conclusion seems to be demanded by the evidence of the present collections. * * *

Mr. White finds that about 50 per cent of the Wichita flora consists of species characteristic of the Permian, while most of the remainder are known to occur in rocks regarded as of Permian age. If we omit the fauna of the Kansas Permian, to include which would be a sort of *circulus vitiosus*, no condition comparable to this has been demonstrated by the invertebrate fossils and, in so far as I have seen the evidence, no such condition exists. I am, therefore, accepting the Permian age of the Kansas and Texas beds, but at present strictly on the paleobotanic evidence.

David White states:

In accordance with the paleobotanical standards of western Europe, I refer the plants of the Little Wichita in Texas to the lower Permian, the terranes being probably referable to the Chase group in Kansas. In this connection it should be observed, however, that the Artinskian flora of the Urals is essentially Permian, and that paleobotanists universally agree with the general usage of the geologists of western Europe in referring the Artinsk to the Permian.

I-J 12-13. UTAH, COLORADO, ARIZONA, AND NEW MEXICO.

The Permian of the Southwestern States is involved in the "Red Beds," which comprise Pennsylvanian, Permian, and Triassic strata variously associated in different districts. As the surveys yet made suffice to distinguish the formations of either age from the others in a few localities only, it is necessary in general to map

them as a whole, and they are all included, so far as they may be present, in the "Red Beds," in the dark greenish-blue areas of the map (9).

Cross has recently divided the "Red Beds" of the plateau province in southwestern Colorado into the Cutler formation (Permian?) and Dolores formation (Triassic). Below the Cutler occur the Rico and Hermosa formations (Pennsylvanian), whose approximate equivalents farther south, in the Rio Grande region, are "red beds" as described by Lee.^{528a}

The Cutler formation is thus characterized by Cross and Howe:¹⁹³

The Cutler formation embraces somewhat more than the lower half of the Red Beds section of southwestern Colorado. Its strata are invariably red in color and include sandstone, arkose grit, conglomerate, shale, and limestone. The maximum observed thickness is about 1,600 feet.

The formation seems conformable with the underlying Pennsylvanian beds, but above it occurs a stratigraphic break with at least local unconformity. The base of the formation is indicated by the Pennsylvanian fossils of the Hermosa or Rico formations and in a broad way by the color line. No fossils have been found in the Cutler beds.

Great variability in lithologic constitution, both vertical and lateral, is one of the most striking features of the Cutler formation. The sandstones are sometimes fine grained and massive, but bedding is ordinarily distinct and few homogeneous beds exceed 10 or 15 feet in thickness. All strata are calcareous, and the finer-grained sandstones grade into calcareous shales and impure marls or into sandy limestones. These rocks are naturally more or less friable and crumbling.

The finer-grained strata are of the strongest red color, which is due to a ferritic pigment, and they are also commonly characterized by abundant bronze or rusty mica, which renders them fissile. Clay beds are rare, as is massive limestone. Commonly the more calcareous strata are nodular or gnarly and grade into calcareous sandstones. Greenish and grayish tints are locally found in the nodular limestones and a mottling with red is common. Some of the nodular limestones appear to be intraformational conglomerates.

The sandstones frequently grade into arkose grits and these into conglomerate. With increasing coarseness of grain the red changes to pink, and locally beds of coarse grit are gray or almost white. In other cases the finer matrix of grits and conglomerates is dark red. The cement of the strata is calcite, and most of the conglomerate and arkose beds are comparatively resistant to weathering and form prominent ledge outcrops on all steep slopes.

The grit beds often reach 35 feet in thickness. They are variably massive, being in some places almost homogeneous from top to bottom, while more frequently divided by several thin shale or sandstone layers. Cross-bedding is almost universal. Sporadic pebbles are present in all grits, and with their increase the stratum becomes conglomerate.

The sandstones are mainly quartzose, the grits contain much feldspar, mica, and small pebbles like the larger ones of the conglomerates. The latter contain pebbles of granite, gneiss, and various schists, of quartzite and limestone, of greenstone and porphyry, and many of red, pink, smoky, or white quartz, part of which may come from veins.

The pebbles are in general larger near the San Juan Mountains. Boulders a foot in diameter are occasionally present, but most pebbles are only a few inches in diameter. The relative abundance of different rocks among the pebbles varies according to locality. The greenstone schists, metadiorite, and green porphyry are most abundant in the Uncompahgre Valley exposures; granites and quartzites are always prominent.

Taking the formation as a whole, the grits and conglomerates comprise about one-third or less of its total thickness in the quadrangles surveyed, and they are distributed throughout the section. It may be assumed that as distance from the source of the pebbles increases, the formation becomes more and more a series of fine-grained sandstones and shales, with subordinate grits and conglomerates.

The assignment of Permian age to the Cutler formation rests on its apparent conformity to distinct upper Pennsylvanian strata and on its unconformity with the overlying Triassic. No fossils have yet been found in it. Its recognition outside of the San Juan district is difficult. Cross^{193b} presents the known facts and suggests the probable correlation of the Cutler with appropriate divisions of the sections observed by his predecessors.

The Red Beds of the Rocky Mountain province have proved to be perhaps the most difficult portion of the Paleozoic and Mesozoic section to analyze and reduce to definite groups and formations. In the first place, the red color has been found unreliable as a guide in correlation. It extends at some places into the fossiliferous Pennsylvanian rocks and may penetrate upward into Jurassic beds. Fossils have been discovered in Red Bed strata in many different localities—here of Permian, there of Triassic affinities. Unfortunately the two kinds of fossil evidence have seldom been found in one section, affording a means of division. Triassic fossils occur in some places very near the top of the Red Beds and in others near their base, in proximity to known Pennsylvanian strata. This apparent range of Triassic fossils has been a prominent factor in forming what seems to be the general opinion that the larger part of the Red Beds is to be assigned to the Trias.

As far as I know, no one has presented evidence of a stratigraphic break within the Red Beds or suggested that the conflicting evidence as to age might be explained by such a break. The Ouray unconformity, however, establishes for southwestern Colorado a definite line between Triassic and pre-Triassic portions of the Red Beds, which can be traced on a lithologic basis where no visible unconformity exists. From evidence which will be presented in following pages it seems certain that the Dolores formation may be positively recognized through its fossils and lithologic character in Utah and Arizona and very possibly in New Mexico. As a step toward a better understanding of the Red Beds I desire to make certain suggestions as to the correlation of the Cutler and Dolores formations with strata in other parts of Colorado, in Wyoming, and particularly in the plateau province of Utah, Arizona, and New Mexico. The discussion is based on a study of the literature, on recent published discoveries, and on unpublished information. Naturally much of the correlation suggested is tentative.

Four principal factors have had influence in this tentative correlation:

(a) *The lithologic character of formations compared.*—This is the most important on the whole, since it is the only one applicable in all places.

(b) *Fossil evidence.*—This guide is becoming more and more important as new discoveries are made. Unfortunately, collectors of fossils and even paleontologists are not always alive to the importance of careful stratigraphic studies and accurate measurement and description of sections in the localities where fossils are obtained. Their work is therefore often shorn of much of the value that should attach to it.

(c) *The influence of post-Triassic elevation and erosion.*—The stratigraphic break at the base of the La Plata sandstone [Jurassic] is one of great magnitude throughout the western portion of Colorado. In several places the La Plata is seen in angular unconformity with the entire Paleozoic and older Mesozoic section. It is possible that synchronous elevations, in gentle folds or low domes, occurred in the plateau district, but have not been recognized.

(d) *The influence of the pre-Triassic elevation and erosion.*—While it appears probable that the pre-Dolores uplift was by no means so extensive as the post-Dolores disturbance, it is plain that its influence must be looked for in the plateau country as well as in the Rocky Mountains.

The type locality of the Cutler formation (Cutler Creek, Ouray quadrangle, Colo.) is in longitude 107° 45', latitude 38°. The plateau province stretches thence westward, cut by the tributaries of Grand River known as Dolores and San Juan

ivers and their branches. Regarding the general geologic conditions bearing on correlation in this region Cross says:

The general conditions under which correlation of the San Juan formations with those of the plateau section must be made are as follows: Adjacent to the mountains there is a broad zone of gentle westward slope in which Cretaceous beds occur. The main streams flowing west and south cut valleys into and in some places through the Cretaceous into underlying formations. Nearer the canyon of the Colorado the valleys widen and broad platforms and terraces of Jurassic and Triassic beds appear, the Cretaceous being restricted to the divides and isolated mesas. The Paleozoic formations appear at first only in isolated exposures in the deeper canyons, but far to the southwest rise to form the broad plain called the Colorado Plateau, on the south side of the Grand Canyon. Thus the older the formation the greater are the gaps between districts of good exposures, and the greater the likelihood that in the covered tracts unsuspected complications have entered into the problem.

Cross also describes the occurrence of Triassic and Jurassic strata and says:

The heart of the plateau is about 80 miles northwest of Ouray, and Cretaceous formations occupy the greater part of the intervening country. The San Miguel River, however, affords a section extending somewhat below the Dakota sandstone for the entire distance from the Telluride quadrangle to its union with the Dolores River, and the Dolores itself penetrates locally through Jurassic and Triassic into Carboniferous formations.

* * * * *

Below the Dolores beds Spencer found coarser Red Beds, often conglomeratic, with pebbles 3 inches or more in diameter, and several hundred feet of such strata were noted. No opportunity was found to measure a section showing the full thickness of these coarser Red Beds, but, as observed by Peale, they are underlain by fossiliferous Pennsylvanian Carboniferous in Sinbad Valley, where there is also much structural complexity obscuring the relations.

Spencer's observations seem to show that the section of the lower Dolores Valley embraces strata to be correlated with the Cutler [Permian?], Dolores [Triassic], La Plata [Jurassic], and McElmo [Jurassic?] formations of the San Juan region.

Peale reconnoitered southwestern Colorado in connection with the Hayden Survey (1875) and mapped as "upper Carboniferous" certain beds which he classed as "probably Permian." These presumably represent the Cutler. Cross^{189b} restudied the section in 1905 and describes the remarkable Permian (?) conglomerates in contact with and near granite outcrops on West Creek.

Where the sediment was seen resting on granite, the lower layers consisted of coarse, angular gravel, scarcely bedded at all. At a distance of a few feet above the granite bedding planes become more distinct, through alternation of finer and coarser material aided by color differences, the finer-grained material being reddish. At 25 feet above the granite the characteristic alternation of grit and conglomerate began. But the distribution of pebbles and boulders is very irregular, the latter are often subangular, and the whole is so little consolidated that the disintegrated beds seem like surface gravels.

Cross gives a detailed section of conglomerate and grit 879 feet thick and continues the discussion of correlation as follows:

The pebbles of the conglomerate strata of this section are principally of granite and the most abundant variety is the very coarse textured one with large orthoclase crystals occurring in the nearest exposures of the Uncompahgre Plateau. Among the pebbles are some of greenstone schist which indicate that the pre-Cambrian complex furnishing this material is similar to that from which the Cutler conglomerate of the San Juan was derived. Similar greenstones were observed in the conglomerates of Grand River valley.

Below the measured section there may be several hundred feet of similar strata, for the somewhat deeper cutting of Dolores River does not reveal the base of the succession of grits

and conglomerates. The next lower formation is probably a series of gypsiferous shales and sandstones and the nearest locality at which such strata are known to occur is in Sinbad Valley, 12 miles south from West Creek. A fault running near the base of the northeastern scarp prevents a clear determination of the relations, but the gypsiferous beds are manifestly older than the strata below the Dolores. These belong no doubt in the series measured on West Creek. Owing to complex folding and faulting * * * the extent and relation of the gypsum-bearing beds can not be ascertained, but they are apparently some hundreds of feet in thickness.

* * * * *

Comparing the strata known on Grand River between the Dolores base and the Pennsylvanian limestones with the Cutler formation (Permian?) of the San Juan Mountains, it is clear that the gypsiferous part of the series has no similar representative in the mountain district. If such beds ever existed in the San Juan region, they were removed prior to the deposition of the saurian conglomerate, and this does not seem at all unlikely, for gypsiferous beds are known in the Paleozoic red beds of northwestern Colorado, as reported by Peale.

The grits and conglomerates of West Creek are so near their source that they differ from the Cutler beds in being much coarser and more strongly arkose, but the section seen on Grand River and Fisher Creek certainly resembles in lithologic character the Cutler beds of the Uncompahgre Valley below Ouray and appears to occupy the same stratigraphic position.

The Cutler formation and the pre-Dolores red-bed strata of Grand River clearly correspond to the lower part of Powell's Shinarump group—that is, to the "Permo-Carboniferous" of the Wasatch and Uinta mountains, according to the nomenclature of the Fortieth Parallel Survey, or to the Permian of Dutton, in the Grand Canyon monograph. Fossils indicating a Permian or Permo-Pennsylvanian age were found by the Fortieth Parallel geologists in the Wasatch Mountains and by Walcott in the Kanab Valley of northern Arizona. The apparent absence of fossils in most localities where these beds have been examined is no doubt due to the fact that they are mainly continental deposits, an origin indicated by their texture.

Concerning the section on Grand River, Cross^{189a} says:

Near Moab, on the northeast side of Spanish Valley, a poorly exposed section reveals about 250 feet of strata, mainly reddish sandy shales, between the "saurian conglomerate" [Triassic] and the uppermost Pennsylvanian limestone. On Grand River about 1 mile above the Moab ferry the "saurian conglomerate" reappears above the level of the river, and, as it rises gradually to the northeast for several miles, a larger and larger section of the pre-Dolores strata is exposed, but nowhere, so far as our observations go, do the Pennsylvanian beds appear, all the sub-Dolores section belonging to the upper (Permian?) series of the Carboniferous. This is itself evidence of a great break immediately below the "saurian conglomerate." That the break represents uplift and erosion producing angular unconformity is well illustrated on both sides of Grand River about 10 or 12 miles northeast of the ferry and just below the mouth of Castle Creek, a stream heading on the west side of the La Sal Mountains. * * * This unconformity * * * may be traced for about half a mile, and it was estimated that at least 600 or 800 feet of beds are visibly truncated by the conglomerate in one continuous exposure. The occurrence of an extensive section of gypsiferous sandstones and shales beneath the Dolores conglomerate in Fisher Valley, on the northwest side of the La Sal Mountain, adds so much to the beds transgressed; and a still higher series of sandstones and conglomerates is known, so that, altogether, it is estimated that not less than 1,500 and possibly 2,000 feet of Permian (?) or upper unfossiliferous Pennsylvanian beds have been eroded in the locality of the section first mentioned, opposite Moab.

Returning to Cross's earlier paper,^{193f} we learn that Gane, in a trip down the San Juan Valley, traced the Triassic (Dolores formation) but had "no opportunity to study the underlying formation."

With reference to the supposedly Permian equivalents of the Cutler formation in the Zuni Plateau, New Mexico (I 12), Cross derives his information from Dutton³⁰¹ and, after describing Newberry's section of the same region, says:

The "Saliferous sandstones" of Newberry's report Dutton divides into three formations. At the base is a formation 450 feet thick, mainly "sandy shales, containing gypsum and selenite in abundance, with here and there thin bands of limestone." At some unspecified horizon in this formation Dutton found "several specimens of *Bakewellia* and an attenuated form of *Myalina*." On this ground he correlates these beds with the Permian of the Kanab Canyon district, where Walcott had discovered a more extensive fauna. "The Permian beds are distinguished for their dense and highly variegated colors—chocolate, maroon, dark brownish reds alternating with pale, ashy gray, or lavender colors."

The Permian strata thus described are overlain by "a very coarse, almost conglomeratic sandstone," some 50 feet in thickness, which Dutton correlates unhesitatingly with the "Shinarump conglomerate" (a particular conglomerate within the Shinarump group), referring to the fact that it is persistent and uniform in aspect wherever it appears throughout the plateau country of Utah and Arizona. He does not further describe it in this report.

Following Walcott, the conglomerate thus identified as the Shinarump in the Zuni Plateau is considered by Dutton as the basal stratum of the Trias.

After discussing the Triassic of Dutton's section, Cross^{193g} continues:

Beneath the Trias in the Zuni district is Dutton's Permian, lithologically a typical Red bed formation. That would correspond to the Cutler formation in stratigraphic position; but other factors enter into the problem at this point and render any definite suggestion of such a correlation premature. Below the Zuni Permian comes the Aubrey group, and beneath the Cutler occurs the Hermosa formation (ignoring the uncertain Rico beds), both Aubrey and Hermosa carrying Pennsylvanian invertebrate faunas. Dr. G. H. Girty informs me, however, that these faunas are not known to have a single species in common, and the equivalence of the two fossiliferous formations is therefore by no means to be assumed, though their stratigraphic position seems to be the same.

In northeastern Arizona, according to Ward,⁸⁶⁵ the Moencopie formation rests in marked unconformity on the underlying Paleozoic strata (Aubrey group) and is therefore not to be classed as upper Paleozoic (Permian). Ward therefore placed the Moencopie in the Triassic, but later work by Darton^{246b} tends to place it in the Permian.

In the northwestern part of Arizona is the Kanab Plateau, traversed by Kanab Canyon, which leads from the north to the Grand Canyon of the Colorado. Here Walcott⁸⁴⁴ determined the presence of Permian strata. He says:

The Permian group terminates above with ripple-marked, banded reddish-brown and chocolate-colored arenaceous shales and sandstone. A plane of unconformity by erosion separates it from the overlying Shinarump conglomerate, which is considered as the base of the lowest Mesozoic group. It is undoubtedly of Triassic age, but, as yet, this has not been determined by paleontological evidence in the Colorado Valley.

The chocolate arenaceous shales give way below to drab or lavender-colored arenaceous and gypsiferous marls and shales, that pass, midway of the group, into reddish-brown shales of the same general character. A thin stratum of impure limestone is intercalated in this bed 44 feet above the summit of the lower division and 15 feet above a band of impure shaly limestone. This band of limestone is of variable thickness and character and forms the base of the upper division. Numerous fossils occur in it and the associated arenaceous layers.

The summit of the lower division was slightly eroded antecedent to the deposition of the limestone. The upper bed is a reddish-brown gypsiferous marl that becomes more arenaceous below, finally passing into a sandstone that rests on the chocolate and cream-colored limestone

beneath. This has suffered extensive denudation by erosion and is now found only in patches from 10 to 20 feet in thickness over limited areas, the sandstone filling the spaces between. Recent erosion has cut channels down through each to the formation beneath, which is a member of the Upper Aubrey group. A slight plane of erosion with an entire change in the character of the rock separates the two groups.

The Permo-Carboniferous of Mr. G. K. Gilbert^a is the same as my lower division of the Permian. It is placed as a subdivision of the group, now that the beds above are known to be of Permian age.

The stratigraphy of the section shows a group separable into two divisions, defined above and below by planes of unconformity by erosion and a decided change in the character of the beds from those of the subjacent and superjacent formations. There is no physical break in the beds above the Permian limestone of the upper division before the conglomerate is reached. This stratigraphical arrangement is sustained by the evidence of the fauna found in the limestones and associated arenaceous layers in the upper division.

The genera *Myalina*, *Schizodus*, *Nucula*, *Aviculopecten*, *Murchisonia*, *Naticopsis* and *Goniatites* are represented in the lower chocolate-colored limestone. The fauna is distinct in specific character from that of the Carboniferous groups beneath, and more intimately related to that of the fossiliferous beds of the Upper Permian division. Mr. G. K. Gilbert obtained from this same horizon *Pleurophorus*, *Schizodus*, and *Bakevellia*, a group of shells, as he states, suggesting the Permo-Carboniferous of the Mississippi Valley.^b

Twenty-three genera represented by thirty-four species comprise the fauna of the upper division. Of these, the following have strong Paleozoic relations: *Scolithus* —?, *Lingula mytiloides*, *Discina nitida*, *Orthis* —?, *Rhynchonella uta*, *Terebratula* —?, *Nucula*, two species, *Aviculopecten*, three species, *Myalina*, four species, *Naticopsis*, two species, *Pleurotomaria* —?, *Macrocheilus* —?, *Cyrtoceras* —?, *Goniatites* —?, and *Nautilus* —?.

The Permian character of the fauna is more marked by the presence of *Pleurophorus*, three species, *Schizodus* —?, three species of *Bakevellia* including *B. parva*, *Pteria* —?, *Mytilus* —?, *Rissoa* —?, and the still more typical Mesozoic genera *Pentacrinus* and *Pileolus* —?.

The *Pentacrinus* plates were discovered by Mr. Edwin E. Howell below the Shinarump conglomerate in southwestern Utah. They belong to a species distinct from *P. asteriscus* of the Jurassic. Three species are now known to pass from the lower division to the limestone of the upper division.

The Permian character of the fauna, taken with the evidence afforded by the stratigraphy, clearly establishes the Permian as a well-defined and distinct group in the Colorado Valley. It occurs at the same horizon as the Permian determined by Mr. Clarence King in northern Utah, western Colorado, and southern Wyoming, fully corroborating the views advanced by him of the age of the beds resting on the "Bellerophon bed" of the Upper Carboniferous.^c

Walcott's section is as follows:

Permian (855 feet):

Plane of unconformity by erosion.

Upper Permian (710 feet): Gypsiferous and arenaceous shales and marls, with impure shaly limestones at the base.

Plane of unconformity by erosion.

Lower Permian (145 feet): Same as upper division with more massive limestone at the base.

Plane of unconformity by erosion.

Upper Aubrey (835 feet): Massive cherty limestone with arenaceous gypsiferous bed passing down into calciferous sandrock.

G. H. Girty^d comments on the above section as follows:

There is hardly room for doubt that Walcott's Permian is equivalent to the "Permo-Carboniferous" of the Wasatch Mountains and to the Permian(?) of the section studied by

^a U. S. Geog. Surveys W. 100th Mer., vol. 3, 1875, p. 177. See also Arch. R. Marvine's report in same, p. 213.

^b Idem, p. 177.

^c U. S. Geol. Expl. 40th Par., vol. 1, pp. 245-246 and atlas.

^d Comment on manuscript.

Weeks in southeastern Idaho, the upper half of which contains the Lower Triassic faunas of J. P. Smith. Personally I expect to find that the lower part of the Permian(?) strata in Weeks's section is not separable paleontologically, as it is scarcely lithologically, from the upper part, all being Permian or Triassic, as the case may be. Walcott's Permian I believe to correlate rather with the upper than the lower part of these strata.

I-J 14. KANSAS AND OKLAHOMA.

The strata assigned to the Permian of Kansas are thinly interbedded limestone and shale of marine origin. They have been minutely distinguished and their study is embarrassed by the number of names attached to thin beds, some of which are but local members. Prosser⁶⁴⁸ gives the following tabulation and discusses the nomenclature and correlation.

Classification of the upper Paleozoic formations of Kansas.

Permian system (?):			
Cimarron series [red beds]:			
Kiger stage:			
Taloga formation.		Feet. ^a	
Day Creek dolomite.....		1-5	
Red Bluff formation.....		175-200	
Salt Fork stage:			
Dog Creek formation:			
Chapman dolomite.....	}	1,000	
Amphitheatre dolomite.....			
Cave Creek formation:			
Shimer gypsum.....			
Jenkins clay.....			
Medicine Lodge gypsum.....			
Glass Mountain formation:			
Flower-pot shales.....			
Cedar Hills sandstone.....			
Kingfisher formation:			
Salt Plain member.....			
Harper sandstone.....			
Big Blue series:			
Sumner stage:			
Wellington shales.....		200	
Marion formation.....		100	
Chase stage:			
Winfield formation.....		25	
Doyle shales.....		60	
Fort Riley limestone.....		40	
Florence flint.....		20	
Matfield shales.....		70	
Wreford limestone [^b].....		40	
Base of the Permian.			

Adams adopts the formation names used by Prosser in the foregoing classification, from Wreford limestone to Wellington shale, both inclusive.

The sequence of strata throughout the Pennsylvanian and Permian is an alternation of limestones and shales without any marked interruption of stratigraphic

^a The thicknesses given up to and including the Wellington shale are from Adams; ^a those of the higher formations from Cragin.^{175,176}

^b Beede has recently traced the Wreford limestone into the McCann sandstone of Gould, yielding typical Texas Permian vertebrates.—Note by S. W. Williston, June, 1909.

or faunal succession. The distinction of Pennsylvanian and Permian has been difficult and is apparently artificial.

Prosser^{648a} discusses the correlation of the Wreford and higher formations as Permian—that is, the equivalent of the Russian Permian—cites the opinions of many geologists on both sides of the question, and considers favorably the distinction of the Permian as a system equal in rank to Carboniferous or Triassic. Beede⁶³ and David White⁹⁰¹ regard the series as Permian. Girty^{371a} accepts the Permian age of the Kansas and Texas beds but largely on the paleobotanic evidence adduced by White.

The Cimarron “series” is not discussed by Prosser, as it is a typical red-bed formation and does not contain marine fossils. Cragin^{175a} gave the following concise description in defining it:

With the Wellington formation ends the Big Blue, lower, or limestone-bearing series of the Permian. Succeeding it without break, but possibly with a gradually introduced angular unconformity, are the Harper sandstones and higher prevailing red formations that comprise the remainder of the Kansas Permian and constitute the Cimarron series, which, for Kansas, is nearly the same as the “red beds.”

So far as known, the series is destitute of any trace of organic remains.

In Oklahoma the shale and limestone strata of the Kansas Permian give place to red beds, the shales becoming red and sandy and the limestones red shales or sandstones. The division into many small formations is lost and a different sequence is recognized. Gould³⁷³ has made the following comparison of the divisions of the Oklahoma Permian with those proposed by Cragin for Kansas:

Relations of classifications of Permian rocks.

Cragin's classification.	Classification used in this [Gould's] report.	
Taloga.	Quartermaster formation.	
	Greer formation.	Mangum dolomite member. Collingsworth gypsum member. Cedartop gypsum member. Haystack gypsum member. Kiser gypsum member. Chaney gypsum member.
Day Creek. Red Bluff. Dog Creek (Stony Hills).	Woodward formation.	Day Creek dolomite member. Whitehorse sandstone member. Dog Creek shales member.
Cave Creek.	Blaine formation.	Shimer gypsum member. Medicine Lodge gypsum member. Ferguson gypsum member.
Glass Mountain. Kingfisher.	Enid formation.	

The several formations are described by Gould^{373a} as follows:

The Enid formation consists chiefly of brick-red clay shales with some interbedded ledges of red and whitish sandstone. It occurs in two general areas, which may be distinguished on lithological grounds as follows: An eastern area, in which there are a few inconspicuous ledges

of sandstone, and a western area in which the sandstones are mostly wanting. In the present state of knowledge it is impossible to draw an accurate line of separation between these two areas, and for this reason the strata in them are not defined as separate members.

The eastern area of the Enid formation is triangular and occupies several counties in the central part of the Territory, in which there is little hard rock of any kind.

* * * * *

Throughout this area the soil is red, except where later deposits cover the uplands or among the sand hills north of some of the streams. Red clays and occasional ledges of thin sandstone outcrop along the bluffs of a few streams.

* * * * *

The rocks of the western area of the Enid consist chiefly of red clay shale, some inconspicuous ledges of soft sandstone, and occasional bands of whitish or greenish shales, which vary from 1 inch to several feet in thickness. The upper strata are in some places highly gypsiferous, and at some localities brine springs issue from them.

* * * * *

The Blaine formation consists of red shales with interbedded strata of gypsum and thin ledges of dolomite. It includes the portion of Prof. Cragin's Flowerpot formation above the base of the Ferguson gypsum and all of his Cave Creek formation. It is named from Blaine County, Okla., where it is typically developed.

The characteristic which justifies its recognition as a formation is the abundance of gypsum contained in it, and its extent and limits are defined accordingly. The bottom of the lowest massive gypsum bed—the Ferguson gypsum member—is the base of the formation throughout its occurrence northwest from Darlington, Canadian County. Where it disappears the shales of the Enid continue up to the base of the Medicine Lodge gypsum member, which necessarily becomes the basal member of the formation. The top is the Shimer gypsum member. Where the gypsum members run out, as they all do north of Darlington, the Blaine can not be distinguished readily from the Enid below and the Woodward above, and this local division of the red beds can not well be traced.

* * * * *

The thickness of the Blaine formation varies considerably with the locality, but it averages about 75 feet.

Above the Blaine are approximately 300 feet of rocks consisting chiefly of shales, sandstones, and dolomites and distinguished from the formations above and below by the prominence of dolomites and the absence of gypsum. The formation includes all the rocks between the two conspicuous gypsum horizons, the Blaine and the Greer, and in general it may be divided into three members—the Dog Creek, the Whitehorse, and the Day Creek—which were all recognized and named by Prof. Cragin from localities in Kansas, except that his term Red Bluff was preoccupied, and for it the name Whitehorse has been substituted. For the formation as a whole, from the top of the Shimer gypsum to the base of the Chaney gypsum, the name Woodward is proposed, from the county in Oklahoma where the strata are well represented.

* * * * *

Above the Woodward formation are red clays, shales, and sandstones, and intercalated beds of gypsum and magnesium limestone or dolomite 150 to 300 feet thick. Gypsum is the characteristic deposit of this formation, as it is of the Blaine. The formation for which the name Greer is proposed, from the county in southwestern Oklahoma where it is well exhibited, is exposed over a very irregular area. For purposes of discussion it may be grouped according to two general areas, an eastern and a western.

* * * * *

The rocks of the eastern area of the Greer formation strike northwest and southeast just west of the outcrops of the Woodward formation. They are chiefly red clay shale, interstratified at several horizons with red sandstone and gypsum, which are, however, very irregularly bedded and can rarely be traced as continuous or definite ledges. Nevertheless, the thickest

ledges of gypsum known in the red beds are found in this area. Thus 5 miles northwest of Weatherford a ledge 60 feet thick was measured; in the vicinity of Cloud Chief, beds 50 feet thick are not uncommon; and in a well near Seger, Washita County, a ledge 115 feet thick is reported. But these beds are not constant, thickening rapidly or disappearing without apparent regularity. Along a single bluff one may see the beds change from gypsum to sandstone within a distance of a few rods, and a quarter of a mile farther the sandstone again merges into gypsum. So variable is the stratification of all the rocks of the Greer formation in this region that no attempt is made to divide it into members. A section would usually not answer for a point half a mile away.

* * * * *

Above the Greer are 300 feet or more of soft red sandstones and arenaceous clays and shales, to which the name Quartermaster has been applied. So far as known this is the highest formation of the red beds in Oklahoma.

In the lower part of the formation the rocks are chiefly shales, typically red but sometimes containing greenish bands and layers. The shales become more arenaceous above and in places form a strong consolidated sandstone, which is rather thin bedded and prone to break into small rectangular blocks and weather queerly into long and narrow buttresses or rounded, conical, or nipple-shaped mounds from 10 to 50 feet or more high. These mounds may be solitary, but in some areas hundreds of them occur in a single quarter section. The sandstone is further characterized by the marked and very peculiar dip of the rocks in certain directions. The strata often dip at angles of from 20° to 40° to all points of the compass, even in a small area. These dips often produce escarpments that have the appearance of those formed by regularly bedded dipping strata. The most plausible explanation of this phenomenon is that the erratic dipping is caused by the undermining of deep-seated rocks, probably some of the various gypsum members of the Greer.

Regarding the age of the red beds of Kansas and Oklahoma, Gould^{373b} makes the following statement:

The scarcity of fossils in the Kansas-Oklahoma red beds has been a matter of comment ever since these rocks have been studied. In Kansas, particularly, Hay, Cragin, Prosser, Beede, Williston, and others have at various times searched carefully over the counties in which these rocks are exposed, but without avail. So far as known not a single fossil has ever been found in the Kansas red beds.

In Oklahoma, fortunately, the results have been more satisfactory. Not that the fossils are abundant, for they are in fact very rare, yet enough forms have been found at various horizons to assist the geologist in the classification of the rocks. Four years ago the geologic age of the red beds was not certainly known, for at that time fossils had been found in but one locality, and these for the purpose of correlation were far from satisfactory. Of the five localities west of the provisional base of the Permian from which fossils have been obtained in Oklahoma, two only have yielded invertebrates, in two other localities vertebrates alone have been found, and from the fifth locality vertebrates, invertebrates, and plants have been secured. A brief description of these localities and the fossils obtained from each will be given.

On the farm of W. T. McCann, 5 miles southeast of Nardin, Kay County, a number of fossils were found in a ledge of sandstone which lies just at the base of the red beds. A vertebrate, identified as *Eryops megacephalus* by Dr. S. W. Williston, a small crustacean, *Estheria minuta*, and some fossil leaves comprise the collection. [The McCann sandstone of Gould is traced stratigraphically by Beede to the Wreford limestone of Kansas. See note b, p. 486.]

Dr. E. C. Case has identified the following forms obtained near Orlando, Logan County:^a

Pisces:

Diacranodus (*Pleuracanthus*) *ampressus* (?) Cope.

Sagenodus (?) sp.

^a Case, E. C., On some vertebrate fossils from the Permian of Oklahoma: Second Biennial Rept. Oklahoma Geol. Survey, 1902, pp. 62, 68.

Batrachia:

- Diplocaulus magnicornis (?) Cope.
- limbatus (?) Cope.
- salamandroides Cope.
- Trimerorhachis sp. Cope.
- leptorhynchus sp. nov.
- Cricotus sp. Cope.
- Cricotillus brachydens g. et sp. nov.
- Eryops megacephalus Cope.
- Crossotelos annulatus g. et sp. nov.

Reptilia:

- Naosaurus sp. Cope.
- Embolophorus (?) sp. Cope.
- Pariotichus ordinatus Cope.
- sp. Cope.
- Pleuristion brachycoelous g. et sp. nov.

A number of vertebrates have recently been discovered 5 miles east of Pond Creek, Grant County. These bones have not been identified, but from superficial examination they appear very similar to the specimens from Nardin or Orlando.

In a ledge of soft, sandy dolomite which underlies the Medicine Lodge gypsum near Ferguson, Okla., a number of invertebrates have been found, among which Dr. J. W. Beede finds the following forms: *Pleurophorus subcuneatus* Meek, *Schizodus* (?) like *S. wheeleri*.

Near Whitehorse Spring, 16 miles west of Alva, a considerable number of invertebrates were obtained. Dr. Beede identified the following genera:^a *Naticopsis*, *Pleurotomaria*, *Pleurophorus*, *Lima*, *Sedgwickia*, *Aviculopecten*, *Bakewellia*, *Conocardium*, and *Dielasma*. The last four genera are represented by new species.

Regarding the age of the red beds, Dr. Williston identifies *Eryops megacephalus*, from Nardin, as a Permian amphibian, described by Cope, from Texas. Of the Orlando fossils, he says: "Altogether these fossils unmistakably point to the Permian." Dr. Case points out the close resemblance of these fossils to similar forms from the Permian of northern Texas, Ireland, and Bohemia.^b

Dr. Beede, in the paper referred to, in speaking of the Whitehorse invertebrates, says:^c

"On the whole, these fossils show an advance over the fossils of the Permian below. Some of the species still persist, as we should expect from the fact that there is no unconformity between these various formations. On the other hand, there is a new species of *Dielasma* belonging to a group new to the American Permian. * * * Taking all this into consideration, there can be little doubt that the age of these beds is Permian."

Of these localities, Orlando, Nardin, and Pond Creek are in the Enid formation, Gypsum Hills locality in the Blaine, and the Whitehorse locality in the Whitehorse sandstone, the middle member of the Woodward formation. So far as known no fossils have been found in the Greer and Quartermaster formations of Oklahoma, but there is no reason for supposing that these beds differ greatly in age from those immediately subjacent.^d

J-K 13. SOUTHERN WYOMING AND NORTHERN COLORADO.

The so-called "Red Beds" of this region, long supposed to be chiefly or wholly Triassic, are now known to be in part at least Permian. The Triassic age of the remaining upper portion has been questioned but is established by Williston. Prior to Williston's publication, Cross^{193m} reviewed the evidence as follows in part:

The Red Bed section of the mountainous portion of Colorado and Wyoming is clearly not divisible into the units traceable throughout the plateau province. * * * The changes in

^a Beede, J. W., Advance Bull. Second Ann. Rept. Oklahoma Geol. Survey, April, 1902.

^b Letter of November 24, 1900.

^c Op. cit., p. 62.

^d Since the above was written fossils found in the Quartermaster sandstone in Collingworth County, Tex., have been identified by Dr. Beede, who finds that they are very similar to those from Whitehorse and of Permian age.

lithologic character in the mountain province are much more notable and render correlations less certain. * * * Until many districts have been reexamined with care, it will be premature to attempt direct correlation of the Dolores and Cutler formations as such with the elements of sections in central and northern Colorado; but there are various facts bearing on the distribution of Triassic and Carboniferous Red Beds which may be briefly presented:

* * * * *

Turning to the lower part of the Red Beds, evidence has recently been presented by the late W. C. Knight showing that in the Laramie Basin of southern Wyoming the Triassic strata of Hayden and King should be referred in part at least to the Carboniferous system and probably to the Permian series. Knight gives a section of 1,578 feet of Red Beds which rest on granite. A little below the middle of this section a fossiliferous sandstone was found, the fauna resembling "to a marked degree the fossils of the Kansas and Nebraska Permian." Only one thin limestone was noted in the section, but Knight made the significant observation "that the strata of the lower portion of the Red Beds are identical with the strata of limestones to the northward, the difference in the lithological characteristics being due to the varied physical conditions during sedimentation."

These limestones also contain in their upper portion a fauna resembling that of the Kansas "Permian," but Knight remarks that Coal Measure fossils have not as yet been collected from the lower beds.

Since Knight could find no stratigraphic or fossil evidence for subdividing the Red Bed section of the Laramie Plains, he refers it as a whole to the Permian and compares it particularly with the Permian of Kansas and Oklahoma. * * *

Accepting the views expressed by Knight concerning the fauna of Red Beds of the Laramie Plains, it is clear that the section above his lowest fossil-bearing horizon is younger than the Rico formation [Pennsylvanian] but may correspond as a whole or in part to the Cutler formation. * * * The unfossiliferous portion whose reference to the Permian is still open to possible doubt is 850 feet in thickness, and it does not appear that the section was complete, up to the Jurassic beds. There is, therefore, ample room for a Triassic formation in the Red Beds of the Laramie Plains.^a * * *

In the vicinity of the Triassic horizon observed by Hills [on Grand and Eagle Rivers, Colorado] the upper Paleozoic section is of very different character from that near Laramie, but its upper portion was assigned to the Permian by Peale on the basis of a few plants considered by Lesquereux as of that age. The strata so referred are gypsiferous shales of various colors, yellow, pink, and creamy, with some limestone, and are not to be correlated either with the Laramie Permian or the Cutler beds on present evidence. These gypsiferous beds are overlain by the Red Beds of Peale, assigned to the Triassic, and seemingly this division must include the bone beds of Hills, since the succeeding formation is apparently the normal fresh water Jura.

* * * The well-known Red Bed section of the Front Range foothills in Colorado was assigned to the Trias upon no definite evidence, by geologists of the Hayden Survey. * * *

In the Denver monograph Emmons and Eldridge named the entire Red Bed section of that district the Wyoming formation, distinguishing within it the lower and upper divisions, on purely lithologic grounds. The Lower Wyoming embraces beds like the Fountain in lithologic character and, in addition, the quartzose Creamy sandstone. Both Emmons and Darton have recognized the resemblance of the red arkose strata of the Lower Wyoming to the Fountain beds; but the suggestion of the latter that the Fountain and Lower Wyoming are quite equivalent is to my mind less natural than to consider the Lower Wyoming a group embracing the Fountain beds and the lithologically distinct "Creamy sandstone," which Darton thinks is equivalent with the Tensleep sandstone of the Bighorn Mountains, Wyoming, and which in any case deserves a special name.

The Upper Wyoming of the Denver region embraces the remainder of the Red Bed section, and it is referred to the Trias by Emmons and Eldridge. Darton, however, in his valu-

^a At Red Mountain, south of Laramie City, characteristic Upper Triassic vertebrates occur in the uppermost "Red Beds." See Williston, S. W., *Jour. Geology*, vol. 13, 1905, p. 339.—B. W.

able discussion as to the correlation of formations of the Black Hills, Bighorn Mountains, and the Front Range presents reasons for supposing that the Upper Wyoming, as developed near Denver, may be wholly referable to the Permian series. This is based on stratigraphic relations and the belief that a limestone occurring shortly above the "Creamy sandstone" is the equivalent of the Minnekahta limestone of the Black Hills, where it contains *Bakewellia* and *Edmundia*, forms apparently identical with those characteristic of the so-called Permian of the Mississippi Valley.

Poorly preserved shells of similar appearance were found in the limestone at Morrison. Darton believes that the Opeche and Minnekahta (Permian) and the Spearfish (Triassic?) formations, distinguished by him in the Black Hills, extend southward through Wyoming into northern Colorado, but as their exposures are not continuous, and as lithologic details vary in the different areas of outcrop, he proposed Chugwater as a group term, which is thus practically equivalent to Upper Wyoming. Darton states that the upper or Triassic (?) portion of the Chugwater group thins out and disappears before the Denver area of Red Beds is reached, leaving only the supposed Permian as present in the Morrison and Golden sections especially described by Eldridge.

From the brief review just given it appears that the Red Bed section of the Front Range foothills contains no member to be correlated with the fossiliferous Triassic (Dolores) of the western portion of Colorado. The views of Darton and the writer harmonize in referring the entire Red Bed section of the Denver region and southward, at least to the Canyon City embayment, to the Paleozoic. The Fountain beds seem to me to be synchronous in origin with the Pennsylvanian formations of the San Juan region. An unconformity separates each from the Mississippian Carboniferous (Millsap or Ouray) and above each in apparent conformable relation is a nonfossiliferous complex of Red Beds. On the west slope these are embraced in the Cutler formation, while at the base of the Front Range is the more variable section of the Wyoming group, succeeding the Fountain. That the beds of the Wyoming group (excluding a possible Triassic portion) are coextensive with the group consisting of the Molas, Hermosa, Rico, and Cutler formations of the San Juan is of course not to be assumed.

J-K 17. PENNSYLVANIA, WEST VIRGINIA, AND OHIO.

The Dunkard group is the highest Carboniferous of the Appalachian basin and is classed as Permian on the evidence of fossil plants. Stevenson^{797b} thus states its occurrence and character:

The Dunkard area is much smaller than that of the Monongahela, embracing little more than 7,000 square miles. It is confined to Washington and Greene counties of Pennsylvania, the western-central counties of West Virginia, and Belmont, Noble, Monroe, Washington, and Meigs of Ohio. Small outlying areas occur in other counties, but they are insignificant. At one time the beds of this formation were continuous eastward to beyond the Alleghenies, as fragments remain in Maryland and west-central Pennsylvania. The extreme thickness, as found in the southwest corner of Pennsylvania at the West Virginia line and determined by oil-well records, is a little less than 1,200 feet. The thickness decreases greatly toward the north, the bottom 475 feet becoming about 165 feet at the most northerly exposure and the succeeding 240 feet is reduced to 150 feet at its northernmost exposure, nearly 30 miles south from that of the lower interval. There is a similar decrease in a northwestward direction, and toward the southwest one finds the bottom 700 feet of the thickest area reduced to barely 500 feet in Tyler of West Virginia, 35 miles away. Nothing can be determined respecting conditions toward the east, as erosion due to great anticlines prevents comparison with the fragments east from the Alleghenies in the deep basins of Broad Top and Maryland.

In the original description of this formation as it is in Pennsylvania, Stevenson divided it into the Washington County and the Greene County group, placing the plane on top of the Upper Washington limestone. Aside from the convenience of a division in a column of such length and complexity, one must recognize in the physical conditions good reasons for this

separation. These, as will be seen, appear only in part along Dunkard Creek, where Dr. White's studies led him afterward to group the whole succession into one formation, the Dunkard. They are best shown farther north, in central Greene County, where they justify a return to the original grouping and to the recognition of the Washington and Greene formations as of equal rank with the Monongahela and others below.

In the Washington and Greene formations, which compose the Dunkard group, Stevenson distinguishes sixteen and eighteen members respectively, alternations of coal, limestone, and sandstone.

The comprehensive study of the Dunkard flora by Fontaine and I. C. White³⁴⁴ was revised by David White.³⁹⁷ Stevenson⁷⁹⁷ reviews the evidence as follows:

The results of this revision were published in 1903. The collections, made at the typical as well as at other localities and horizons, led Mr. [David] White to place the forms in five categories—(a) those characteristic of the Rothliegende or higher formations of the Old World; (b) those closely allied to Permian types; (c) those whose habit and facies suggest a late date; (d) those of Mesozoic aspect; (e) Coal Measures type.

In the first category Mr. White places three species of *Callipteris*, one each of *Goniopteris*, *Pecopteris*, *Alethopteris*, *Odontopteris*, *Caulopteris*, *Equisetites*, and *Sigillaria*, with two species of *Sphenophyllum*; in all, 12 species. In the second are also 12, but the author states that the number might be extended according to the personal equation of the observer or to the amount of material available for comparison, while, at best, evidence of this class is of subordinate value, some of the forms placed here belonging with equal propriety also in succeeding categories. He places in the third category 14 forms, all of them new and unknown elsewhere; these in their general facies suggest a later date than Coal Measures. He places 9 forms in the fourth category and regards their presence as an interesting and important argument for Permian age, for they are types whose nearest relatives are Mesozoic or whose facies strongly suggest types characteristic of Mesozoic. Here are species of *Equisetites*, *Saportæa*, *Jeanpaulia*, and *Tæniopteris*, as well as other genera. On the other hand are forms belonging to the fifth category, a considerable element of Coal Measure species, whose presence is invincibly against reference of the beds to a level above the basal Permian. The number of species common to the Dunkard and lower formations, only 22 at the time when Profs. Fontaine and I. C. White published their work, is now known to be much greater, as the Monongahela flora has been studied in part. Mr. White enumerates 29 common forms which are of ordinary occurrence in the Coal Measures, these being only the more widespread forms, more than one-half of them appearing frequently in the Allegheny or Conemaugh.

Mr. White finds in the Dunkard plants a transitional flora, such as would be expected in a region where conditions remained practically the same. The boundary between Coal Measures and Dyas is to be determined by the appearance of characteristic Rothliegende species rather than by the presence of persistent Coal Measure types. In western Europe the presence of *Callipteris*, simple fronded *Tæniopteris*, *Callipteridium* of the *gigas* or *regina* type, and the genus *Walchia* in a flora consisting largely of forms common to the Coal Measures is regarded as sufficient evidence of Rothliegende age, though *Callipteris conferta* and even *Walchia* may appear lower down. In the Appalachian region a small form of *Callipteris conferta* appears at the horizon of the Lower Washington limestone, while the typical larger form, with *Callipteridium gigas* and others, is unknown below the Dunkard coal bed. The evidence of Rothliegende age for beds below the Lower Washington limestone consists in the presence of *Equisetites rugosus* and several less important forms and of some others which have Mesozoic or Permian aspect; but these latter are extremely rare, having been found only in a single coal drift, though careful search has been made for them elsewhere.

Mr. White regards the beds below the Lower Washington limestone as containing a transitional flora and not distinctly Rothliegende, but above that limestone the flora becomes increasingly characteristic. As in that limestone is the first appearance of *Callipteris conferta*, he thinks the lower limit may be drawn safely at that horizon. The flora of the upper Dunkard

is to be compared with the Stockheim and Cusel beds in Germany and the series in the basin of Brives, in France. None of the characteristic coniferous genera *Ullmannia*, *Tylodendron*, *Walchia* occurs in Dunkard beds, though all are in Prince Edward Island and *Walchia* is reported from Texas; and similarly many genera of ferns characterizing the Rothliegende of Europe seem to be wholly unrepresented.

In connection with Mr. White's conclusions, it is well to recall some relations noted in preceding pages. The general physical conditions during Allegheny and Conemaugh were practically the same, for while the basin was contracting there was no material variation in character of the movements, but with the beginning of the Monongahela the area of greatest subsidence was shifted a hundred miles and a new condition remained unaltered throughout the Monongahela and Washington, which in this respect are one as the Allegheny and Conemaugh are one. A notable change occurred at the Washington, and Mr. White has shown that the strongly marked lower Rothliegende flora makes its appearance near the bottom of the Greene formation.

K 10. KLAMATH MOUNTAINS, CALIFORNIA.

Certain limestones of the Klamath Mountain region are faunally more closely related to the Guadalupe group of the Permian of trans-Pecos Texas than to any other terrane in the United States.^a (See pp. 359-360, Chapter VIII.)

K 12-13. WYOMING, NORTHERN COLORADO, AND UTAH.

In the Park City mining district, northeastern Utah, Boutwell distinguished the Woodside shale, Thaynes formation, and Ankareh shale. (See section given on p. 380, Chapter VIII.) The Woodside is a fine-grained unfossiliferous red shale 700 to 1,180 feet thick, which conformably overlies the Park City formation (Pennsylvanian). The Thaynes is characteristically calcareous and rich in fossils. It is 1,190 feet thick. In 1907 Girty reported that "the fauna and horizon are those which in the Fortieth Parallel Survey reports are called Permo-Carboniferous" and said: "It seems probable that the fauna will be correlated with the Permian of the Grand Canyon section." Revising this statement in 1910, he states: "Latest information makes it doubtful whether these are not Triassic, in part almost certainly equivalent to the Triassic of Idaho."

The Ankareh shale is a siliceous red shale and sandstone, 1,300 feet thick, which on rather meager paleontologic evidence is classed as Permian.^{93a}

The Woodside and Thaynes formations of northeastern Utah were recognized by Veatch⁸³⁹ in southwestern Wyoming, where they have a development similar to that at Park City. Above the Thaynes limestone and below the fossiliferous marine Jurassic, Veatch distinguished the Nugget formation, which he classed as Triassic(?). His Nugget comprised two members, a bright-red sandy shale, reaching a maximum thickness of 600 feet (now correlated by Gale with the Ankareh shale), and an upper sequence of light-colored sandstones (to which the name Nugget is now restricted).

The divisions of the red beds recognized by Veatch were in 1906 traced northward by Schultz^b into central Uinta County, Wyo.

The region examined by Boutwell, Veatch, and Schultz is the western part of the province in which the red beds of Permian and Triassic age are developed.

^a Girty, G. H., personal communication.

^b Schultz, A. R., personal communication.

Formations similar to those described occur about the Bighorn Basin and Mountains, but the divisions have been called by local names, as equivalent formations in the two areas are not identified.

In the Bighorn Mountains Darton^{237, 239b} distinguished the Amsden formation, the upper part of which contains a distinct Pennsylvanian fauna and the lower part of which in some areas is of Mississippian age. Succeeding the Amsden, he recognized the Tensleep sandstone (Pennsylvanian), the Embar formation (Pennsylvanian and Permian?), and the Chugwater formation (Triassic or Permian). The Tensleep is a massive white sandstone, in part calcareous, and the Embar consists of limestones with associated shaly and cherty beds. The characteristic fossil of the Embar is *Spiriferina pulchra*, which occurs just below the "Permo-Carboniferous" of the Wasatch Mountains and the Permian of the Grand Canyon. The Embar thins out northward and in the northern part of the Bighorn Range the Chugwater formation rests on the Tensleep sandstone.

The Chugwater formation thus occupies part or all of the stratigraphic interval between the Pennsylvanian and the marine Jurassic (Sundance formation), in northern Wyoming. It is a typical red-bed formation from 600 to 1,200 feet thick. Darton^{239d} describes it as follows, in part:

The rocks are mainly soft, massive, red, fine grained sandstones, merging into red shale, but extensive gypsum deposits and a few thin limestone beds are also included. * * *

The general character of the Chugwater deposits does not vary greatly in different portions of the region. Toward the top and bottom red shales predominate, while in the middle soft sandstones and alternations of sandstones and shales are the principal features. Near the base there is invariably a thin bed of purplish-gray limestone, generally varying in thickness from 5 to 15 feet. Fifty feet or more higher there is another bed of limestone, mostly massive, of dirty-gray or buff color, in which weathering develops a characteristic porous structure. This bed has a thickness of 10 to 15 feet along the east side of the uplift and to the south, but along the west-central and northwestern slopes of the mountain its thickness increases considerably and it forms a conspicuous ledge. Toward the top of the formation there is always a succession of thin-bedded, light-colored limestones separated by red shales. These limestone bodies vary from two to four in number, and they are usually separated by from 10 to 50 feet of shales. Gypsum deposits occur in the Chugwater formation in irregular bodies in the lower and upper portions, the most persistent bed or series of beds being not far from the base. The formation attains its greatest thickness in the region northwest and southwest of Buffalo, where it measures 1,230 feet. In the region west of Sheridan the amount is 1,100 feet but it gradually diminishes to the north, being only about 600 feet at Bighorn River. On the west side and southern portion of the range the average is about 800 feet, but it diminishes somewhat to the north, the amount being not over 700 feet near Horse Creek.

Darton cites occurrences of fossils from the lower part of the Chugwater formation which are, however, poorly preserved or for other reasons indeterminate as to age. In the opinion of Girty and Schuchert they are probably Permian. The upper part at least of the Chugwater is regarded as probably of Triassic age, and both Darton^{239e} and Fisher^{331a} doubtfully assign the whole formation to the Triassic.

K 13. BLACK HILLS, SOUTH DAKOTA.

The Permian of the Black Hills comprises some indeterminate part of the red beds, which Darton has separated into the Opeche, Minnekahta, and Spearfish for-

mations. The Opeche and Minnekahta are now regarded as Permian, but the Spearfish is believed to be probably of Triassic age. Below the red sandstones of the Opeche occur other sandstones which have yielded "indistinct casts of *Productus semireticulatus* and *Seminula dawsonii* (*Athyris subtilita*)" and which are provisionally assigned to the Pennsylvanian. Concerning the formations Darton^{237c} says:

Opeche formation.—In this formation the first of the red beds makes its appearance in the Black Hills region. The materials are soft red sandstones, mainly thin bedded and containing variable amounts of clay admixture, having a thickness varying from 120 feet in the southeastern part of the hills to about half that amount to the northwestward. The basal beds of the formation are usually red sandstones, the beds varying in thickness from 4 to 13 inches. Gypsum occurs at a few points in beds which are neither thick nor extensive.

The age of the formation has not been definitely determined, for so far it has yielded no fossils. From the fact that the overlying Minnekahta limestone is of Permian age, and the deposition of gypsiferous red beds in other regions began in Permian time, the formation is provisionally assigned to that division.

Minnekahta limestone.—Overlying the Opeche red beds there is a limestone persistent over a wide area in the Northwest, which I have designated the Minnekahta limestone. Though thin, averaging less than 50 feet in thickness, it is hard, flexible, and, by the easy erosion of the red beds in which it is inclosed, outcrops in long slopes and prominent ridges.

The rock is uniform in character throughout, being a thin-bedded light-colored limestone, containing magnesia and more or less clay. Its thin bedding is a characteristic feature, although the thin layers are so cemented together that the outcropping ledges present a massive appearance. * * * On weathering, it breaks into slabs usually 2 to 3 inches in thickness. On the western side of the hills its coloring is slightly darker, varying from a dove color to lead-gray, and some of the beds present a seminodular structure. An increased admixture of clay is also observed in some layers. The general appearance of the formation is always slightly pinkish, with a tinge of purple, from which fact the old term "purple limestone" originated.

The limestone contains fossils at a number of localities, but the forms are not well preserved and not altogether decisive as to the age of the deposits. At a locality 15 miles west-northwest of Hot Springs there were observed *Bakewellia* and *Edmundia* similar to those observed in the Kansas Permian, and from this evidence the limestone is assigned to the Permian. Near Sturgis similar fossils occur.

Spearfish formation.—The designation Spearfish formation has been applied to the main body of gypsiferous red beds which outcrop in a broad zone encircling the Black Hills uplift. This formation consists of from 350 to 700 feet of red sandy clays, with intercalated beds of gypsum which sometimes are 30 feet thick. The bright-red color of the shales and the snowy white of the gypsum are striking features of the formation. Were it not for the gypsum the formation would present no noticeable features of stratigraphy, as the sedimentary material is almost entirely a red shale containing varying amounts of fine sand admixture. It is generally thin bedded. The gypsum occurs in beds at various horizons, some of the larger beds extending continuously over wide areas. There is also throughout the formation more or less secondary deposition of gypsum in small veins.

The thickness of the Spearfish formation can seldom be determined with accuracy, owing to the softness of the material and the predominance of low, variable dips which are difficult to measure. Along the east side of the Black Hills the formation appears to have a thickness of from 350 to 400 feet, but the amount increases to the northward to 492 feet in the well at Cambria, 695 feet in a well at Sturgis, and at least 650 feet in a deep boring at Aladdin. To the south-eastward the principal bed of gypsum generally varies from 5 to 15 feet, increasing southward in the vicinity of Hot Springs to the maximum development, in which the principal beds have a thickness of 33½ feet, with a 10-foot parting of red shale between. * * * Along the west

side of the uplift there is usually a bed of gypsum at a horizon about 150 feet above the base of the formation, and east of Newcastle for some distance there is a 25-foot bed of gypsum at the top of the formation, * * * several thin beds in its center, and at its base a local thin bed of gypsum lying directly on the Minnekahta limestone. Throughout the Black Hills the formation is distinctly separated from the underlying Minnekahta limestone by a very abrupt change of material, and from the overlying marine Jurassic deposits by a well-marked erosional unconformity.

K 15. IOWA.

Deposits of gypsum associated with red shale and sandstone which occur in isolated areas in the vicinity of Fort Dodge, Iowa, have been assigned to the Permian on the ground of lithologic relations, no fossils having been found. The occurrences are described in detail by Wilder,⁹²⁹ who considers also the alternative possibilities of Triassic or Cretaceous age.

L 20. NEW BRUNSWICK, NOVA SCOTIA, AND PRINCE EDWARD ISLAND.

The Permian (in some of the reports called "Upper Carboniferous") of Nova Scotia and New Brunswick was described by Dawson,^{263c} Logan,⁵⁴⁵ and later by Fletcher^{334c, 335e} and Bailey.^{45c} In Fletcher's later report^{335e} he subdivides the Permian as follows:

1. New Glasgow conglomerate.
2. Middle gray sandstone and shale group, with small coal seams.
3. Upper red sandstone and shale group, with thin bands of limestone.

These groups lie in parallel belts along the shore of Northumberland Strait between Merigomish and Wallace, dipping seaward, generally at a low angle, but broken by faults sometimes of considerable magnitude. Between the second and third groups there is no distinct line of demarcation and the subdivision is only one of convenience.

The position of the New Glasgow conglomerate in relation to the productive coal measures (Pennsylvanian) has been a matter of doubt, as it resembles the "Millstone grit" at their base. Fletcher concludes that the "New Glasgow conglomerate is newer than the coal measures." He describes an unconformity between the New Glasgow and the "Millstone grit." The dip of the former is not so steep as that of the latter and "gray sandstone with greenish and reddish tints, dipping 42° to 51°, is overlain by thick beds of very coarse conglomerate which fills depressions in the lower beds." Again the conglomerate, though mostly composed of material from the Devonian, contains large pebbles, some of which "are certainly derived from the Millstone grit or coal measures." This basal conglomerate of the Permian overlaps upon Devonian and Silurian rocks and varies greatly in thickness, being in places perhaps entirely lacking or overlapped, yet elsewhere apparently 1,300 feet or more thick.

Sections of the higher Permian rocks, with a maximum total thickness of 8,000 feet, are given in much detail by Fletcher.

Dawson,^{263c} who called these strata "Upper Carboniferous," did not recognize the Permian in Acadia and devotes a brief chapter to the "Permian blank." His description of the "Upper Carboniferous" is included in that of the Joggins section^{263d} and of other coal fields of the region.

Bailey ^{45c} has the following to say in regard to the "Upper Carboniferous" of New Brunswick:

Upper Carboniferous (Permo-Carboniferous ?).—In the Geological Survey maps of south-eastern New Brunswick, a considerable area bordering Baie Verte and portions of Northumberland Strait, and extending thence across the Chicignecto Peninsula to Cumberland Basin and Shepody Bay, is referred to under the above designations, while in the accompanying report (1884) its author, Dr. R. W. Ells, describes the group as consisting generally of soft reddish or purple-brown sandstone, grits, and shales, resting unconformably upon either the Millstone grit or the Lower Carboniferous. Upon the western side of the Merangouin Peninsula, where one of the unconformable contacts is well exposed, they are estimated, by the author named, to have a thickness of 1,250 feet. As seen in the vicinity of Sackville, they are said to resemble very nearly the sandstones and associated beds of Capes Bald and Tormentine and of Prince Edward Island.

Discussion of this area by Ells and Bailey will be found in Chapter VIII (p. 384).

The rocks of Prince Edward Island are discussed by Dawson and Ells. The bulk of the island has been determined by Ells to be of "Permo-Carboniferous" age, though held by Dawson to be Triassic, except for portions along the southern and western coasts. Dawson ^{266a} says:

The principal addition to our knowledge of this formation is that contained in the report by Dr. Harrington and myself published in 1871.^a In this we separated as Upper Carboniferous, or "Permo-Carboniferous," an underlying series of red and gray sandstones and shales, holding Carboniferous plants, extending from near Cape Wolfe toward the north point, and a similar series found at Governor's Island and Gallas Point in Hillsborough Bay. These are undoubtedly extensions of the Carboniferous of Nova Scotia. All the rest of the island is occupied with Triassic rocks, in one place (Hog Island, in Richmond Bay) associated with trap. The general relations of these rocks are seen in the sections.

The beds of the Triassic series, as seen in Prince Edward Island, consist chiefly of soft red sandstone, with some buff-colored beds and red and mottled clays. Associated with them are conglomerates and hard calcareous and concretionary sandstones, passing into bands of arenaceous limestone, which is in some places a dolomite. * * * [Section in Orwell Bay and vicinity given.]

The whole thickness of these beds can not much exceed 500 feet. Of this the lowest 270 feet * * * may be referred to the lower division, or "Bunter," and the remainder to the upper division of the formation, or "Keuper." The dips are so low and the beds so much affected by oblique stratification that those of the Trias can not be said to be unconformable to the underlying Carboniferous rocks, and for this reason, as well as on account of the similarity in mineral character between the two groups, some uncertainty may rest on the position of the line of separation. That above stated depends on fossils, or a somewhat abrupt change of mineral character, and on a slight change in the direction of the dip. These beds spread over the greater part of the island, presenting a nearly horizontal attitude or lying in very flat synclinals and anticlinals. They are well seen in the coast cliffs in many places, and several of these coast sections are given in the report above referred to.

Ells ³⁰⁸ in his report on explorations in the Gaspé Peninsula discusses the age of the strata of Prince Edward Island and their resemblance to the rocks of New Brunswick and concludes:

It will be seen by reference to the report on this province by Drs. Dawson and Harrington (1871) that though the larger part of the island was at that time considered by the authors as of Triassic age, certain portions, among which are the coast from West Cape to Nail Pond

^a Report on the geological structure and mineral resources of Prince Edward Island.

and the vicinity of Gallas Point, were considered as pertaining to the upper Carboniferous. It is, however, manifest, from a close study of the various strata from Cape North to Point Prim, that both from their lithological character and the stratigraphical evidence no such separation can be carried out. The great similarity also of all the plant remains from so many points tends to confirm the impression that the whole of the strata exposed along the south and west coast must be assigned to the same horizon. The occurrence also of similar beds in the province of New Brunswick, about whose age but little doubt can exist, as well as on the coast of Pictou and Colchester, which have already been assigned to the upper portion of the Carboniferous, strengthens this view. We have therefore from the careful consideration of all these facts been led to remove the great bulk of the island rocks, from the position which they have so long held as Trias and to classify them under the head of Permo-Carboniferous.

CHAPTER XII.

TRIASSIC.

Color, dark green (horizontal ruling).

Symbol, 10.

Distribution: Central America, Mexico, New Mexico, and Texas; Nevada and California; British Columbia and Alaska; Atlantic slope from North Carolina to Nova Scotia.

Content: Marine Triassic of western Nevada and California; marine Triassic of Zacatecas and red beds in Mexico; red beds of Texas and New Mexico; Newark group, North Carolina to Nova Scotia; marine Triassic of the Arctic. In the Canadian Rockies the marine Triassic is mapped with the "Paleozoic undivided" (19, 20). In Oregon, Idaho, middle western United States, and part of Alaska it is combined on the map with Jurassic (9).

Triassic areas.

D 16. HONDURAS AND NICARAGUA.

Sapper,^{696a} in his account of the geology of southern Central America, states:

In the department of Tegucigalpa there occurs a series of marine clays, slates, sandstones, conglomerates, and interbedded limestones which have been determined as upper

FIGURE 14.—Sketch map showing the distribution of Triassic rocks and of undivided Triassic and Jurassic rocks that are so represented on the geologic map of North America and the key to references in the text.

Triassic on the basis of the discovery of cycads near San Juancito. It remains, however, a mooted question whether these fossils are sufficiently characteristic to establish the age with certainty. [See below.] The thickness is considerable (more than 800 feet) and the petrographic character is very variable. Red colors predominate. According to Leggett the formation occurs not only in the vicinity of Tegucigalpa and San Juancito but also near Sabana, and Dr. Fritzgartner states that it has a wide occurrence in the neighborhood of Danli, where the limestones attain a notable development.

The petrographic resemblance of the Tegucigalpa formation (as it was called by Fritzgartner) with the Metapan terrane [see Chapter XIV, Lower Cretaceous, p. 585], is so great that I was unable, in the absence of fossils, to distinguish them. It may therefore well be the case that a portion of the Metapan terrane, as shown in the departments of Tegucigalpa and Olancho, belongs to the Tegucigalpa formation.

Mierisch described a series of strata observed in Nicaragua which he was inclined to consider as Triassic and which I have therefore designated in my map accordingly. These are beds which in Prinzapolca occur in a horizontal or gently dipping east-west attitude and comprise red fine sandy clays and soft yellowish to white sandstones; soft red sandstones on the Cuicuina River; reddish white to white clays and iron-stained sandstones on the Cuculaia River; fine-grained reddish sandstones which pass over into loose gravelly marls near Ojoche; red sandy clays and gravelly and pebbly strata which are strongly impregnated with iron and contain numerous included quartz blocks near La Guardia; red sandstones below Sirena, on the Rio Grande; soft red clayey sandstones on the Rio Tuma, on the lower Vaspuc; and red sandy clays on the Rio Coco near Saki, Quisalaia, and Saclin. These latter occurrences I have mapped as Tertiary, since the flat position of the completely unfossiliferous strata is in such contrast to the steeply dipping Mesozoic formations of the middle Rio Coco as to indicate without question a younger age. Having in this region begun to doubt the determination of the age by Mierisch, I came to regard his Triassic formation with some question, the more so since he rested his correlation only upon petrographic resemblance with the new red sandstone in the eastern part of the United States, together with the occurrence of splendidly preserved but not very surely determined silicified cycad trunks from the vicinity of Ojoche, as well as upon the intimate relationship between these rocks and the melaphyres, porphyry, and the associated tuffs. * * * It is true that Mierisch calls attention to the fact that the obviously very young "Tertiary" sands, clays, and gravel beds of Prinzapolca rest unconformably upon the Triassic.

Inasmuch as Sapper in several successive publications implies that Newberry's determination of the Rhætic age of the cycads from Honduras should be accepted only with doubt, the present compiler referred the question to F. H. Knowlton, who under date of December 9, 1910, answered as follows:

At your request I have again looked over Newberry's paper on "Rhætic plants from Honduras" and, without going exhaustively into the subject, I see no reason for seriously questioning the correctness of his age determination. Newberry compared this flora with others from various parts of the world and found closest agreement with those of southern Sweden (Bjuf) and India (Rajamahar). There is also a species very close if not actually identical with one in the Triassic (Rhætic) of North Carolina.

In this connection I may add that Dr. Arthur Hollick, of New York, happens to be here now, and I have asked him about this matter. The specimens upon which Newberry based his paper are in the care of Dr. Hollick, and he permits me to say that in his opinion their reference to the Rhætic is justified.

Mierisch⁵⁹⁴ states briefly that Triassic rocks occur in Nicaragua. He says:

The path from Muy-muy to Guardia leads through a swampy savannah, "Jicaral," but the district is of geological interest on account of the occurrence of Triassic strata. They

are red sandy clays, together with highly ferruginous conglomerates containing numerous quartz blocks; the latter particularly indicate Triassic age, as they are characteristic of a district north of La Guardia, where the age of this formation is placed beyond question by the occurrence of silicified cycad trunks ("Farnstrunke").

Regarding rocks on the River Vulvul, Mierisch says:

Near Ojoche Trias occurs again in the form of a fine-grained red sandstone which is fairly firm. * * * At Ojoche it is rather a loose pebbly mass containing many quartz blocks and fern trunks, which are superbly preserved. Even the bark and attachments of the roots may occasionally be clearly recognized and the internal structure of the wood is retained to the most delicate details. These forms probably belong to the genus *Tubicaulis*.

The cycads to which Mierisch and Sapper refer were collected by T. H. Leggett and sent to Newberry, who recognized 13 species and assigned them without question to the Upper Triassic. Newberry^{612, 613} says:

From the notes furnished me by Mr. Leggett it appears that the plant beds of San Juancito form part of a series of argillaceous shales now converted into hydromica schists several hundred feet in thickness. Below these, limestones crop out which are said to contain Carboniferous fossils, while above them are heavy masses of eruptive rock. The plant-bearing shales are much disturbed and metamorphosed, and are cut by a series of silver-bearing veins which have been worked for many years with considerable success. The outcrops which contain the plants are much decomposed and few good specimens have been obtained from them, but the number of species represented is large and it is evident that further excavation would result in the accumulation of much interesting material.

The age of the deposit as indicated by its plants is plainly Upper Triassic and the flora as a whole has a great resemblance to that of the coal-bearing strata on the Yaki River in Sonora, Mexico, described by me in the report of the San Juan exploring expedition, and to that described by Schenk in "Die fossile Flora der Grenzschichten des Keupers und Lias Frankens" and to Nathorst's "Florau vid Bjuf," a number of the species being identical and others closely allied.

The localities nearest to Honduras where fossils indicative of Triassic age have been before discovered were in Sonora, Mexico, 2,000 miles north, and in the Andes of Peru, where Triassic rocks were found by David Forbes, 2,000 miles south. The plants contained in the collection made by Mr. Leggett are here briefly described.

D-E 15. CHIAPAS AND GUATEMALA.

Sapper^{694a} describes the Todos Santos terrane of Central America as a sequence of red or yellow sandy and argillaceous conglomerates, which are but slightly tilted and not apparently conformable to the underlying Carboniferous. They are unfossiliferous but may be Triassic, as similar deposits of that age have been found in Honduras and Nicaragua. Sapper says:

At the northern base of the Sierra Madre in the State of Chiapas one may observe a series of puddingstones, sandstones, and shales, of red or yellow color, which I have called the Todos Santos strata. The beds are but slightly inclined toward the north at various places where I have been able to observe the dip. They do not rest conformably upon the Carboniferous limestone, and it appears that these deposits were laid down after the formation of the first elevation of the Sierra Madre in the margins of a sea later than the Carboniferous but before the Cretaceous, so that they suffered but little dislocation or alteration.

I can not give any exact data in relation to the age of these strata, as I have not found any fossils in them. There are very similar deposits of the Triassic period which have been found in the Republics of Honduras and Nicaragua.

In a later article⁶⁹⁸ Sapper stated that he had not been able to observe the contact of the Todos Santos beds with the underlying Carboniferous and could not be sure that the two were unconformable, although that conclusion was probably correct.

Böse⁹⁰ in 1906 repeats Sapper's description and adds that the Todos Santos strata appear to belong to the "Triassic-Jurassic," as they are similar in position and lithologic character to strata of those ages which are known in other parts of Mexico (Puebla and Oaxaca) and also in Honduras.

E-F 14. CENTRAL AND NORTHERN MEXICO.

Aguilera^{9a} in 1906 thus summed up the occurrences of the Triassic in central and northern Mexico under the heading "Neo-Triassic":

Marine deposits of the Carnien stage are represented in the vicinity of the city of Zacatecas by siliceous shales and argillaceous and sandy rocks which contain a number of species of Paleoneilo, Halobia, Avicula, Cassianella (Burckhardtia), and some ammonites: *Serenites smithi* Burckh., *Anatomites mosjvari* Burckhardt, Clionites, and Trachyceras. The Triassic beds of Zacatecas are intimately associated with spilitic rocks (greenstones). We may mention in the same connection the marsh and lacustrine deposits of Juravien age which correspond probably to the Keuper and extend up to the Rhætic. They are composed of quartzose sandstones of gray or reddish-brown color, gray, black or varicolored slates, and some beds of red conglomerates with small pebbles in the region of Los Bronches, at the Barranca of San Marcial and San Jose de Pimas in Sonora.

A list of fossils comprising 30 species follows, and Aguilera continues:

Conglomerates and red sandstones which alternate with gray and black slates and which, inasmuch as they include fossil plants of the same genera and species as those of Los Bronches, are of the same age, have been found in Puebla and Oaxaca, and probably also beneath the beds of Miquihuana, in Tamaulipas.

In the geologic map of North America the occurrences of the Triassic in central and northern Mexico have generally been mapped with the Jurassic in accordance with the manuscript map furnished by the Mexican Survey. (See also quotations under Jurassic in Chapter XIII.)

The Triassic of Zacatecas was described by Burckhardt and Scalia.¹¹¹ After describing ancient sericitic schists, whose age they say is probably pre-Triassic, as they are unconformably overlain by beds of the upper Triassic, the authors continue:

The upper Triassic strata rest in discordance upon the ancient schists forming the central portions of the two recumbent synclines that are open toward the east and which may be observed in the valley of the Pimienta. The existence of these synclines is proved by the arrangement of two bands of Triassic strata intercalated in the ancient schists. One may observe quartzites and quartzitic sandstones of dark-gray color containing fragments of quartz and feldspar in the center of the two Triassic occurrences, while these rocks are limited on both sides by quite a thickness of siliceous and argillaceous schists which are black or dark blue and alternate with green sandstones and greenish or gray argillites. All of these rocks dip toward the east. * * * The Triassic fossils occur in two different localities; the first is situated close to the point where the Arroyo Calavera or Pimienta is crossed by a bridge, the bridge of Ahogado. At that point, in the northern flank of the eastern syncline of the Trias, fossils occur in the black siliceous slates as well as in a gray argillaceous rock. These beds are filled with fossils, especially with small bivalves, while ammonites are rare and fragmentary.

The fossils that were collected at this point were independently determined by Mojsisovics and J. P. Smith as belonging probably to the Carnien stage of the Upper Triassic of Europe. A second collection of fossils was obtained in greenish sandstones and argillaceous rocks in the western syncline of the Triassic. The authors continue:

It is proved by the discovery of these fossils that the upper part of the slates of Zacatecas belong to the upper marine Trias.

A full description of the fauna is given by Burekhardt.¹⁰⁸

I 11. SOUTHERN CALIFORNIA.

The several areas of Triassic rocks southeast of Los Angeles are described by W. C. Mendenhall for this report as follows:

The Santa Ana Mountains, usually regarded as a southern extension of the Coast Ranges, form a portion of the boundary between Riverside and Orange counties in southern California. The group, which lies for the most part south of the lower course of Santa Ana River and west of the Temescal Wash, culminates in Santiago Peak, 5,680 feet high. Its axis is made up of a series of dark-gray or black slates with minor amounts of interbedded brown sandstones, the whole sparingly intruded by a series of medium acidic dikes and overlain unconformably by remnants of the associated effusives whose aspect is generally that of andesites or slightly more acidic rocks.

The slates exhibit varying degrees of metamorphism. They usually have a well-developed cleavage, which, however, is generally not sufficiently perfect to obscure the original bedding planes. In general appearance they resemble the Mariposa slate of central California, although as a rule they are less extensively altered. These sediments are the oldest rocks of the mountain range in which they occur. The effusives already mentioned overlie the slates but have been affected by a part of the same metamorphism.

Both the sediments and the associated effusives have been intruded and slightly altered by great masses of granitic rocks, and this threefold series after a long time interval, represented by an extensive physical unconformity, has been at least partly buried under Cretaceous conglomerates and shales of Chico aspect that are now entirely unaltered though extensively deformed. These Upper Cretaceous rocks form an encircling outcrop that flanks the dome of older rocks.

The determination of the age of the slates is based on small collections made in Ladd Canyon, on the south slope of the range, and near the mouth of Bedford Canyon, on its north slope. These collections were examined by Dr. Stanton, who reports as follows on the Bedford Canyon collection:

“The two Triassic lots, both from the neighborhood of Bedford Canyon, evidently came from essentially the same horizon. No. 230 contains fine specimens of a large species of *Rhynchonella* of a Mesozoic type and a single specimen of *Spiriferina*. No. 321 contains the same species as 230 and in addition a plicate form of *Terebratula* and fragments of crinoid stems. These fossils taken together clearly indicate the Triassic age of the fauna, but in the absence of ammonites and other diagnostic forms it is not possible to determine the exact horizon, although it is probably Upper Triassic rather than older.”

Thus the collections, although meager, seem abundantly sufficient to establish the Triassic age of the slates. Accepting this age, then, as determined, we must assign the later granitic intrusions to the Jurassic or the early Cretaceous.

The Triassic beds probably extend considerably beyond the area in the Santa Ana Mountains where they have been carefully examined. Similar beds are known to occur in Railroad Canyon between Elsinore and Perris, and fragmental masses of them apparently caught up in

the widespread granitic intrusions of the area occur farther east in the vicinity of Poloma and Los Alamos valleys, in Riverside County.

I 13-14. EASTERN NEW MEXICO AND WESTERN TEXAS.

The Triassic of eastern New Mexico occurs in the escarpment along the valley of Canadian River, and probably elsewhere as the uppermost part of the red beds beneath strata which are believed to represent the Morrison formation (Jurassic or Cretaceous). The strata are 100 to 200 feet thick and are sandstones of reddish color with lighter-colored balls of clay.^a Triassic vertebrate remains have been found by Stanton^{781b} near Folsom and by Lee⁵²⁸ at a point southeast of Tucumcari.

The original section of Mount Tucumcari ("Pyramid Mountain") was observed by Marcou and is thus described by Blake:⁸⁵

Pyramid Mountain.—The finest and most complete section of the horizontal strata of the bluffs along the route was obtained at this mountain by Mr. Marcou. The point was peculiarly favorable, being one of the isolated mounds, a remnant of the Llano, and exposing the strata on all sides. It is only one of the many mounds dotted over the wide space eroded by the river from the Llano, and called Plaza Larga by the Mexicans. This mound was ascended by Mr. Marcou, and others of the party, and we find the following record of the succession of the strata in the notes under date of September 22:

Section at Pyramid Mountain.

"Jurassic:"

White limestone.
 Yellow limestone with bluish-gray bed at the bottom.
 Bed containing *Ostrea* ——— (?).^b
 White sandstone.
 Yellow sandstone.
 White sandstone.

"Triassic:"

Gray and green bed in contact with the superior Trias.
 Red and green sandstone.
 White marls with concretions.
 Red and green marls.
 White.
 Red.

[Thickness,] 500 feet.

Mr. Marcou considers that the base of this mound is formed of the beds of the superior Trias, the upper portion being Jurassic. It does not appear to me that the evidences are quite sufficient to warrant this decision, but the discussion of this subject will be left for a subsequent portion of the report.

A sketch of this mound was carefully taken in colors by Mr. Möllhausen, the tints agreeing as nearly as possible with those presented by the strata. The sketch has been lithographed and is appended. It will serve to convey an idea of the relations of the strata, especially the white and red series, and may be received as an exhibit of the general aspect of the bluffs of the Llano, where the beds are exposed. The section and locality derives great interest from the occurrence of fossils. The bed containing the *Ostrea* is said to be of grayish-blue clay and subschistose, and 2 inches thick. The *Ostrea* is subsequently called *Ostrea dilatata*, and is again mentioned in the résumé. This is the fossil called *Gryphæa tucumcarii* in the collection (No. 133) from Pyramid Mountain, and referred to in the résumé under the same name, it

^a Lee, W. T., personal communication.

^b The specific name can not be deciphered in the original. It looks like *comanche*.—W. P. B.

being said to have the greatest analogy with the *Gryphæa dilatata* of the Oxford clay.^a It is probably a new species or a variety of *Gryphæa pitcheri*, and a description of it will be found in Chapter IX, under the name *G. tucumcarrii*, originally proposed by Mr. Marcou.

From these various observations we may conclude that the great plateau, the Llano Estacado, consists of horizontal strata of light-colored white or grayish-white and yellowish sandstones and bluish clays and marls, resting conformably upon beds of red clay, red sandstone, and gypsum, and these, according to Mr. Marcou, are intercalated with grayish or light-colored sandstones, as on Rocky Delaware Creek. It also appears that the light-colored sandstones and calcareous beds constitute the main part of the bluffs and that the red marls and clay of the gypseous series are at their base and occupy the space between them and the river.

The strata assigned to the Jurassic by Marcou were by Cummins¹⁹⁷ shown to be Lower Cretaceous. The Triassic age of the lower part of the section is neither proved nor disproved. The strata beneath the Cretaceous may be Triassic, or they may be older red beds (Permian or Pennsylvanian) from which the Triassic beds were eroded.

In western Texas Cummins distinguished and Drake²⁹³ described the Dockum group, of Triassic age, a sequence of calcareous sandstone, clay, cross-bedded sandstone, and conglomerate, deposited on an eroded surface of Permian. Drake recognized three divisions, which he described in detail.

The Dockum beds underlie all or nearly all of the Staked Plains of Texas and southeastern New Mexico, extend farther back into New Mexico northwest of the plains, and have some extension under the Cretaceous area south of them in Texas.

The limit of the plains on the east, north, and west is marked by an escarpment which is usually from 100 to 200 and sometimes 300 or 400 feet high. The basal portion, sometimes nearly all of this escarpment, is composed of the Triassic beds. These beds usually extend 6 or 7 miles from the base of the escarpment and nearly surround the plains by a narrow band.

* * * * *

Sandstones, conglomerates, and clays constitute nearly all of the strata of this formation. The materials composing the different strata vary somewhat in lithological characteristics at different localities and even at the same locality, but the general characteristics are quite uniform and are so different from the underlying Permian and overlying Cretaceous or Tertiary that they are usually easily recognized. This is especially true of the sandstones and conglomerates.

Sandstones.—The sandstones before exposure to weather are generally nearly white, but sometimes gray, red, or bluish in color. Massive, shaly, and false bedding are common. The texture varies from a fine, even-grained to a grit or conglomeratic sandstone. White and a few brown mica flakes, varying in size from a mere speck to one-eighth of an inch in diameter, are nearly always present. This mica is so abundant in some of the rocks as to make them fissile. The sandstones are usually friable but weather with a smooth, flat surface and with an average sharpness of angle for sandstone rocks.

Conglomerates.—The conglomerates are of two kinds. The one most characteristic and widespread is composed of small pieces of brownish, yellowish, or bluish colored subangular indurated clayey sandstone fragments, averaging about the size of a pea, embedded in a matrix of sand or grit, usually calcareous. The other is composed of siliceous pebbles in a matrix of sand and grit. The pebbles are usually small and well rounded and of nearly all shades of color, but white quartz are the most numerous. The quantity of siliceous pebbles varies at different localities from more than half the rock mass to very few. Both conglomerates contain silicified wood at some localities. The bedding of the siliceous conglomerate is usually even and regular or slightly false, while that of the first named is false almost without exception. These two conglomerates graduate into each other, and even where one is the most characteristic the other usually enters into it more or less.

^a The genus *Gryphæa* was formerly included with the Ostracea.

Clays.—The clays are a dark red or blue, with some variations of yellowish and purple, and are calcareous and arenaceous. The blue clays are not very common, are nearly always highly arenaceous, and frequently contain vertebrate remains. The red clays are seen at nearly every outcrop and are often more than 100 feet thick, with probably a few thin layers of sandstone distributed through the strata.

Thickness and unconformability.—The slight difference in dip and sudden change in lithological character of the Triassic beds from the Permian point conclusively to a break in the sedimentation of the two formations. At some localities the Triassic beds are overlain by Cretaceous, but generally by Tertiary material. The Cretaceous escarpment or butts resting on the Triassic beds are often 200 feet thick and mostly limestone. The denuding forces that for an immense length of time were cutting these Cretaceous rocks back toward their present limits must have carried away a great deal of the Triassic before it was covered by Tertiary. The strata thus inclosed between two unconformable beds must of necessity vary in thickness, and so we find it varying from a few feet to nearly 400 feet. Even in localities close together the beds vary considerably in thickness. The average, however, will probably reach 200 feet.

Stratigraphy.—The following classification or grouping is not intended as a correlation with any other Triassic beds, but only to apply to the Dockum beds over the area examined. The Dockum may be divided into three beds, though some localities show more, that are more or less well marked. * * * These three main beds are as follows: A lower bed of sandy clay, which is from 0 to 150 feet thick; a central bed or beds of sandstone, conglomerate, and some sandy clay, which is from 0 to 235 feet thick; an upper bed of sandy clay and some sandstone, which is from 0 to 300 feet thick. While these groups represent the different geological horizons over most of the Triassic area, there is nevertheless at some places a thinning out of one, and a thickening of another, which shows that at the same time the conditions of deposition were somewhat different at different localities. The same geological horizon is, therefore, more or less represented in other beds than that which generally represents it. Then, while these three beds do not absolutely represent geological horizons, they do so approximately and are so well marked as to be of much stratigraphical value.

These strata are fresh-water deposits and their age is determined on vertebrate remains by Cope.

I-J 17. NORTH CAROLINA.

Kerr⁴⁸⁹ thus described the rocks of the Dan and Deep River belts, the Triassic of North Carolina:

The rocks are sandstones, clay slates, shales, and conglomerates, generally ferruginous and brick-red, but often gray and drab. The shales are occasionally marly, and these and the sandstones are sometimes saliferous. Many of the beds consist of loose and uncompacted materials and are therefore easily abraded.

The most important and conspicuous member of the series is a large body of black shales, which incloses seams of bituminous coal, 2 to 6 feet. This coal lies near the base of the system in both belts and is underlain on Dan River by shales and on Deep River by sandstones and conglomerates, the latter constituting the lowest number of the series and being in places very coarse. And near the eastern margin in Wake County, where the belt reaches its greatest breadth (some 15 miles), the conglomerates are of great thickness and very coarse, uncompacted and rudely stratified, resembling somewhat the half-stratified drift of the mountain slopes, the fragments often little worn and sometimes 10 and 12 inches in diameter, and evidently derived from the Huronian rocks of the hills to the eastward. The conglomerates of the Dan River belt are among the upper members of the series and are mostly fine and graduate into grits and sandstones.

The black shales near the base of the system contain beds of fire clay and black-band iron ore, interstratified with the coal. They are also highly fossiliferous, especially on Deep River. Silicified trunks of trees are very abundant in the lower sandstones, as may be seen conspicu-

ously near Germanton, in Stokes County, the public road being in a measure obstructed by the multitude of fragments and entire trunks and projecting stumps of a petrified Triassic forest; and similar petrifications are abundant in the Deep River belt, occurring in this, as in the other, among the sandstones near the horizon of the coal.

The Triassic coal-bearing terrane of North Carolina has also been described by Woodworth,⁹⁴⁹ as follows:

There are two coal-bearing Triassic areas in North Carolina. These are the eastern or Deep River area, including the Wadesboro detached area, and the western or Dan River area. The principal productive coal beds are found in the Deep River district, in Chatham and Moore counties. The Dan River region is regarded as of little promise. * * *

The Deep River area forms a northeast-southwest belt in the central portion of the State, extending northward nearly to the Virginia line and southward into South Carolina. The productive area, about 30 miles long, lies wholly within North Carolina.

The rocks of the area appear on the north about 6 miles southeast of Oxford, in Granville County, whence they extend southwestward to the Cape Fear River. South of this stream they continue as a somewhat tortuous belt in the Deep River region to within about 10 miles of the Yadkin River. On the Yadkin, and a few miles west of the southern end of the Deep River area proper, the Wadesboro area begins and extends in the same general direction 6 or 7 miles into South Carolina, in the vicinity of Carew. The total length of the whole belt is over 60 miles. Its average width is about 12 miles, its greatest width being as much as 18 miles. The total area has been estimated at between 250 and 300 square miles. Between the larger northern and southern areas are small detached basins of Triassic rocks not known to be coal bearing.

The area displays the prevailing structure of the Triassic belts along the Atlantic coast, the basal strata of one side of the belt reposing on the ancient crystalline rocks of the Piedmont district, the opposite margin bearing evidence of being thrown down by faults. The usual dip of the strata in this area is southeast, the angle being about 15°. According to Russell, the notches in the boundaries probably indicate faults, several of which are exposed in railroad cuts within the area. Evidence of faulting is also seen in the narrow strip of Triassic strata near the western border, in the vicinity of Lockville.

The coal-bearing beds show a distinct curvature where crossed by the Deep River northeast of Cummocks. In other respects the structure, as revealed in workings, appears to be more regular than that of the Richmond area in Virginia.

The strata, numbered from the bottom upward, are given as follows in the State reports:

Strata in Deep River area, North Carolina.

	Feet.
3. Sandstones, grits, and upper conglomerates.....	3,000
2. Black shales, with coal beds.....	500 to 600
1. Conglomerates and sandstones.....	1,500

As in the Richmond and other Triassic areas, the coal beds are near the base of the Newark formation. * * *

Five coal seams have been proved at the Farmville and Hornesville mines. Their thicknesses, beginning with the highest, are given as 3, 1, 3, 2, and 4 feet. At the Cunnock mine there are two beds, one 4 and the other 2 feet in thickness, separated by 2 feet of black-band iron ore. At Taylor's mines three seams were reported, with a thickness of from 18 to 30 inches, 2.5 to 2 feet, and 4 feet, respectively. At Wilcox's the Murchison seam is described as being 8 or 9 feet thick but containing shale. The coal outcrop has been traced for 30 or 40 miles in the central part of the State southwestward from the vicinity of the Cape Fear River.

Chance ^a found at Farmville, N. C., five beds of coal in the following section, which measured 40 to 50 feet from the roof of the uppermost coal bed to the floor of the lowest.

^a Trans. Am. Inst. Min. Eng., vol. 13, pp. 517-520.

Section of coal beds at Farmville, N. C.

Slate roof.	
Coal, good.....	3 feet to 3 feet 2 inches.
Black band and slate.....	1 foot 8 inches to 3 feet.
Coal, poor, shaly.....	1 foot to 2 feet.
Pure clay floor.	

I-K 12-13. UTAH, COLORADO, NEW MEXICO, AND ARIZONA.

Along the fortieth parallel so-called Triassic rocks were originally distinguished by King and his associates,^{505d} whose observations are thus summed up:

In the region of the Rocky Mountains we have seen that the Trias frequently overlaps the older rocks and comes directly into nonconformable contact with the great Archean islands that now form the three ranges of the Rocky Mountain system in our latitude. The Trias is in general a series of sandstones; the upper half is always of lighter colors than the lower half and is always intercalated more or less with beds of dolomitic limestone and gypsum. The series varies from 300 to 1,000 feet in thickness. Wherever it stands at a high dip, it is most compressed in thickness and most compacted in lithological character. Wherever its position approaches horizontality, the texture of the rock is that of a loose, friable sediment. The lower half of the series is usually from brick to vermilion red and buff, with occasional exceptions of white and brilliant vermilion. The intercalated dolomitic and gypsum beds are never continuous but are shallow deposits of no great lateral extension. On approaching the Archean rocks the Trias have always more or less local conglomerates, derived directly from the shores against which they abut. There is considerable variability in color, in thickness, and in special arrangement and sequence of the sediments. From 1,000 feet maximum in the region of the Rocky Mountains the deposit thickens in passing westward, until, in the neighborhood of the eastern part of the Uinta, it is fully 2,000 to 2,500 feet thick. The division between the lower dark-red member and the upper buff or white member is much more distinct in the Uinta region than to the east. Here, however, are still the intercalated gypsums and dolomites in the upper half of the series, the gypsum sometimes reaching 40 feet of pure white crystalline sulphate. There are also in the Uinta considerable intercalations of clayey matter, which are rare in Colorado.

Passing still farther westward, against the Wahsatch, there is again a noticeable diminution of thickness and a corresponding increase of stony compactness. Under the microscope no single specimen was observed that had not a considerable amount of carbon and a trace of crystals of carbonate of lime. In approaching the Wahsatch, also, there is a considerable increase of conglomerates. This constitutes another argument indicating the approach of a land mass to the west, whence detritus is derived. But one fossil, a new species, was found in the entire Triassic series of the east, and that was obtained from one of the limestone beds—a greenish-drab lithographic limestone—a little above the middle of the series, on the south flank of the Uinta. That fossil had a distinctly upper Triassic or Jurassic facies. The upper horizons, especially the uppermost member of all, varying from 200 feet in Colorado to 600 in the Uinta and sometimes more than that upon the flanks of the Wahsatch, is characterized by remarkable cross stratification which is prominent over most of the exposed area east of the Wahsatch. The flow and plunge structure is developed in a perfection rarely seen, the plane of the cross stratification often inclining to the true bedding planes at an angle of 30° to 35°.

The upper half, bearing irregular sheets of gypsum and of dolomitic limestone, is always directly conformably overlain by the Jurassic beds, which, when first seen on the east flank of Colorado Range, vary from 250 to 275 feet in thickness, and increase steadily until on the flanks of the Wahsatch they have reached fully 1,800 feet. There is a very great physical contrast between the general character of the materials of the Triassic and the Jurassic series. The former is, on the whole, free from lime, except in the sulphate and dolomitic beds, and is with the exception of certain parts of the Uinta rather free from intercalated clays. On the other hand, the Jurassic, in the Rocky Mountain region, is entirely made up of soft clays; argillaceous and calcareous marls, and thin intercalations of fine lithographic limestone. In

the Uinta and Wahsatch region the lower 600 or 800 feet are a bed of solid but very fine grained, slightly argillaceous limestone, and the upper 800 feet are made of fine calcareous argillites. As a whole the series is a lime and clay deposit.

Later observations have shown that part of the supposed Triassic is Permian, some part is Triassic, there are pre-Jurassic unconformities, and the Triassic and Permian deposits which were considered to be marine are in fact largely continental. Cross has recently reviewed the literature and field evidence of this red-beds problem. His statements regarding the probable correlation and distribution of the Permian have been quoted at some length (pp. 480-484), and extracts from those relating to the Triassic follow. The San Juan district of southwestern Colorado is the type locality of the Dolores formation (Triassic). Of this region Cross ^{193a} writes:

The Dolores formation embraces the Triassic portion of the red beds of southwestern Colorado, several hundred feet in thickness. It is limited both above and below by planes of unconformity. In most places it rests on the Cutler formation [Permian?] and is overlain by the La Plata sandstone [Jurassic]. It consists of sandstones, shales, and fine-grained conglomerates, all more or less calcareous. There are two divisions of the formation; the lower embraces variable sandstones, conglomerates, and shales, partly greenish or gray in color and persistently fossiliferous at several horizons; the upper portion is a very fine and evenly grained sandstone and shale of strong red color.

The lower portion of the Dolores formation consists of an alternation of reddish sandstones, more or less shaly, with conglomerate, consisting chiefly of very small limestone pebbles. These conglomerates characterize several bands within the lower 300 or 400 feet of the Dolores, and, owing to their fossil content and notable lithologic characteristics, these beds are the most diagnostic of the whole formation. The conglomerate beds are very variable in number. In some places a ledge 20 feet thick may be seen to consist chiefly of conglomerate with numerous sandy partings and common cross-bedding. A few yards distant the same strata may be composed chiefly of sandstone with a number of thin layers of conglomerate.

* * * * *

The conglomerates are commonly associated with thin-bedded gray sandstones or greenish-gray sandy shales. A complex of such alternating strata 50 to 75 feet in thickness can be traced for long distances on the flanks of the San Juan Mountains. Carbonaceous material is common in the shaly beds, but determinable leaves have not been observed. The lowest stratum of the Dolores is generally more or less conglomeratic and in some localities is a harder stratum, forming distinct ledge outcrops. The thickness of the lower division of the Dolores seems to vary considerably, increasing from the mountains west and southwest toward the plateau country.

The upper member of the Dolores is commonly a very even fine-grained reddish sandstone, free from conglomerate but variably shaly in different places. The shales are, however, always very sandy and there are seldom pronounced division planes of great lateral extent. The bands of parallel massive sandstone are often 20 feet or more in thickness. The material is mainly quartz sand, with a calcareous cement. In color this upper sandstone is usually bright brick-red or vermilion, shading sometimes into purplish above and a dull darker red below. In texture this red sandstone is very much like the overlying La Plata sandstone, and where the latter is highly colored the two formations seem sometimes inseparable, but the La Plata is commonly orange or yellow in color when it departs from the normal gray or white.

The upper member of the Dolores is absent in the Ouray and parts of the Telluride quadrangles but presents an increasing thickness southward through the Rico and La Plata quadrangles. Nearly 500 feet of quite uniform sandstones were observed on the eastern flanks of the La Platas. The variation in thickness and the disappearance of the red sandstones to the north is due chiefly to the post-Dolores erosion.

The limestone conglomerates of the lower Dolores contain scanty but very widely distributed fragments of bones and teeth belonging to vertebrate animals. Much less frequently invertebrate and plant remains of identifiable character occur in the same strata. The vertebrate remains have never been found as connected skeletons, or even closely associated bones belonging to one individual. They are usually worn and often broken. The most common fossils are the teeth of crocodiles and dinosaurs. Material collected from many localities has been studied by F. A. Lucas. The greater number of the remains belong to the belodont crocodiles, while less numerous are those belonging to a megalosauroid dinosaur, perhaps *Palæoctonus* of Cope. It is probable that the belodont remains belong to the genus described by Lucas under the name *Heterodontosuchus ganei*, or to allied forms. Poorly preserved outlines of *Unio* have been seen in several places and a small gastropod shell has been found in the Rico and La Plata quadrangles. According to Stanton, the latter belongs to the genus *Viviparus* or to a closely allied form.

Tracing the various strata from the San Juan district west and north in the plateau country, through the work of Peale and Spencer, Cross^{193c} identifies the Dolores formation in the Dolores, San Miguel, and Sinbad valleys.

Below the La Plata, distinguished by Spencer, there occurs a much deeper red sandstone formation, vermilion or brick-red in hue and corresponding to the upper division of the Dolores as it has been described in this paper. Apparently the lower part, characterized near the San Juan Mountains by the variable strata carrying fossiliferous limestone conglomerate, is not, on the Dolores, markedly different from the upper in texture or color. Spencer has found limestone conglomerate rich in bone fragments in several places, and on La Sal Creek this horizon was but about 100 feet below the La Plata sandstone. The total thickness of the nearly uniform Dolores formation is about 1,000 feet in the neighborhood of Sinbad Valley, while much less in other localities.

Over certain areas of the Uncompahgre Plateau in western Colorado the Triassic is lacking, probably in consequence of pre-Jurassic erosion.^{193d} Northwest of Grand River in Utah, however, the strata appear with the characteristics of the Dolores formation. Cross^{189c} gives the following section measured by W. H. Emmons and L. H. Woolsey:

	<i>Section near Grand River, opposite Moab, Utah.</i>	Feet.
Top		
32.	Sandstone, massive or shaly, dark red at base and bright red at top.....	20
31.	Shaly, conglomeratic sandstone, reddish limestone pebbles, the size of a pea or smaller, with few bone fragments.....	6
	<i>Dolores Triassic.</i>	
30.	Sandy shale, red and green.....	5
29.	Débris slope, of red shale fragments.....	20
28.	Limestone conglomerate, with a few inches of limestone at top, fossil wood, and bone fragments; pebbles less than 2 inches diameter.....	10
27.	Sandstone, gray, massive.....	20
26.	Limestone conglomerate grading into sandstone.....	1½
25.	Sandstone, gray, massive becoming shaly near top.....	23
24.	Calcareous sandstone and fine-grained conglomerate mainly sandy, with conglomerate near base and top. Pebbles of limestone and sandstone with occasional bone fragments; pebbles vary from size of peas to several inches.....	9
	<i>Permian (?)</i> .	
23.	Red sandy shales, alternating with sandstone.....	8
22.	Conglomerate, containing pebbles of limestone and sandstone.....	1
21.	Sandstone and shale alternating, red and green, the shales sandy and friable.....	35
	<i>Hermosa Pennsylvanian.</i>	
20.	Blue limestone, weathering dirty buff, near top a layer contains pipe coral.....	10

In the San Juan Valley, in southeastern Utah, the La Plata sandstone (Jurassic) as identified by Gane is in part red and has been mistaken for Triassic. It is underlain by the fossiliferous limestone conglomerate of the Dolores formation (Triassic).^{193e}

The Zuni Plateau, in western New Mexico, comprises Permian, Triassic, and Jurassic strata, according to Dutton.^{301a} Cross^{139g} comments on Dutton's divisions and finds correlatives with the formations distinguished in Colorado.

Comparing the formations of the Zuni Plateau, as described by Dutton, with those of southwestern Colorado, it seems probable that the Zuni sandstones represent the Gunnison group. Dutton's section is not sufficiently detailed to permit a suggestion as to the exact equivalents of the La Plata and McElmo formations, but it is difficult for me to suppose that the Navajo Church is constituted of anything but one of the La Plata sandstone members.

The Wingate sandstone corresponds in position and character to the upper, vermilion-colored sandstone of the Dolores formation. The absence or subordination of cross-bedding and the constancy of the red color both tend to support such a correlation. If the Wingate is upper Dolores, it would appear probable that the "lower Triassic" of Dutton is at least approximately the equivalent of the lower Dolores, and it may well be that the basal conglomerate called the Shinarump by Dutton is actually the same as the basal conglomerate of the Dolores. Dutton does not speak of limestone conglomerates in the Trias, nor did he find fossil remains in it, except the abundant fossil wood.

Regarding northeastern Arizona, Cross^{193h} says :

From the Zuni Plateau a wide tract of upland stretches for 150 miles or more northwest to the brink of the Colorado Canyon. On the northeast is the San Juan Valley and on the southwest is the Little Colorado. It is the land of the Moqui and the Navajo Indians. Beneath the Eocene and Cretaceous strata of the higher central plateau appear the Jurassic and Triassic beds, the character of which on the San Juan side has already been considered. That the same systems are represented continuously from the Little Colorado to the Zuni Plateau was long ago ascertained by Newberry, though definite evidence of the Triassic age of any particular strata has been but recently brought to light.

In the paragraphs following the one just quoted Cross refers to vertebrate fossils from northeastern Arizona which had been identified by Lucas.^{551, 552} The stratigraphic data relating to this area are taken from Ward,⁸⁶⁵ and concerning them Cross¹⁹³ⁱ says:

The vertebrate fauna discovered by Ward occurs near the middle of a section some 3,500 feet in thickness, all of which is assigned to the Trias. Ward divides this section into three parts. At the base are the "Moencopie beds," 700 feet in thickness consisting chiefly of dark reddish-brown soft laminated argillaceous shales, nearly destitute of silica (quartz), highly charged with salt and gypsum. Some calcareous beds grade into white impure limestone. No fossils were found in the Moencopie beds, and Ward states that "the whole series, wherever the contact can be found, always rests in marked unconformity upon the underlying Paleozoic rock (Upper Aubrey)."

* * * * *

Succeeding the Moencopie come 1,600 feet of variable strata called by Ward the Shinarump. Within this he distinguishes two formations, each 800 feet thick, the lower being the "Shinarump conglomerate" and the upper the "Le Roux beds."

The Shinarump conglomerate of Ward is by no means all conglomeratic. His concise characterization is as follows: "Conglomerates and coarse cross-bedded sandstones, with clay lenses interstratified with gray argillaceous shales and variegated marls." In fact, the marls become locally most prominent in zones which are elsewhere strongly conglomeratic.

The Le Roux beds are principally variegated marls, argillaceous and calcareous, followed upward by sandstone, limestone, with flint fragments, and at the top more calcareous marls.

Fossil wood occurs all through the Shinarump group and none is found beyond it. The petrified forests occur within the Le Roux beds and the vertebrate remains were only found in these strata. Bones and fossil wood were found together in many places.

The "Painted Desert beds" of Ward follow the Le Roux beds and consist of sandstones. The lowest stratum, 100 feet thick, is soft, friable, highly argillaceous, and of orange color. Above this come 800 feet of variegated sandstones, regularly stratified and brilliantly colored. Brown cross-bedded sandstones (200 feet) and white massive sandstones (100 feet) form the top of the section studied.

No doubt the Shinarump group of Ward is in a large degree equivalent to the Shinarump of Powell, Dutton, and others, as developed in the plateau country of Utah, and the vertebrate fauna of the Le Roux beds serves to correlate them with the lower Dolores strata containing the same fauna; but until the unconformity reported by Ward at the base of the Moencopie beds has been traced sufficiently to demonstrate the importance of the stratigraphic break it indicates, further correlation of the Moencopie strata is difficult. It is reasonable to suppose that the base of the Moencopie is actually the base of the Triassic section and that deposition began in Arizona much earlier than in southwestern Colorado. On the other hand, it may be that the belodont fauna will be found at horizons lower than the base of the Le Roux beds. If the Moencopie beds are Triassic the stratigraphic break below them accounts for the absence of strata equivalent to the Permian of Kanab Valley found by Walcott. * * *

The lower 900 feet of the Painted Desert beds of Ward may plausibly be referred to the Vermilion Cliff or upper Dolores sandstone, while the brown and white sandstones above probably represent a part of the White Cliff or the La Plata sandstone.

A detailed description of these formations is given by Ward.^{866a}

In northern Arizona and southern Utah Permian and Triassic strata are separated by an unconformity as determined by Walcott.⁸⁴⁴ (See p. 484.) Cross^{193j} gives a detailed section by Walcott of the Jurassic and Triassic of this region, which may be summarized as follows:

Section of Jurassic and Triassic formations in the Kanab Valley, Utah.

White and red sandstone and shale, more or less gypsiferous with a variable conglomerate bed (1-7).....	Feet. 745
Magnesian limestone intercalated with sandy shale, fossiliferous near the top (8-12).....	215
White Cliff sandstone (13).....	585
Vermilion sandstone (14).....	650
Red and gray, often massive sandstone with some shale beds (15-20).....	950
Red and gray sandstone with shaly partings, carrying carbonized fragments of wood (21-22)....	235
Thin-bedded and massive sandstone with shale layers, fish teeth and other fossils (23-25).....	100
Reddish-brown and greenish friable sandstone and shale (26-29).....	860
Gray conglomerate and sandstone (30).....	50

[4, 390]

The numbers in parentheses refer to Walcott's detailed section as given by Cross and serve to distinguish the beds on which Cross^{193k} comments as follows:

In this Kanab section it is evident that Nos. 1 to 12 inclusive, aggregating 960 feet in thickness, represent the upper Jurassic group called the Flaming Gorge by Powell. No. 13 is the White Cliff sandstone, considered as the lower Jurassic in this discussion but placed by Powell in the Trias. Mr. Walcott comments in his notes upon the absence of a sharp line between this sandstone and that below it. Reasons why an apparent transition at this horizon is natural have been presented. This thickness of the vermilion-colored sandstone, 14 of the section, was found to vary from 600 to 700 feet on opposite sides of the valley where the section was made, a variation which may possibly be due to erosion.

It is noteworthy that the White Cliff sandstone is thinner in Kanab Valley than it is to the east, where Dutton and Powell refer to it as 1,000 feet thick. Beneath the White Cliff sandstone occur 2,845 feet of beds, which are referable to the Trias. It is not certain just what represents the Vermilion Cliff sandstone of Dutton, said by him to be 2,000 feet thick near the Vergen River and 1,400 or 1,500 feet thick in the zone crossed by the Kanab. It would appear, however, that beds 14 to 20, inclusive, in all 1,600 feet of sandstones, represent the Vermilion Cliff of Dutton, although the distinctive color is not present throughout. Assigning the beds specified to the Vermilion Cliff, the remainder of the section, embracing 1,245 feet of beds, must be referred to the Shinarump group of Powell.

The Shinarump of Kanab Valley, thus delimited, carries fossil wood in the basal conglomerate and at various horizons in the upper portion. Far more interesting than the silicified wood, which has not been studied by paleobotanists, are the fish and other animal remains obtained by Walcott in beds 23-25 of the section—that is, in the upper third of the Shinarump.

These fossils were sent to the National Museum, and in the confusion of adequate storage facilities were lost sight of until a few months ago. On being found they were sent to Dr. C. R. Eastman for identification and description. Dr. Eastman's complete identifications are not yet available, but he has published a brief preliminary reference to the ichthyic fauna, from which the following is abstracted:

"These remains * * * are extremely fragmentary and do not permit of accurate specific determination. Of the few genera which are tolerably well indicated, such as *Pholidophorus* and several *Lepidotus*-like forms, it can not be said that they evince anything in common with the Triassic fauna of the Eastern States. Some resemblance is to be noted between the Kanab fish fauna and that of Perledo near Lake Como, but the general aspect of the material collected by Dr. Walcott is suggestive of Jurassic rather than of Triassic relations. This might very well happen, notwithstanding the horizon be definitely proved by stratigraphic and other evidence to be of Triassic age, as other instances of pioneer faunas and overlapping contingents are not uncommon.

Associated with the fish remains there were found several representatives of other classes of animal life, concerning which Dr. Eastman has given me the following comments, pending more careful investigation: "There is one ammonite in the collection, or rather the portion of the outer volution of one, which is very suggestive of the Liassic *Arietidæ*, and in the opinion of Dr. Jackson and Mr. Shimer who have examined it, does not seem to belong to the class of forms known from the Pacific Coast Trias." There are numerous *Estheria* in the collection and fragmentary saurian teeth, but whether of crocodylian or ichthyosaurian forms Dr. Eastman is unable to determine.

From the statements of Eastman it appears that the Kanab fauna obtained by Walcott is unique and raises several interesting problems for solution. The fossil-bearing strata were traced by Walcott from the Kanab eastward to the Colorado River and thus are known to occur not far from the area in which the saurian fauna of the Little Colorado was obtained by Ward and Brown, both faunas belonging apparently to the Shinarump group. The relations of the two fossiliferous horizons are as yet quite unknown. From the stratigraphic standpoint it is difficult to see how the Kanab fossils can possibly be of Jurassic age, unless there are complications, hitherto wholly unsuspected, in the great section of the plateau country.

In the preceding comments on Walcott's Kanab section of the Jurassic and Triassic, Cross regards the White Cliff sandstone as Jurassic. It had been considered Triassic by Powell, and also by King, Emmons, and C. A. White, in northeastern Utah and northwestern Colorado. Cross¹⁹³¹ refers to certain "Permo-Carboniferous" fossils collected by Howell from the Shinarump, which were erroneously identified as Jurassic. Weeks^{873b} sums up his own observations, as well as those of previous observers in the Uinta Range, as follows:

The Trias was defined by Emmons as consisting of red sandstones with a series of clayey beds at the base, having an estimated thickness of 2,500 feet. Powell did not separate the

Jura from the Trias. He divided the Jura-Trias beds into the Shinarump, Vermilion Cliff, White Cliff, and Flaming Gorge groups, having a total thickness of 3,845 feet. The Trias of the Fortieth Parallel Survey appears to correspond to the Shinarump, Vermilion Cliff, and White Cliff groups of Powell. The writer has classed the shales at the base of the Trias with the Permo-Carboniferous. The line of division between the Trias and the Permian is placed at the base of the massive cross-bedded sandstones.

In the Uinta uplift the Trias, Jura, and Cretaceous strata are largely covered by Tertiary sediments or glacial débris. The principal areas of the outcrop are in the Flaming Gorge Canyon of the Green River in the vicinity of Split Mountain and Ashley and Dry Forks creeks, and on the Duchesne River several miles below the mouth of West Fork, on the south side of the range. The Trias is much thicker in the eastern part of the range. In the western part the clayey beds of the upper part of the Trias were apparently not deposited. The coarse cross-bedded sandstone, 300 to 400 feet thick, is a dark-buff color in the Duchesne region, which varies to lighter color to the eastward.

The Jura is composed of sandstones, shales, and clay beds, with a prominent limestone series having a maximum thickness of 200 to 300 feet, the whole averaging from 600 to 800 feet in thickness, as determined by the Fortieth Parallel Survey. The Flaming Gorge group of Powell is considered to represent the Jura. The writer considers the prominent drab limestones to form the base of the series, the remainder of the Jura being formed of the overlying sandstones, shales, and clays.

The areas of outcrop of the Jura in the Uinta uplift correspond to those of the Trias and appear to have a greater thickness of beds in the eastern part of the range. In the Duchesne Valley the Jura is represented by a compact drab and gray limestone and soft red calcareous shales. The transition from the buff or brown cross-bedded sandstone of the Trias to the Jurassic oolitic and granular limestone is made in less than 10 feet of strata.

In northern Colorado Triassic rocks have been identified by fossils found on Red Dirt Creek, a tributary of Grand River near the headwaters, northwest of Leadville and south of the fortieth parallel.⁴⁴⁷ Still farther north, in central Wyoming, Triassic fossils have been collected near Lander from strata called by Williston⁹⁴¹ the Popo Agie beds and described as being from "40 to 80 feet in thickness" and occurring in the red beds, about 200 feet below their top and 600 feet above their base. The type locality is Popo Agie River, near the east end of the Wind River Range, and thus not far from the Owl Creek and Bighorn ranges, in which Darton has distinguished the supposed Triassic under the name Chugwater formation. (See K 12-13, pp. 530, 531.)

Regarding the possible absence of Triassic on the eastern side of the Front Range in Colorado, where the red beds are believed to be largely if not wholly Permian, Cross's views have been quoted. (See Chapter XI, pp. 490-492). Williston⁹⁴² refers to the discovery by Marsh⁵⁷¹ of *Hallopus* in Garden Park, near Canon City, and regards the fossil as significant of the Upper Triassic, although the exact horizon can not be identified.

Fenneman³²⁸ describes the Fountain, Lyons, and Lykins formations of the Boulder district, Colorado (north of the Canon City district), as possibly Triassic. The Fountain, however, is of Pottsville age—that is, lower Pennsylvanian. (See Chapter VIII, pp. 369-370.) The Lyons and Lykins are either Triassic or Permian. Fenneman says:

The rocks in this region, hitherto regarded as of Triassic age and called "Wyoming," embrace three formations—the Fountain, the Lyons, and the Lykins. The term "Red Beds" is popularly used without definite limitations, but the authors of the monograph on the Denver

Basin have conveniently limited the use of this term to the lowest and largest member of the series. The popular use of the term "red rock" is similarly restricted.

The subdivision into "Lower" and "Upper" Wyoming, adopted for the Denver Basin, would also be appropriate to the Boulder area. The lower division, however, clearly embraces two lithological units which it is desired to distinguish in this report. The lower and major part consists chiefly of rather coarse arkose sandstones and conglomerates of reddish color, while the upper and lesser part is a finer-grained quartzose sandstone of white, "creamy," or light-reddish color. The coarse red sandstones were called the Fountain formation by Cross in the Pikes Peak folio, a type section being crossed by Fountain Creek, near Manitou. The summit of the Fountain formation is not exposed in the Pikes Peak quadrangle, but Darton^a has found the character of the Fountain, as described by Cross, to continue to a white sandstone corresponding with the "Creamy sandstone" of Eldridge, occurring in the Garden of the Gods, to which the name Lyons sandstone is here given.

No Triassic beds are known on the eastern slope from Canon City, Colo., south to northern New Mexico, but in that region, northwest of Santa Fe, first Newberry and later Cope found Triassic fossils in red beds. Cross¹⁹³ⁿ comments as follows:

While Marcou and other early explorers of New Mexico announced the presence there of Triassic formations, the first fossils indicating the correctness of this assertion were obtained by Newberry in 1859. The fossils described by Newberry himself were fossil plants obtained from the old copper mines near Abiquiu, a locality on Chama River some 20 miles or less above its junction with the Rio Grande. The plants are mainly cycads and conifers, and as they have not been identified at many other localities they are of less importance to the present discussion than the vertebrate remains described by Cope, to which reference will soon be made.

The formation from which the Abiquiu plants were obtained is described by Newberry as consisting mainly of red sandstones, with conglomerates and many variegated beds of soft shales, with abundant saline efflorescences, which led him to characterize the red beds of New Mexico and Arizona in general as the "Saliferous series." Fossil wood, often in tree trunks, is mentioned.

Although I can not find that Newberry mentioned vertebrate fossils in the Triassic beds of the Chama Valley, it appears that he found some, for Cope, who followed him in the exploration of the region, states that the first invertebrates from the Trias of the Rocky Mountains were collected by Newberry with the Macomb expedition. Cope visited Chama Valley and the Gallinas Mountains, lying west of it, in 1864, while on the Wheeler Survey, and obtained various vertebrate fossils from the Triassic beds.

The fragmentary remains described by Cope embrace teeth and bones of three dinosaurs, two of which were generically determined as *Laelaps* and *Palæoctonus*. Similar portions of a belodont crocodile were called *Typhothorax coccinarium*. Associated with these were found five species of *Unio*.

This assemblage of forms suggests the fauna of the Dolores "saurian conglomerate." The locality is less than 100 miles southeast from the easternmost known exposures of the Dolores formation, the intervening country being occupied by Cretaceous formations. It is therefore very natural to suppose that the vertebrate and plant bearing Trias of Chama Valley may be the direct equivalent of the lower Dolores formation. Apparently the fossiliferous strata of New Mexico are not overlain by a massive red sandstone equivalent to the Wingate sandstone of Dutton. The "Variegated marls" of Newberry, which seem clearly to belong to the McElmo or Morrison beds, intervene between the "Saliferous series" and the Cretaceous.

In regard to the Triassic portion of the Shinarump group of Powell in southern Utah and northern Arizona, Cross¹⁹¹ published the following statement:

The Shinarump is the lowest of three formations or groups assigned by Powell to the Trias, the others being the intermediate Vermilion Cliff sandstone and the White Cliff sandstone at

^aBull. Geol. Soc. America, vol. 15, 1904, p. 22.

the top. The Triassic was thus supposed by him to embrace everything present in the great section north of the Grand Canyon between the upper Aubrey (Pennsylvanian) and the marine Jurassic.

Dutton and other writers have referred the White Cliff sandstone to the Jurassic, and this reference is no doubt correct, since the continuity has been established between this very well marked formation and the La Plata sandstone of Colorado, which is in angular unconformity with the Triassic and the entire Paleozoic section.^a The Triassic age of the Vermilion Cliff sandstone has not been directly questioned, neither has it been fully proved, and it will appear in the course of this discussion that there is some slight basis for the suggestion that it is lower Jurassic.

As for the Shinarump group, Walcott long ago found Permian fossils^b in the lower beds referred to it by Powell and possibly Jurassic fossils^a in the upper part, while a Triassic vertebrate fauna occurs near the middle of what Ward refers to the Shinarump.^c The question as to the real character, scope, and correlation of this group is, then, plainly one requiring further study and consideration.

It has been established that the Dolores formation of the San Juan region of Colorado is of Triassic and probably of upper Triassic age. An angular unconformity has been found below the Dolores by which the whole upper Paleozoic red-bed series and a part of the Pennsylvanian strata are locally cut out. No middle or lower Triassic beds have been found and none demonstrably Permian. The stratigraphic break below the Dolores is thus shown to be of much importance.

The Dolores formation has been traced from the mountains into the heart of the plateau district along two lines of approach. The most important fact established is that the fossiliferous basal member of the formation extends west and northwest from the San Juan Mountains as far at least as Grand River, in Utah, where the angular unconformity below it is very marked, and 1,500 to 2,000 feet of probable Paleozoic beds are gone at some places. An overlap of the basal Dolores conglomerate from Permian (?) beds directly to the pre-Cambrian complex occurs on the western side of the Uncompahgre Plateau, in Colorado, where it was observed by Peale in 1875. The fossiliferous lower strata of the Dolores have also been traced down the San Juan Valley nearly to the Glen Canyon of the Colorado, below the Henry Mountains.

While nothing similar to the Dolores fossiliferous conglomerate has been described from the original area of the Shinarump group in Utah or Arizona, the discovery by Ward^c on the Little Colorado River of the vertebrate fauna characteristic of the Dolores shows plainly that a correlation of great importance is to be anticipated when the requisite studies have been made.

J 17-18. RICHMOND BASIN, VIRGINIA.

The stratigraphy of the Richmond Basin was first worked out in detail by Shaler and Woodworth.⁷³¹ They say:

A casual observer traversing the Richmond area on any one of the section lines described in this report can not but note that there are several leading lithological features displayed in bands by which the strata may be thoroughly grouped. When one seeks to trace out these bands along the strike of the strata the futility of the task is at once apparent. It is only on the broadest possible lines with a considerable error in the placing of boundaries between distinguishable groups of strata that a mapping of the basin can at present be carried out.

The accompanying table of divisions is an expression of the present knowledge concerning the lithological and biologic characters of the area.

^a Cross, Whitman, and Howe, Ernest, Red Beds of southwestern Colorado and their correlation: Bull. Geol. Soc. America, vol. 16, 1905, pp. 447-498.

^b Walcott, C. D., The Permian and other Paleozoic groups of the Kanab Valley, Arizona: Am. Jour. Sci., 3d ser., vol. 20, 1880, pp. 221-225.

^c Ward, L. F., Geology of the Little Colorado Valley: Am. Jour. Sci., 4th ser., vol. 12, 1901, pp. 401-413.

Formations in the Richmond area.

Lithologic—		Biologic divisions.	General characters.
Divisions.	Subdivisions.		
Chesterfield group.	Otterdale sandstones.....	Araucarioxylon beds...	Coarse sandstones, often feldspathic, with silicified trunks of Araucarioxylon; well developed north, south, and west of Otterdale. Thickness, 500 feet.
	Vinita beds.....	Estheria beds.....	Black fissile shales, carrying <i>Estheria ovata</i> , passing upward and intercalated with gray sandstones; in James River bluff, west of Vinita station, on Tomahawk Creek. Thickness, 2,000 feet.
Tuckahoe group.	Productive coal measures....	Macrotaeniopteris beds..	Interstratified beds of bituminous coal (usually three seams), coke, black shales (<i>a</i> , fish bearing; <i>b</i> , <i>Estheria</i> shales; <i>c</i> , vegetal shales), sandstones (feldspathic and micaceous), fossil plants; teeth, bones, and tracks of reptiles. Thickness 500 (?) feet.
	Lower barren beds.....	Sandstones and shales under coal beds, often with arkose. Thickness variable, from 0 to 300 feet.
	Boscabel boulder beds.....	Local deposits; boulders of gneiss and granite. Thickness variable, 0 to 50 feet.

The divisions are described in much detail and with reference to exact localities in the pages following this tabulation in the report cited.

J-K 10. NORTHERN CALIFORNIA.

The Triassic of Shasta County, Cal., from which fossils were first described by Gabb,³⁴⁹ has been studied by Smith, who distinguished the Pitt shale (now spelled Pit), Swearinger slate, and Hosselkus limestone. (See table, p. 374, Chapter VIII.) The Pit shale is the upper part of the so-called "Pitt formation," concerning which Smith^{762a} writes:

The Pitt formation overlies conformably the McCloud limestone and consists, roughly estimated, of about 3,000 feet of siliceous and calcareous shales, conglomerates, and tuffs. The rocks in most places are highly metamorphosed, very poor in fossils, and folded to such a degree that the stratigraphy is obscure. The general strike is north and south and the dip generally toward the east, since most of the folds are overthrown.

The formation is largely developed in the region near the junction of the Pitt and the McCloud rivers. It contains both Carboniferous and Triassic rocks, in an apparently conformable series, both with a decisive fauna, the presence of Upper Carboniferous and Middle Trias being proved by fossils.

The lower part of the "Pitt formation" consisted of the "McCloud shales" (Carboniferous). This name has now been abandoned by the Survey, the shales being included in the Nosoni formation of Diller²⁷⁹ (Pennsylvanian). The name McCloud is, however, retained for the underlying limestone (also of Pennsylvanian age).

Details of faunas and local occurrences of the two divisions of the "Pitt formation" are given by Smith in the paper cited above, followed by an account of the

"Cedar formation," comprising the Swearinger slate and Hosselkus limestone. Smith ^{762b} says:

The Cedar formation was first named by J. S. Diller ^a to include the Upper Triassic slates and limestones of Indian Valley, Plumas County, and Cedar Creek, Shasta County. It therefore includes the original Trias described by Gabb ^b from "Gifford's ranch."

In the Pitt River region the formation is very similar to that in Plumas County, being composed of finely laminated shales overlain by massive limestone, each rich in fossils. It seems to overlie conformably the siliceous shales of the Pitt formation, but the contact could not be observed.

The Triassic of Plumas County, Cal., has been discussed by Diller ²⁷¹ and Hyatt. ⁴⁶⁷ In a recent publication on the geology of the Taylorsville region Diller ²⁸⁰ gives the following section:

Triassic:

Unconformity.	Feet.
Swearingerslate: Dark slaty calcareous shales, with thin limestones and some siliceous beds.	200
Hosselkus limestone: Dark-blue to light-gray limestone.....	140
Unconformity.	

The Hosselkus limestone is dark blue on fresh fracture but weathers light gray. * * * It is thin bedded and in some places decidedly slaty * * * and characterized by small ammonites. * * * In the Redding region * * * the upper part is lighter colored and more massive, with a *Spirifer*-like shell, and the lower part thinner bedded and darker, with small coiled forms.

The fossils collected from this limestone by Prof. Hyatt and others in the Taylorsville region have not yet been fully worked up. A partial list is given by Hyatt: ^c

- I. *Arcestes*, phylum of *A. tornati*.
- Arcestes*, phylum of *A. galeati*.
- Arcestes*, phylum of *A. bicarinati*.
- Arcestes*, phylum of *A. sublabiati*.
- Badiolites*, allied to *B. eryx* Mojsisovics.
- Juvavites*, allied to *J. erlichii* Mojsisovics.
- Tropites*, may be young of species occurring in *Halobia* slates.
- Atractites*.

"*Arcestes* (I) is very abundant, but whether the other forms are abundant or not it is difficult to say at present. The materials gathered show that the rock is full of fossils, but these can not be obtained in any reasonable time by means of surface work. Besides the species mentioned, there is a form of *Acrochordiceras*, with finer costæ than those occurring in the *Muschelkalk*, a possible *Balatonites*, like *B. waageni* of the Noric, and some other fragments of *Ceratitinae*, all indicating a fauna rich in ammonoids, which will some day yield a good harvest to patient work."

Prof. Hyatt concludes that the age of the Hosselkus limestone as indicated by the fossils is upper Triassic. To this list *Spiriferina* and fish vertebra, as determined by Stanton, were added last summer. This limestone has not yet been thoroughly examined for reptilian remains, such as J. C. Merriam has found in the Redding quadrangle, but as the limestone of the Taylorsville region is more altered and much less fossiliferous, reptilian remains are less likely to occur. In the Redding region the more massive upper portion of the Hosselkus limestone is characterized by the presence of *Spiriferina*, while the lower, darker, thin-bedded portion often abounds in small ammonites. * * *

The reference of the Hosselkus limestone to the upper Triassic and the Robinson formation to the upper Carboniferous indicates a decided gap between them, a gap which is at least partially filled in the more complete section of the Redding region, where a great thickness

^a Lassen Peak folio (No. 15), Geol. Atlas U. S., U. S. Geol. Survey, 1895.

^b Paleontology of California, vol. 1.

^c Bull. Geol. Soc. America, vol. 3, 1892, pp. 399-400.

(over 1,000 feet) of andesitic and rhyolitic lavas, with 1,500 feet of overlying shales, sandstones, and tuffs of Triassic age, comes between the horizon of the Robinson formation and that of the Hosselkus limestone. It is evident, therefore, that in the Taylorsville region there is a decided interruption between the Hosselkus limestone and the Robinson formation. It is possible, however, that their contact in the Taylorsville region is a plane of displacement, and that the formations of the Redding region missing in the Taylorsville region may, in part at least, be thus accounted for.

* * * * *

The Swearinger formation is composed chiefly of dark slaty shale, sometimes becoming more or less calcareous and at others decidedly siliceous, but the thin beds of limestone or chert form only a small proportion of the whole mass. In the side of the Swearinger slate adjoining the Hosselkus limestone thin lenticular beds of limestone become more abundant. They are generally dark, with irregular cherty or sandy layers, and fossiliferous.

* * * * *

The greatest thickness of the Swearinger slate exposed along Genesee Valley, where measured, is about 200 feet, but the amount cut off by the granodiorite or covered by the overlapping Trail formation we have no means of estimating except by comparison with formations of the same horizon in other regions; such comparison indicates that the thickness is probably not over 400 feet.

The fossils of the Swearinger slate were discovered and described by the Geological Survey of California under Prof. J. D. Whitney. Our knowledge of the fauna was greatly extended by Prof. Alpheus Hyatt, who has published^a lists of the forms found in the subordinate paleontological horizons within the formation. They need not be repeated here except to note that the form from these beds once regarded as *Monotis subcircularis* is now considered by J. P. Smith and others to be *Pseudomonotis*. Prof. Hyatt regarded the Swearinger slate as belonging to the upper Triassic, equivalent to the upper Noric of the Alpine Triassic, and as far as I am aware this reference has not been changed essentially by the somewhat later researches of Prof. Smith.

J-K 10-11. NEVADA AND EASTERN CALIFORNIA.

The Triassic section of Nevada was originally described by King^{505e} in the following summary of the data stated more at length on other pages of his report.

Passing now to the district of western Nevada, the sections, which often do not reach the base of the conformable series, expose two distinct, easily recognizable groups of the Trias. The Koipato, already described, is made up of siliceous and argillaceous beds, whose chemical peculiarity is the almost total absence of soda and lime and the high percentage of alumina and potash—a series probably derived from the disintegration of the heavy Weber Carboniferous quartzite, which must for a long time have constituted the main surface of the erosion of the newly lifted Mesozoic land. This series has an observable thickness of about 6,000 feet, with an unknown quantity to be added for the bottom unseen beds. Conformably over the Koipato is the great Alpine Trias Star Peak series of 10,000 feet, composed of an alternation of three great limestone zones and three interposed quartzite zones, the lower quartzite closely following the physical and chemical peculiarities of the Koipato series below, the upper two quartzites representing moderately pure siliceous sediment. The fossils of these limestones, as already described, repeat with marvelous exactness the facies of the St. Cassian and Hallstadt beds of the Austrian Alps.

Smith^{764a} states that beneath the strata of Middle Triassic age in Inyo County, southeastern California, occur Lower Triassic beds. He says:

In 1896 Dr. C. D. Walcott discovered some ammonite-bearing limestone in Inyo County, Cal., on the east side of Owens Valley, 10 miles east-northeast of Lone Pine, 3 miles southeast of

^a Bull. Geol. Soc. America, vol. 3, 1892, pp. 397-400.

the Reward Mill, and about 1,500 feet up above the mill, on the Union Wash trail from Independence over the Inyo Range into Saline Valley. The fossils were submitted by Dr. Walcott to the writer for identification, and referred to the Lower Trias, on the basis of the occurrence of several genera characteristic of the Brahmanic stage of the Scythic series in the Oriental region. In a preliminary report the writer did not venture to describe new species or genera, but noted the occurrence of Nannites, Clypites?, Koninckites, Meekoceras, Kingites, Gyronites?, Xenaspis, Dinarites, and a new genus of Tropitidæ. Later collections and better material have confirmed most of these identifications, but the form referred to Clypites has proved to be a new genus of the same group; the supposed Kingites is very uncertain; the Dinarites has turned out to be a Paralecanites; and the supposed new genus of the Tropitidæ belongs to the Hungaritidæ.

Later collections, by Mr. H. W. Turner, of the United States Geological Survey, and by the writer, have added greatly to the list of genera and species, bringing out even more strongly the relations of this fauna to the Brahmanic faunas of the Asiatic regions.

At the base of the section seen on the Union Wash are massive siliceous and calcareous beds supposed, on the basis of fossils found in the float, to belong to the Carboniferous; then several hundred feet of calcareous shales with obscure traces of ammonites; then about 15 feet of hard gray siliceous limestone, from which all the fossils listed from this horizon were taken. Above this limestone lie about 800 feet of dark shales with a few impressions of ammonites; then about 5 feet of impure earthy black limestone with numerous ammonites, Ptychites, Hungarites, Acrochordiceras, Xenodiscus, thought by the writer to belong to the base of the Middle Trias, or the Subrobustus beds of the Oriental region.

Lindgren⁵³⁸ describes the Sailor Canyon formation and associated slates, quartzites, and schist in the Colfax quadrangle, California, west of Lake Tahoe, as "Juratrias," having found ammonites and other shells in the beds.

J-K 18. NEW JERSEY, PENNSYLVANIA, AND MARYLAND.

The Newark group is typically developed in New Jersey, and the rocks occur in several distinct belts from Massachusetts to North Carolina.⁶⁸³

The Triassic sediments of New Jersey and New York were described without definite subdivision prior to the work by Kümmel,⁵¹¹ from which the following extracts relating to the separate formations (Stockton, Lockatong, and Brunswick) and the associated igneous rocks are taken.

The Newark series consists of sedimentary and igneous rocks. The former are chiefly shales, sandstones, and conglomerates; the latter diabase, to which the more general term trap has usually been applied. Along the Delaware River the sedimentary rocks are divisible, on lithological grounds, into three groups, which have been called Stockton, Lockatong, and Brunswick.

Stockton group.—The basal beds of the series are found at Trenton, where they rest unconformably upon the older crystalline rocks. They consist of (a) coarse, more or less disintegrated arkose conglomerates; (b) yellow, micaceous, feldspathic sandstone; (c) brown-red sandstones or freestones; and (d) soft red argillaceous shales. These are interbedded and many times repeated, a fact which indicates rapidly changing and recurrent conditions of sedimentation. Although there are many layers of red shale in this subdivision the characteristic beds are the arkose conglomerates and sandstones, the latter of which afford valuable building stones.

In addition to the cross-bedded structure which often prevails in the sandstones, mud cracks and impressions of raindrops occur. The rapid alternation from conglomerates to shales and vice versa, the changes in composition in individual beds, the cross-bedding, ripple marks, etc., all indicate very clearly that these beds were deposited in shallow water in close proximity to the shore. The bulk of the material of which they are composed was derived from the crystalline rocks on the south and southwest, but where they were found to rest upon Silurian shales,

limestones, and quartzites, as was the case along the northwestern border north of Flemington, material from these formations has determined their local character. * * *

The rocks of the Lockatong group overlie the Stockton beds conformably. They consist of (a) carbonaceous shales, which split readily along the bedding planes into thin laminæ but have no true slaty cleavage; (b) hard massive black and bluish-purple argillites; (c) dark-gray and green flagstones; (d) dark-red shales approaching a flagstone; (e) and occasional thin layers of highly calcareous shales. There are all gradations between these somewhat distinct types, so that the varieties of individual beds are almost countless. Both ripple marks and mud cracks occur at all horizons, showing that shallow-water conditions prevailed throughout the time of their deposition. On the other hand, the absence of strong currents or violent shore action is indicated by the extreme fineness of the material.

* * * * *

In general the Brunswick group consists of a monotonous succession of very soft argillaceous red shales which crumble readily to minute fragments or split into thin flakes. Much of it is porous, the minute, irregular-shaped cavities being often partially filled with a calcareous powder. Calcite veins and crystals are common in some layers. Locally lenticular masses of green shale occur in the red. In size these range up to a foot or two in diameter, and vary in shape from nearly spherical to lenticular masses, narrowing down to thin sheets along cracks. They are undoubtedly due to chemical changes resulting in the leaching of the shale.

Although the majority of this series are soft red shales, there are some hard layers, chiefly near the base, and occasional beds of fine-grained sandstone and flagstones, some of which afford valuable building material. Massive conglomerates along the northwestern border are in part the shoreward correlatives of the red shales.

Evidence that the shales were deposited in shallow water is abundant. Ripple marks, mud cracks, and raindrop impressions occur at many horizons. In some quarries imprints of leaves, of tree stems, or the stems themselves are frequently found. The numerous reptile tracks which have made the Newark beds famous occur chiefly in this subdivision. Typical exposures occur along the Raritan River, particularly near New Brunswick.

* * * * *

Important lithological changes occur in all these beds as they are traced along their strike. As the northwestern border of the formation is approached, near Pittstown, the subdivisions lose their distinctive characteristics and merge along the strike into coarse sandstones and massive conglomerates. This change is most striking in the case of the Brunswick and the Lockatong groups, where red shales or black argillites change to sandstones and then into conglomerates, the pebbles of which are frequently 6 or 8 inches in diameter. Under these conditions it is impossible to differentiate and limit these groups in this part of the field.

* * * * *

Important changes are found to occur as the beds are traced along the strike northeastward into New York. The Stockton beds disappear beneath the later deposits a few miles east of Princeton.

* * * * *

The Stockton beds certainly persist into New York, but the typical coarse arkose sandstone beds apparently thin out, and north of Nyack the group can not be identified with any degree of certainty. The trend of the strata apparently carries the beds of this subdivision beneath the Hudson River.

Northeast of Princeton the outcrop of the typical Lockatong group grows narrower and the thickness is less. Either the rate of deposition was slower to the northeast during the time represented by the Lockatong beds elsewhere, and therefore they are thinner here, or else, the rate of deposition being the same as elsewhere, the conditions favoring the deposition of black argillite and shale did not last so long to the northeast of Princeton as nearer the Delaware. A few miles northeast of Princeton the Lockatong beds also are covered by the Cretaceous deposits, but they have been traced by borings as far as the Raritan River. They do not, however, appear in the region west of the Palisades and north of Newark.

* * * * *

The Brunswick beds likewise change in texture toward the northeast. They are predominantly soft argillaceous shales from the Delaware River as far as Elizabeth. In some layers an increase in coarseness is noticeable, which continues northeastward along the strike, until in the vicinity of Newark and Orange the beds are chiefly sandstones. Many of these beds resemble the brownstones of the Stockton series—so closely, in fact, that hand specimens can be distinguished with difficulty, if at all, from much of the sandstone at Trenton and Stockton.

* * * * * * * * *

Still farther north layers of conglomerate appear interstratified with the sandstones and shales. In addition to well-marked beds of conglomerate, many layers of the sandstone contain pebbles scattered through them. The pebbles are chiefly of quartzite or sandstone, quartz, slate, limestone, feldspar, and rarely of flint. Not a single gneissic or granitic pebble was found, although a careful search was made for them. The coarse sandstone and conglomerates, with some shale beds, continue through Bergen County, N. J., and Rockland County, N. Y.

Beds of coarse conglomerate occur at a number of points along the northwestern border. Some of these are composed chiefly of quartzite, others of limestone, and in one case of gneissic and granitic material. The quartzite conglomerate contains a few pebbles of limestone, shale, and gneiss, but almost the entire mass of the rock is made up of quartzite or sandstone pebbles, which are well rounded and frequently 6 or 8 inches in diameter. They are best exposed in the "pebble bluffs" along the Delaware River about 5 miles above Frenchtown. The conglomerates are interstratified with sandstones and shales, forming lenticular beds, which thin out within a few rods to be replaced by beds of a different texture. This alternation and rapid change betoken shore conditions.

* * * * * * * * *

The calcareous conglomerate is in appearance almost the exact counterpart of the famous "Potomac marble" quarried at Point of Rocks, Md. The limestone pebbles are usually bluish or gray, sometimes reddish, set in a red mud matrix, so that the rock has a variegated appearance. The average diameter of the larger constituents is 6 or 8 inches, but boulders 5 feet in diameter have been seen, and at a quarry $2\frac{1}{2}$ miles northeast of Suffern, N. Y., boulders 12 feet in diameter are reported to occur. The larger fragments are generally rounded, but the majority of the smaller are sharp-cornered or at most subangular. Compared with the pebbles in the quartzite conglomerate, the limestone pebbles are but little worn, a fact of some significance in connection with the origin and sources of the materials, since with equal transportation the softer limestones must have been most worn.

* * * * * * * * *

The relations of these conglomerates to the older rocks along the border are significant of faulting. In some cases the calcareous conglomerates adjoin small areas of Paleozoic limestone, from which the materials may have been and probably were derived. In other cases, and this is true of the largest areas, the calcareous conglomerates abut against the gneissic rocks, and for much of the distance it is certain that no limestone occurs between the gneiss and conglomerate, at least not at the surface horizon. Crystalline pebbles, however, are comparatively rare in the conglomerate. Substantially the same conditions prevail in the case of the quartzite conglomerate. For the most part it adjoins the gneiss, but gneissic pebbles in it are rare. The known areas of quartzite along the border are small, and in general not near the massive conglomerate beds. Lithologically, moreover, they are unlike the bulk of the quartzite pebbles.

It is evident that along the greater part of this border the beds of the Newark series were not derived from the older rocks which now immediately adjoin them. Shore currents doubtless transported more or less material somewhat widely, and yet they do not afford us the complete explanation for these facts. The northwestern border is for the most part marked by faults. Here the dissimilarity of constitution is the most marked. Where the border is not faulted and the newer rocks rest undisturbed upon the eroded edges of the older beds, they are

composed of fragments derived from them plus a small contribution by shore currents. Allowance can be made for the work of the currents, but the widespread dissimilarity of constitution is due chiefly to the faulting which has occurred. The waves of the sea in which the Newark beds were deposited did not on the northwest border in general beat against the rocks which now adjoin this area.

The relation of the conglomerates to the shales is also significant. They do not form a single horizon which may be used in interpreting the structure. Instead, they grade either into argillaceous shales, or black argillites, or arkose sandstones. Time and again the pebbly layers were seen to appear in the shales and to increase in thickness and numbers until they become massive conglomerates.

* * * * *

The trap rocks of the Newark beds in New Jersey and New York have been described more or less in detail by several geologists, and it has been demonstrated that overflow sheets, intrusive sills, plugs, and dikes occur.

* * * * *

The most important of the overflow sheets are the three concentric ridges forming the Watchung Mountains. These sheets are to all appearances strictly conformable, both to the underlying and to the overlying shales. Nowhere is there any indication that the trap breaks across the sandstone or shale layers. Wherever the basal contact is exposed, and exposures several hundred feet in extent are known, the trap is seen to follow exactly the bedding plane of the shales.

Moreover, the extensive metamorphism of the associated sedimentary beds, a marked feature in the case of all the intrusive sheets, is entirely absent. Locally, the shale is slightly altered for a few inches beneath the trap, but even this is not always the case. When this is compared with the intense alteration which has affected the shales beneath the Palisades, an intrusive sill, for a distance of over 100 feet, the difference between the sheets is emphasized.

Upper contacts have not been observed in many cases, but the upper surface of these sheets is frequently vesicular, amygdaloidal, and scoriaceous. Locally, a thin layer of water-worn trap particles, intermixed with red mud occurs between the vesicular trap and the unaltered typical red shales, or the vesicles are filled with red mud. The overlying shales conform to the slightly irregular, ropy surface of the trap. In frequent exposures the rolling-flow structure, named by the Hawaiian Islanders pahoehoe, is visible. Nowhere have any tongues of lava been found extending from the main sheet into the neighboring shales.

* * * * *

The Palisades of the Hudson, the Rocky Hill sheet north of Princeton, the Sourland Mountain sheet near Lambertville, and the Cushetunk Mountain near White House are the largest and most prominent of the intrusive sheets. * * * In addition to these, which are demonstrably sills or sheets, there are more irregularly shaped masses northwest of Pennington, near Stockton, and at Point Pleasant (west of Stockton), the precise relations of which to the inclosing beds are not clearly revealed. They are beyond all doubt intrusive masses, but it is questionable whether they are strictly sheets. In the absence of positive knowledge as to their relations with the sedimentary beds, I prefer to speak of them simply as intrusive masses.

The evidence of the intrusive origin of all these masses, sills and others, is as follows. Dikes radiate from the upper part of the sills and penetrate the overlying shales for distances up to 7 miles, as measured on the surface. The sills are locally unconformable to the inclosing strata, although in general they extend for long distances parallel to their strike.

* * * * *

The adjacent sediments have often been greatly metamorphosed. So intense has been this alteration that at distances, often of 100 feet, the rocks are as completely "baked" as those immediately adjoining the trap. Measured along the surface, traces of metamorphism are frequently found 1 foot from the nearest trap outcrop. The complete absence of scoriaceous rock, of amygdules, of the vesicular or the rolling-flow structure is negative evidence of their

intrusive origin which must not be neglected. Moreover, masses of shale and sandstone have been embedded in the trap near both the under and upper surfaces, and the trap itself shows evidence in its texture of having cooled more slowly (and therefore presumably at greater depths) than the overflow sheets.

* * * * * * * *

The overflow sheets are contemporaneous with the beds between which they lie—that is, the upper third of the Brunswick shales.

The intrusive masses extend, for the most part, well up into the Brunswick shales and are therefore younger than these. Moreover, so far as the evidence goes, they antedate the disturbances which closed the deposition of the Newark beds. There are good reasons for believing that many, perhaps all, of the intrusive masses are younger than the extrusive sheets, although the evidence is not conclusive. From a priori considerations it may be suggested that the lava formed intrusive sheets after the formation became so thick that it could not readily rise to the surface, whereas earlier in Newark time the lava was able to break through the inner beds and overflow.

Kümmel ^{511a} gives his first careful estimate of the maximum thickness of the sedimentary formation of the Newark group as follows:

	Feet.
Stockton.....	4, 700
Lockatong.....	3, 600
Brunswick.....	12, 000
	20, 300

These figures his later investigations led him to modify, his revised estimate ^{511b} being:

	Feet.
Stockton.....	2, 300– 3, 100
Lockatong.....	3, 500– 3, 600
Brunswick.....	6, 000– 8, 000
	11, 800–14, 700

The Newark group passes from New Jersey into Pennsylvania in the Trenton quadrangle and is described in detail by Darton ⁵⁹ in the Trenton folio.

The continuation of the belt northwest of Philadelphia is discussed by Darton, ^{58c} who says:

The Newark group in Pennsylvania occupies a broad belt extending across the southeastern portion of the State from Delaware River to the Maryland line south of Gettysburg. It is 32 miles wide on the Delaware, 12 miles on the Susquehanna, 4 miles in northern Lancaster County, and 14 miles at the Maryland line. It is bounded by shales, limestones, sandstones, quartzites, mica schists, gneisses, and granites, varying in age from Ordovician to pre-Paleozoic, which it overlaps along irregular boundary lines. In some portions of the area its margin is determined by faults, but these marginal faults appear not to be extensive either in throw or in length. Over wide areas the dips are to the north and northwest, but in some districts there are flexures of moderate amount and extent. The group is traversed by numerous normal faults, mostly extending northeast-southwest and with downthrow on the east side of the fault plane. One of these extending through Bucks and Montgomery counties has a vertical displacement of several thousand feet.

In the rocks of the Newark group in southeastern Pennsylvania, as in other regions, the typical red-brown sandstone and shale predominate, and there are igneous rocks in intrusive sheets and dikes. The classification which has been established in New Jersey is applicable here, and comprises three formations—the Stockton, Lockatong, and Brunswick, the last named being the youngest. A series of names proposed by the Pennsylvania Geological Survey has not been found acceptable because of their indefinite application.

The Stockton formation comprises gray to buff arkosic sandstone, red-brown sandstone, and numerous masses of red shale in no regular succession and presenting many local variations in stratigraphy. It lies on gneiss, schist, quartzite, and limestone, in Montgomery, Bucks, and northern Chester counties. Many of the sandstones are cross-bedded, and the finer-grained rocks exhibit ripple marks, mud cracks, and raindrop impressions, which indicate shallow-water conditions during deposition. The lower beds usually are arkose—a sandstone containing more or less feldspar and kaolin derived from the gneiss. The Lockatong formation consists mostly of dark-colored, hard, compact, fine-grained rocks originally composed of a mixture of clay and fine sand in variable proportions. Some beds are moderately massive, others vary from shaly to flaggy, and many of them exhibit mud cracks and other evidences of shallow-water deposition. Some of the beds contain carbonaceous material. The Brunswick shale consists mainly of a great thickness of soft red shale with some thin sandstone layers.

These three formations are not sharply separated by abrupt changes of materials but usually merge through beds of passage which appear to vary somewhat in thickness and possibly also in stratigraphic position in different areas.

Clark¹⁴³ gives the following brief account of the Newark formation in Maryland. The belt passes thence into Virginia. (For a discussion of the Richmond field, see pp. 518–519.)

The deposits of the Newark formation unconformably overlie the limestone and phyllite which have been above described and cover a considerable area along the western border of the Piedmont Plateau. Beginning as a belt some 10 miles in width in northern Carroll and Frederick counties, the formation gradually narrows toward the south, until in the region of Frederick its full width does not exceed 1 mile, while at one point directly to the west of Frederick the continuity of the beds is completely broken. Farther southward, in western Montgomery County, the belt of Newark deposits again broadens to a width of several miles.

The rocks of the Newark formation consist largely of red and gray sandstones and conglomerates of both siliceous and calcareous varieties. The finer-grained and deeper-colored deposits generally have their individual elements united by a ferruginous cement, while the calcareous conglomerate, which is largely made up of rounded limestone pebbles, is generally embedded in a reddish calcareous matrix. All of the deposits present structures which indicate that they were formed in shallow water; the coarse conglomerates, the ripple-marked surfaces, and the tracks of animals all point indisputably to this conclusion.

J-L 10-12. WESTERN UNITED STATES.

A philosophic discussion and correlation of American Triassic stratigraphy has been given by J. P. Smith.⁷⁶⁵ The marine Triassic of the western United States is found in Oregon, Idaho, California, and Nevada. Its distribution and relations are summed up by Hyatt and Smith⁴⁶⁹ as follows:

The marine Triassic section of [western] America is unusually complete, and its thickness compares favorably with that of any other region. All three subdivisions—Lower, Middle, and Upper Triassic—are represented by calcareous deposits, aggregating approximately 4,000 feet in thickness. Of this amount, about 800 feet belong to the Lower Triassic, about 1,000 feet to the Middle Triassic, and about 2,000 feet to the Upper Triassic.

The entire section is not represented at any one locality, nor is the thickness of each division constant. Furthermore, the marine Triassic is not everywhere developed as a calcareous formation. In the United States the Triassic system is represented by marine deposits only in the Western States, in Idaho, Nevada, Oregon, and California.

The Lower Triassic is known only in Idaho and southeastern California, where about 800 feet of shales and limestones contain fossils characteristic of this series. The most important genera are Meekoceras, Danubites, Columbites, Flemingites, Aspidites, Lecanites, Ophiceras,

Nannites, Ussuria, Pseudosageceras, Hedenstrœmia, Cordillerites, Tirolites, and Proptychites, most of which are represented by closely related species in the Lower Triassic of India and Siberia.

The Middle Triassic occurs chiefly in Nevada and southeastern California. In the Inyo Range, southeastern California, about 200 feet of shaly limestones contain the following genera characteristic of the lower horizon of the Middle Triassic: Acrochordiceras, Xenodiscus, Hungarites, Ptychites, Tirolites, Ceratites, and Parapopanoceras.

In central Nevada, in the West Humboldt Range, the higher beds of the Middle Triassic are represented by about 800 feet of shaly limestones, in which the most characteristic genera are Ceratites, Analcites, Dinarites, Danubites, Celtites, Hungarites, Beyrichites, Acrochordiceras, Balatonites, Eutomoceras, Ptychites, Joannites, Lecanites, and Atractites among the cephalopods, Daonella among pelecypods, and Cymbospondylus among vertebrates.

The Upper Triassic is best represented in northern California, where the Hosselkus limestone and the shales below and above this formation contain characteristic fossils. The Hosselkus limestone and the interbedded shales have a thickness approximating 500 feet. Fossils are very abundant throughout this formation, although much better preserved near the base. The best known fauna belongs to the zone of *Tropites subbullatus*, and contains as its most important members the following genera: Tropites, Paratropites, Discotropites, Juvavites, Sagenites, Leconteia, Trachyceras, Clionites, Arpadites, Polycyclus, Metatirolites, Hauerites, Dieneria, Arcestes, Paraganides, Proclydonautilus, Cosmonautilus, and Atractites among cephalopods, Halobia among pelecypods, and Shastasaurus among the vertebrates.

Above the Hosselkus limestone lie the Pseudomonotis slates, of unknown thickness, characterized by Halorites, Rhabdoceras, Arcestes, and Pseudomonotis.

In the West Humboldt Range in Nevada the Star Peak limestone, about 1,200 feet thick, appears to represent the Hosselkus limestone, although very few fossils have ever been found in it. Above the limestones lie the Pseudomonotis beds, about 800 feet of shales and shaly limestones, in which are found *Pseudomonotis subcircularis*, Rhabdoceras, Halorites, Placites, and Arcestes, an association characteristic of the Noric horizon.

K 12. SOUTHEASTERN IDAHO.

Peale and White first described the probably Lower Triassic rocks of southeastern Idaho occurring in the Blackfoot Basin near John Grays Lake, in latitude 43°, longitude 111° 30'. Peale⁶³⁰ gives the following section:

General section of Jura-Trias in southeastern Idaho and western Wyoming.

Jura-Trias.	Jurassic.	Belemnites beds.	5. Red and gray shales with green sandstones and irregular greenish arenaceous limestones at the top. Thickness, 700 feet.
		Pentacrinus beds.	4. Laminated limestones, blue at base, passing into gray at top, succeeded above by grayish calcareous shales; many of the layers are probably arenaceous. Thickness, 800 feet.
	Triassic (?).	Red beds.	3. Red quartzitic sandstones with shaly arenaceous and calcareous layers at the base of the section. These are probably the equivalent of the typical "red beds" of the Eastern Rocky Mountains. Thickness, 1,000+ feet.
		Meekoceras beds.	2. Alternations of reddish and greenish sandstones and arenaceous and calcareous shales with blue and gray limestones, generally laminated. Thickness, 3,000+ feet. These with No. 1 are the beds of the section given in Dr. White's paper (as that of locality No. 1). The beds are fossiliferous at four horizons, containing species of a new Triassic (?) genus named Meekoceras by Prof. Hyatt, together with forms that have been heretofore regarded as of Jurassic age.
Carboniferous (?).		1. Massive grayish-blue limestone, overlain by quartzite and dark-blue laminated limestones. Thickness, 1,200+ feet.	

The "Meekoceras beds" of Peale are not recognized either by him or by Schultz in western Wyoming, 25 miles east of John Grays Lake. Smith⁷⁶⁴ gives the following description of the occurrences in Idaho:

Many years ago Dr. A. C. Peale discovered in southeastern Idaho and southwestern Wyoming a series of fossiliferous beds lying below the red beds and above the Carboniferous limestone. The fossils found in this formation were described by Dr. C. A. White and assigned to the Lower Trias. Cephalopods were found at but two places—locality No. 1, in southeastern Idaho, 65 miles north of Utah, 18 miles west of Wyoming, and 5 miles west of John Grays Lake; locality No. 2, 15 miles east of south from locality No. 1.

The section at locality No. 1, according to Dr. C. A. White, is as follows:

	Feet.
A. (Uppermost beds.) Limestones and shales, with <i>Terebratula semisimplex</i> White, <i>T. angustata</i> Hall, <i>Aviculopecten idahoensis</i> Meek.....	} 1,000
B. Limestones, with <i>Eumicrotis curta</i> , and <i>Aviculopecten idahoensis</i> Meek.....	
C. Greenish and reddish shales and sandstones, with <i>Aviculopecten pealei</i> White.....	850
D. Bluish-gray limestones, fossiliferous near the base, with <i>Meekoceras gracilitatis</i> White, <i>M. mushbachanum</i> White, <i>Arcestes? cirratus</i> White.....	700
E. Reddish and greenish sandstones.....	400
F. Dark-blue sandstone.....	
G. Quartzite.....	} 800
H. Massive gray limestone.....	400

At locality No. 2 were found *Meekoceras gracilitatis* White and *M. aplanatum* White, in limestone similar to that marked D in locality No. 1, and this part of the section unquestionably belongs to the Lower Trias, although it is not likely that the entire thickness of beds there is referable to this division. In a later paper Dr. C. A. White expressed the opinion that the Meekoceras fauna of Idaho ought possibly to be placed in the Permian rather than in the Trias, because of the conformity with the Carboniferous beds below, and because of the presence in the fauna of certain Carboniferous elements. These were precisely the arguments used 10 years later by F. Noetling for placing the Lower Triassic faunas of India in the Permian, but there is just as little ground for this in the one region as in the other. This question has been fully discussed by the writer in a recent paper.

In 1888 Prof. Alpheus Hyatt discovered a third locality for Lower Triassic ammonites in southeastern Idaho, in the Aspen Mountains, in Wood Canyon, about 9 miles east of Soda Springs. In 1900 and 1903 the writer visited this same locality, which lies only a few miles southwest of locality No. 2 of White. The joint collections of Prof. Hyatt and the writer yielded the following ammonites:^a *Danubites whiteanus* Waagen, *Danubites* sp. nov., *Meekoceras gracilitatis* White, *Meekoceras*, three new species (of which one may be identical with *M. boreale* Diener), *M. (Koninckites) mushbachanum* White, *M. (Gyronites) aplanatum* White, and two other species of the same subgenus, *Aspidites* sp. nov., *Flemingites* sp. nov., *Ophiceras* sp. nov., *Hedenstrœmia* sp. nov., *Clypites* sp. nov., *Ussuria* two new species, and *Nannites* sp. nov. Besides those here listed there were found several new genera of the same families.

This fauna is intimately related to the Lower Triassic faunas of India and eastern Siberia, with several species that may even be identical with those from Asia. It contains several genera hitherto known only from the Lower Trias of India, and others previously found only in the Proptychites beds of Ussuri Bay in Siberia; it is therefore referred with certainty to the Brahmanic stage of the Scythian series. It may be correlated with the Ceratite marls and the lower part of the Ceratite sandstone of the Salt Range of India.

The following notes are contributed to this manuscript by C. L. Breger:

The "Meekoceras beds" are in southeastern Idaho nearly 3,000 feet thick and include Lower Triassic and apparently also Middle Triassic, while at the top, underlying the red beds, is a zone which appears to be of Upper Triassic age, containing *Myophoria* cf. *lineata* Mstr. and

^aThe new genera and some of the species of this fauna have been described in Prof. Paper U. S. Geol. Survey No. 40, by Hyatt & Smith.—B. W.

Spiriferina cf. lippoldi Bittner. If this identification is correct, the overlying red beds (corresponding to the Nugget formation of Veatch and the Teton formation of the Yellowstone Park), which have by some writers been classified as Triassic, would perhaps find a more suitable resting place in the lower Middle Jurassic.

The Pentacrinus shaly limestones of Peale, of the Hayden Survey, correspond to the Twin Creek formation of Veatch and the Ellis formation of the Yellowstone Park-Montana district. They are commonly regarded as of Upper Jurassic age. In southeastern Idaho their thickness is much greater than that given by Peale, reaching 3,000 feet or more.

K 12-13. WYOMING AND ADJACENT AREAS.

Triassic strata are not generally distinguished in this region, but they are assumed to be represented in the upper part of the red beds, the lower portion being assigned to the Permian. (See pp. 490-492, Chapter XI.) An exception to the general uncertainty is found in the beds near Lander to which Williston applied the name Popo Agie, and in the highest strata of Red Mountain near Laramie, from both of which Williston has described Triassic vertebrates.

Of the Park City district, Utah, Boutwell^{93b} states:

Within this district no sediments have been found which carry Triassic fossils. To the north and northwest, however, the Park City formations pass upward through several hundred feet of red shale into brown, red, pink, and white sandstones. These are frequently massive and heavily bedded, in striking occurrences are coarsely cross-bedded, and toward the top are quartzitic. Disregarding possible faulting, they aggregate about 1,550 feet thickness. The age of these sandstones has always been regarded as Triassic, as they overlie Permian and underlie Jurassic.

In western Wyoming Veatch^{839b} distinguished as Triassic (?) the Nugget formation, consisting of red shales below (since correlated by Gale³⁵⁶ with the Ankareh shale) and lighter-colored sandstones above (to which the name Nugget is now restricted).

Throughout the Bighorn Basin and Mountains the red beds are known as the Chugwater formation. Both Darton^{239c} and Fisher³³¹ place the formation doubtfully in the Triassic but cite fossils from the lower portion which suggest Permian. (See p. 495, Chapter XI.) Darton^{244c} says:

Fossils found at various horizons in limestones in the Chugwater red beds do not afford conclusive evidence as to age. Those in the lower limestones in the Bighorn Mountains and other uplifts are believed to be "Permian" in the sense in which the term is used in the Mississippi Valley. Many fossils occur in the limestone 150 feet below the top of the formation, on the east bank of Bighorn River, 3 miles below Thermopolis. According to Dr. G. H. Girty, the principal species is *Natica lelia*, usually considered diagnostic of the Triassic, but probably it is older. *Bakewellia* and probably *Pleurophorus* may also be present, and an *Aviculipecten* occurs resembling *A. curticardinalis*, which is characteristic of the Permo-Carboniferous of Utah. Dr. Girty is inclined to correlate the fauna with the Permo-Carboniferous of the Wasatch Mountain section. The 150 feet of red shales and sandstones which overlie this limestone may possibly represent part of the Triassic. In the lower portion of the Chugwater formation, 10 miles southwest of Casper, a cast of *Schizodus wheeleri* was found. This form is usually regarded as Pennsylvanian.

The Chugwater formation also occurs in the Laramie Basin, where Darton has recognized it and included in it 200 feet of light-colored sandstone not typical and not observed to the northeast. The top of the formation nearly everywhere in this region is the base of the fresh-water Morrison formation,²⁴⁷ the intervening Sundance formation (Jurassic) generally being absent.

Darton ^{244b} has traced the Chugwater throughout central Wyoming and, describing it under the heading "Permian-Triassic," gives its general relations as follows:

The Chugwater formation ranges in thickness from 900 to 1,200 feet and consists of sandy shales or soft, massive sandstones, nearly all of bright-red color. Gypsum deposits occur in most places. There are extensive exposures along the lower northeastern slope of the Wind River Mountains in the Owl Creek, Bridger, and Rattlesnake uplifts, in the flexures south of Casper and Douglas, above Alcova, in the Shirley and Freezeout hills, in the anticlines north and east of Medicine Bow, and along the east side and across the south end of Laramie Basin. It appears also at intervals along the east slope of Laramie Mountains. In the greater part of the south-central Wyoming region the Chugwater formation lies on Tensleep sandstone, but in the southern end of the Laramie Basin it lies on red beds of the Casper formation, from which in places it is not easily separated.

Detailed descriptions of the formation for all the ranges mentioned are given in the paper cited.

In the red beds thus placed by Darton in the Chugwater formation, in the ranges between Rawlins and Lander, Wyo., Williston ^{941a} has traced a series of beds near the top of the formation carrying Triassic vertebrates. He says:

The University of Chicago paleontological expedition to Wyoming the past summer was fortunate in securing a valuable collection of stegocephalian and reptilian remains from the Trias, a part of which is described in the present paper.

The beds whence the fossils were obtained, from 40 to 80 feet in thickness, are about 200 feet below the top of the red beds and about 600 feet above their base. Their description will be given in a later paper by Mr. N. H. Brown, their discoverer, and the writer. Meanwhile the horizon may be distinguished by the name Popo Agie beds, as suggested by Mr. Brown, from the Popo Agie River, along whose branches they are most characteristically shown.

The forms described comprise *Dolichobrachium gracile*, *Eubrachiosaurus browni*, *Brachybrachium brevipes*, and *Paleorhinus bransoni*.

Williston ^{942a} also found Triassic vertebrates in the red beds (Chugwater) of Red Mountain south of Laramie. He says:

We found there numerous fragments of bones scattered along a thin stratum near the top of the red beds. The marine Jurassic is here wanting, as at Canon City, the sandstone of the Morrison or Atlantosaurus beds overlying the red beds without marked unconformity. The lower members of these beds consist of a grayish or yellowish sandstone and are unfossiliferous, the first vertebrate fossils occurring 75 feet or more above the red beds horizon. [This stratum yielded] very characteristic labyrinthodont plates and vertebræ, proving conclusively the Triassic age of the deposits.

The differences of these fossils from those obtained in the Lander region [Popo Agie beds of Williston] from a horizon fully 250 feet below the top of the beds, are such that their contemporaneity of deposition is very improbable. * * * I am much inclined to believe that the Popo Agie beds, which may be contemporaneous with those yielding vertebrate fossils in Utah, Arizona, New Mexico, and Texas, are of early Keuper age, while the Connecticut Valley, the Red Mountain, and Hallopus beds of southern Colorado are later in time.

Darton in a later note ²⁴² states that the red beds of Red Mountain grade into upper Carboniferous sandstones and limestones, which along the Rocky Mountain front become the Lower Wyoming division of Eldridge and the Fountain formation of Gilbert and Cross. Darton cites Knight's discovery of upper Carboniferous fossils in the red beds of the Laramie Basin and concludes that the evidence is contradictory.

Knight's article ⁵⁰⁶ contains a very detailed section, measured "in the vicinity of Red Mountain," from the pre-Cambrian granite on which the red beds rest. The section shows the typical variations of sandstone and conglomerate, prevailing red or reddish. At 728 feet from the base occurs a fossiliferous layer of "grayish to reddish sandstone containing the following genera of fossils: *Allorisma*, *Pleurophorus*, *Bellerophon*, *Myalina*, *Aviculopecten*, *Dentalium* (?), *Pleurotomaria* (?), several small gastropods, and some remains of vertebrates." Knight says:

The genera [in the fossiliferous layer in his section] are so characteristic that it is not necessary to discuss their geological position; they belong to the Paleozoic and resemble to a marked degree the fossils of the Kansas and Nebraska Permian. This places all the strata below the fossiliferous band in the Paleozoic. There remains a formation of about 800 feet in thickness [total 850 feet as measured, comprising red sandstone, shales, and gypsum beds], with the gypsum beds at its base, in a questionable position, and some may wish to retain these beds in the Triassic.

On the evidence of the fauna found by Knight 850 feet below the top, and the vertebrate remains collected by Williston near the top, we must conclude that the passage from Permian to Upper Triassic occurs in the upper half of the red beds.

K 18. CONNECTICUT AND MASSACHUSETTS.

The Triassic of the Connecticut Valley belongs to the Newark group. (See pp. 522-527.) Davis ²⁴⁸ discussed the conditions of deposition. Emerson ^{319a} classified the strata and described them in detail, particularly with reference to their occurrence in Massachusetts. He says:

The Triassic rocks have been divided by the author in an earlier publication as follows:

1. The Sugar Loaf arkose, or the sandstone and conglomerate made up of the débris of granite.

2. The Mount Toby conglomerate, or the coarse conglomerate made up of large schist and quartzite pebbles.

These two numbers are, speaking generally, the west and east shore deposits.

3. The Longmeadow brownstone, or the red sandstone generally marked by so-called fucoidal forms, which are probably concretions.

4. The Chicopee shale, or the calcareous red shale.

These two are the offshore and central beds of the series.

5. The Granby tuff, or the diabase tuff.

6. The Holyoke and Deerfield diabase beds.

7. The Black rock volcanic necks and the posterior diabase beds.

The last three distinctions cover the fragmental, interbedded, and intrusive occurrences of the diabase, respectively; except that the posterior sheet is placed with the injected necks, with one of which it is directly connected.

Russell ⁶⁸³ considered these particular strata in comparison with those of New Jersey and other localities where the Newark occurs.

In the Pomperaug Valley in western Connecticut is a small outlier of the Newark group which has been described in detail by Hobbs, ⁴⁵⁶ who distinguishes the following formations in descending order:

Posterior shales.

Main basalt sheet.

Anterior shales.

Anterior basalt sheet.

South Britain conglomerate.

K-L 13. BLACK HILLS, SOUTH DAKOTA.

The Spearfish formation, the uppermost division of the red beds in the Black Hills, was described by Darton^{232c} as probably Triassic. He states:

The formation consists of from 350 to 500 feet of red sandy clays, with intercalated beds of gypsum which sometimes are 30 feet thick. * * * It is thought to be Triassic in age because it lies unconformably beneath marine Jurassic deposits and is underlain by the Minnekahta limestone, which is known to be of Permian age.

The tendency is now to correlate the Spearfish formation with the upper part of the Chugwater formation, which is also regarded as Triassic, the lower part of the Chugwater probably belonging to the Permian.

L 11. NORTHEASTERN OREGON AND WESTERN IDAHO.

Lindgren^{540a} discusses briefly the occurrence of the Triassic in western North America and describes the Triassic strata in eastern Oregon and adjacent Idaho as follows:

With widespread Triassic areas in California, Idaho, and Nevada, and with similar areas north of the international boundary line, it seemed strange that no rocks of the same age were found in Oregon or in Washington. This gap has been partly bridged by the discovery of very extensive Triassic beds in the Eagle Creek Range, extending from there across Snake River into Idaho, to the vicinity of the Seven Devils. If the sedimentary rocks in the vicinity of Huntington belong to the same age, as is possible though by no means certain, the area of the Triassic would be still further extended.

A characteristic feature of the Triassic of the Eagle Creek Range is the occurrence of large masses of limestone and some shale, with an abundance of more or less altered lavas poured out during the time when these beds were being deposited.

The Triassic sediments are best exposed on Eagle Creek. All along the foothills of the lower Powder River the Triassic lavas contain smaller bodies of limestone and shale, but on Eagle Creek below the forks, the sedimentary series prevails and consists of calcareous shales and limestone in horizontal or slightly inclined position. Volcanic breccias are interbedded with the limestone. The total thickness of the series, including the volcanic beds, is probably several thousand feet. Many of the exposed limestone masses are several hundred feet in thickness. Above the junction * * * the limestones become converted into marbles and the volcanic breccias into schists, while the whole series acquires a dip of 60° E.

Dr. T. W. Stanton examined fossils collected one-third mile below the mouth of East Eagle Creek and reports them to consist of numerous specimens of *Halobia* and two indeterminate fragments of an ammonite. The *Halobia* is apparently an undescribed species, but the genus itself is characteristic of the Trias. Another lot, collected from the limestone bluff on East Eagle Creek 2½ miles above its mouth, contains *Pentacrinus* columns with spines and fragments of tests of echinoids. From the Miles placers, 1½ miles below the mouth of East Eagle Creek, I obtained through Mr. F. R. Mellis, of Baker City, a cast of a gigantic gastropod found in the limestone bedrock during drifting operations on this claim. Dr. Stanton remarks that it has the form of a very large *Turritella* or *Pseudomelania*. Nothing of this character approaching it in size has been described from the west coast, but similar forms described as *Chemnitzia* and *Pseudomelania* are known from the Trias and Jura of Europe. The total length of this cast is 8 inches and its diameter at the thickest end 3 inches.

Along Snake River canyon, below the mouth of Pine Creek, Triassic lavas and tuffs are again exposed in the bluff below the Neocene basalt flows which cap the hills. These Triassic igneous rocks contain thin beds of black shales and limestone with imprints of a large species of *Daonella* or *Halobia*. A limestone mass 4 miles below Ballard Ferry contained a *Lima* with

fragmentary imprints of a *Halobia* (?), and is also probably Triassic. The last two fossils were obtained from Mr. E. Antz, of Ballard Ferry.

From these data and from what is known of the field relations of the strata it is safe to conclude that a Triassic series is developed on a large scale in this region; but from the paleontological evidence at hand it would not be possible to say which one of the numerous subdivisions of the series is present.

J. P. Smith states^a that he visited the Triassic beds of the Blue Mountains in 1908 and determined them as certainly of Upper Triassic age (Karnic and lower Noric of Europe).

L 12. YELLOWSTONE NATIONAL PARK.

The occurrence of Triassic strata in the Yellowstone Park region is doubtful. Between the Ellis formation (which is now known to contain a Middle and Upper Jurassic fauna) and the Quadrant quartzite (Carboniferous) occurs the Teton formation, which is thought to be at least in part of Triassic age. The section exposed on Cinnabar Mountain in Yellowstone Park is, according to Iddings and Weed.^{393a}

Section of the Mesozoic sedimentary rocks exposed in Cinnabar Mountain and Electric Peak.

Cretaceous.	Dakota.	Dakota conglomerate and sandstone.....	Feet. 175
		<hr/>	
Juratrias.	Ellis.	Reddish shales and impure limestones.....	85
		Limestones and calcareous sandstones, occasionally a conglomerate; carries an abundance of fossil remains, which are generally fragmentary near the base.....	75
		Red argillaceous shale.....	8
		Gray calcareous shales and impure limestones, characterized by an abundance of fossil remains, particularly in the upper strata. The beds are separated near the center by oolitic limestones..	132
		Green and red shales.....	50
	Teton.	Sandstone, saccharoidal in texture, generally light gray or buff in color, but red or brown on weathered surface.....	50
		Red beds, consisting of very fissile sandstones and impure arenaceous clays.....	75
		Limestone, compact in texture, gray in color, and carrying remains of <i>lingulas</i>	20
		Limestones, dark gray in color, generally fetid, often arenaceous and frequently characterized by rod-like masses of chert, which are seen to consist of grains of sand embedded in the siliceous matrix, the concretions having a white chalky surface.....	125
		Quadrant quartzites. [These are not a part of the Teton formation and in this table were bracketed with it through a typographic error.]	

In the Yellowstone National Park folio³⁹² the Teton formation is said to be the "probable equivalent of the well-known red beds of Wyoming and Colorado" and is described as follows:

The formation consists of the basal sandstone, usually dull brown in color and more or less calcareous, characterized by rods and rolls of white chert, and carrying interbedded gray limestones containing linguloid shells. Above this basal bed are gray and greenish calcareous shales, often micaceous and capped by a red arenaceous shale that forms a conspicuous part of the formation. This series of beds is capped by a sandstone, generally bright yellow, with red weathered surface, this rock delimiting the overlying Ellis formation.

Lithologic resemblances and similar stratigraphic relations suggest correlation of the Teton with the Nugget and other formations of southwestern Wyoming. (See p. 530.)

^a Personal communication.

Concerning the scanty paleontologic evidence of the age of the Teton formation Stanton^{393f} says:

The Teton formation, of supposed Triassic age, yielded a few specimens of a *Lingula* at a locality on the summit of Quadrant Peak. This fossil resembles *Lingula brevirostris* M. and H., from the Jurassic of the Black Hills, but in the absence of other fossils it should be given little weight in determining the age of the beds. Linguloid shells are so slightly differentiated that it would not be safe to distinguish, by them alone, even between Paleozoic and Mesozoic. The determination of the age of this formation must, for the present at least, rest on the evidence of stratigraphy and lithology. The paleontologist can only say that the underlying beds yield Carboniferous fossils, while the overlying formation has a well-developed Jurassic fauna.

L 20. NOVA SCOTIA.

The Triassic of Nova Scotia comprises the rocks which have long been known by the descriptive term "New Red sandstone" and which belong to what is now called the Newark group. According to Dawson,²⁶³ the terrane consists "principally of coarse and soft red sandstones with a calcareous cement. * * * In the lower part of the formation there are conglomerates made up of well-worn pebbles of the harder and older rocks." The Triassic strata lie with gentle dip, in marked unconformity to the subjacent steeply dipping Carboniferous rocks. They are associated with sheets of trap rock, in part massive, in part amygdaloidal or tuffaceous. Describing the characteristic relations as they are exposed at Cape Blomidon, Dawson^{263a} says:

The history of this fine precipice is, then, shortly as follows. In the Triassic era, thick beds of sandstone were deposited off the coasts of Horton, just as the red mud and sand of the flats are now deposited. Volcanic phenomena on a great scale, however, broke forth from beneath the waters, scoriæ and dust were thrown out and spread around in thick beds, and currents of lava were poured forth. Subsequently the whole mass was elevated, to be again submerged under the boulder-bearing sea, by which and the present atmospheric and aqueous agencies it was worn and wasted into its present form.

Dawson's account of the general relations of the Triassic of the Bay of Fundy^{263b} is as follows:

The red sandstones now described appear to have been deposited in an arm of the sea, somewhat resembling in its general form the southern part of the present Bay of Fundy but rather longer and wider. This ancient bay was bounded by disturbed Carboniferous and Silurian strata, and the detritus which it received was probably chiefly derived from the softer strata of the Carboniferous system. The arenaceous nature of the New Red sandstone, as compared with the character of these older deposits, indicates that the ancient bay must have been traversed by currents, probably tidal like those of the modern bay, which washed away the argillaceous matter so as to prevent the accumulation of muddy sediment. When we consider the large amount of land in the vicinity of the waters in which the New Red sandstone was deposited, the deficiency of organic remains in its beds is somewhat surprising, though this is perhaps to be attributed rather to the materials of the deposit and its mode of accumulation than to any deficiency of vegetable or animal life at the period in question.

The volcanic action which manifested itself in the bed and on the margin of the bay of the New Red sandstone is one of the most remarkable features of the period. It has brought to the surface great quantities of melted rock, without disturbing or altering the soft arenaceous beds through which it has been poured and whose surface it has overflowed.

Reports later than Dawson's give much local detail regarding the Triassic as it occurs in the counties of Nova Scotia adjoining the Bay of Fundy. Fletcher^{335f} describes the distribution and states:

The relations of the sedimentary rocks of this formation, with their associated traps, to the older formations have also been described in great detail by Jackson and Alger, Gesner,^a Sir J. W. Dawson,^b and others. The contact with the older rocks is always clear and unmistakable, so that there is no ambiguity with regard to the limits of the formation. Sometimes, particularly on the north side of the basin, this junction is a fault; sometimes coarse beds lie at a low angle upon and fill inequalities in the underlying rocks of which they are composed. Many of the sandstones are very calcareous. The total thickness of the formation is doubtful.

In Clifford Brook, east of Valley station, the lowest Triassic rock is a pea and nut conglomerate lying horizontally on the red slates of Union. On the road to the Telegraph road east of the manganese mines, and also in the neighborhood of the mines, many pieces of Triassic sandstone are in the soil and perhaps point to outliers among the Devonian.

From the railway station at Valley across the bridge and out the road to the Telegraph road the strata are Triassic, and to the eastward along the Telegraph road and for some distance up the river these rocks are also exposed. In Half Moon Hill Brook the contact with the Devonian is well seen, the Triassic being bright-red, crumbly, coarse sandstones, scarcely more coherent than the sand of a sand pit, with layers of grit, less bright than the other beds, containing pebbles an inch in length derived from the red argillites. Lower down is a gray, crumbly, flaggy pebbly sandstone, dipping at a low angle, with thin beds and blotches of light green.

In the branch of Farnham's Millbrook which flows from Penny's Mountain are dark brick-red, soft, marly, very fine sandstones, containing patches of gray calcareous sandstone and of coarse conglomerate, with a vertical dip which appears to indicate a fault. In another little brook farther west, brick-red sandstone and nut and egg conglomerate form ledges which dip at a very high angle.

M 9-10. VANCOUVER ISLAND.

In 1885 Dawson made a reconnaissance of the northern portion of Vancouver Island and determined the presence of Triassic limestone and argillite in an immense series of volcanic rocks, all of which are penetrated by granite intrusions. In 1902 the west coast was reconnoitered by Webster³⁶⁸ and Haycock,⁴¹⁵ who identified the same series of rocks but added nothing to Dawson's original description,^{256a} from which the following extracts are made:

By far the greater part of the area of the northern portion of Vancouver Island is occupied by rocks of volcanic origin, which at first sight and as judged by eastern American analogies might often be supposed to represent formations occupying a very low stage in the geological scale. These volcanic rocks, originally composed of minerals already crystalline, have since been subjected to metamorphism more or less intense, to which, in consequence of their composition, they have easily yielded, and now form, for the most part, rocks which might be spoken of as "traps and greenstones." These frequently show locally little or no evidence of their bedded character. Such rocks, however, when closely examined and followed from point to point, are found to form portions of a stratified series of great thickness, which includes, besides the preponderant volcanic materials, certain argillites and limestones, holding Triassic fossils.

The greater part of this old volcanic series appears to have been built up of basaltic and trachytic lava flows, alternating with rough volcanic breccias and tuffs largely composed of fragments derived from such flows. These rocks are now represented by hard amygdaloids and agglomerates of general dark-greenish colors, though often grayish and sometimes reddish or purplish; by felsites, more or less porphyritic; and by hard, regularly stratified ash beds, which, where the alteration has been most pronounced, are locally changed to hornblendic or micaceous schists.

* * * * *

^a Geology and mineralogy of Nova Scotia, p. 239.

^b Acadian geology, p. 99; Geol. Jour. London, vol. 4, p. 50, with a map.

In association with these volcanic rocks limestones, argillites, and quartzites occur, possibly at several different horizons, but one of these, which is of considerable thickness and great persistency and possesses very distinctive characters, has now been recognized at a number of places, from the northern part of the Strait of Georgia round the north end of the island and in Quatsino Sound. This intercalated zone is of considerable thickness, having been estimated at 2,500 feet at one place on the north coast of the island, where it appeared to be fully displayed. Massive limestones, which, when the strata are considerably altered, pass into marble, form its lower portion. The upper part of the limestone becomes interbedded with argillites in regular flaggy layers, and black flaggy argillites interbedded with quartzites overlie these. Where the top of this argillite series is seen it often holds tufaceous and fine agglomeratic beds, and is followed in ascending order by a great thickness of the altered volcanic rocks. In other localities, the limestone is found to become interbedded with volcanic materials beneath, and though no complete section of the entire series can be offered, it is quite clear, from observations made in a great number of places, that these sedimentary materials form an intercalation in the great volcanic series.

The importance of this fact is apparent when it is stated that the only means of fixing the age of the entire series is afforded by the fossils obtained from the limestone and argillite intercalation. These occur chiefly in the argillites and in passage beds between these and the more massive limestones, and are referable to the so-called Alpine Trias. No fossils except these of this age have yet been found in association with this sub-Cretaceous series in the northern part of Vancouver Island, while the Triassic forms have been recognized in numerous localities. The evidence on which these rocks are, therefore, colored as Triassic on the map, is identical with that on which the reference of the precisely similar series of the Queen Charlotte Islands is based. It is quite possible, in both cases, that the lower portion of the series may include rocks of greater age than Triassic, and the association of Triassic and Carboniferous volcanic rocks in the southern part of the interior of British Columbia lends a degree of probability to the conjecture that rocks of the Carboniferous period may form a portion of those here described. There is, however, no direct evidence of this, either in the northern part of Vancouver Island or in the Queen Charlotte Islands.

The rocks beneath those of the Cretaceous age in the southern portion of Vancouver Island are likewise, in great part, altered volcanic materials, which are interbedded with limestones and in some places with argillites. The conjecture that beds of Carboniferous age may occur together with those referable to the Trias, in the Queen Charlotte Islands and the northern part of Vancouver Island, is strengthened by the fact that the late Mr. J. Richardson obtained a few poorly preserved fossils from limestones interbedded with the altered volcanic rocks of the Ballinac Islands, between Nanaimo and Comox, and at Mount Mark, in the center of Vancouver Island, between Qualicum and Alberni, which were supposed by Mr. Billings to be either Carboniferous or Permian, and probably the former.

Though an unconformity has been proved to exist in at least one place between the Triassic and Carboniferous volcanic rocks of the southern interior of the province, no such break has yet been found in any part of the sub-Cretaceous series of Vancouver Island, and if rocks of both these periods actually occur there, they can not be at present separated.

The series as a whole indicates throughout a continuance or recurrence of volcanic phenomena on an enormous scale, and must be at least several thousand feet in thickness.

As a convenient name for the whole I shall employ the term "Vancouver series," including for the present under this name not only the entire mass of volcanic materials which unconformably underlie the Cretaceous but also the interbedded limestones and flaggy argillites and quartzites. This name may also be understood to include the similar beds of the Queen Charlotte Islands, as well as those of the southern part of Vancouver Island, to which it was originally applied by Dr. Selwyn in 1871. If this great mass of rocks should eventually prove separable into Triassic and Carboniferous portions, I would suggest the retention of the name Vancouver series for the former.

The beds of the Vancouver series are the oldest known to occur in the district here described and in the Queen Charlotte Islands and are frequently found in contact with or resting on

granitic rocks. They have not, however, been deposited upon a granitic floor, as the granites are evidently later in date than the rocks of the Vancouver series, and nothing whatever is known of the character of the surface upon which its volcanic and other associated beds were originally formed.

The fossils obtained from the Vancouver Triassic are described by Whit-eaves.^{913,914}

M 10. KAMLOOPS DISTRICT, SOUTHERN BRITISH COLUMBIA.

The Nicola formation, which consists largely of volcanic rocks with associated fossiliferous marine sediments, was originally assigned by Dawson in 1878 to the Triassic on somewhat meager evidence. In 1894 Dawson^{261a} reviewed all the evidence which had then accumulated and concluded:

It will be observed that the original reference of the series as a whole to the Triassic has been gradually strengthened by later discoveries. These, taken in connection with the stratigraphy, in fact seem to show that while the great bulk of the Nicola formation is undoubtedly equivalent to the Triassic, it passes up in a few places into rocks of Lower Jurassic date. The structure and lithology do not appear to afford any means of separating the two faunas or of drawing any line through the great mass of rocks, chiefly of volcanic origin, in which they occur, and it is therefore appropriate and necessary to treat of the Nicola formation as a whole, although recognizing the fact that it probably extends higher than the typical Trias.

An unconformity is indicated between the lowest strata of the Nicola and the underlying Paleozoic rocks. Regarding the composition of the Nicola formation Dawson says:

Within the area of the Kamloops sheet the Nicola formation consists essentially of a great mass of volcanic deposits, with a total thickness of probably 10,000 to 15,000 feet. In the lower part of the formation some thin and probably irregular beds of limestone occur. Here and there throughout the formation a limited thickness of argillites is found, and, forming the summit, so far as yet ascertained, is another bed of limestone.

The greater part of the volcanic rocks may be described generally under the useful name of "greenstones." Lithologically, these rocks are for the most part found to be altered diabases, with, exceptionally, augite porphyrites, also considerably altered. In regard to their state of aggregation, these volcanic materials represent all the usual products of eruptions, including effusive rocks, sometimes amygdaloidal, and tuffs. There is also, throughout the entire series, more or less evidence of subaqueous deposition and bedding, while no proof has so far been obtained in this district of the existence of subaerial accumulations.

The following summarized general sections, based on more detailed descriptions given in the sequel, best represent what is known of the Nicola formation, in the eastern and western parts of its area respectively. The sections are in descending order.

Thompson River, south of the Ashcroft Cretaceous area.		Vicinity of Nicola Lake.	
	Feet.		Feet.
Limestone (20 feet or more).....	20	Fine-grained feldspathic rocks, generally well bedded.....	1, 200
Fine-grained feldspathic rocks, sometimes well bedded, generally gray.....	1, 800	Diabases, chiefly effusive and sometimes amygdaloidal; some tuffs; two thin beds of limestone near the base.....	3, 700
Tuffs, or ash rocks, passing into agglomerates, with some fine-grained felsites, gray, purplish and green; a few small limestone beds near the base.....	7, 840	Chiefly green diabase agglomerates, occasionally amygdaloidal. Thickness at least 2,600 feet and possibly 6,000 feet (say).....	2, 600
Chiefly green diabase agglomerates, often coarse. Several calcareous beds and limestones. Dark felsites at base.....	3, 930	Approximate total (minimum).....	7, 500
Approximate total.....	13, 590		

In explanation of the above sections, it may be added that although placed in parallel columns, the equivalency of the several groups of beds is intended merely to be suggested in the most general way. If the maximum thickness be assigned to the lower group in the Nicola section, there would be a nearer approximation to correspondence in total thickness, but the rendering of this part of the section is doubtful. Further it must be noted as possible that the amphibolites and argillites of the Douglas Lake vicinity, with a thickness of about 7,000 feet, may eventually have to be added to the Nicola formation in that region. * * *

In the year following that in which the Triassic age of these rocks was recognized in the inland region of British Columbia and the name Nicola series proposed for them, Triassic rocks of essentially the same character were discovered in the coast region, in the Queen Charlotte Islands. At a still later date, the formation last referred to was found to be continued to the southeastward, in the line of the same mountain axis, and to form the greater part of the older rocks of the northern portion of Vancouver Island. Like the Nicola formation, the Vancouver formation, as it was then called, is chiefly composed of old volcanic products. * * * [See pp. 536-538.] With these volcanic products limestones and argillites holding characteristic Triassic fossils are interbedded.

In the Vancouver formation, or series, the limestones and argillites are somewhat more important than in the Nicola formation, but otherwise the resemblance between the two, both in regard to their original mode of production and their present appearance, practically amounts to identity. Notwithstanding this fact, it is believed to be appropriate to retain distinctive local names for the two great developments of Triassic rocks in British Columbia. In both cases the lower and upper limits of the formation remain more or less indefinite, chiefly because of the absence throughout the great masses of the strata of any organic remains, and thus one may extend in its lower or upper beds through a part of the geological time scale considerably greater than the other. It is moreover found to be a general rule in this part of the Cordillera that exact equivalency of formations is scarcely to be sought for at any considerable distance across the prevalent northwest and southeast trend of the main orographic features, and in this case the nearest recognized representatives of the two formations are separated by a gap of about 150 miles transverse to this direction.

In an immediately succeeding paragraph Dawson refers to the occurrence of "Triassic" red beds in latitude $49^{\circ} 30'$ in the Rocky Mountains. The rocks are described in an earlier report,²⁵⁵ and were later placed by Willis⁹⁴⁰ in his Kintla formation, which belongs to the Belt series (pre-Cambrian).

N 8-9. QUEEN CHARLOTTE ISLANDS.

On Dawson's map of 1878 the southern portion of the Queen Charlotte Islands is represented as consisting of Triassic rocks. The report states:^{252a}

In a preceding report on British Columbia it has been found necessary to include for the present the Paleozoic and Triassic rocks under a single heading.^a They lie together unconformably beneath well-characterized Cretaceous beds but are so much involved that no attempt has been made to separate them except locally. In the southern part of the interior of British Columbia both Carboniferous and Triassic fossils have been found among these older rocks, but no forms of greater antiquity. In the Queen Charlotte Islands, now reported on, fossils have been discovered in the rocks unconformably underlying the Cretaceous in a number of places. These serve to characterize a certain zone of argillites and limestones, which is frequently repeated in sections along different parts of the coast, as distinctively Triassic, and show it to represent the so-called Alpine Trias which is so largely developed in California and Nevada. No forms distinctively Carboniferous or Paleozoic have yet been discovered, but from the intimate association of Carboniferous and Triassic rocks in the southern part of the province, and more particularly from the occurrence of great masses of rocks largely volcanic

^a Report of Progress, 1877-78.

in origin and believed to be Carboniferous in age, in the southern part of Vancouver, which forms part of the same axis of elevation with the Queen Charlotte Islands, it is highly probable that the rocks of this age may come to the surface in some places. Mr. Whiteaves, who has examined the fossils, does not find any clearly Triassic forms among those from Rose Harbor, the old copper mine in Skincuttle Inlet, and the south end of South Island in Skidegate Inlet. The limestones of these localities may therefore possibly be of Carboniferous age, and if so a large portion of the associated rocks of volcanic origin must be attributed to the same period. As it is at present impossible to unravel the structural complexity of the sub-Cretaceous rocks of the islands, it has been thought best to color them together on the map as Triassic, in correspondence with their characteristic fossils.

Though no report is here made on observations in the northern part of Vancouver Island, it may be mentioned that Triassic forms identical with those from one of the localities on Houston Stewart Channel, have been obtained on Forward Inlet and Browning Creek, Quatsino Sound.

Any unconformity which may have existed between different beds of this sub-Cretaceous mass of rocks may now be masked by their complete folding and the great disturbance and fracture to which they have been subjected. The occurrence of great masses of contemporaneous volcanic material during both the Triassic and Carboniferous periods, in British Columbia, has been demonstrated in former reports; and in the event of the lower and possibly Carboniferous rocks proving to be really Triassic, their general character would accord closely enough with that of those known elsewhere.

* * * * * * * *

Tabular view of formations represented in the Queen Charlotte Islands.

Post-Pliocene.	Sands and gravels. Plastic and boulder clays, gravel beds, etc.
Unconformity, with evidence of some flexure and disturbance of Tertiary beds.	
Tertiary, probably Miocene.	Volcanic rocks of the north part of Graham Island. Sandstones, with marine fossils and lignites of Skunun Point. Shales, clays, and lignites of Ma-min River and Chin-oo-kun-dl Creek.
Complete unconformity, with evidence of great disturbance. Chief period of mountain making.	
Cretaceous.	A. Upper shales and sandstones. B. Coarse conglomerates. C. Lower shales and sandstones. D. Agglomerates. E. Lower sandstones.
Unconformity, but without evidence of great disturbance.	
Triassic, but possibly passing below into Carboniferous.	Agglomerates and ash rocks of Logan Inlet, etc. (These possibly represent subdivision D, supra.) Flaggy calcareous argillites and thin limestones. Massive limestones. Massive dioritic and feldspathic volcanic accumulations, probably including minor limestone beds, occasionally schistose.

TRIASSIC.

The rocks seen in the shores of Houston Stewart Channel are everywhere very much disturbed, shattered by faults, and traversed by innumerable dikes. This region lies in the line of the mountainous axis of the islands, and though no extensive granitic masses appear

here, the intensity of the force brought to bear on this region is well exemplified. About the middle of the southwest reach of the channel, in a bay on the southeast side, are extensive exposures of limestones and flaggy argillites, with general westerly dips. The limestones are generally in thin beds, bluish black on fresh fracture, and frequently fetid when struck. They are cherty and contain blackish rounded or rootlike concretions of silica and blend with the shales or flaggy argillites, which appear to occupy a superior position. The argillites are calcareous throughout, and generally each bed is a few inches thick, though in some cases finely shaly. Fossils were found in abundance in some of the shaly layers and in the limestones. Mr. Whiteaves enumerates the following species from this locality. They are evidently synchronous with the so-called Alpine Trias of Nevada:

1. *Amplexus* (?) sp. nov.
2. *Monotis subcircularis* Gabb.
3. *Halobia lommeli* Wiss.
4. *Sphæra whitneyi* (?) Meek.
5. *Arcestes gabbii* Meek.
- 6 and 7. Fragments of two species of ammonitoid shells, one of which appears to be new. They probably belong to different genera.
8. *Belemnites* sp. nov.

Feldspathic dikes, generally of pale greenish-gray color, traverse the rocks in all directions and stand out like ruined walls when the softer beds have been weathered away from them. These so complicate the section as to render accurate measurement impossible, but there is probably 500 feet or more in thickness of the limestones and argillites.

Detailed descriptions of various occurrences of so-called Triassic rocks, which probably include Paleozoic rocks also, are given on the succeeding pages of Dawson's report. In 1905 Ells³¹⁶ examined the coal fields of the northern (Graham) island, but he did not investigate the pre-Cretaceous rocks except incidentally.

N-O 11. PEACE RIVER PASS, BRITISH COLUMBIA.

On Peace River, in the canyon by which it traverses the eastern ranges of the Rocky Mountains, McConnell^{562a} noted the presence of "dark *Monotis*-bearing calcareous shales and impure limestones of Triassic age." This occurrence is in the range of the Triassic strata on the Liard. (See O 9, pp. 542-543.)

O 5. COOK INLET, ALASKA.

Stanton and Martin^{786a} describe the Triassic of Cook Inlet as follows:

Upper Triassic rocks have been seen on the north shore of Bear Cove and on Bear Bay, both on the west shore of Cook Inlet, and on the Alaska Peninsula at the entrance to Cold Bay and extending several miles eastward. They are also probably present at numerous localities on the south shore of Kachemak Bay, as at Halibut Cove and Seldovia, where there is a great development of thin-bedded and contorted cherts, with some siliceous limestone and igneous rocks. This series is tentatively correlated with the fossiliferous Trias on the west shore of Cook Inlet on account of lithologic and structural resemblances and because of its association with the Lower Jurassic.

The Triassic rocks of Cold Bay, Bear Cove, and Bear Bay, whose age has been definitely determined by fossils, consist of thin-bedded chert, limestone, and shale of varied colors. The chert and limestone are usually dark (black, green, or dark red) when fresh, but weather to lighter shades. No measurement of the thickness has been made, but it is estimated to be at least 2,000 feet in the exposures seen by us, in which the base was always cut off by intruded igneous rocks.

These rocks are always closely folded and are frequently crumpled. They are usually cut by numerous dikes of diverse character and composition, varying from granite to andesite

and basalt. The more acid dikes are apparently characteristic of the Triassic rocks and were intruded soon after the folding which must have closely followed Triassic time, for they do not cut the younger rocks. * * *

The Triassic fauna of the region as now known is almost limited to the single species *Pseudomonotis subcircularis* Gabb, which is very abundant in certain layers of shale and limestone at Bear Cove and Cold Bay. Specimens from the latter locality were described and figured by Fischer as *Monotis salinaria*, which it resembles in its general features, but a comparison of a large series of specimens from Alaska with a similar series of Gabb's California species shows that they are not separable. The species belongs to the group of *Pseudomonotis ochotica*, which is characteristic of the Upper Triassic of Siberia and the boreal regions generally.

In California *Pseudomonotis subcircularis* is confined to the Swearinger slates, which form the uppermost Triassic formation of that region. Similar beds with the same fossil occur in Vancouver and Queen Charlotte islands and on the mainland of British Columbia, and they cover considerable areas in the Copper River region of Alaska.

At Bear Bay the much-folded Triassic limestone yielded imperfect specimens of a Halobia, and at Cold Bay a few imperfect ammonites not generically determined were obtained in beds overlying the *Pseudomonotis* layers, but possibly still within the Triassic.

O 7-8. SOUTHEASTERN ALASKA.

The first determination of Triassic in Alaska was made by Paul Fischer³³⁰ in 1872. Rocks of this age in the Mount St. Elias Range are also described by C. W. Hayes.⁴¹⁶ Referring to the "Vancouver series," Brooks^{101g} says:

It is to be expected that this Triassic series will be found in the adjacent parts of Alaska, but up to the present time it has not been positively identified. It has been shown that certain metamorphic terranes carry Permian fossils, and it is quite possible that the Triassic beds may be infolded with these, as is the case with the Carboniferous of Queen Charlotte Islands. This view is borne out by some obscure fossils (probably Mesozoic) which have recently been found by Prindle near Fort Wrangell. While reconnoitering the southern part of the Alexander Archipelago a succession of conglomerates, black shales, and slates was encountered and called the Gravina series, from the name of the island where they occur. These rocks are closely infolded with the Vallenar series (Devonian), but the two formations are probably separated by an unconformity. So little was learned of the distribution and structural relations of this horizon that the wisdom of giving it a distinct name now seems open to question. The Gravina was correlated with Dawson's Queen Charlotte group (Cretaceous), but on reviewing the evidence its identity with the Vancouver series (Triassic) seems equally probable. In 1904 Wright found a conglomerate and slate series on Admiralty Island which yielded Lower Cretaceous or Jurassic forms.

In the same insular region there are large areas of massive, basic igneous rocks, chiefly of effusive origin, which were grouped together under the name Kasaan greenstone and were provisionally assigned to the Mesozoic. On the Queen Charlotte Islands, to the south, rocks of a similar character occur in both the Triassic and in the Cretaceous, and the Kasaan effusives may belong to either period, but in the report cited were provisionally placed in the Cretaceous and correlated with the rocks of the Queen Charlotte group.

O 9. DEASE AND LIARD RIVERS, BRITISH COLUMBIA.

Certain strata, "consisting of regularly bedded, dark, calcareous, flaggy argillites, alternating with gray flaggy and massive limestones" were observed "at the second great bend" of the Dease in 1887 by Dawson,^{258a} who notes their lithologic resemblance to the "Triassic of the west coast" but, not having found fossils, regards the evidence as "too imperfect for a reference of the beds."

On the Liard McConnell ^{560a} obtained more definite information:

Beds holding Triassic fossils occur along the Liard in the eastern foothills of the Rocky Mountains. They consist of dark shales, usually rather coarsely laminated, and passing into calcareous shales interstratified with sandstones and shaly and massive limestones. The latter are moderately crystalline, are dark in color, and are usually very impure. They are harder than the shales and at Hell Gate narrow the valley into a canyon. The beds undulate, usually in easy folds, along the valley, and are exposed in numerous disconnected sections, but it was found impossible in hurrying through to make even an approximate estimate of their thickness. Triassic fossils were found at the Rapids of the Drowned, at Hell Gate, and at one intermediate point. It is probable, however, that a considerable portion of the barren shales east and west of these points are also of Triassic age. All the fossils collected have been examined by Mr. Whiteaves, and the following list of species, nine of which are described by him in volume 1, part 2, of the "Contributions to Canadian paleontology," is furnished by him:

<i>Spiriferina borealis.</i>		<i>Nautilus liardensis.</i>
<i>Terebratula liardensis.</i>		<i>Popanoceras mcconnelli.</i>
<i>Monotis ovalis.</i>		<i>Trachyceras canadense.</i>
<i>Halobia (Daonella) lommelli</i> Wissman.		<i>Trigonodus? productus.</i>
<i>Halobia occidentalis.</i>		<i>Margarita triassica.</i>

Triassic beds were not detected along the eastern edge of the Liard Cretaceous basin. They are also absent from the valley of the Mackenzie, as the Cretaceous rocks were found there in a number of places resting directly on the Devonian.

P 7. WRANGELL MOUNTAINS, ALASKA.

The Triassic of the Wrangell Mountains and adjacent regions comprises the Chitistone limestone, which was formerly referred to the Carboniferous, and the overlying black shales and limestones, up to the unconformity with the Kennicott formation (Upper Jurassic or Lower Cretaceous). The facts have been discussed in successive Alaskan reports, of which the latest is one by Moffit and Maddren,⁶⁰¹ who quote from earlier investigators and say:

In 1907 fossils were collected from the Chitistone limestone at a number of localities between Kotsina River and Chitistone River, and they definitely determine its age as Triassic. Part of these fossils were found in place, but a majority were collected from the talus débris below cliffs of the limestone, yet there was no place where it seemed possible that the limestone fragments containing the fossils could have come from any other source than the cliffs above them, and no hesitation is felt in accepting their evidence for the age of the Chitistone. The fossils were determined by T. W. Stanton, who describes them as follows:

"Several different localities are represented in the collections, but the fossils, with one exception, are all said to be from the Chitistone limestone and closely associated formations. The collection is small and somewhat fragmentary, but it has proved sufficient to show quite conclusively that the beds in question are of Triassic age. The ammonites, especially, are all characteristic Triassic types, and the few brachiopods obtained are also Mesozoic. There is no indication of Paleozoic fossils in any part of the section represented."

Schrader and Spencer,⁷⁰⁹ who included the Chitistone limestone in the Carboniferous, said:

The Chitistone formation is composed of very massive limestones, without any important intercalations of shale. When weathered, it has a white or gray color, which makes it prominent in contrast with the greenstone upon which it lies, but when broken it is found to have a blue

color, which is indicative of considerable carbonaceous material in its composition. In texture it is fine grained throughout. * * *

Studies of the Carboniferous and Triassic strata of the Wrangell district have not been sufficiently detailed to afford evidence as to where the line between these two formations should be drawn. Above the massive basal series of limestones there is a series of thin-bedded limestones with shaly partings, which is apparently in perfect conformity with the underlying beds and which passes by gradation into the black shales above. These black shales contain the fossils by means of which the Triassic age of the formation has been determined. The provisional and arbitrary line between the two formations has been placed at the top of the massive limestone series. The thickness of the Chitistoné formation, as thus defined, is somewhat variable. Its maximum development is probably in the region of Nizina River, where it reaches a thickness of approximately 2,000 feet. In the Kotsina and Strelna region its thickness is somewhat less, but it can not be made out that there is any progressive thinning toward the west. * * *

The rocks which have been included in the Triassic series comprise all the strata that lie above the Chitistone limestone and below the unconformable Kennicott formation, of Jura-Cretaceous age. In the lower part, and resting conformably upon the Chitistone limestone, is a series of thin-bedded limestones, in strata from a few inches to a foot or more in thickness, supported [separated ?] by thin partings of black shale. The thickness of this member is approximately 1,000 feet, and the limestone, so far as observed, did not contain fossil remains. Above the thin-bedded limestones, and sharply defined from them, are black shales containing occasional bands of impure limestone, locally affording fossils, from which the age of the formation has been determined. The thickness of the upper member of the Triassic is very great, possibly more than 3,000 feet, but no opportunity was offered for its direct measurement, since its occurrence as the surface formation beneath strata lying unconformably upon it, together with the attitude which it has assumed as the result of folding and faulting, renders its relations complicated and obscure. A few thin flows of greenstone, similar to that of the Nikolai series, were observed here and there interbedded with the black shales of the Triassic. The Triassic series may be easily recognized from its general homogeneous nature and the fine-grained character of its black carbonaceous shales.

Locally the thin-bedded limestones are very intricately folded and contorted.

P 8. STEWART RIVER SECTION, YUKON PROVINCE.

Keele ^{47a} assigns to the Triassic certain rocks in the northern Rocky Mountain section, where the map of North America shows undifferentiated metamorphic Paleozoic. He says:

The crystalline limestone, provisionally classed as Upper Paleozoic, rests unconformably on the crystalline schists, while it is apparently overlain by Triassic rocks. No fossils were found and the contact with the Devonian rocks to the north was not seen. A similar rock mass occurs on the Macmillan River which was classed as Carboniferous from evidence of some fossil remains found in that locality.

This occurrence also overlies crystalline schists unconformably and is followed by what are probably Mesozoic rocks.

The rocks grouped as Triassic are almost altogether of sedimentary origin. Thin bedding and diversity in the color and composition of the beds are characteristic features. They have been greatly folded and crumpled in some localities, while in other places they are horizontal. Cleavage planes have been developed and certain of the beds have undergone slight alteration during the processes of mountain building.

The rocks which underlie the eastern extremity of the area marked Triassic on the accompanying map sheet are chiefly made up of sandstones, grits, red slates, limestone, and some volcanics, while toward the western end shaly argillites with thin quartzite and limestone beds prevail. Beds similar to the latter also occur in the section to the west.

The evidence gathered from the study of a few fossils found in the area, while not conclusive, is in favor of referring at least a portion of the series to the Triassic.

A group of rocks similar in many respects to the above occurs along the Macmillan River 40 or 50 miles to the south, but the black chert beds found in that area are absent in the Stewart River series.

R 3. CAPE THOMPSON, NORTHWESTERN ALASKA.

In describing the section of Carboniferous and Triassic strata which lie in a syncline south of Point Hope and Cape Thompson, Kindle^{500a} says:

The higher beds of the Cape Thompson section are brought in contact with the beds already described [Carboniferous] in the midst of a zone of rather local but complicated folding and possibly of faulting, which renders it impossible to give even an approximate estimate of their thickness as seen from the top of the southeastern portion of the Cape Thompson cliffs; but between the second and the fourth deep ravines separating the high ridges just southeast of the cape along the coast the exposures are continuous for 2 miles, exposing a section of northerly dipping beds in which the dip decreases from 35° to 0 near the middle of the synclinal. We find in the series of cliffs which face the sea to the southeast of the second ravine below Cape Thompson a section which passes without structural complications from the fossiliferous Carboniferous limestones to the top of the highest beds exposed in this vicinity. This section is as follows:

Section 2 miles southeast of Cape Thompson.

	Feet.
(e) Soft black shales.....	500+
(d) Dark cherts and thin-bedded cherty limestones with some greenish bands.....	25
(c) Argillites with bands of black, green, and dull red cherts.....	600
(b) Light-gray limestone, weathering buff, with some bands of dark chert; apparently barren of fossils.....	2,000+
(a) Light-gray limestone similar to the above, but with less chert and containing numerous fossils in which corals are conspicuous.....	3,000+

In the upper part of the lowest division of this thick limestone series, *a* of the section, fossils are fairly abundant. * * * Only a few were collected, however. These are given in the following list by Dr. Girty, whose remarks on the general faunal relations of these faunas have already been given.

Lot 15 A.—Zaphrentis sp., *Spirifer* aff. *striatus*, Composita? sp.

The close physical resemblance of the second division (*b*) of the limestone series to the lower leaves little doubt that it is also of Carboniferous age. It may represent the Upper Carboniferous, which has not been recognized anywhere on the northwestern coast of Alaska, though known on the Yukon and in southeastern Alaska.

The lithologic change at the top of this limestone series is abrupt. The beds included in *c* and *d* are essentially similar, and represent the same formation, although there is less of the calcareous element in the lower beds. Fossils were found, however, only in the upper beds marked *d* in the section. They occur in great abundance in certain strata in this portion of the section. About 7 feet near the top are composed almost exclusively of shells which have been largely altered to chert. Dr. T. W. Stanton has furnished the following report on the fossils secured from this horizon:

“Lot 15*d*. Mouth of creek 2 miles southeast of Cape Thompson.

“This collection consists of limestone fragments with numerous specimens of aviculoid shells referable to *Pseudomonotis subcircularis* (Gabb) or to a closely related species. No other recognizable species are associated with it. This species occurs in an Upper Triassic horizon in California, and it has been accepted as sufficient evidence for the Triassic age of rocks containing it at Cold Bay and in the Copper River region of Alaska. In my opinion, the horizon which yielded it at Cape Thompson is also Upper Triassic.

“Among the collections obtained by Mr. Collier in the Cape Lisburne region some years ago there are several small lots consisting mainly of a form that seems to be identical with

Pseudomonotis subcircularis and probably comes from about the same horizon as this Cape Thompson locality. These fossils were at that time identified as *Aviculopecten* and referred to the Carboniferous, chiefly because of the stratigraphic relations they were supposed to hold with well-characterized Carboniferous faunas. If Mr. Kindle's interpretation of the structure is correct the horizon in question at Cape Thompson is above all the Carboniferous faunas and offers no stratigraphic difficulties in its reference to the Triassic."

(See Chapter VIII, pp. 396-399.)

R 27. NORTHEAST COAST OF GREENLAND.

The facts which are known regarding the Jurassic rocks of eastern Greenland have been summarized by Skeat.⁷⁴² According to the observations of the Danish expedition of 1891-92, at Neill's Cliffs there is a succession of strata which comprises the following:

1. At the base a green sandstone, not found north of Cape Stewart.
2. Next a gray sandy clay shale, with many fossil plants. This is seen in the valley, 160 to 180 feet above sea level, and also crops out immediately below on the shore.
3. The next part of the slope is completely obscured by weathered fragments, which conceal the underlying beds.
4. Above is a very impure reddish-colored limestone, very rich in fossils. The limestone varies very considerably in different parts. It may be sandy and unfossiliferous; or full of small pebbles sometimes rolled and sometimes angular, so that the rock is now a conglomerate and now a breccia; lastly, it may be a typical shell breccia, crammed with fossils of Jurassic age. These variations occur near each other and pass over into each other. The bed is 7 feet thick and occurs at a height of 186 feet above sea level.
5. Above this is a sandy shale without fossils.
6. Next comes a sheet of basalt 10 feet thick.
7. This is overlain at the end of the valley by a yellow sandstone, 6 feet thick, with a few carbonized plant remains, which forms the uppermost deposit at Cape Stewart.

Continuing along Hurry's Inlet, Neill's Cliffs get higher and higher, owing partly to the position of the beds, but probably also to the fact that other beds crop out both above and below those already mentioned.

The members of the expedition landed toward the northern end of the inlet, approximately southwest of the Fame Islands. Here the lowest bed exposed was a flaggy sandstone with, once more, the fossiliferous limestone above. The limestone in this exposure is pure toward the middle but conglomeratic or brecciated upward and downward. Not far but yet not immediately above this limestone is the basalt again, which here appears at a height of 1,300 feet, with alternating layers of sandstone and dolerite above. Several beds which are seen here belong to a higher horizon than those of Cape Stewart, and farther inland yet newer deposits occur. The fossils obtained were mainly lamellibranchs and brachiopods; many were new species, but certain typical Middle European forms, namely, *Avicula munsteri* cf. Goldf., *Limea duplicata* Sow., *Ostrea sandalina* cf. Goldf., were interspersed among them, the former in large number. These species are of Middle Jurassic or Callovian age, and the fauna is altogether characteristically Callovian; moreover it has close affinities with the Middle European type. Lundgren, who examined the fossils collected on this occasion, identifies the Cape Stewart beds with the Callovian of Kuhn Island; the lowest shales containing plant remains were proved by Hartz to be of Rhætic or Rhætic-Lias age.

The Swedish expedition of 1899 under Nathorst reports Rhætic plant remains and a yellow sandstone with numerous *Ostreas* and *Belemnites*. The map which is published with Nathorst's work represents horizons of the Keuper, Rhætic, and Jurassic.

The Danish expeditions of 1898 and 1900 reported numerous fossils including many ammonites and others of Jurassic or Cretaceous age. Fossils comprising plant remains of Rhætic or Liassic age, and marine fossils of various divisions of the European Jurassic are cited by Skeat. The principal occurrences of the Jurassic are assigned to the Callovian. A clearly older fauna occurs at Mount Nathorst, which is probably of upper Bajocian or lower Bathonian age.

In Jameson's Land there is evidence of the white Jura or Upper Jurassic, approximately of upper Kimeridge or Portland age. Of the Triassic of this region Nathorst^{609b} writes:

It is supposed that Rhætic layers may possibly be present at Falsche Bay, mentioned above, from which locality Payer brought home a piece of sandstone with *Rhynchonella fissicostata* Suess. * * *

One of the most important geological results of the Danish expedition was the announcement that rocks belonging to the Rhætic and Jurassic system occur on the west side of Hurry Inlet from Cape Stewart northward. They are the same rocks that Jameson referred to the Carboniferous.

At Cape Stewart the lowest layers are Rhætic, consisting of a gray, somewhat sandy clay slate that in certain beds is quite rich in fossil plants. It is supposed to be underlain by a greenish sandstone and is thought to be at least 45 to 55 meters thick. The fossil plants are described by N. Hartz, who has called attention to their Rhætic age. Several of these are to be found in the coal-bearing beds of Skone, Sweden. As characteristic may be mentioned *Cladophlebis roesserti* Presl. sp. var. *grænlandica*, *Equisetum munsteri* Sternb. sp., *Pterophyllum subæquale* Hartz, *Podozamites lanceolatus* Lindl. sp., and *schenkii* Hr., *Czekanowskia rigida* Hr. and *setacea* Hr., *Stachyotaxus septentrionalis* Agardh sp., besides others.

(See also R-S 27, Chapter XIII, pp. 577-578.)

T 11, 13-16. ARCTIC ARCHIPELAGO.

Low⁵⁵⁰¹ summarizes the available information regarding the Mesozoic of the Arctic Archipelago:

The discovery of the Sverdrup group of islands has greatly extended our knowledge of the Mesozoic rocks of the Arctic basin. The Franklin search parties discovered rocks of this age on the northern shores of the Parry Islands; at Point Wilkie, in Prince Patrick Island; Rendezvous Hill, near the northwestern extreme of Bathurst Island; and at Exmouth Island and places in the vicinity, near the northwest part of North Devon. The explorations from the *Fram* now show that these are but the southern edge of a wide basin of rocks which form the islands of King Oscar, Ellef, and Amund Ringes, while they constitute the lowlands of Axel Heiberg and the western shores of Ellesmere along both sides of Eureka Sound. There they consist largely of sandstones with shales, schists and limestones.

For a general discussion of the faunal relations of the Arctic Triassic, especially with reference to that of Siberia and its affinities with North American faunas, see papers by Mojsisovics.^{603, 604}

U 18-21. GRINNELL LAND AND NORTHERN GREENLAND.

The Cape Rawson beds of Grinnell Land have been classed as "Huronian or Lower Cambrian," and lately as probably Triassic, at least in part. Dawson,²⁵⁷ commenting on the original description by Feilden and De Rance,^{326a} says:

After noting the Laurentian system as the fundamental one for the region [Ellesmere Land, Grinnell Land, and the neighboring coast of north Greenland] and as forming Cape Isabella

(latitude $76^{\circ} 20'$) and the entire east coast of Ellesmere Land, they give the name Cape Rawson beds to an important overlying series which occupies the coast of Grinnell Land from Scoresby Bay to Cape Cresswell, in latitude $82^{\circ} 40'$ north. These rocks are described as being thrown into a series of sharp folds, with a general west-southwest strike, the beds being often vertical and frequently cleaved. The rocks consist of jet-black slates, with impure limestones traversed by veins of quartz and chert, and of a vast series of quartzites and grits. They are compared to the gold-bearing series of Nova Scotia, and doubtfully referred to the Huronian system. Their lithologic character, however, as compared with the Canadian rocks, and in view of the occurrence elsewhere to the north of a great Lower Cambrian series, appears to me to favor their inclusion in that series rather than in the Huronian.

Schei^{707a} discovered extensive exposures of "quartz sandstones with subordinate schists and limestones" on both shores of Heureka Sound (between Grinnell or Ellesmere Land and Heiberg Land) which he describes as Mesozoic. They contained ammonites and lamellibranchs, among others possibly *Daonella lammelli*.

CHAPTER XIII.

JURASSIC.

Color, greenish blue (horizontal ruling).

Symbol, 9a.

Distribution: Central America, Mexico, California, Oregon, Alberta, and parts of Alaska.

Content: Jurassic limestone and shale of Nevada; Mariposa slate, Sierra Nevada; Franciscan formation, Coast Range, California; Jurassic of Mexico; Chinitna shale and Tuxedni sandstone ("Enochkin formation"), also Naknek formation, of Alaska Peninsula. The Jurassic of Humboldt Range, Nevada, and the marine Sundance formation of the Rocky Mountains are mapped with the Triassic, as "Triassic and Jurassic" (9), the areas being too small to distinguish the system separately.

D 16. GUATEMALA.

Dollfuss and Mont-Serratt²⁸⁶ cited the identification of Jurassic fossils reported to have been collected on the shores of Lake Isabel in eastern Guatemala and contained in the collections of the Collegio Tridentino, but Sapper does not mention any such occurrence, and the rocks described by Dollfuss and Mont-Serratt under the Jurassic appear to be Cretaceous.

E 14. OAXACA.

At Tlaxiaco, in Oaxaca, according to Felix and Lenk,^{327c} Jurassic strata constitute the greater part of the Cerro Titania. At the base are thin-bedded clay slates

FIGURE 15.—Sketch map showing the distribution of Jurassic rocks that are separately represented on the geologic map of North America and the key to references in the text.

of bright-red and greenish tints which suggest the European Triassic as well as some Jurassic clays. As they are unfossiliferous their age is not determinable. Above them lies a great thickness of calcareous and in part marly deposits, which are without doubt of Jurassic age. They include dense light-gray limestone which appears in general to be unfossiliferous with the exception of the remains of a small *Exogyra* that could not be more exactly determined. Above this lower sequence outcrop certain marly strata which contain numerous thin lenses of brown iron ore and which like the preceding are very poor in fossils. They have yielded an impression of an *Apiocrinus* stem and an ammonite, *Stephanoceras paucicostatus*. This species belongs to a group of the ammonites whose youngest representatives do not range above the Oxfordien, and the marls therefore belong either to that horizon of the white Jura of Europe or are to be assigned to the brown Jura of Europe.

The crest of the Cerro Titania is formed by gray marly limestone which is highly fossiliferous. The character of the contained fauna is that of the white Jura and probably represents the European Sequanien.

E-F 14. PUEBLA AND VERA CRUZ.

According to Felix and Lenk ^{327b} the late Mesozoic is represented in the states of Puebla and Vera Cruz by fossiliferous strata containing fauna related to that of the Lias (Lower Jurassic) of Europe. Most of the specimens found belong to *Arietites jamesdanae* Barcena, and are as a rule but poorly preserved. The rock is a black to yellow clay slate which contains no lime but which on the other hand includes plates of mica and is somewhat metamorphosed, so that it resembles Paleozoic rocks rather than Mesozoic.

Felix and Lenk give a list of nine localities at which fossils have been found. The Lower Jurassic strata are overlain by black calcareous slates interbedded with black limestones that contain *Perisphinctes* and are assigned to the Upper Jurassic. These in turn are followed by limestones of the Lower Cretaceous. According to a section through Barranca de la Calera and Barranca del Rio Potrero Seco, both in Vera Cruz, by Böse, the strata are conformable from Lower Jurassic to Lower Cretaceous.

F 14. SIERRA DE CATORCE, SAN LUIS POTOSI.

Felix and Lenk ^{327a} state that the Jurassic is widely distributed in Mexico but does not appear anywhere to form areas of great extent. The occurrences are small in area and widely separated, and they are also notably different in faunas.

In the Sierra de Catorce, in San Luis Potosi, certain unfossiliferous gray slates are succeeded by late Mesozoic strata which have been separated by Castillo and Águilera ¹³² into two divisions, and the lower of these has been again divided into two terranes—an upper one, the Cieneguita, and a lower, the Alamitos.

The Alamitos formation consists of fine sandstone and marly or clayey slate interbedded with each other. It contains numerous fossils, a list of which is given in both of the works cited. The Cieneguita formation also consists of marly slates and sandstones which contain more or less carbonate of lime. A number of fossils have been found. The upper of the two major divisions contains in the upper part ash-gray compact limestones which are more or less siliceous. The lower part is shaly and the whole is very poor in fossils. The Alamitos and Cieneguita forma-

tions are regarded as representatives of the Russian Volgien (Jurassic) and in a general way the Alamitos corresponds with the lower Volgien or Tithon, but the Kimmeridge may be represented in it. The Cieneguita, which is distinguished by an abundance of Aucella, represents the upper Volgien or Neocomien (Lower Cretaceous).

F 17-18. CUBA.

T. W. Vaughan contributes the following notes on the Jurassic of Cuba:

Strata of Jurassic age have been reported from Cuba and the Isle of Pines since the time of Humboldt. Recently Dr. Carlos de la Torre has collected Jurassic ammonites, referred by him to the genus *Idoceras*, in the vicinity of Viñales, and has published excellent photographic illustrations.^a Dr. T. W. Stanton agrees with De la Torre in considering these ammonites of Jurassic age. Jurassic limestone forms the axial portion of the Sierra Organos, in the Province of Pinar del Rio, and is the oldest geologic formation revealed in a cross section of the island taken along a line passing through Viñales, in the vicinity of which are excellent exposures. The limestone is hard and blue, and, though not distinctly crystalline, it is intersected by small white veins of calcite.

Overlying the Jurassic limestone, south of Viñales along the road to Pinar del Rio, are reddish argillaceous schists, which form two parallel ridges. These schists were evidently derived from the metamorphism of a shale series that contained a few beds of sandstone and some layers of limestone.

G 13-14. SIERRA DE MAZAPIL, ZACATECAS AND COAHUILA.

Burckhardt¹⁰⁹ has classified and described the Jurassic and Cretaceous of the Sierra de Mazapil district, in the "Mesa Central" of Mexico, as follows:

Jurassic and Cretaceous series of the Sierra de Mazapil and Santa Rosa.

Formation.		Lithologic character and thickness.	Principal fossils.	Age.	
Cretaceous.	Upper Cretaceous.	Shales with <i>Inoceramus</i> .	Shales and limestones; 150-200 meters.	<i>Inoceramus</i> sp.	Turonien.
	Middle Cretaceous.	Cherty limestones. (b) Limestones with gastropods. (a) Limestones with open ammonites.	Gray limestones with black cherts; 400-500 meters.	<i>Scaphites</i> sp., <i>Schloenbachia acutocarinata</i> (Shum.) Marcou, open ammonites (Hamites).	Middle Cretaceous.
		Parahoplites beds.	Clear yellow marls and gray limestones; several meters.	<i>Parahoplites</i> cfr. <i>milletianus</i> Pict. (non D'Orb.), <i>Parahoplites</i> cfr. <i>aschiltaensis</i> , <i>Anthula</i> cfr. <i>treffryanus</i> , <i>Anthula</i> (non Karsten), <i>Parahoplites</i> , many undetermined species.	Delimiting beds between the Aptien and the Gault.
	Lower Cretaceous.	Grayish limestones with large cherts; bluish limestones.	400-500 meters.	<i>Holcodiscus</i> sp.	Lower Cretaceous.
		<i>Holcostephanus</i> beds.	Yellowish marls with nodules of oxide of iron and gray and yellowish limestones; several meters.	<i>Astieria</i> aff. <i>pslostoma</i> N. and U., <i>A.</i> cfr. <i>atherstoni</i> Sharpe, <i>Hoplites</i> aff. <i>michaelis</i> Uhl., <i>H.</i> cfr. <i>hystricoides</i> Uhl., <i>H.</i> cfr. <i>neocomiensis</i> D'Orb., <i>H.</i> cfr. <i>thurmanni</i> P. and C.	Valanginien.

^a An. Acad. cien. Habana, Rev. cien., vol. 47, July, 1910, pl. facing p. 22.

Jurassic and Cretaceous series of the Sierra de Mazapil and Santa Rosa—Continued.

Formation.		Lithologic character and thickness.	Principal fossils.	Age.
Portland.	Whitish marly limestones with chert.	10 meters.	<i>Perisphinctes</i> cf. <i>koeneni</i> Steuer, <i>P. permulticostatus</i> Steuer, <i>Hoplites</i> cf. <i>calistoides</i> Behr, <i>H.</i> many species of the group of <i>H. calisto</i> D'Orb.	Base of the Berriassen?, Upper Portland.
	Grayish phosphatic limestones. (c) <i>Cucullæa</i> horizon. (b) Fossiliferous limestones with <i>Perisphinctes</i> . (a) Limestones with bivalves.	Fossiliferous and highly cherty limestones, grayish; black limestones; 5-6 meters.	<i>Perisphinctes santarosanus</i> nob., <i>P. victoris</i> nob., <i>burkartii</i> nob., <i>Hoplites</i> cf. <i>rjasanensis</i> Lah., <i>Hoplites</i> cf. <i>wallichi</i> Gray, <i>Neumayria subbrasilis</i> nob.	Upper and Lower Portland.
	Reddish phosphatic limestones.	1-2 meters.	<i>Phylloceras apenninicum</i> Can., <i>Eurynoticeras zitteli</i> nob., <i>Perisphinctes</i> cf. <i>danubiensis</i> Schlosser, <i>P. nikitini</i> Mich., <i>Virgatites mexicanus</i> nob., <i>Aspidoceras cyclotum</i> (Opp.) Steuer, <i>A. fallax</i> nob., <i>A. phosphoriticum</i> nob., <i>A. cajense</i> nob., <i>A. zacatecanum</i> nob.	Base of the Portland.
Upper Jurassic. Kimeridge.	Shales with <i>Waagenia</i> .	Brownish shaly clays, highly ferruginous; 10-30 meters.	<i>Waagenia</i> cf. <i>harpephora</i> Font, <i>W. aff. beckeri</i> Neum., <i>W. cf. knopi</i> Neum., <i>W. cf. harpephora</i> Neum.	Summit of the Kimeridge.
	<i>Haploceras fialar</i> beds.	Black compact limestones; 1 meter.	<i>Oppelia</i> cf. <i>trachynota</i> Font. (Oppel), <i>O. aff. strombecki</i> Oppel, <i>Haploceras fialar</i> Oppel, <i>H.</i> many species, <i>Craspedites mazapilensis</i> nob.	Upper Kimeridge.
	Aucella horizon.	Brownish shaly limestones, slightly phosphatic.	<i>Aucella</i> , many species of the groups of <i>A. pallasi</i> Keys and <i>A. bronni</i> Rouill.	Upper Kimeridge.
	<i>Idoceras</i> beds.	Shaly clays and marls with lenses and nodules of compact black limestone; 15-30 meters.	<i>Neumayria profulgens</i> nob., <i>Oppelia aff. nereus</i> Font., <i>O. flexuosacostata</i> Qust., <i>Macrocephalites epigonus</i> nob., <i>Simoceras</i> cf. <i>doublieri</i> D'Orb., <i>Aspidoceras contemporaneum</i> Favre, <i>A. bispinosum</i> Qust., <i>A. cf. acanthicum</i> Oppel, <i>Idoceras laxevolutum</i> Font, <i>I. balderum</i> Oppel, <i>Aulacostephanus zacatecanus</i> nob., etc.	Delimiting beds between the lower and upper Kimeridge.
	Limestones with <i>Nerinea</i> .	At the summit a stratum of black and reddish limestone with <i>Trigonia</i> . The principal mass is grayish massive limestone with interbedded gray marls containing bivalves and beds of coral; of great thickness.	<i>Nerinea</i> various species, corals with the marine bivalves (<i>Pholadomya</i> , <i>Trigonia</i> , <i>Asartarte</i> , <i>Opis</i>), gastropods (<i>Harpagodes</i>), and brachiopods (<i>Terebratula</i>). At the top of the limestone <i>Simoceras</i> cf. <i>doublieri</i> Lortol (D'Orb.).	Upper Jurassic (probably Sequanien).

Burekhardt's description¹¹⁰ is as follows:

The Jurassic and Cretaceous series of the Sierra de Mazapil is composed of four great natural subdivisions. At the base one may observe heavy-bedded limestones which attain great thickness and are the limestones with *Nerinea*. These are the Upper Jurassic limestones which form the center of the anticlines of the two ranges and which, since each chain is composed of a single anticline, occupy generally the highest portions, the peaks and crests of the sierras.

The flanks of the two chains are also formed by heavy masses of limestone of great thickness which locally resemble the limestones with *Nerinea*, but which, even so, may be readily distinguished by their petrographic character. These limestones are generally well stratified and contain a great deal of chert in beds and lenses which alternate with them. The fossil fauna of these limestones indicates that they correspond to different divisions of the Lower and Middle Cretaceous.

Between the two masses of limestones which have been described there occurs a zone of less compact strata composed of clays, marls, and slates, with intercalations of limestone. * * * The colors of these rocks are generally dark and contrast strikingly with the clear colors of the limestone masses between which they occur. The beds are very fossiliferous and have furnished a large number of well-preserved specimens, which demonstrate that they belong to the Kimeridge and Portland.

The latest stratigraphic division which may be observed in the region, in the valleys and at the foot of the sierras, covers the Cretaceous limestones that have been cited. It consists of shales, in part sandy and in part argillaceous, of which the lower portion, the shales with *Inoceramus*, belongs to the Upper Cretaceous (Lower Turonian).

H 13. TEXAS.

In southwestern Texas, just north of latitude 31°, near the line of the Southern Pacific Railroad, Malone Mountain rises from the desert plains north of the Quitman Mountains and is formed in large part of Jurassic strata. The fauna was discovered and described by Cragin,¹⁷⁷ and the general geology of the region has been stated by Stanton in a brief chapter in Cragin's report, which contains also a detailed section. Stanton says:

The most complete section that I observed, in which the thicknesses were estimated with some care, extends across the mountain from a point on the east side about one-half mile south of Malone station. The eastern face of the mountain shows an apparent thickness of about 1,200 feet of blue and gray limestones, with a few intercalated beds and bands of conglomerate and sandstone, the beds all dipping strongly westward with increasing dips until they become vertical on the crest. On the west slope there is a succession of limestones, conglomerates, and gypsum beds, nearly vertical, and not well exposed, and farther down these are apparently repeated with a westerly dip, overlain by conglomerates, limestones, etc.; fairly well exposed and not much disturbed in the lower ridges to the west. The gypsum beds and the limestones immediately associated with them appear to be the oldest rocks exposed.

I-K 10-11. COAST RANGE, CALIFORNIA.

The Franciscan formation of the Coast Range of California is regarded by Lawson as of Cretaceous age but is generally placed in the Jurassic. The basis for Lawson's view is the relation of the Franciscan formation to the Montara granite, which is one of stratigraphic unconformity. Lawson correlates the granite tentatively with the late Jurassic granite of the Sierra Nevada and infers accordingly that the sedimentary Franciscan formation, which rests unconformably upon the granite,

is probably Cretaceous. (See table of the geologic formations of the Coast Range of California in the vicinity of the bay of San Francisco, p. 816, Chapter XVII.)

For a description of the Franciscan, we may refer to Lawson's original account.⁵²⁴ According to that statement, it consists of the following petrographic elements:^a

(1) A basal formation of conglomerates, coarse grits, sandstones, shaly sandstones, shales, and argillaceous limestones, exposed in the vicinity of San Pedro Point. These rocks require no detailed discussion.

(2) The San Francisco sandstone, the dominant sedimentary formation of the series, consisting of a moderately fine grained sandstone, fairly uniform in character over large areas, with subordinate beds of shale and conglomerate. The sandstone is uniform, not only in its lateral extension, but vertically for great thicknesses. In the older writings it has commonly been referred to as the San Francisco sandstone, and the term is here adopted from that usage. It is interbedded with the formations 3-5 which are named below.

(3) Foraminiferal limestones.

(4) Radiolarian cherts.

(5) Volcanic rocks, including basaltic lavas, diabases, pyroclastic accumulations, etc. Besides these there are intrusive rocks of a corresponding character, some of which are probably connected with these extravasations, and also intrusive peridotites and pyroxenites, now serpentinized.

In addition, there are certain metamorphic schists, which are the products of the local alteration of the sedimentary or volcanic formations of the series and, according to the writer's interpretation of them, do not constitute a separate formation. There are also a few patches of a peculiar veinlike rock associated with the San Francisco sandstone, but of rather uncertain genetic relations. In his field notes the writer has been in the habit of referring to this as silica-carbonate sinter, and it will be further described under that designation.

J 10. SIERRA NEVADA, CALIFORNIA.

Along the western base of the Sierra Nevada in California the Mariposa slate forms three narrow bands. The strata are prevailingly clay slates, which are sandy and contain pebbles of rocks from the Calaveras formation (Carboniferous). Tuffs from contemporaneous porphyrite eruptions also occur in them. The fossils of these beds, such as *Aucella* and *Perisphinctes*, indicate a late Jurassic age.

In the folio describing the Sonora quadrangle Turner and Ransome⁸¹⁵ give a detailed account of the characteristics of the rocks in the three bands in which the formation outcrops, especially as observed at localities within that quadrangle. Lindgren⁵³⁸ describes a more northern occurrence of the Mariposa in the Colfax quadrangle, where it succeeds the Sailor Canyon formation (Triassic). He states that it consists of black shales or slates, usually not very fissile, alternating with dark-gray sandstones of coarser or finer grain, and a great number of conglomerate beds. The rocks are tuffaceous and contain much iron. The conglomerate beds, though rarely very thick, are very abundant and contain pebbles of chert, quartz, slate, and limestone evidently derived from the older Calaveras formation. The Mariposa was clearly deposited in a gulf or shallow bay, the conglomerates indicating immediate proximity of the shore line.

The fauna contained in the Mariposa formation has been discussed by Hyatt^{468a} and by James Perrin Smith.⁷⁶³

^a For a detailed description of the subdivisions see the work cited.

J 11. HUMBOLDT RANGE, WESTERN NEVADA.

The Jurassic of western Nevada was briefly described by Hague³⁹⁰ and King.^{505b} The latter says:

In the Nevada province the Jurassic consists of a limestone between 1,500 and 2,000 feet thick and overlying slates probably about 4,000 feet thick.

Louderback⁵⁴⁷ refers to the Jurassic as composed chiefly of gray to greenish-gray slate with subordinate limestone, which in Muttleberry Canyon carries *Arietites* sp. nov., referred by Smith^{764b} to the Lower Jurassic or Lias of Europe.

J 12. SOUTHERN UTAH AND PLATEAU DISTRICT, COLORADO.

Dutton³⁰⁰ describes the Jurassic of the High Plateaus of Utah in part as follows:

The Jurassic series consists of two members, the lower being a massive sandstone of great thickness, the upper a series of calcareous and gypsiferous shales from 200 to 400 feet thick. Underneath the sandstone is a small group of shaly beds, which are presumed to be of Jurassic age, but no determinable fossils have been taken from them. * * * Comparing the Jurassic section of the Uintas with that of the High Plateaus and Kaibabs, we find a concordance in the several members.

	Uinta section.	Kanab section.
	<i>Feet.</i>	<i>Feet.</i>
Calcareous shales, limestone and gypsiferous shales [a]	1,000	500
Massive, cross-bedded white sandstone.....	1,100	1,400
Thin calcareous shale.....	100	50
Vermilion Cliff series.....	1,100	1,500
Upper Shinarump shales and conglomerate.....	1,000	750
Belted shales.....	400	400
Lower Shinarump shales.....	300	500

^a T. W. Stanton makes the following comment on the manuscript: "The marine Jurassic fauna ranges through the lower 250 feet of the uppermost member of this section."

The lithological characters of the Jurassic white sandstone render it a very conspicuous formation. Through a thickness of more than 1,000 feet, sometimes of nearly 2,000 feet, it is one solid stratum, without a single heterogeneous layer or shaly parting. * * * The color of the rock is almost always gray, verging toward white. Occasionally it is a very pale cream color, and again pale red. The red becomes more common as we recede from the old shore line toward the east. But of all the features of this rock the most striking is the cross-bedding. It is hard to find a single rock face which is not lined off with rich tracery produced by the action of weathering upon cross lamination. The massive cliff fronts are etched from summit to base with a filagree as intricate and delicate as frost work. The same phenomenon is seen

in the Vermilion Cliff sandstones below, often so rich and complex that it excites constant admiration. Dr. Newberry speaks of it with enthusiasm as presented in the Triassic sandstones of New Mexico. But it is far less wonderful than the cross-bedding which the Jurassic presents at every exposure. * * * The Jurassic sandstone was deposited over an area which can not fall much short of 35,000 square miles, and the average thickness exceeds 1,000 feet. The imagination is utterly baffled in the endeavor to conceive how a mass so vast and at the same time so homogeneous and intricately cross-bedded throughout its entire extent could have been accumulated.

The cross stratification of the Jurassic sandstones of southern Utah has been discussed by Huntington ⁴⁶⁶ as an evidence of wind action. Dutton continues:

Overlying the white sandstone is a series of beds which may be called shales with some reservation, and here we find for the first time an abundance of distinctive fossils. They are clearly of Jurassic genera and species and enable us to correlate the horizon with confidence. They belong to a well-marked formation, which is represented not only throughout the greater part of the plateau province, but also in Colorado, Wyoming, and northern New Mexico. From many large areas, indeed, it has been denuded, but throughout Utah it is never wanting from those exposures where its presence could be looked for.

The constancy of lithological character which is so conspicuous in older Mesozoic members does not prevail in this one, for it is highly variable not only in the mass but also in the constitution of the beds. In some exposures it is more than 1,000 feet thick; in others, it is less than 200. Where its volume is greatest it is more arenaceous, and where the volume is less the beds are shaly, marly, and calcareous. Usually several seams of limestone occur, and in these the fossils are found, often abundantly. One notable feature is the small amount of cement in the arenaceous layers, which are, therefore, very poorly consolidated, and the rock weathers and wastes away with extreme facility. Gypsum and selenite occur abundantly in these beds and especially noticeable is the latter mineral, which is seen sparkling and glittering in the sunlight in the badlands to which the decay of the strata gives rise.

A section of the Triassic and overlying Jurassic observed by Walcott in the Kanab region is quoted by Cross in an article on the red beds. (See I-K 12-13, Chapter XII, p. 514.) Stanton ^a comments on Cross's suggestion that the La Plata sandstone of southwestern Colorado may be correlated with the White Cliff sandstone of Utah and says that in that case the La Plata is well down in the Jurassic, because the White Cliff sandstone underlies marine Jurassic beds that are of the same age as the Twin Creek, Ellis, and Sundance formations.

In western Colorado at the east end of the Uinta uplift Gale ^{353b} has found marine Jurassic fossils in a white sandstone which he correlates with the White Cliff and the La Plata.

In southwestern Colorado the Jurassic is represented by the La Plata sandstone and probably by the McElmo formation, although the age of the latter is not definitely known to be Jurassic; it may be Lower Cretaceous. The La Plata and McElmo are equivalent to the Gunnison formation farther north. Cross ¹⁸⁹ gives the following classification and descriptions:

^a Comment on manuscript.

Correlation of formations.

San Juan folios, U. S. Geological Survey.			Peale.	Holmes.	Powell.
Cretaceous.	Mancos.
