during an attack. An old colored man whom I recently had under my care in the County Hospital usually lay down, on the sidewalk or porch, or wherever he was taken, until the attack was over. His sudden death, two weeks after describing to me and to the class in clinic the typical manifestations of the disease, and the finding of sclerosed aorta, aortic valves and coronaries, confirmed the diagnosis of angina. This is, I think, the only patient I have seen who by choice would lie prone during an anginal seizure, though I have several times seen patients in a half-sitting posture, or have had such position described to me as the one assumed. A woman of 45, who had definite loud basic murmur, apparently due to roughened aorta and aortic valves, would, during the pain of angina, get on her hands and knees in bed. She was neurotic and admitted that there was a hysterical element in her case, but insisted that the pain was real and that this position gave her the greatest relief.

Once or twice I have had the diagnosis of angina questioned because of the prominence of eructation or vomiting. Flatulence or vomiting may be marked. At times the attack ceases with the belching of gas or the raising of the contents of the stomach. That a stomach distended with gas or food may cause epigastric or precordial distress is a well-known fact, but it should also be remembered that true angina not infrequently follows a hearty meal, or is accompanied by striking gastric symptoms.

PROGNOSIS

A word about prognosis. There is in some quarters the opinion that the disease is not only inevitably fatal, but that death is sure to follow in a short time, or after two or three attacks. There is surely good reason for viewing this condition as one of extreme gravity. Death, and often sudden death, is the common result. But it is also worth noting that the fatal termination may be deferred for years and, exceptionally, complete recovery seems to ensue. If one includes under the head of angina pectoris the toxic, as for example, tobacco angina, and the neuroses with precordial angina-like pains—the so-called pseudo-anginas—the mortality percentage, while high, would not be so startlingly large. But even excluding the neurotic forms and limiting the statement to the true cardiovascular types, the mortality is not 100 per cent., as some think; and even in the fatal cases death may be postponed for many years. In a paper recently presented to the Chicago Medical Society, Dr. Forchheimer of Cincinnati cited one of his cases, in which the first attack had been seventeen years before death. Dr. Billings had seen a patient live fifteen years after the first paroxysm. A physician whom I cared for had his first severe and nearly fatal angina seven years before his fatal attack. Morison describes a case in which the pains recurred at intervals for seven years. Stokes had a case in which for ten years the patient suffered from attacks of excruciating severity. John Hunter had attacks for twenty years.

The recognition of the malady, the regulation of the mode of life to that most suited to the cardiovascular condition, involving, as it often does, change in diet and habits of work, the proper use of remedial drugs; in a word, appropriate treatment may materially alter the prognosis. The condition of the heart and vessels as to aneurism, valvular disease, general sclerosis, myocarditis and fatty changes, must determine to a marked degree the length of life. And so, too, does the condition of the kidneys.

NITRITES AND DIGITALIS

I wish to refer briefly to certain fallacies concerning the use of nitrites and digitalis.

The nitrites have, especially of late, been held by some in less repute than formerly, because they fail completely in some instances to relieve or ward off the attacks. Others seem so convinced of their efficacy that, when in a case of supposed angina the nitrites fail to relieve the suffering, and to relieve it promptly, they conclude that they are dealing with something different from true angina. Now, the truth seems to be that nitrites in some cases give most prompt, marvelously prompt relief. The testimony of many physicians is available on this point. It is hard to understand, then, how some good men—Romberg, for example—regard this remedy as either of no benefit or of very insignificant value, at least during a seizure. Unless convinced by repeated trials as to its uselessness in the attacks, no patient should fail to keep in his pocket either the pearls of nitrite of amyl or the pill or tablet of nitroglycerin, gr. 1/100 to 1/50. Some attacks are surely cut short by the use of these remedies, and often the patient has a slight warning of the onset, and the timely use of the drug may prevent a paroxysm.

No matter how strong the prejudice against the use of digitalis in cardiac hypertrophy and general arteriosclerosis may be; no matter what may have been said against its employment in weakened myocardial states, there can be no question that in some cases of angina—not easily described, either—this drug does more good than all the iodids or nitrites.

SUMMARY

These views may be summarized by making the statements as a series of negations:

1. With "true," organic cardiovascular angina pectoris there cannot always be made out peripheral arteriosclerosis, cardiac hypertrophy and high blood-pressure.
2. The finding of aneurism or lesion of the aortic valves does not exclude angina, but rather argues in its favor.
3. The attacks are not always few in number and brief in duration; they do not occur solely after exertion.
4. While the prognosis is grave, life is not necessarily limited to a few months.
5. The disease is by no means to be excluded because the symptoms are found in a woman, even in a nervous or hysterical woman.
6. The pain is not necessarily severe; it may be mild or even lacking; its radiation is variable.
7. The statement that the patient is always conscious, that he is always immobile and erect must be modified so as to read "usually" instead of "always."
8. Eructations or vomiting during an attack do not argue conclusively against the cardiovascular origin of the angina.
9. It is not correct to look on the nitrites as of no benefit in relieving symptoms; nor, on the contrary, is one justified in concluding that a case unrelieved by nitrites is not angina.
10. Digitalis is not necessarily contra-indicated; it is often of very great value.

Closer observation of the atypical as well as the typical cases, with collocation of the results with those of anatomic and experimental studies will lead to unifying knowledge concerning the pathogenesis of this disease, to greater precision in its recognition, and to more appropriate treatment.

150 Michigan Boulevard.

ABSTRACT OF DISCUSSION

DR. JOSEPH L. MILLEE, Chicago: If we followed the statements made in text-books regarding angina pectoris, the diagnosis of this disease would frequently not be made. A statement often made is that patients suffering from angina pectoris always remain quiet, whereas, many patients with typical attacks of this disease will move about. I believe that the term "pseud-angina" should be entirely abandoned. Patients with symptoms resembling angina pectoris, in whom we can exclude an ordinary neuritis, should be considered as suffering from true angina. I do not believe that the value of digitalis in angina pectoris is fully appreciated; I think that there are many patients who receive permanent benefit when taking this drug, the attacks recurring less frequently. It has been shown experimentally that a much more extended ligation of the coronary artery may be made without serious consequences when the animal is under the influence of digitalis or strophanthus, and I think that the same holds true in human beings. There may be obstruction of a coronary artery with less serious consequences if the heart is under the influence of digitalis.

DR. GEORGE W. McCASKEY, Fort Wayne, Ind.: I had under observation last year a patient who had anginous attacks occurring sometimes during exercise, but the majority occurred during the night. The patient awakened in the night with this precordial pain and a sense of approaching death, etc. These attacks were as typical during the night as during the day. This patient referred to finally died and came to autopsy. The heart was exhibited to the Fort Wayne Medical Society, and showed both coronary arteries extensively involved. There is a group of cases which has interested and troubled me very much, in which this precordial pain is more or less persistent, with occasional severe exacerbations. Whether such cases should be placed in the group of angina pectoris is a question that must be answered according to the definition of angina pectoris. But there are some cases, indistinguishable by their symptoms, in which there is serious organic disease and in which the heart is able to adjust itself to the new conditions. If the nutrition be improved, some of these patients will make a relative recovery.

I recall the case of a patient, aged 60, who came to me about four years ago, suffering from severe typical attacks of angina pectoris. His family physician, on several occasions when called in to attend him, thought he would die. I placed him on the usual treatment. He was given the nitrites, small doses of digitalis, and iodids. This patient made a complete symptomatic recovery. I saw him within the last six months and he apparently is in good health.

Another patient that I now have under observation has more or less persistent pain. This man is very intelligent and cooperates with me in observation of his case. He says that he never was free from a sense of constriction, but what annoys him most is this pain, which at times is almost continuous; at other times he has a sense of pressure. If he exercises he brings on an attack. He has no paroxysms during the night. Still another case of an entirely different type was in a boy of 11, who, about 3 years ago, had what apparently were typical attacks of angina pectoris. The precordial pain lasted a few minutes and the attacks occurred mostly during the night, though they also occurred at times after exercise. One would not expect any trouble with the coronary arteries in a boy of this age; he made a complete recovery and is well to-day.

I think that the majority of these cases occur about middle life or later, and are due to changes in the coronary arteries. But what causes the pain in angina pectoris? I think there must be some interference with the circulation in the heart muscle or disturbance of the neuromuscular mechanism of the heart. This is certainly far from a satisfactory explanation, but is the best we have at present.

DR. GUSTAV BAAR, Portland, Ore.: Some years ago, Billroth said that in cases of angina pectoris he gave one-half grain of digitalis leaves every day and that the patients could then keep at work. Since then, I have employed this agent in this form and dosage, and with very good results. At the same time I must caution against the promiscuous

use of digitalis in heart disease. I have seen a number of "bronchial asthma" patients in collapse—cold extremities, imperceptible pulse, etc. In these cases I have injected 1 mg. of strophanthin, intravenously. A young woman, after injection of this amount of strophanthin, within three minutes displayed bounding and rapid pulse and is alive to-day. Through my experience in this case I was much encouraged in the use of strophanthin. Some time later, I was called to see a patient with "angina pectoris," who had been under the digitalis treatment for three years. I found this patient in collapse and injected 1 mg. of strophanthin; after injecting the drug I left, but was called back at the street corner: the woman was dead. Undoubtedly, the death was due not to the angina pectoris, but to the strophanthin. Since then, I have given up the use of strophanthin in any case of arteriosclerosis, a condition which is usually associated with angina pectoris.

DR. SCOTT P. CHILD, Kansas City, Mo.: I should like to report a case of angina pectoris in support of Dr. Herrick's contention that many cases are atypical. The patient was an active Episcopal bishop of western Missouri, aged 70, height 6 feet 2 inches, weight 180 pounds. While attending to the duties of his diocese, and following an evening meal, he ran upstairs and was immediately taken with what he termed the most severe pain he ever suffered. The pain, beginning at the base of the heart, back of the sternum, ran up into the neck and jaws of both sides and down both arms to the finger tips. The pain lasted an hour and a half, being relieved only by a hypodermic injection of morphin. During the attack of pain the patient suffered from intense cold, which was followed by profuse perspiration. Two days following the attack, the pulse was quite regular, the rate varying from 120 to 130; the blood-pressure in the right arm was 140 mm. Hg, that of the left 126 mm. Hg. This patient has been under my observation for two years (no previous attack suffered), with a well-established myocardial insufficiency, the heart being enlarged well beyond the nipple line and down to the sixth interspace. So far, no valvular signs have developed. This patient for several years has had evidence of interstitial nephritis, with a constant albuminuria, hyaline, and frequently granular casts. Two days following this attack of angina, the urine revealed 0.5 per cent. of albumin and numerous hyaline and granular casts. At the end of a week, with rest in bed and a regulated diet, the pulse was down to 92 and regular, the blood-pressure was low, and the urinary findings very much improved.

DR. JOHN A. WITHERSPOON, Nashville, Tenn.: It is unfortunate that so many physicians are looking for such cases of angina pectoris: they look for cases of such severity that the patients are made perfectly quiescent, with fixation of the body, cyanosis, and so forth. They do not seem to realize that there may be cases of angina pectoris, with intermittent attacks of mild character, which have been threatening the patients for years. I learned long ago that the pulse in angina pectoris was unreliable; I have found a low pulse and a rapid pulse in bad cases, as well as in mild cases of this disease. If these cases are properly conducted and properly managed between the attacks the attacks will become less severe. Like Dr. McCaskey, I like to give the iodids with the digitalis.

I doubt very much the diagnosis of angina pectoris made in the case of the boy of 11 years: I have yet to see a true case of angina pectoris occurring in a patient so young. We are likely to get an increase in the blood-pressure, with evidences of an accentuated second sound of the heart, but no evidence of atheroma of the coronary arteries. Many of these cases may be explained and will be found not to be due to angina pectoris. The nitrites act happily in some cases, but when most needed they most often fail to give relief. It is especially in the bad cases that the nitrites seem to fail us.

DR. ALLEN A. JONES, Buffalo: We cannot always judge of the condition of the coronary circulation in the heart from the condition of the peripheral circulation as we see and feel it. I have now under observation a patient with typical attacks of angina pectoris. He has suffered any number of attacks; he is an individual in middle life, and pulse, blood-

pressure, and heart are practically normal. The pain may be present in an unusual situation, and not in the classical situation, precordial and running to the left shoulder and left arm, or to the wrist and thumb. In a paper read at a session of this Association in Atlantic City some years ago, I called attention, in discussing "Abdominal Symptoms of Thoracic Disease," to the fact that we might encounter epigastric pain as well as cardiac. The pain may be typically epigastric, and may be called gastralgia; in fact it often is. Between the attacks of angina pectoris it is not an uncommon experience to find individuals complain bitterly of gastric symptoms, and more especially of a collection of gas in the stomach, a "pneumatosis," the pressure of which on the diaphragm frequently leads to an attack. I think that one should exercise great caution in his choice of cases; in a patient with high blood-pressure, with cardiac hypertrophy and with a competent heart, digitalis is not to be used except under extreme watchfulness. On the other hand, given a case of angina pectoris with opposite conditions, in a frail and spare individual with low blood-pressure, and with attacks often coming on after exercising, then the administration of small doses of digitalis over a long period frequently does good.

DR. JAMES B. HERRICK, Chicago: The question of treatment I purposely omitted from my paper, except the few words concerning digitalis and the nitrites. I agree, however, with what has been said in regard to the use of the iodids; they certainly are of great benefit.

THE VISCERAL ANESTHESIAS OF TABES DORSALIS IN RELATION TO THE DIAGNOSIS OF ACUTE INFLAMMATORY CONDITIONS IN THE ABDOMEN

WITH AN ILLUSTRATIVE CASE *

LEWIS A. CONNER, M.D.
NEW YORK

The value of pain as an element of safety in the body economy and the disastrous effects of the absence of the normal sensibility of a part are illustrated in the destructive ophthalmia which so frequently follows a lesion of the trigeminal nerve, and in the familiar "Charcot joint" of tabes. Although trophic disturbances probably have some part in the development of both of these conditions the absence of the normal sensibility seems to play an important rôle in determining the progressive and destructive character of both processes. Slight injuries pass unfelt and unheeded. In the case of the tabetic arthropathy the absence of pain results in the absence of all reflex protective contraction of the muscles controlling the joint movements; the continued free use of the limb increases constantly the existing damage and there ensues a gradual, painless disintegration and destruction of the joint. A recent experience has brought home to me the fact that sensory disturbances in tabes may, indirectly, lead to grave damage to the body in ways other than by the development of "Charcot joints" or perforating ulcers of the foot. The following case illustrates this fact:

FATAL PERFORATIVE APPENDICITIS IN A TABETIC WITH COMPLETE ABSENCE OF PAIN, TENDERNESS AND MUSCULAR RIGIDITY

Patient.—A brakeman, aged 42, was admitted to the medical service of the New York Hospital on August 14, 1909, with an acute febrile attack of three days' standing. His history as given at that time was as follows: Family history is un-

* Read in the Section on Practice of Medicine of the American Medical Association, at the Sixty-first Annual Session, held at St. Louis, June, 1910.

important. The patient had measles in childhood; malarial fever twenty years ago; chancre seventeen years ago; treatment for a few weeks only; indefinite secondary symptoms; gonorrhoea twice; last time four years ago. He was a heavy drinker up to eight years ago; since then has used no alcohol. For the past year has had some difficulty in controlling his bladder and rectum and has had frequent sharp, darting pains in the legs. About four weeks ago he began to have a "weak, tired feeling" in the legs; could not feel distinctly with his feet and would stumble when attempting to walk in the dark. Three days ago he began to be very feverish. Since then he has had several shaking chills and some profuse sweats. There has been no regularity in the appearance of the chills; no pain; no other symptoms except prostration and malaise.

Physical Examination.—Male subject, large frame, poorly nourished. Skin and mucous membranes of good color. Admission temperature 104.6 F., respiration 24, pulse 108.

Eyes: Left pupil smaller than right. No reaction to light in either pupil. Prompt reaction in accommodation. Tongue moist and clean. Superficial lymph-nodes not enlarged.

Pulses: Equal, regular, rapid, of good size and force, moderate tension. Arterial walls slightly thickened.

Heart: Apical impulse diffuse. Seen and felt in fourth and fifth intercostal space 13 to 14 cm. to left of mid-line. Right border of relative dullness not satisfactorily determined; left border 13 cm. to left of mid-line. Heart sounds clear except at apex, where a short, soft systolic murmur is heard.

Lungs: Percussion gives everywhere a somewhat short, "wooden" resonance. Lungs voluminous. Respiratory murmur is everywhere vesicular. No adventitious sounds.

Abdomen: Flat, soft, thin-walled. No rose spots. Liver dullness extends from sixth intercostal space to free border of ribs. Edge of spleen can be indistinctly felt just above the costal border. In the right iliac fossa a soft, elastic, elongated and freely movable mass (cecum?) can be distinctly felt through the soft, relaxed, abdominal wall. In the left iliac fossa a similar, somewhat smaller object can be felt. Neither mass is tender on palpation. No tender points can be elicited anywhere in the abdomen, nor is there anywhere muscular rigidity.

Genitals: Small scar on glans.

Extremities: A number of pigmented, depressed scars over both shins. Knee-jerks and Achilles jerks cannot be elicited. Plantar reflex absent. Marked diminution in tactile and pain sensibility over feet and legs.

Course of Disease.—On August 15 the patient vomited several times. The temperature continued high and irregular. The mind was clear. The patient complained only of the fever and general malaise; required catheterization. Urine contained a trace of albumin and a good many hyaline and granular casts but no pus. Leukocytes were 9,700; polymorphonuclear cells 83 per cent.; lymphocytes 17 per cent.; hemoglobin 85 per cent. The Widal test was negative. There were no malarial plasmodia. The abdomen was soft, flat and entirely free from tenderness.

During the next six days the patient's condition grew slowly but steadily worse. The temperature fluctuated between 100 and 104 F.; the respirations between 24 and 32, and the pulse gradually grew more rapid and feeble. The patient continued to vomit frequently, the vomited matter consisting usually of bile-stained fluid. The bowels were readily moved by laxatives or enemas. The patient complained of no pain whatever, and frequent examinations of his lungs, heart and abdomen failed to supply any clue to the diagnosis. The Widal test was repeatedly negative. Two examinations of the scanty sputum failed to reveal tubercle bacilli. The urine gave no evidence of a pyelitis or cystitis. The soft elastic mass in the right iliac fossa seemed rather to diminish in size, could be readily displaced under the finger and was never tender to pressure or manipulation. It seemed to be only the normal cecum felt through an unusually thin and relaxed abdominal wall.

The stomach contents, expressed after an Ewald test breakfast, showed nothing abnormal. Examination of the stools was negative for blood, mucus or ova. Rectal examination revealed nothing abnormal.

On August 17 the leukocytes numbered 18,800 and the percentage of polymorphonuclear cells was 83. A blood culture taken on this day remained sterile. On August 20, the leukocytes were 37,800 and the polymorphonuclears 92 per cent. The abdomen at this time was somewhat tympanitic but was free from muscular rigidity and tenderness. The area of liver dullness remained unchanged. The heart sounds also had not changed. A few crackling râles could be heard at the bases of both lungs; the tongue was dry and brown.

It was evident that the patient was suffering from some severe septic condition but the nature and site of the trouble was still altogether obscure.

August 21, the patient failed rapidly, passed into a stupor, developed pulmonary edema and died at 9 p. m. In the light of the subsequent autopsy findings it is to be regretted that a systematic examination of the sensibility of the trunk should not have been made, but our attention was centered on the acute, febrile condition which seemed to be quite unrelated to the antecedent tabes.

Autopsy.—Fifteen hours after death. Dr. Symmers (condensed report). On opening the peritoneum about 500 c.c. of milky fluid escaped. The peritoneum is diffusely opaque, swollen, edematous and in many places covered with an abundant fibrinous exudate. The serosa of the intestines is opaque and the intestines are in many places matted together by fibrinous exudate. In the appendix a round perforation, the size of a 10-cent piece, is found. The edges of this are necrotic and covered with fibrinous exudate. A probe passes directly into the lumen of the appendix, the mucous membrane of which is necrotic and discolored.

Pleura and pericardium normal.

The heart is moderately increased in size and flabby. The endocardium is in good condition. The aorta is large, the intima presents many yellowish plaques alternating with pale, hyaline, wrinkled areas. Heart muscle shows post-mortem changes.

The lungs show only emphysema and edema.

The spleen is increased in size, soft and friable. The Malpighian bodies are not visible.

The kidneys are moderately increased in size. The capsule is thin, strips readily and leaves a smooth, pale surface. Cortex and medulla are well differentiated. Cortex is broad, swollen, opaque. Markings very indistinct.

Liver considerably increased in size. Cut surface smooth, yellowish in color and very friable. Markings indistinct.

Stomach presents the lesions of atrophic gastritis.

Intestines show little change.

Bladder and prostate fairly normal.

The spinal cord shows considerable grayish discoloration, involving the posterior and lateral tracts, which is chiefly confined to the dorsal region.

Microscopic Examination (Dr. Schlapp).—From the sacral region up into the upper part of the dorsal there is a very marked degeneration involving practically the whole of the posterior columns, showing that the root zones in the dorsal region were involved as well as those in the lumbar and sacral region. The fibers in the cornucommissural tract are partly normal as are also a few fibers in the root zones. The root zones and the column of Burdach are intact in the cervical region. In both of Clark's columns the fibers are missing. On one side of the cord most of the cells are missing and those that are present show an abnormal condition in that they are very much smaller than is the normal cell in Clark's column. The cell-body has shrunk, the nucleus has also shrunk and most of the cells in both of Clark's columns contain a large amount of pigment. The cells in the anterior horn seem to be normal except that they contain quite an amount of pigment. The fibers in the posterior nerve-roots are almost entirely degenerated. The anterior nerve-roots throughout the sections of the cord are normal with the exception of a small bundle on each side which shows a marked degeneration. This degeneration, however, is sharply confined to this small bundle of fibers. The lesion extends up to the nucleus of Goll and Burdach, confining itself more or less to the column of Goll in the cervical region.

Here, then, was a man in good health, except for the rather mild symptoms of tabes, in whom an acute appen-

dicitis developed, progressed to perforation and a diffuse peritonitis and ended in death, without there having been at any time spontaneous pain, tenderness or protective muscular rigidity.

Instances of the almost complete absence of these three symptoms in the peritonitis which follows the perforation of a typhoid ulcer are not very rare, but they occur only in patients showing profound prostration and apathy as a result of the severe intoxication of the primary disease. In the present case, on the other hand, the appendicitis developed in a man in his usual health and with an alert mind and a clear sensorium. Under these circumstances it can hardly be doubted that the explanation for the absence of these three cardinal symptoms must be sought in the sensory disturbances of the tabes.

DISTURBANCES OF VISCERAL SENSIBILITY IN TABES

Disturbances of visceral sensibility in tabes manifest themselves in (1) the well-known painful "crises" of the stomach, intestines, bladder, larynx, heart, etc., and (2) a loss or diminution of the normal sensibility of certain of the viscera.

That such organs as the bladder, urethra, rectum and testicle may sometimes become anesthetic or analgesic has long been recognized. Gowers,¹ writing twenty-five years ago, notes the occasional loss of testicular pain, and adds that "the anesthesia may extend to the viscera when the trunk is involved. In consequence of the loss of sensation grave injuries to the limbs, such as burns, may be unperceived, and visceral disease may be unattended with the customary pain. Pleurisy, for instance, may be absolutely painless."

In recent years the subject of visceral anesthesia in tabes has received much attention from the French writers. It has been shown that complete anesthesia of both testicles occurs in about half of the cases and incomplete anesthesia in many more.

Normally, deep pressure or blows on the epigastrium cause a peculiar, painful sensation, with distress, collapse and sometimes even death. In about 20 per cent. of the cases examined this sensitiveness was completely lost.

In many cases there is a disappearance of the pain and distress usually produced by deep pressure on the trachea.

The pain occasioned by pressure on the globe of the eye and on the mamma is also frequently lacking.

Carrez,² who has reviewed the whole subject of the visceral anesthesia in tabes, concludes (1) that there exists no connection between the enfeeblement or abolition of the deep sensibility, testicular, mammary, epigastric, tracheal, ocular; and the superficial analgesia or anesthesia and (2) that there is no necessary relation between the deep analgesias and preexisting painful crises.

THE NATURE OF VISCERAL PAIN

Although it seems clearly established that in locomotor ataxia there is frequently a complete loss of the normal painful response to irritation of certain of the viscera, the mechanism by which, under normal conditions, visceral pain is produced is by no means well understood.

It is a fact familiar to physiologists and surgeons (see Lennander³) that such organs as the heart, stomach, intestines, liver, gall-bladder, uterus, etc., are usually entirely insensitive to procedures (cutting, pinching, burning, etc.) which in the superficial tissues would

cause severe pain; and it has always been difficult to harmonize this fact with the every-day experience that in disorders of these viscera pain is a common symptom. Mackenzie⁴ has recently offered a hypothesis to explain this paradox, and supports it by many interesting facts. He believes that the pain excited by disturbances in the viscera is due, not to the propagation of true sensory impulses from the viscera themselves, but to the reflex stimulation of the cerebrospinal nerves supplying the tissues overlying these viscera; in other words, that the pain and tenderness are felt, not in the organ itself, but in the tissues of the thoracic or abdominal wall over it. Afferent impulses passing from the viscus along the sympathetic fibers to the cells of the spinal cord excite there the neighboring centers of the sensory and other cerebrospinal nerves. "If a morbid process in a viscus gives rise to an increased stimulus of the nerves passing from the viscus to the spinal cord, this increased stimulation affects neighboring centers, and so stimulates sensory, motor and other nerves that issue from this part of the cord. Such stimulation of a sensory nerve will result in the production of pain referred to the peripheral distribution of the nerve whose spinal center is stimulated, so that visceral pain is really a viscerosensory reflex. If the increased stimulation affects a motor center, then a contraction of a skeletal muscle results, and thus is produced the visceromotor reflex."

This view of the nature of the pain excited by visceral irritation accords well with the familiar facts that such pain is often felt far beyond the boundaries of the affected organ, and that there is often an associated hyperesthesia or tenderness of the skin and underlying tissues. In angina pectoris, for example, not only is the pain often felt in one or both arms but there is frequently also hyperesthesia of the chest wall and of the inner surface of the painful arm.

If this theory of the nature of visceral pain is correct (and there is much evidence to support such a view) it is obvious that the absence, in tabes, of the normal painful response to visceral irritation might be explained by assuming a destruction either of the sympathetic fibers bearing the afferent impulses from the viscera to the spinal cord, or of the spinal centers of the corresponding sensory cerebrospinal nerves. In the case cited here a lesion of the sensory cells of the cord alone would not, indeed, account for the conspicuous absence of muscular rigidity.

A lesion of the sympathetic fibers with interruption of the afferent impulses to the cord would, however, explain the absence both of sensory symptoms and of the reflex muscular rigidity. Is there evidence that such lesions of the sympathetic fibers occur in tabes?

LESIONS OF THE SYMPATHETIC IN TABES

Little was known concerning the condition of the sympathetic system in tabes until Roux,⁵ in 1900, published his investigations on that subject. In all of the seven cases of tabes examined he found atrophy of a large proportion of the small myelinated fibers in the cervical, thoracic and abdominal sympathetic trunks, whereas in ten subjects dead from various other diseases no such changes could be found. He believes that he is justified in concluding that this destruction of the small myelinated fibers is a special pathologic condition of tabes, and that this lesion is responsible for the disturbances

1. Gowers: Diseases of the Nervous System, 1. édition 3, p. 454.

2. Etude clinique de quelques analgésies viscérales profondes dans le tabes. Thésis, Paris, 1903.

3. Observations on the Sensibility of the Abdominal Cavity, Translated by Baker, London, 1903.

4. Symptoms and Their Interpretation, London, 1909.

5. Les lésions du système grand sympathétique dans le tabes et leur rapport avec les troubles de la sensibilité viscérale, Thésis, Paris, 1900.

of visceral sensibility in that disease. In this view he has the support of Déjerine and Thomas.⁶

In the case recorded here no examination of the sympathetic system was made.

Whatever may be the true cause of the disappearance of visceral sensibility in certain cases of tabes, the fact that such visceral anesthesia does sometimes occur seems to be well established. That this fact has a practical application is evidenced by the fate of the patient under consideration, whose life was lost because of the failure to recognize an acute inflammatory process in the abdomen, demanding immediate surgical relief, which under ordinary conditions would have been only too obvious.

Concerning the frequency with which the abdominal viscera, in tabes, lose their normal, painful response to visceral irritation we have at present no data. It is known that complete loss of testicular pain is found in about half of the cases and a loss of "epigastric sensibility" in 20 per cent, or more. If the lesions of the sympathetic trunks found by Roux are as frequent as his investigations seem to indicate, it is not unlikely that disturbances of visceral sensibility in tabes may be much more common than has been supposed.

Concerning the means of recognition of such anesthesia of the abdominal viscera little can be said. Carrez concludes that there is no relation between the disturbances of visceral sensibility and of that of the overlying skin. The absence of testicular pain and of that produced by deep pressure on the epigastrium would at least suggest that there might be similar sensory disturbances in the abdominal viscera.

SUMMARY

The purpose of this report is to direct attention to the fact that in locomotor ataxia a loss of the normal sensibility of the viscera sometimes occurs, and that in such cases acute inflammatory diseases of the abdomen, such as appendicitis or peritonitis, may develop and run their course without at any time presenting any of the three symptoms of pain, tenderness and muscular rigidity. The loss of painful response to visceral irritation in tabes probably depends on a lesion of certain of the sympathetic fibers passing between the affected viscera and the spinal cord.

ABSTRACT OF DISCUSSION

DR. LAWRENCE LITCHFIELD, Pittsburg, Pa.: I should like to ask Dr. Conner whether there was distention of the abdomen in the later stages of the man's illness, and, further, I should like to emphasize the point which he did not bring out sufficiently, that there was no relation between the superficial sensory nerves and those of the deeper structures. Within the past week I have seen a case of Pott's fracture in a tabetic, a man about forty-two years old, a syphilitic, who had been walking on his broken leg apparently for about two weeks before seeking advice. He had no anesthesia of his feet, he had no analgesia, he had barely appreciable hypalgesia of feet and limbs. He had good joint sense. Manipulation of the fragments elicited no pain. There was excessive swelling, which subsided after rest, with the application of icebags, after which the fragments were brought into alignment without the slightest sensation of pain.

DR. JOHN H. MUSSER, Philadelphia: It is one of the tragedies of appendicitis that it may frequently occur without either pain or tenderness or reflex spasm, and I have observed, in common with others, absence of these phenomena. Cer-

tainly, I have seen a number of these cases in various periods of life that I feel bound to say were not attended by or accompanied by locomotor ataxia. I am not stating this to disprove the statement of the author of the paper. I merely wish to emphasize the fact that these symptoms may be absent, and particularly is this the case in the gangrenous forms of appendicitis, in which, on account of the intensity of the infective agent, there has been an absolute cut-off of the nerve paths, consequently bringing about an absence of tenderness and an absence of reflex spasm. The one case that comes to my mind at the present time is that of a healthy adult who had various attacks. At first, the usual preliminary characteristics of slight gastro-intestinal disorder ensued, with vomiting, some slight distention, a little pain, slight fever and then disappearance of symptoms in forty-eight or sixty hours, no abdominal reflexes, no tenderness, no pain. The man was quite an athlete and amused himself by contracting his own abdominal muscles in order to show us that he was absolutely free from pain. Notwithstanding the fact that we urged operative procedures, he refused until the onset of symptoms of peritonitis in two or three days, which were then characteristic. The toxemia was sufficient to carry him off inside of forty-eight hours, notwithstanding the fact that we had an operation and found that he had a gangrenous appendicitis. The only serious symptom that he had was that due to distention of the abdomen. Of course, the peritonitis was recognized by the other phenomena of disease.

DR. C. F. HOOVER, Cleveland: The dissociation of sensory percepts in tabes brought out by Dr. Litchfield, recalls to me a similar experience with a patient with Pott's fracture which was perfectly painless. The man could perceive the vibration of the tuning fork perfectly well. If the fragments were rubbed together he would say "I can feel a grating, but can feel no pain."

DR. LEWIS A. CONNER, New York: The patient had, in the last two or three days of his illness, moderate distention, although the abdomen still remained soft. Of course, as Dr. Musser says, cases of appendicitis do sometimes occur, especially in children, in which the usual symptoms of pain, tenderness and muscular rigidity are almost entirely lacking; but, in my experience at least, some one or other of these symptoms has always appeared at some time in the course of the disease. In the case under discussion, it was the complete absence of these symptoms throughout the entire illness that made it seem so remarkable.

TEACHING THE PRINCIPLES OF SURGERY *

MARTIN B. TINKER, S.B., M.D.

Assistant Professor of Surgery, Cornell University Medical College,
ITHACA, N. Y.

The surgical practice of twenty-five years hence will be what the surgeons of to-day make it, but the teachers of our medical schools cannot accomplish needed reforms until the members of the profession as a whole recognize the importance of such changes and give their support. When we consider the conditions in medical education twenty years ago—no preliminary requirements for medical study, a two years' course and little clinical and laboratory teaching—we realize how much has been accomplished. The higher place of the profession in public regard, better medical care for our own families and friends, larger fees, with the increased comfort and pleasure in living that they bring, have resulted from the efforts of the veteran leaders in the profession of to-day. These changes have not been brought about in a day, but are the result of long-continued and united effort. There is no possibility of standing still; we must advance or

6. *Maladies de la moelle épinière*, Nouv. traité de méd. et de thérap., 1909, xxxiv, 585.

* Read in the Section on Surgery of the American Medical Association, at the Sixty-first Annual Session, at St. Louis, June, 1910.

fall back. It is difficult or impossible to influence the work of the older members of the profession. Our chief hope for better things lies in more efficient training of the students who are to make up the body of practitioners ten years from to-day.

SOME FAULTS OF PRESENT SURGICAL TEACHING

One great fault of present-day teaching is that too little consideration is given to the relative value of what is taught. In practically all of our medical colleges surgery is taught as if all the graduates were to become surgeons. In much the same way instruction in nose and throat, eye and ear, or in anatomy, is given as if our medical graduates were all to be specialists. Relatively few graduates will actually practice major surgery, yet in several schools the students are taught to perform gastro-enterostomy on animals, in many cases apparently to the neglect of instruction how to treat a carbuncle, felon or lacerated wound, which every graduate, whether a surgeon or a general practitioner, should know how to handle. This is true of many other of the common surgical diseases and injuries, which are more or less neglected while the students are taught the technic of major operations which most of them will never perform. It seems almost unnecessary to insist that medical students should be taught most thoroughly those things which all practitioners should know, whether they specialize in surgery or not. Among these important fundamental topics may be mentioned anesthesia, antiseptics, the arrest of hemorrhage, more thorough training in surgical diagnosis, symptomatology and prognosis, and the treatment of common forms of surgical disease and injury. Such men as are ambitious to specialize in surgery should give themselves the years of training in hospitals and as assistants to experienced surgeons which alone will fit them to undertake major surgery safely.

The clinical teaching of to-day has undoubtedly many advantages over the strictly didactic teaching of former years, but there is still too much teaching at long range. A clinical lecture before an amphitheater full of students too far away really to see anything is not necessarily a better form of teaching than the didactic lecture; the subject is far less likely to be well thought out and to be clearly and systematically presented. In both the general clinic and section teaching there is always the temptation to present the unusual and rare conditions, conditions which interest the teacher, to whom the ordinary disease and injury are commonplace. As a result of this tendency many of our present-day graduates are quite as likely to be better posted on the latest technic of blood-vessel suture or brain surgery than on the diagnosis of appendicitis or gall-stones, to say nothing of the treatment of leg ulcer. And, finally, the value of student acquirement is tested by a written examination in which the man with the glibest gift of language succeeds best, but which is really scarcely a more rational way of testing a student's practical knowledge than it would be to test a tailor's ability to select good material and make a well-fitting suit of clothes by a written examination. As long as the student knows that the chief criterion of his work is to be a written examination he will devote a large part of his time to cramming for such examination at the expense of those facts with regard to diagnosis and treatment which will serve him best in actual practice. Experience of many years in Germany has demonstrated that there are other ways than the written examination of testing the fitness of a student. There, clinical and

laboratory examinations are regularly given, and it is encouraging to note that many of our hospitals and some state boards are beginning to require some such tests.

TOO LITTLE ATTENTION TO TEACHING SURGICAL DIAGNOSIS

Nearly all who are familiar with the situation in modern surgery will admit that a very large number of patients whose best interest demands prompt surgical care fail to get to the surgeon early enough and in many cases not at all. In the acute diseases, especially abdominal and bone diseases, the results to the patient are often disastrous. The blame for this state of affairs lies in large part at the door of our teachers of surgery. The hours which should be spent in teaching surgical diagnosis are given over to clinics which are more useful in demonstrating to the student the skill and boldness of their teacher as an operating surgeon than those subjects which would be really most useful to them in practice.

Hence it comes that many cases of early joint tuberculosis, osteomyelitis, flat-foot and other conditions are treated for rheumatism until the patient's chances for satisfactory recovery are greatly reduced; hence cases of chronic appendicitis, gall-stones, gastric cancer and ulcer are frequently treated for dyspepsia until the favorable time for surgery is past; hence many unnecessary deaths from intestinal obstruction, perforated gastric or intestinal ulcer; hence in many cases chronic ulcers or gall-stones give rise to cancer, or the ulcerated cervix, uterine fibroid or benign breast-tumor undergoes malignant change. The original condition is readily curable; neglected, it too often results in a hopeless situation. These facts regarding malignant degeneration of benign growths and influence of chronic irritation and ulcer in causing cancer have been often reported by reliable observers. We cannot make a skilled diagnostician of every practitioner, but more teaching of surgical diagnosis instead of operative surgery will certainly help.

LABORATORY METHODS IN TEACHING ANTISEPSIS

When, as has sometimes happened in the past, a surgeon gets into trouble with infection, he calls in the bacteriologist to locate the break in technic. We then acknowledge that the laboratory is the final test of our aseptic and antiseptic technic. Why should we not study hand disinfection, sterilization of instruments, sutures and ligatures, dressings and textile materials in the laboratory? For six years such laboratory teaching in antiseptic technic has been given the students of Ithaca division of Cornell University Medical College, and from this practical experience it has been found that such laboratory teaching can be given within a very limited laboratory period, providing the course is well organized. The students are greatly interested in the work and get great benefit from it. When such first-hand teaching of the value of antiseptic methods is common the widely advertised proprietary antiseptics which are claimed to be as powerful germicides as phenol and mercuric chlorid will not have so wide a sale.

In such laboratory teaching the students are assigned several of the more generally used methods of skin disinfection. They smear their fingers with a bouillon culture of bacteria, some using an ordinary vegetative form and some a spore-bearing form. Non-pathogenic bacteria may be used to eliminate any possible danger of infection; for example, *Bacillus subtilis* is a harmless germ to use but very difficult to kill. After rubbing the culture into the skin thoroughly the student proceeds to

scrub as he would for an operation. Two tests of the efficiency of the clean-up are made. First, a piece of sterile string is drawn through the fingers several times, giving about the amount of friction one gets from ordinary handling of instruments and materials. The string is then dropped on an agar slant, and placed in the thermostat, where developments are watched. Second, to ascertain whether the deeper layers of the skin have been disinfected, the superficial epithelium is scraped off with a sterile scalpel and some of the deeper epithelium is put on a culture medium. Before these tests of results are made the excess of antiseptic is washed off with sterile water. Results show that a fairly long and thorough scrub is necessary if complete disinfection is to be obtained, and that there is a decided difference in the value of commonly used methods. To test the thoroughness of disinfection of materials a piece of string saturated with culture is placed in the inside of various pads which are tested in the ordinary steam sterilizer without pressure, the formaldehyd sterilizer, the hot-air sterilizer and the autoclave with superheated steam under pressure. These experiments easily show the students the superiority of superheated steam under pressure and that under ordinary conditions it is about the only reliable and practical agent by which spores in textile materials may be certainly killed.

The disinfection of instruments is tested by grasping a bit of infected string firmly in the jaws of forceps which are tested by boiling, soaking in antiseptic solution and exposure to formaldehyd vapor. It is easy to demonstrate the fact that a few minutes' boiling or soaking in phenol solution will not certainly kill spores and bacteria which may be lodged in some crevice of an instrument. These practical tests of common methods will explain many cases of low-grade infection, phlebitis, embolism and disastrous cases of tetanus which are sometimes considered unexplainable accidents of surgery.

THE TEACHING OF ANESTHESIA

Almost any graduate in medicine, if confronted with the necessity of an operation for himself or one of his family, would consider the choice of an anesthetist next in importance to the choice of his surgeon. Not only the safety but the comfort of the patient is greatly concerned. Practically every graduate has sooner or later to give a general anesthetic, yet students in many schools are still graduated without any practical instruction in the administration of anesthesia.

Three kinds of instruction seem to me highly important in general anesthesia: first, class-room instruction; second, laboratory demonstration, or, better still, individual laboratory work for each student to determine definitely the effect of the more generally used anesthetics on circulation, respiration and, if possible, also on the kidneys. A student who has followed carefully the heart's action on a smoked drum with ether and with chloroform will have no question as to the relative heart depressant effect of these two most commonly used anesthetics. Regular charting of the blood-pressure curve is also valuable, although not nearly so striking as the effect on the heart itself. Such instruction has been given in the laboratory of physiology and pharmacology at the Ithaca division of Cornell University Medical College for several years, and it cannot fail to have a great influence in deciding the intelligent student as to his choice of an anesthetic.

A third and more important matter is instruction in the practical administration of anesthesia. This may be readily managed in such a way as not to prejudice the chances of the patient. Any surgeon who has enough operative experience to fit him to teach at all should be able from his own clinical material to give his students at least a limited practical experience in general anesthesia. I am accustomed to detail each student of my class in turn to go with the anesthetist during one or more general anesthetics. The student is instructed about the amount of anesthetic to use, indications for more or less anesthesia, how to hold the jaw, protect the eyes, look for false teeth and many other details which experienced anesthetists always keep in mind. After observation of the anesthetist and practical instruction in one or more cases the student is allowed to give the anesthetic himself, always under the direction of an experienced anesthetist. Some students give twelve or fifteen anesthetics and become fairly proficient. Practically all of them are impressed with the importance of the subject and become familiar with a few, at least, of the principles. All are certainly much better equipped to give a general anesthetic than they would be if the subject of anesthesia was entirely neglected in the class-room and no practical instruction given, as was the case when many of us graduated in medicine. The laboratory work, together with thorough discussion of the subject in class, adds much to the value of the practical instruction in the operating room. The student has thought about the matter before, knows what to look for, what to observe and gets much more out of a few carefully supervised anesthetics than he would from many times the number given haphazard without any previous thought on the subject.

USE OF CURRENT LITERATURE RATHER THAN EXCLUSIVE USE OF TEXT-BOOKS

The progress of medical men after graduation is influenced greatly by the journals and books which they read and the way in which this reading is done. The average text-book is fully five years behind in many important topics. Considering the great value of systematic reading of journals, it seems worth while to try to stimulate students to do independent reading, to select the valuable from the worthless and to economize time in getting over the vast literature which is appearing to-day. With this object of teaching students better to use surgical literature, during the past five years I have in certain subjects assigned articles in current journals rather than in text-books. As an example, in studying the subject of general anesthesia the students have been assigned articles dealing with the effects of general anesthetics on the heart, the kidneys, articles reporting large series of spinal anesthetics, ethyl chlorid and nitrous-oxid anesthetics, local anesthetics, etc. Each student has to make a short written abstract which can be read in five minutes. Several of these abstracts are read, criticized and commented on in class at a kind of conference. With a few suggestions on the selection of the important from the unimportant in medical reading, it is surprising how well the average student will succeed in getting the meat from a journal article. Many of the abstracts compare very favorably with the abstracts appearing in most of our medical journals. Each student gets a good deal of definite knowledge about one of the subjects, and in the class discussion he hears the latest ideas, culled by other students from other articles. In this way the entire sub-

ject can be covered by abstracts taking up various phases of the question and the students are invariably much more interested than in text-book recitation work, and they get the latest knowledge. They also become familiar with some of the best journals and know where to look for reliable information when they are thrown on their own resources. Very much of the progress of most practitioners depends on their ability to use surgical literature efficiently, and without much systematic, effective reading, very few men keep abreast of modern methods. It requires a little additional thought and good judgment on the part of the teacher to select and assign references for the subject under discussion, but it is surprising how easily possible it is to get together a student symposium on almost any surgical topic from the current literature if one has this method of teaching in mind. A difficulty is too much good material to assign rather than too little.

Thus far I have spoken chiefly of the faults of present methods of teaching and of a few methods which seem better adapted for instruction than those now in general use. Far more important than methods of teaching is the quality and previous preparation of the students who are to be taught, the qualifications and the abilities of their teacher and the facilities for work. With regard to the student himself and his preliminary preparation for medical study, I believe that few if any teachers in universities requiring a college degree as a preliminary to medical study would feel satisfied to go back to teach high-school graduates. It is true that the higher entrance requirement shuts out some worthy men, but there will always be plenty of schools that will offer these men as good facilities for work as they can profit by. If the secondary schools would rearrange their curriculum and select only those subjects necessary for college entrance it would be possible for students to take the preliminary degree at 21 without any difficulty, and this is really about as early as a man can profitably begin the study of medicine. With such an arrangement a student would take practically all of his science work in a college, where facilities for teaching are far better than in any except in a few of the best preparatory schools.

The ideal medical school should be a department of a well-established university, for the universities are in a position to uphold the higher standard of education. In too many cases the university only lends its name and has no influence in appointment of teachers, in methods or standards of work, maintenance of the indispensable laboratories and clinics or financial support for expensive teaching. The financial rewards of surgical practice are great enough so that special effort is necessary to get men who will devote sufficient time, thought and effort to teaching. Conditions in engineering and law are similar, but have universities not done much more for these than for surgery and the practical branches in medicine? Even some of our best universities at present are obliged to choose their professors because of their affiliation with some large hospital which supplies clinical material. The university clinic should be independent of outside influences and the university should be free to choose as professors any man of ability, regardless of hospital connection. A university surgical clinic used for the joint purposes of relieving the sick, teaching, and investigating important problems, is as necessary a part of the equipment of a university as the laboratory of chemistry or of anatomy. In selecting teachers of surgery, teaching ability as well as operative skill should be considered. In

some cases the professor of surgery is appointed because of hospital connection, and the hospital connection comes as a result of political, financial, social or even religious influences. Such factors should not figure to any extent in appointments. The professional and teaching ability and high character of the man should be the test. The university medical college can best maintain the necessary high standard for entrance and solid requirements for work during the course and for graduation.

While there are many teachers among us who are devoting much thought and effort to their teaching and accomplishing great results, there is probably no subject in the medical curriculum more poorly taught than surgery. This is easily understood when we remember that a majority of teachers in surgery devote nine-tenths of their thought and effort to the practice of their profession and one-tenth to teaching. Practically all teachers are inadequately paid considering the compensation which a surgeon can earn in the actual practice of his profession. Not all successful practitioners are good teachers. A certain amount of practice in teaching is important to successful teaching, and the man who is ambitious to teach might well begin in a subordinate position early. Men of scholarly tastes and good ability who are willing to make some sacrifice should be given the preference, but they should be sufficiently well paid so that they can afford to devote a reasonable amount of effort to actual teaching. Ability to present a subject clearly and systematically is to a great degree born with the man, and born teachers should be sought for and promoted in this country as they are to-day in Germany.

The general public is really most concerned of all in the efficient teaching of surgery. The field of surgical intervention is widening every year. In the future more than in the past the health, happiness, efficiency and even the lives of a large number of people in every community will depend on the judgment and skill of the surgeons of their community. When the public realizes this more fully, support of our medical colleges and research laboratories will be much more liberal than it has been in the past. All the profession are also concerned, not only for the welfare of ourselves and our families, but for the honor and prestige of our profession. The student is concerned, for on the efficiency of his instruction depends much of his success in earning a livelihood. Our universities are concerned, for the progressive work of their teachers will spread their name and fame to the community. Those at the head of educational affairs in our universities have accomplished great things in the past and much will depend on their interest and effort whether they progress as rapidly in the future. The whole medical profession must work for better methods of teaching in surgery as well as in other subjects. The Medical Council of the Association has done splendid work during the past few years, and we may look for a great deal from their effort in the years to come.

CONCLUSIONS

To recapitulate some of the methods and conditions which seem likely to promote ideal teaching: Emphasis should be laid on the principles and methods rather than on a mass of disconnected facts presented without coordination. Thorough study of a few essential subjects is much to be preferred to a superficial covering of much ground. Antisepsis and arrest of hemorrhage may well be taught by practical work in the laboratory and operating room as well as in the class room. Anesthesia

should also be taught in the laboratory and operating room as well as in the class room. Practical and laboratory tests should be given when possible, instead of written and oral examinations. Current literature can be profitably used in some cases instead of exclusive text-book instruction. University connection and standards of work are desirable. The university should control its independent hospital, where students will have an opportunity to study important surgical diseases and injuries throughout the entire course of the cases. Surgical diagnosis should be given more attention than major operative surgery. The public should be trained to appreciate the importance of sound medical and surgical teaching and urged to supply sufficient funds so that our universities and clinics can be well equipped and supported. Surgical teaching should be paid liberally enough so that a professor can afford to limit his practice and devote the necessary time to well organized, systematic teaching without too great sacrifice. Many of these ideals are practical and realized or being realized in some schools. Other conditions demand earnest and united effort of the whole profession if we are to advance in future as in the past.

ABSTRACT OF DISCUSSION

DR. J. CLARK STEWART, Minneapolis: We have certainly come to the parting of the ways in surgical teaching, and both standards and methods of teaching need revision. All physicians are familiar with the readiness of recent medical graduates to rush in and do major surgery, their first attempts at abdominal operations being saved from fatal results by the grace of God and access to a clean operating-room. These operations preserve the life of the patient, but how little benefit is often obtained in the absence of careful diagnosis and knowledge of the conditions exposed! Our older methods of clinical teaching, by which the teacher, depending for his remuneration entirely on the glory attained among his students, presented to them only the most showy and unusual operations, together with the general exaltation by the profession of technical skill over pathologic knowledge, is largely responsible for this attitude. All this must be changed. Pathology and diagnosis must be taught, and the operative clinic must be minimized. Clinical teachers must be paid for their time, and must teach students surgical diagnosis at the bedside and in the amphitheater. Each school should have its own hospital, where extern work can be done by all advanced students, and the operations before the class should be restricted, so far as possible, to the cases carefully studied by the students. Clinical examinations, where students actually diagnose surgical conditions, are most important tests of student knowledge.

The need of improvement in surgical qualifications is a crying one, and well understood by the laity, who are becoming restive under the indiscriminate operations of the profession. In Colorado recently this feeling culminated in a bill to restrict the practice of surgery to the licensees of a state board appointed by the governor. This bill, fortunately, was defeated, for although the end desired was worthy, the means assigned needed much improvement. Such legislation is likely to be advanced in other localities in the near future, and the profession must be prepared to meet the demand for better and more responsible surgeons. In Minnesota we are going to anticipate such popular demand by offering an advanced degree in surgery, master in surgery, open to graduates of reputable schools of five years' standing, including one year's satisfactory hospital service and based on the results of one year's work in surgery done in residence in the University of Minnesota. We think this degree will be popular and that enough of our younger surgeons will avail themselves of it to form a nucleus of high standard men to whom the public will look when they ask for higher surgical qualifications.

DR. L. J. HIRSCHMAN, Detroit: The trouble has been that the faculty of the average medical college has consisted largely of general surgeons, so that the students have received a lopsided education in surgery. Then they are turned out to be abdominal surgeons. How many students are taught how to treat a simple case of hemorrhoids or to enucleate a tonsil, which everybody is called upon to do? There has been too much spectacular amphitheater teaching and too little real teaching. State boards must require a more rounded-out education than they now do. The Association of American Medical Colleges mentions in its curriculum twenty-seven different subjects; diseases of the rectum and anus are not included in the list, but are supposed to be taught under general surgery, though as a rule they are not. There is no subject which is so important and which is such a fruitful source of income for the advertising quack.

COMPRESSION OF THE SPINAL CORD CAUSING PARAPLEGIA

AND ITS SURGICAL TREATMENT *

A. PRIMROSE, M.B., C.M. (EDIN.), M.R.C.S. (ENG.)

Surgeon to the Toronto General Hospital; Associate Professor of
Clinical Surgery in the University of Toronto

TORONTO, CAN.

The conditions which demand surgical interference in paraplegia due to compression of the spinal cord are by no means clearly defined. There are two chief reasons for this: first, the difficulty in diagnosing accurately the cause of the paraplegia; and second, the difficulty of distinguishing between cause and effect when we attempt to determine the results attained by our surgical interference. When a cure results after operation it is often impossible to make sure that recovery would not have ensued had Nature been left unaided to pursue her course. Nevertheless, it is obvious that certain cases are definitely improved by surgical interference, and not infrequently it holds out the only hope of relief. In attempting to define the indications for operation I have made a study of fourteen cases which have come under my care.

Hemorrhage within the neural canal may be the cause of the compression. This may be extradural from rupture of the spinal veins, or subdural; or it may be into the substance of the cord. When an interval of time elapses between the infliction of the injury and the occurrence of the paralysis the possibility of the compression being caused by extravasated blood must be borne in mind. This point is illustrated in the following cases:

CASE 1.—A man fell from a height of 16 feet to the ground, he got up, picked up his hat, which had fallen off, and used both hands to put it on his head. He said that he was not hurt and walked four or five yards to his house where he lay down on the sofa. Five or six minutes afterward he observed a numb sensation in his arms and hands and he rapidly became completely paraplegic below the sixth cervical spinal segment. Operation was refused and the man died six months after the injury without improvement.

CASE 2.—A man, aged 35, fell off the top of a lumber-pile 8 feet to the ground. He got up with the help of two men and having his arm over the shoulder of each he walked to his house 50 yards distant, being able, though weak, to move one foot in front of the other. Within an hour he became completely paralyzed below the seventh cervical spinal segment. He died a year afterward without any

* Read in the Section on Surgery of the American Medical Association, at the Sixty-first Annual Session, at St. Louis, June, 1910.

material improvement in his condition. On autopsy a transverse fracture of the sixth cervical body was found without forward dislocation, the anterior posterior diameter of the neural canal was narrowed to one half its normal width. Unfortunately no examination of the cord was made.

It may be impossible to determine whether the hemorrhage is extradural or beneath the meninges. Severe pain may indicate pressure on the nerve-roots, where considerable hemorrhage has occurred, either within the dura or outside of it. On the other hand, hemorrhage into the cord is more likely to give definite and isolated tract lesions, so that we may have such conditions as "crossed paralysis," etc. Then, again, hemorrhage may be confused with the effects of congestion at the seat of injury. The results of hemorrhage are likely to manifest themselves at an early date, often within a few minutes after the injury, while the paralysis due to congestion may be deferred for twenty-four hours or more.

Where there are symptoms pointing to hemorrhage outside the cord causing paralysis, it is, I believe, the better plan to operate at an early date and not to delay with the hope that absorption of the clot may take place. The fact is that absorption may not occur and valuable time may pass during which operation might have been of service. This was illustrated in the following case:

CASE 3.—A lad 10 years of age was accidentally shot in the neck. The bullet (22 caliber) was extracted above the right shoulder-blade. The patient was immediately paralyzed below the eighth cervical spinal segment. Four months and a half subsequently laminectomy revealed dense connective tissue surrounding the dura, due possibly to a perithecal inflammation, or, more likely, an old hemorrhage with organized blood-clot. The dura beneath appeared quite normal. No improvement followed the operation. It is now nine and a half years since the injury, and the lad is still alive in the Home for Incurables, Toronto.

It is obvious from this case that surgeons are wrong in teaching that bullet-wounds producing cord lesions should be left without operation.

Individuals who are subjected to severe injury to the spine and the cord may succumb to the initial shock, death usually taking place within a few days of the accident. This is illustrated by the two following cases:

CASE 4.—A man aged 30 was admitted to hospital. Four hours previously he had fallen 12 feet and been struck by a plank as he fell. He became immediately paralyzed below the seventh cervical segment. The patient died within a week of the injury, never having recovered from the shock.

CASE 5.—The patient was a laborer aged 30, on whose back a brick chimney fell from a height of 10 feet. Complete motor and sensory paralysis below the level of the eighth dorsal segment occurred immediately. On admission the patient was in a state of complete collapse from which he rallied somewhat but died on the third day. Autopsy revealed a fracture dislocation at the level of the sixth and seventh dorsal vertebrae.

Acute flexion of the cervical spine producing stretching of the cord with hemorrhage into its substance is noted in one of my cases.

CASE 6.—A lad, 14 years of age, was standing in a shed when the roof fell and pinned him down with his neck flexed acutely forward. He was rendered unconscious for a time, but, on being released, found that he had lost the power to move the right leg and both arms and all sensation in both arms and legs. Twenty minutes after the accident sensation began to return, but voluntary control of the muscles was only gradually restored. In the course of a few weeks, however, the patient was able to walk fairly well. Twelve weeks after the accident his medical attendant is said to have operated for the purpose of removing a piece

of bone which was pressing on the spinal cord. The immediate result of the operation was completely to abolish motion and sensation in the upper and lower extremities. Subsequently this was restored to a limited extent but the condition did not change much for twelve months; then the patient came under my observation. There was then extreme wasting of the muscles of the upper extremities, but the loss of motor power was not absolute. There was almost complete paralysis of the trunk muscles and those of the lower extremities, but there was no impairment of sensation, and the bladder and rectum were under voluntary control. There had obviously been destruction of the anterior horn of gray matter of the brachial enlargement below the sixth cervical segment with damage to the motor conducting paths. The sensory conducting paths had evidently escaped injury. The patient died unimproved of pneumonia five years after the accident.

Early operation for the relief of compression after fracture is occasionally instrumental in restoring function, notably in those cases in which the compression is caused by fragments of the neural arch which have been driven forward into the neural canal.

CASE 7.—A man, aged 37, was struck on the top of the head and knocked over on his back. Paralysis below the fourth lumbar segment immediately ensued. At operation, which I performed, fifteen days after the accident, the neural arch of the third lumbar vertebra was found to have caused a rent in the dura mater; it was depressed on the cauda equina. The lamina of the second lumbar vertebra was also fractured and depressed and there was a small quantity of blood-clot in the neural canal. Sensation was restored and motor power gradually improved. By the end of the third month the patient had complete control of the bladder and rectum. At the end of the year he could walk with very slight assistance and complete recovery seems probable.

The benefit of operation in such cases is also illustrated in the following case:

CASE 8.—A lad, aged 16, was hit on the back by a falling tree and immediately lost sensation and motor power below the first lumbar segment. Laminectomy was performed on the thirty-second day after the accident. The laminae of the twelfth dorsal and first lumbar vertebrae were fractured and the superior articular process of the first lumbar was also fractured. These fragments of bone were driven into the neural canal, and there was a rent 1 cm. long in the dura mater. Two days after the operation sensation began to improve, and one month thereafter some restoration of motor power was noticeable. Gradual improvement took place. It is now two years and eight months since the operation and the patient is able to stand with slight support but he cannot walk alone. He has, however, complete control of the organic reflexes, giving him control over the bladder and rectum, and this fact alone would be sufficient to warrant operative interference, if, indeed, in this case the restored function is to be attributed to the surgical measures employed.

It is quite impossible to determine with absolute certainty that the spinal cord is completely severed. Undoubtedly the most reliable sign of a complete transverse severance of the cord above the lumbar enlargement is the complete and permanent abolition of the knee-jerks and ankle-clonus; but valuable time is lost if we wait for this test in traumatic cases. One must urge that in the light of experience we should operate early where doubt exists. The following is an instance in which, unfortunately, the damage to the cord was irreparable:

CASE 9.—A man, aged 40, fell 8 feet and injured his spine. Doubt existed as to the amount of damage to the cord. There was complete paralysis of sensation and motion below the tenth dorsal segment. Three days subsequently laminectomy was performed. The left inferior articular process of the ninth vertebra, along with a

portion of the neural arch, had been driven in on the cord, which was completely severed and pulpified, the two ends being separated nearly 2 cm. The wound healed by a primary union, but the patient died suddenly 25 days after the operation from pulmonary embolism, which at autopsy was found to have originated in the prostatic venous plexus, the thrombosis there having possibly been induced by the frequent use of the catheter.

Passing now from traumatic lesions of the spinal cord, I shall refer briefly to compression paraplegia the result of disease. The most common condition here is that encountered during the progress of spinal caries. The cause of the compression may be thickening of the dura (pachymeningitis), a collection of caseous material in the neural canal, or the pressure of an abscess. A tuberculoma may exist in the interior of the spinal cord, as in a case reported by Kraus and McGuire.

Paraplegia in Pott's disease is frequently amenable to less severe measures than laminectomy. Many patients may be cured by rest with extension, but occasionally operative interference is necessary, and it certainly is so in cases in which abscess is the cause of the trouble.

In the two following cases, in which I operated, I found an abscess invading the neural canal from in front and pressing on the spinal cord:

CASE 10.—A man, 60 years of age, with compression paraplegia more or less complete and due to spinal caries, the symptoms having existed for two years, was subjected to laminectomy. The sixth, seventh, and eighth dorsal laminae were removed. The cord was compressed by an abscess which had invaded the neural canal in front of the dura. The man died, forty-one days after the operation of tuberculous meningitis. The autopsy showed a sterile condition of the mediastinal abscesses, which contained no longer fluid, but a mass of caseous material which had replaced the pus.

CASE 11.—The patient was a child 6 years of age with paraplegia from Pott's disease existing for eighteen months prior to operation. Pus was found in the neural canal at the level of the fifth dorsal vertebra. The wound healed completely, but the child was unimproved and died eighteen months after the operation. Unfortunately no autopsy was obtainable.

The lesson I have learned from these two cases is that operation for the relief of paraplegia in Pott's disease should not be deferred too long. I did not have an opportunity of operating at an earlier period, but I am sure that the chances of success are diminished when operation is postponed beyond a reasonable time. I should urge that if paraplegia is not relieved after treatment by extension applied for, say, three months, then laminectomy should be done unless contra-indicated by the general condition of the patient.

It is obvious that in many instances, notably in tumors, valuable time is lost while medicinal measures are persisted in. Meanwhile the cord is damaged beyond repair, and operation is undertaken too late to effect a cure or again a malignant growth may have advanced so far that radical removal is impossible.

My point is illustrated by the following case, in which a tumor pressing on the spinal cord produced paraplegia, but operation was not undertaken until it was too late to eradicate the growth:

CASE 12.—A man 52 years of age with symptoms of impaired sensation and motion below the seventh dorsal segment was treated assiduously by drugs for some two years when laminectomy was performed, and a sarcomatous growth revealed, which was pressing on the spinal cord at the level of the fifth dorsal vertebra. Subsequent to operation a certain amount of motor power returned but pressure symptoms recurred and the patient died eleven months after operation.

At autopsy extensive recurrence of the growth was demonstrated.

Similarly, in the following case, operation was undertaken too late:

CASE 13.—A girl, 19 years of age, for eight months prior to admission, had had progressive weakness of the lower extremities with a dull pain over the sacral region and extending down the thighs, and finally loss of the organic reflexes. Distribution of the areas of disturbed sensation was symmetrical on the two limbs and indicated a lesion involving the spinal cord below the third lumbar segment. Laminectomy was performed, and a soft gelatinous material was found lying on the dura. This was removed. The patient subsequently improved to a marked but limited extent with restoration of sensation and voluntary motor power, also some control over the bladder and rectum. After the lapse of two months she again began to lose ground. Five months subsequently a tumor under the left iliolumbar muscle proved to be a round-celled sarcoma. The patient is still alive, seven months after the first operation, but rapidly going down hill.

The following case illustrates the impossibility of determining the existence of a tumor pressing on the cord. Operation was clearly indicated and in such cases should always be carried out early, before the cord is damaged beyond repair.

CASE 14.—A man, 30 years of age, complained of pain and stiffness in the back of the neck, extending down the limbs, with great weakness in the legs. These symptoms have gradually developed for a period of two years. Immediately prior to operation the paralysis was almost complete below the level of the fourth cervical segment and a laminectomy was performed, removing the fifth, sixth, and seventh cervical arches, when a vascular membrane was found on the surface of the dura and was removed. Three days after the operation, sensation began to improve and there was a gradual return of motor power, so that in the course of two months the patient had made an almost complete recovery and has now for more than a year been able to work continuously as a laborer. Dr. Goldie and I have elsewhere reported the case as one of cervical hypertrophic pachymeningitis in which it was impossible to determine prior to operation whether or not a tumor was present. It is of interest to observe that the removal of a very small mass of tissue seemed to produce very definite improvement.

The question of the advisability of seeking relief by operative procedure in compression paraplegia is by no means one in which there is unanimity of opinion among the profession. One may say that in studying the series of fourteen cases presented in this paper one may come to certain conclusions which seem justifiable. We may dismiss at once the cases in which paralysis occurs as the result of compression in Pott's disease. Undoubtedly the patients should be submitted to operation when one fails to effect a cure by efficient rest and extension. The brilliant results obtained by operation in many instances is illustrated by a paper recently published by Mr. Donald Armour,² in which he records the history of a patient in whom a large abscess surrounded the cord and implicated the laminae and bodies of the third and fourth cervical vertebrae. The abscess was opened, curetted and closed without drainage and healed by first intention. After four and a half months the patient was able to walk without assistance.

Similarly it is obvious that if a new growth is the cause of the compression the tumor should be removed

when that is feasible. The consensus of opinion at present would suggest that even when the growth is a syphilitic gumma operation for its removal is a wiser course than an attempt to cause its disappearance by the administration of drugs.

Pearce Bailey³ quotes Stursberg to the effect that the percentage of cures in operation for tumor of the spinal cord is 32.2 per cent., but it is obvious that hitherto surgical interference has been delayed far too long in the majority of instances. The operation of laminectomy carefully carried out is not a dangerous procedure. I have not failed to get sound union in all the cases in which I have operated and there has been no operative mortality. Moreover, the stability of the spinal column is not appreciably interfered with by laminectomy.

Horsley,⁴ reporting twenty-one cases, describes the condition of chronic spinal meningitis in which the symptoms simulate tumor and which is relieved by opening the theca and washing out with strong mercurial lotion. In his cases there was excess of cerebrospinal fluid under pressure. Bliss⁵ describes a somewhat similar condition as "cysts within the spinal canal" and Spiller has recorded a case of like nature.

Paraplegia the result of traumatism presents a more difficult problem. Allen⁶ of Philadelphia published the history of nine cases with post-mortem findings. His observations lead one to conclude that regeneration of the cord after complete transverse lesion is impossible, and this view is maintained by Spiller,⁷ Murphy⁸ and others.

Murphy records the results of experiments on dogs by various investigators and shows that in complete transverse section in these animals there is no restoration of function.

In the human cord restoration of function after division has not been demonstrated. It is true that there are some cases on record which would inspire the hope that regeneration of the cord might be possible after division.

Shirres⁹ and Armstrong attempted to secure regeneration in a severed cord in man by placing a segment, 3 inches long, of the spinal cord of a large dog alongside the severed ends of the spinal human cord. The patient unfortunately died of a large abscess in the kidney three and a half months after operation. Up to that time there had been some subjective sensations in the lower extremities and in the lower abdomen, and a certain amount of tone was observed in the muscles of the right thigh and leg. At autopsy the dura and tissue at the site of the grafting experiment showed a mass of minute myeline sheaths of nerve fiber, which lay closely adherent to the dura mater, and when traced upward and downward united with the segments of the cord above and below.

A case is recorded by Harte and Stewart¹⁰ of bullet wound in the mid-dorsal region in which the severed cord was sutured with partial restoration of function; and the report of a somewhat similar case with partial success is published by G. R. Fowler.¹¹ In such instances, however, one must entertain the suggestion that the severance of all conducting paths of the cord was not complete. Moreover, in operating on the injured cord it is not always easy to determine the exact amount of damage; the careful operator is willing to leave the cord undisturbed when all pressure is relieved, knowing full well that very slight manipulation of it may do further irreparable damage. Solieri reports a case most favorable for successful results after suture if such were attainable. It is that of a clean severance of the cord at the third dorsal segment by a long knife. Suture sixteen hours after injury was performed, but with negative results as to restoration of function.

It seems an undoubted fact that regeneration of the severed cord is impossible. Repair of nerve fibers ceases where the primitive sheath ends; the latter seems necessary for regeneration, and hence the fact that we have restoration of function in severance of peripheral nerves but the absence of such restoration in severance of the cord.

Kilvington¹² of Melbourne suggests the feasibility of nerve-crossing in the neural canal in cases of severed cord, and he has had most encouraging results in experiments on dogs by suturing the central end of one of the limb nerves to the peripheral ends of the nerve supply to the bladder and rectum. If it is possible by such means to restore control over the bladder and rectum it would indeed greatly diminish the misery of many unfortunates. He finds on the human cadaver that it is possible to unite the eleventh and twelfth dorsal, and possibly the tenth dorsal, directly to the second, third and fourth sacral nerves. The operation would necessarily be severe, and of course there would always be a danger of making matters worse by such operative measures.

Spiller concludes from his experiences that in most cases operation may do harm. He is not prepared to assume, however, that operation should not be performed in any case of fracture. We have undoubtedly learned that our gross manipulation of the spinal cord in operation may do a great deal of harm, but surely there is a possibility of guarding against this, at least to a great extent, and in our technic we should be extremely careful not to do damage. It is possible, for example, to remove depressed fragments of bone without any appreciable disturbance of the cord, and to remove a blood-clot which may be causing pressure. One cannot but be convinced that many such patients are benefited by operation, and without doubt the chances of success are greatly enhanced if the operation is done early. Doubt often exists as to the cause of the compression. After studying 244 cases of fracture of the spine occurring over a considerable period of years in the Boston City Hospital, Burrell concludes that in many instances it is impossible to ascertain, except by open operation, whether the cord is crushed or pressed on by bone, blood or

exudate; he further emphasizes the fact that if pressure on the cord is allowed to remain for many hours irreparable damage may take place. I agree with Carson¹³ that unless it is perfectly clear that the cord is immediately damaged an open operation should be done to determine the condition present and to relieve pressure where that is found possible.

It has been demonstrated by several observers, *e. g.*, Allen,¹⁴ Holmes¹⁵ and others that the spinal cord may show very little alteration even on microscopic study and yet in reality may have ceased to be a conducting mechanism. May we not assume that such conditions may result from traumatism and that if so the continuance of conditions which might be relieved by operation may permanently destroy function? On this ground early operative interference is urged in traumatic cases wherever the element of doubt as to the cause of the paraplegia exists.

TRAUMATIC FACIAL PARALYSIS

ANASTOMOSIS OF FACIAL NERVE TO SPINAL ACCESSORY, AND THE PERIPHERAL END OF ACCESSORY TO THE DESCENDENS HYPOGLOSSI*

W. W. GRANT, M.D.
DENVER

In nerve anastomosis, surgeons recognize the desirability of maintaining, by substitution where possible, the functions of all important muscles.

In paralysis of the face, no matter whether the spinal accessory or the hypoglossal nerve is used, paralysis of the trapezius and sternomastoid, or of the tongue, has been a necessary result, substituting a lesser for a greater evil. If this can be avoided by a more elaborate operative anastomotic procedure, it is a consummation most earnestly to be desired. The following case gives hope of a more promising future. I believe the complete operation in the cure of facial paralysis has not heretofore been done, and, for this reason, I have embodied considerable detail in the technic and clinical history.

Patient.—W. P. B., of Evanston, Ill., aged 26, while in his room at night on Sept. 15, 1908, received a pistol wound, .32 caliber, through his right ear, resulting in considerable hemorrhage and shock, and immediate paralysis of the right side of the face, with complete loss of hearing on the same side. He was confined to bed for two or three weeks, at the end of which time the wounds were healed. There was no evidence in the clinical history that the bullet had entered the brain. Four months and one week after the injury, the patient and his mother came to Denver to consult me as to the possibility of relieving the facial paralysis.

Examination.—This showed a scar at tip of mastoid where the bullet entered. The auditory canal was completely obliterated by bone. The tuning-fork was negative as to hearing; the right face completely paralyzed from the frontalis muscle to the mouth, with the usual facial asymmetry, the right side drooping and heavy from fatty degeneration. The right eye was a source of great discomfort from inability to close it and

from profuse lacerimation. A radiograph previously taken showed the bullet lodged on the floor of the middle fossa in front of the ear. A second one (Fig. 1) taken by Dr. S. B. Childs of Denver showed the course of the bullet through the petrous portion of the temporal bone, leaving fragments of lead in its course and lodging in the middle fossa. From this, and the fact that there was no disturbance of taste, the conclusion was reached that the course of the bullet was forward and upward and cut the facial nerve in the space between the chorda tympani and the stylo-mastoid foramen. The chorda tympani leaves the facial at the lower part of the Fallopian duct where it turns downward, and quits the tympanic cavity just inside of the Glaserian fissure, finally joining the lingual nerve and ending in the anterior part of the tongue. There was no evidence of its being seriously injured. If the facial nerve was severed by the bullet after leaving the foramen, it would complicate the operation and make it difficult to find the stump.

Experiment.—I concluded to use the spinal accessory for the anastomosis; but before performing the operation, I desired to ascertain if it was practicable to make anastomosis of the peripheral end of either the spinal accessory or the hypoglossal, to a convenient motor nerve. With this purpose in view, and by the courtesy of Dr. S. B. Childs and Dr. G. A. Staunton of the Medical Department of the University of Denver, I was given the privileges of the dissecting-room, and with their assistance, dissected the necks of three cadavers, using the accessory and the hypoglossal as the base of operations. The result was the selection and use of the spinal accessory and descendens hypoglossi in the complete operation. It was first performed on the cadaver. The descendens hypoglossi, usually called a branch of the hypoglossal, arises from the first and second cervical nerves, and beneath the base of the skull joins the hypoglossal and accompanies it in the same sheath to the posterior belly of the digastric muscle where they part company. The descendens hypoglossi is distributed to the depressor muscles of the hyoid bone. Below the point of section, it forms a loop with communicating branches from the second and third cervical, which go to the above muscles. No perceptible paralysis of the muscles resulted.

Operation.—The patient was sent to St. Luke's Hospital, where, on Jan. 26, 1909, assisted by Drs. Childs and Staunton, I performed the operation now described. An incision was made through skin and fascia three inches long from just above the tip of the mastoid process down the neck in front of the sternomastoid muscle; then a crescentic incision from the upper angle of the wound beneath the lobe of the ear and terminating in front at the middle of the tragus (the Kocher incision). From this stage, the dissection was continued, chiefly, with the conical handle of a scalpel and blunt scissors. The posterior border of the parotid gland was gently elevated and pushed forward. The ear was pulled upward and working gradually downward and inward in the narrow space between the mastoid process and the ramus of the jaw, the facial nerve was exposed where it enters the gland. To identify it, it was traced to its first bifurcation, in the gland, into the temporo-facial and the cervicofacial branches. The upper or temporo-facial seemed softer and more fragile than the larger or cervicofacial branch. The nerve was now traced and isolated to the stylomastoid foramen; and for convenience in the further progress of the operation, it was not now cut but a large silk loop put around it. The spinal accessory was now found and traced to its entrance into the fascia of the sternomastoid, which is about opposite the angle of the inferior maxilla on a straight line. A silk loop was put around it. The hypoglossal was next exposed. This nerve turns forward and crosses the occipital and external carotid arteries about the central tendon of the digastric muscle. It lies on the hyoglossus muscle and at this point the digastric was cut, posterior to the tendon, and the ends turned out of the way. The descendens leaves the hypoglossal at this point and goes down the neck on the great carotid sheath. A silk loop was put around it. With long, slender, probe-pointed scissors the facial was now severed at the stylomastoid foramen and the stump pulled outward. The accessory was now pulled upward by the silk thread, in order to estimate accurately the place of division, that no tension should exist after union; and for the same reason the patient's

head was turned, at this juncture, decidedly to the left. The nerve was severed just before its entrance into the sternomastoid muscle, and with the aid of my assistant in holding the ends of the nerves squarely together, I applied the finest linen stitch with a delicate round, curved needle at each side, including probably some of the nerve fibers, and tied them only moderately tight. A third stitch was applied on the inner surface through the neurilemma only. The object of this stitch was chiefly to secure more certainly apposition of the nerve ends against tension. To prevent strangulation from excessive connective tissue proliferation, the sutured ends were enveloped in Cargile membrane. The descendens hypoglossi was severed fully three-quarters of an inch below the bifurcation of the hypoglossal, turned upward and stitched to the peripheral stump of the spinal accessory with the same technic as with the facial. The digastric muscle was reunited with chromicized gut. Not a single vessel was ligated. The original drawing (Fig. 2) made for me by Mr. Frederick Cavallo of Denver, shows correctly the complete anastomosis of the nerves and their relation to the parotid gland and the sternomastoid muscle. The wound was wiped out gently with warm salt solution; the parotid was pressed gently down; the fascia united with a running stitch of No. 1 chromicized catgut, and the skin with subcuticular silkworm-gut. At the upper angle of the wound, the skin stitch was carried once completely through the skin and then continued around the ear as a subcuticular. This

Fig. 1.—Skiagraph taken Jan. 12, 1909, showing lateral view of the head of W. B. with right side next the plate. Spectacles *in situ*. The arrow points to the shadow of a bullet lying in the middle fossa of the skull. The finger indicates the point of entrance of the bullet just in front of the tip of the mastoid process and also the shadows of numerous small pieces of lead which have been chipped off the bullet in its course through the petrous portion of the temporal bone.

technic, in an uneven or long wound, greatly facilitates the removal of the stitch by clipping the loop. The neck was dressed with sterile gauze and bandage. No fixed dressing was applied to head and neck, and the patient was instructed not to turn his head to the left, but if he should inadvertently do so, no harm would result as the nerves were given plenty of slack.

The last complete operation on the cadaver was done in half an hour. On the living subject, two and a half hours were consumed. The anesthetic (ether) was administered skilfully by Dr. Karl Roehrig, and there was neither nausea nor the slightest shock.

Postoperative History.—The patient's two weeks' stay in the hospital was uneventful. The stitch was removed on the tenth day. There was no infection and union was perfect through out. In a week more, the patient left for home in good condition and cheerful in the promise of a good result. He was carefully instructed to use the constant, or galvanic, current five to ten minutes daily, with gentle massage to face, neck and shoulder. As soon as the muscles responded to the faradic current, it was substituted for the constant. This was not manifest until the expiration of three and one-half months.

These important measures were not carried out properly and systematically the first two months, but were afterward. At the end of fifteen weeks, patient noticed feeble, associated movements of shoulder and face. At end of four months, he could voluntarily contract the muscles slightly at the corner of the mouth. I saw him at this time and observed it. A week later, I saw him again and it was distinctly noticeable, showing manifest improvement. Three months after the operation, he could depress and elevate the shoulder with ease, and at the same time could elevate the extended arm above the head, as shown in the photograph (Fig. 5), which, though taken five months after the operation, shows also a perfectly symmetrical face. There was slight atrophy of the muscle of the supraclavicular region, outer half. For two or three months after the operation, there was slight dull pain and a feeling of fatigue of the shoulder muscles after manual exercise, but no other inconvenience from section of the spinal accessory was manifest. In August, he built a sailboat, doing much of the manual labor himself, without pain or discomfort to the shoulder. On August 9, six months after the operation, he wrote me as follows: "In order to play the flute well, it is necessary to have quick and absolute control over the lips. On July the first, I could just make a note with considerable effort, but now I can play a piece through with few mistakes, though I have not absolute control over the instrument as I had before the paralysis occurred." This is conclusive testimony as to the rate and degree of improvement, and is verified by a letter from his father to the same effect. The patient also said that the coincident movement of shoulder and mouth first attracted his attention when he lifted, or pulled at an object, slowing that the facial expression was an involuntary response to a forced voluntary movement of the shoulder at that time. He was in the habit of carrying the right shoulder lower, and had been frequently admonished about it when a student at the Western Military Academy. He was instructed when the photographs displaying the shoulders were taken to assume an easy natural position. Other photographs show the patient's ability to close the eye voluntarily at four months, and the power to contract, retract and balance the muscles of the mouth at five months. When the arm and shoulder were used suddenly and strongly, associated movements were marked from the fifth to the eighth months. After this it was more in harmony with his will and effort to control it. Three months after the operation, the lines of the incision were hardly noticeable at close range. I last saw the patient at the University Club, Chicago, in October, 1909, nine months after the operation. He looked well, was cheerful and happy. The bullet had given no trouble. He talked and smiled without observable paralysis, but when he laughed the disparity was very noticeable. The latter is the last defect and manifestation of weakness to disappear. The associated movements were less marked, and the muscles of neck and shoulders symmetrical. There was no discomfort or weakness in the functions of arm and shoulder, and no atrophy of the trapezius. The entire result was most gratifying.

Ballance expresses the opinion that "perfect symmetrical movements of the facial muscles from emotional stimuli can only be obtained by devoting the whole nerve, either spinal accessory or hypoglossal, to the cure of facial palsy."

Ballance and Stewart¹ say that "degeneration, after a nerve is divided, proceeds just as rapidly though it is immediately sutured to the proximal end; that the axis cylinders are destroyed in six or seven days; and that with the absorption of fats and myelin and the conversion of connective tissue into fibrous tissue, the peripheral nerve is, in six or seven weeks, a fibrous cord."

Regeneration is a slower process. It commences in two weeks after anastomosis, and is manifested in muscular reaction in about four months in facial palsy, but is not completed until a much later date.

Fatty degeneration of the muscles is also worthy of consideration. Though it follows degeneration of the

1. Ballance and Stewart: Healing of Nerves, Macmillan.

nerve, it also disappears coincidentally with regeneration. As long as fatty degeneration exists, the muscles are not likely to respond to the faradic current.

It seems reasonable and natural to believe that, if a divided nerve is immediately reunited to a proximal nerve stem, degeneration of the peripheral end will not be so complete, and that, with regeneration beginning in two weeks, it ought to be completed earlier than is usual in the case of a nerve which has been, from injury or disease, in a state of degeneration for many months or years.

Ballance,² in reporting a case of facial palsy, expresses preference for the hypoglossal for the reason that the

Fig. 3.—Patient, four months after operation: shows facial asymmetry, but improved since operation.

cortical centers of these nerves are in closer relation than is the spinal accessory to the facial. Practically, there seems no force to this preference, as in anastomosis with the spinal accessory, success is as prompt and certain as with the hypoglossal, while associated movements are equally common to both.

He has used the lingual nerve in anastomosis with the peripheral hypoglossal, but failed, and has abandoned it. The lingual is a sensory nerve, and failure, under these conditions, is not surprising. No convenient available nerve for anastomosis with the peripheral hypoglossal has been demonstrated in operations for facial palsy. In a severed nerve, degeneration of the proximal end is exceedingly limited while, in the peripheral, it is finally complete. Both Ballance and Stewart, the leaders of the new, or peripheral, school, oppose the neuron theory held by Waldeyer, Ranvier and others that regeneration proceeds necessarily downwards from the proximal side, the axis cylinders growing into the empty spaces and finding momentary rest and renewed life and energy in the nodes of Ranvier, the conclusion being that regeneration and the restoration of function

is impossible unless direct connection is restored and maintained with the ganglion centers. J. B. Murphy,³ in the best American monograph on the subject, states that complete repair will not occur without this connection. He and others also maintain that regeneration is impossible without a neurilemma. Ballance and Stewart assert that the neurilemma cells of the peripheral segment regenerate, even the axis cylinders, independently of the proximal end, or union with it, but that regeneration is not complete in function, etc., without such connection. With this concession, it is hardly necessary to emphasize the absolute dependence on anastomosis to the proximal side, for the complete regeneration of the nerves and the restoration of the functions of the muscles.

If peripheral axis cylinder processes do fuse together to form continuous paths, independently, as maintained by the new school, though incompletely, it is a point in favor of immediate, or early, anastomosis, for such inherent power of the peripheral neurilemma cells must, it seems, retard complete degeneration, and with the stimulus of the proximal ganglion centers restored, early and more certain regeneration ought to be assured, notwithstanding the statement that "the length of time the paralysis has existed bears no relation to the rapidity of the return of function." I hope, and am inclined to be-

Fig. 4.—Patient, four and one-half months after operation, showing improvement and characteristic appearance of eye in facial paralysis.

lieve, that further experience will invalidate the closing statement above. This hope is further justified by the statement of Ballance and Stewart that "regeneration begins before degeneration is complete."

From the writings and experiments of Ballance and Stewart of London and Murphy of Chicago, and the references by them to continental writers, and the opinions expressed by distinguished American surgeons, I am enabled to formulate some probable conclusions of interest and value. The field is too new and the data

² Lancet, London, June 12, 1909.

³ Murphy, J. B.: Surgery of Nerves.

yet too limited and incomplete to justify a dogmatic treatment of the subject.

"Nerve fibers are capable of maintaining their normal nutrition only when they are in uninterrupted connection with their trophic center, which controls the nutritive processes."⁴ Also in reporting experiments on animals, Landois states that the degenerative process is arrested at each node of Ranvier, and that later fatty degeneration takes place simultaneously in the entire peripheral portion.

Langly and Anderson, quoted by Murphy, say that "regeneration is a downward growth." It is, too, in keeping with the Ritter-Valli law that the death of a nerve advances from center to periphery, and supports the Wallerian law that portions of fibers, separated from their trophic centers, degenerate. It is equally plausible that regeneration should proceed in the same way.

I believe the conclusion justifiable that the sooner a nerve is reunited after division or the destruction of its function by disease, the more certain, prompt and satis-

tion of both nerves and end-to-end anastomosis are to be preferred. Splitting is objectionable, because axis cylinder end-to-end apposition is necessary to regeneration, and is uncertain in splitting. "Implantation of one end through a slit in another is unscientific."⁵ Transverse division of half the diameter of a nerve and then splitting the proximal end for anastomosis with a peripheral nerve, end to end, may be justifiable in some cases as was done by Ballance in one case with the spinal and peripheral hypoglossal.

His statement that symmetrical and perfect facial expression is more certain with complete division of the nerves is worthy of the highest consideration. The best

Fig. 5.—Patient, five months after operation. Arm and shoulder elevated with equal facility three months after operation. Note improvement in face and expression.

Fig. 6.—Patient, six and one-half months after the operation, showing voluntary action of facial muscles including eyes. Note deficient action of right corrugator supercillii.

technic for exposure of the facial nerve is along the lines followed in the subject of this paper. It should not be approached through the body of the parotid gland, for that would needlessly endanger the integrity of the nerve which, soon after entering the gland on the under surface posteriorly, bifurcates and gives off other smaller but important branches. Besides, there would be the danger of annoying hemorrhage.

There are many unusually interesting physiologic and pathologic problems involved in the surgery of the nerves, none more novel than that of associated movements from the anastomosis of one motor nerve to another serving different groups of muscles.

Why should movement of the shoulder muscles, in spino-facial anastomosis, produce simultaneous movement of the facial muscles? The nerve supplying the former is cut and diverted to the latter. Hereditary habit must be a potent influence. Will the cortical and ganglion centers reeducate the nerves and muscles in the performance of new duties? With the aid of the will and voluntary habit, it is probable.

In the anastomosis of nerves, it is necessary to make some provision against the encroachment of excessive connective tissue production. Egg and Cargile membrane

factory will be the union and the restoration of function. In facial palsy, the spinal accessory is to be preferred, if for no other reason than the fact that the peripheral end can, without unusual difficulty, be stitched to the descendens hypoglossi, and with practically no additional dissection than is necessary in spino-facial anastomosis. The descendens is a little smaller than the spinal, but that is not an important objection. The spinal is a little smaller than the hypoglossal, but that is no disadvantage in facial anastomosis. Complete sec-

4. Landois: *Physiology*, Ed. 10, p. 635.

are recommended. Murphy has buried the ends in fascia or muscle. Cargile membrane is very thin and delicate, yet believed to be sufficiently resistant to meet the indications satisfactorily. "It is prepared from the peritoneal lining of the ox or other similar animal," by Johnson and Johnson. Nerve anastomosis is one of the most practical and beneficent of modern operations. No operation is more certain and successful in the absence of infection; with infection, none more certain to fail. In final results, it is one of the distinctive triumphs of recent surgery.

930 Pennsylvania Avenue.

ABSTRACT OF DISCUSSION

ON PAPERS OF DRs. PRIMROSE AND GRANT

DR. JOHN T. BOTTOMLEY, Boston: The subject of surgery of compressive paraplegia is now in the developmental stage. No one man has had sufficient experience to give him a great deal of first-hand knowledge on the subject, so that any one who has had some experience in this line should contribute it for the benefit of all. It is only from a study of many cases that general laws can be made for future guidance in this particular field. We know that while certain cases, perhaps a great many, are not helped by operation, yet some few cases are helped in this way. We know, further, that previous to operation we cannot in many cases say which of them will be and which will not be helped by an operation. Here, then, is a field where exploratory laminectomy is often indicated. With careful technic the operation is not dangerous to life, and with careful handling of instruments and tissues the patient's condition will not be made any worse. Therefore, I plead for exploratory laminectomy in many of these cases.

One point Dr. Primrose did not touch on in the non-traumatic pathology of compressive paraplegia is the occasional presence beneath the dura of small collections of fluid well localized in thin-walled cysts. Some of these cases have an antecedent history of trauma, some have not. But an adult, usually of middle age, who has slowly progressing paralysis, usually of the lower limbs, with, perhaps, more or less paralysis of the upper limbs as well, and an indefinite, variable degree of sensory disturbance, will sometimes be found to have, if an exploratory laminectomy is done, such a collection of fluid beneath the dura. When this is removed, the patient in many instances recovers, but recovery, as a rule, is slow. Yet any gain in these particular cases is well worth the attempt.

DR. FRANK WARNER, Columbus, O.: Dr. Bottomley seems to think that any one who has had even a limited experience in this line of work should report his cases. I have had some experience in compression from Pott's disease, and I was very glad to hear Dr. Primrose recommend operation in such cases. We should not delay too long in trying over-suspension or any other treatment tending toward the relief of compression. It would be better to make an early laminectomy, and I have been very well satisfied with the results obtained in that class of cases.

Another class of cases, in which it seems to me well to operate, is the one Dr. Murphy mentioned—in vertebral fractures, in which the bone has penetrated the cord and in which we might think that possibly the cord has been crushed. Yet occasionally we find at the operation that it is only a splinter of bone that has entered the cord, or that a portion of the cord has been crushed, but by relieving the compression these patients recover. Anyway, these patients die without operation, and therefore it seems to me that we should give the patient the benefit of the doubt and operate.

DR. A. PRIMROSE, Toronto, Can.: The speakers have apparently agreed with me. The discussion has emphasized the point brought out, that we should employ exploratory laminectomy when we are in doubt, and that was what I was particularly anxious to insist on in my paper.

DR. W. W. GRANT, Denver: I would like to emphasize the necessity of the use of the spinal accessory nerve in preference

to the hypoglossal, for the reasons given. It has been claimed that one might use the trapezius branch of the spinal accessory only. That has been done in Europe in cases of primary facial paralysis. I do not believe, however, that it is a wise procedure, because the trapezius branch makes a wider gap between that and the facial, and it must be severed in the posterior rather than in the anterior triangle. I do not believe that the splitting operation is justifiable. The whole nerve, both proximal and peripheral, should be used in this anastomosis. I have taken pains to dissect this region before doing the operation, knowing the importance of preventing the paralysis that results from the operation as ordinarily performed. I regard paralysis of the tongue as being more serious than paralysis of the trapezius muscle. I would do this operation even if I could not use another motor nerve for the peripheral, as in this case.

INTESTINAL OBSTRUCTION, DUE TO ASCARIS LUMBRICOIDES, WITH AUTOPSY

CHARLES WHELAN, M.D.

Surgeon to St. Vincent and Hillman Hospitals
BIRMINGHAM, ALA.

The case report with its post-mortem findings demonstrates the fact that the roundworm is at least worthy of consideration as an etiologic factor in the production of bowel obstruction in children. The case should further demonstrate the fact that no cautious surgeon should ever pass unnoticed the statement of an anxious mother that "the baby has worms," in casting about for an explanation of the suspected trouble in certain obscure

Section of obstructed intestine after opening into lumen, showing worms.

abdominal cases occurring during childhood. Then perhaps fewer certificates would be issued in which the cause of death was attributed to "intestinal paralysis, superinduced by toxemia."

History.—On Aug. 4, 1910, I was called in consultation with Dr. Elwyn Ballard to see E. J. W., a male child, aged 5½ years. The following history was given me by the child's mother: From the date of its birth the child had been unusually strong, never having had even the diseases common to childhood, except measles, from which it promptly recovered. About April 1, 1910, however, according to the mother, the child became peevish, restless at night, had poor appetite, sad low complexion and complained frequently of stomach-ache. She said that there was always more or less "swelling in the

Fig. 2.—Spinofacial anastomosis, and periphospinal to descendens hypoglossi; also showing hypoglossal where it turns forward and the descendens leaves it.

stomach," and she thought that "it was worms." During all this time the baby was obstinately constipated, but in no stool was a worm ever noted. On Aug. 2, 1910, about 11 p. m., the child awoke crying with pain in its stomach, and soon afterwards began to vomit. Castor oil was at once administered by the mother. The dose was repeated at noon on August 3. The vomiting continued and there were no bowel movements. On the morning of August 4 the child's abdomen appeared greatly distended, and accordingly the mother gave another dose of oil followed by an enema, with no result. Then it was that Dr. Ballard was called in. He found the child in convulsions, which, according to the mother, began about an hour previous to his arrival. The doctor found the abdomen greatly distended, vomiting was incessant, pulse rapid and extreme shock evident. At 11 p. m. on August 4 I saw the patient with Dr. Ballard. At 11:20 p. m. the child had a convulsive seizure and died. An autopsy was asked for by me and permission was obtained to explore only the abdominal cavity.

Autopsy.—The body was that of a reasonably well nourished, white, male child, apparently 3½ feet long, apparent weight about 40 pounds. Rigor mortis beginning. The body presented no malformations, and on its surface there were no marks of discoloration. The entire abdomen was greatly distended. On entering the peritoneal cavity through the median line a small quantity of a straw-colored fluid escaped from the incision, followed by an immediate outburst of distended intestines.

Stomach: This organ was greatly distended with gases. On opening into its interior a small quantity of a dirty brown liquid of fecal odor was present. Pylorus was open.

Duodenum: This was greatly distended with gases. No fecal contents were found on opening the bowel.

Jejunum: The upper portion was greatly distended, and on opening into its interior there was found a quantity of liquid fecal material. The lower 6½ inches of this portion of the bowel appeared to be obstructed with an impacted mass of some kind. To the touch the mass was firm. Inspection of this part of the intestine revealed a more or less collapsed condition, with varying circumferences along the continuity of the bowel. For the first 2 inches the circumference was larger than in any other portion of the obstructed bowel, then there was a constriction. About an inch further down there was a distinct "kink," then from this point on for 2 inches the bowel contained a mass. On opening the bowel, a "bunch" of roundworms was found, completely filling in the lumen of the first 2 inches. Two worms were found lying side by side in the direction of the long axis of the bowel through the constricted portion. The lower 2 inches of the bowel were also occluded by a "bunch" of worms similarly arranged to those found in the first 2 inches of the jejunum. This is well shown in the accompanying illustration.

Ileum: This portion of the intestinal canal was collapsed, and on opening into its interior no gases or fecal contents were noted. About 6 inches from its beginning the bowel presented a well-marked diverticulum.

Organotherapy in Scleroderma.—The *Annales de Dermatologie*, 1910, page 3383, contains a report of extensive work in this line by E. Roques at Toulouse. He tried extracts of various organs in treatment of scleroderma and found a decidedly favorable effect from thyroid treatment in 63.73 per cent. of 67 patients with diffuse scleroderma and in 70 per cent. of 10 patients with the circumscribed lesions. Thyroid treatment is not, he says, the specific in scleroderma which it has proved in myxedema, but the large proportion of improvements and cures justifies a trial of it. The best results were obtained with small doses given regularly for months and years and commenced early, while the tissues still resemble myxedema. Extracts of other glands demonstrated comparatively slight efficacy. The scleroderma may be due to various causes but a tentative course of thyroid treatment is certainly indicated as this may happen to hit the predominant factor in the individual case in question. The work of other clinicians in this line is also reviewed.

A SIMPLE AND EFFICIENT MEANS OF APPLYING ARTIFICIAL HEAT

STEPHEN E. TRACY, M.D.

Gynecologist to the Stetson Hospital
PHILADELPHIA

Following operation when the patient is relaxed, the temperature subnormal, and the functional activity of the organs diminished, it is an essential that reaction should be brought about promptly and every means which will promote this result should be employed.

This relaxed abnormal condition of the patient is best overcome by the application of external heat, which is the

Fig. 1.—Asbestos cradle containing incandescent electric lamps for applying heat to patients in shock, post-operative depression or collapse, or for producing diaphoresis.

Fig. 2.—Apparatus in position over patient and connected with electric light circuit.

greatest of all stimulants at this time. Artificial heat is usually applied by placing several hot-water bags about the patient, which is quite sufficient when there is no shock and the temperature is normal. A very small portion, usually the edge of the hot-water bag, comes in contact with the patient, and as a rule the water in the bags is only warm, as the nurses will not use hot water for fear of burning the patient, which means expulsion from most training schools.

In cases in which the patient is weak, advanced in years, or in a septic condition, or in which the operation

has been prolonged, or much blood has been lost, or for other reasons there is considerable shock, we have found that the most simple and efficient means of supplying artificial heat is by electricity.

For this purpose we use a frame covered with asbestos, supplied with six or eight 16-candle-power electric lamps, which extends from the shoulders to the feet of the patient. When the patient is returned from the operating room she is wrapped in a blanket, the apparatus is placed over the body, the ends covered with blankets to retain the heat and the light turned on. In a few minutes the surface of the body is warm, reaction

Fig. 3.—Method of retaining heat by covering with blanket.

takes place promptly, and, in the large majority of cases, the necessity for hypodermic medication is eliminated.

After ten or fifteen minutes it is usually necessary to turn out one or more lamps, as the amount of heat is excessive and will cause profuse perspiration.

The apparatus is used also in cases in which it is desirable to keep the skin moist, as in renal insufficiency.

The appliance is simple, inexpensive, light and easily moved about, and can be connected to any electric lamp fixture.

1429 Spruce Street.

A CASE OF FOREIGN-BODY CALCULUS

I. S. HIRSCH, M.D.

Pediatricist to the Jewish Maternity Hospital
NEW YORK CITY

History.—F. D., girl, aged 5 years, was brought to the children's clinic of the Beth Israel Hospital with the following history: Except for an attack of measles at the age of 2, she had been in good health until seven months ago, when she seemed to have lost control of the bladder function. The incontinence was present both day and night. During the last two months the micturition has been extremely painful, the pain being more severe toward the end of the act and being referred to the vulva. There has never been any pains in the loins, nor has there been hematuria. During the past six months the child has been examined in several dispensaries and has been treated for enuresis, cystitis and vaginitis.

Examination.—General physical examination showed an apparently normal, though pale and under-sized child. Local

examination disclosed a reddened and congested vulva, but no vaginal discharge. The mouth of the urethra was edematous and pointing. Bimanual rectal examination showed a movable mass about the size of a walnut, apparently in the bladder.

Urine.—The urine was clear, of an amber color, had a faint acid reaction and a specific gravity of 1025. Albumin and casts were absent. A moderate number of red and white cells and a few crystals of calcium oxalate were present.

Bladder Examination.—A sound was inserted into the bladder and the distinct grating sensation characteristic of stone was obtained. A radiograph of the pelvis revealed a large stone within the bladder. In the center of the stone a shadow of a rod-like piece of metal was apparent.

Treatment.—The child was referred to the Beth Israel Hospital and was operated on by Dr. L. J. Ladinsky, who removed, by suprapubic cystotomy, a stone weighing 5.5 grams. The recovery was uneventful. On section a pin was found within the center of the calculus. Chemical analysis showed the stone to consist of calcium phosphate, with magnesium phosphate and calcium oxalate. The crust, which had a brownish appearance, was entirely phosphatic.

Since it would be entering into too large a domain to undertake even a brief consideration of the subject of foreign bodies in the female bladder, only a few points, such as have a direct bearing on this case, will receive consideration.

MANNER OF INTRODUCTION OF THE FOREIGN BODY

It is almost impossible to give a positive answer to the question of how in this case the pin reached the bladder. Although the vast majority of the foreign bodies found in the female bladder are introduced during masturbation, and though it is generally recognized that this vicious practice is prevalent among girls far below the age of puberty, it is nevertheless difficult to conceive that even a child would employ a sharp object like a pin for

Fig. 1.—Radiograph showing calculus in bladder. Pin discernible as dark line through shadow of stone.

the purpose. The bodies usually utilized for these practices are smooth, dull and rounded.

Foreign bodies have been accidentally introduced by attendants while dressing children. Such an occurrence may be safely ruled out in this case, because of the insistence of the mother that only safety pins were ever used in the child's clothing. Malicious introduction is to be considered as an explanation of the way in which such foreign bodies reach the bladders of young children, the malicious practice being similar to that which finds its expression in the "point-tying" practice of male children.

There is another way in which foreign bodies may reach the bladder, namely, by perforation through the intestine. Authentic cases have been recorded in which sharp objects entered the bladder in this way. Chopart, for instance, records several post-mortem examinations in which a fistulous opening was found through which a foreign body had passed from the intestine into the bladder. Van der Viel reported the case of a boy of 8 years who swallowed a pin, and after several years of suffering with difficult and painful urination, the pin, encrusted with calcareous matter, was extracted from the bladder. Austin reported the case of a boy of 14 years who suddenly developed the symptoms of cystitis which persisted for a year despite treatment. The diagnosis of a foreign body in the bladder was made and a long pin, the shaft of which was covered by a calcareous deposit, was extracted. The patient then recalled the swallowing of this pin about a year before the bladder symptoms appeared.

In these and similar cases it is impossible, without a demonstration of such a pathologic condition as would permit the entry of a foreign body from the intestine into the bladder, to state with certainty that this actually occurred. The story of the affected individual cannot be depended on, while the motive for withholding the true history is apparent. Still it is important to remember that this method of entry is a confirmed possibility.

Fig. 2. Radiograph of calculus showing smaller formation over point.

Fig. 3. Photograph of calculus showing pin *in situ* and granular condition of brownish surface.

ENCrustATION

There is one pathologic process of considerable interest in the history of foreign bodies in the bladder, namely, encrustation. A variable period after the entry of the foreign body successive layers of urinary salts may be deposited on it, resulting in the formation of a calcareous structure which gives a train of symptoms identical with that given by ordinary calculi.

Ebstein divides calculi into two classes, primary and secondary, basing the classification on the conditions of the urine. If the formation and development takes place in undecomposed urine the calculus is classed as primary, while a calculus which is formed from the ammonium urate, triple and earthy phosphates precipitated by the ammonia formed during alkaline fermentation, is a secondary formation. The great majority of foreign body calculi belong to the latter class. In our case the cystitis was accompanied by a slightly acid urine, and the encrustation consisted of substances found in such urine.

Calculi do not consist merely of amorphous or crystalline deposits alone. Ebstein has shown that an organic framework is essential. Schöde has proved experimentally that crystallization takes place through the agency of the colloids of the urine which act as a matrix for the crystalline deposit.

The crystalline deposits formed through the agency of the colloids of normal urine are reversible precipitates because they may be redissolved by simple chemical means. Normal urine contains no colloid which is not thus capable of being redissolved after precipitation. Fibrinogen, however, such as is produced by inflammation, is just such an insoluble and irreversible colloid as will furnish a stroma suitable for the formation of permanent crystalline deposits or calculi. A foreign body in the bladder becomes encrusted, therefore, only as a result of the inflammatory process it initiates, and the nature of the crystalline deposit depends to a great extent on the reaction of the urine associated with the cystitis. This theory regarding the pathogenesis of urinary calculi explains the variability in the rapidity of the production of a calcareous deposit about foreign bodies. In some cases encrustation will appear in 48 hours, while in other cases it will not occur for months or years. It depends to a great degree on the extent and severity of inflammatory reaction. The inflammation in turn depends on the nature and condition of the foreign object, and the condition of the bladder prior to the entry of the substance.

Sooner or later after the entry of the foreign body a cystitis is set up, and when sufficient colloid has been produced to serve as a stroma for the urinary crystalloids, these are deposited in successive layers on the foreign object. The shape of the resulting calculus is considerably influenced by that of the foreign nucleus.

Such calculi may be spherical, ovoid, fusiform or irregular. Once begun the process proceeds very rapidly, and these concretions may grow to considerable size in a short time. Encrustation usually begins in the center of the foreign body, the ends remaining free, and if the object is long and slender, like a needle, a fusiform calculus is thus formed. Frequently the ends of the object remain entirely free. This may be due to the constant contraction of the bladder walls, for objects which are long and rigid usually lie transversely with their extremities against the walls of the organ. The resultant friction prevents the accumulation of deposits. When one end of the foreign body is pointed it may become imbedded in the bladder wall, and then the free end alone becomes encrusted. Exemption of the end from encrustation may also be due to its position, *e. g.*, in the urethral orifice. After sufficient deposition has taken place in the middle of the object so that the ends become less mobile, one or the other end may also become encrusted, forming a double calculus similar to our specimen.

DIAGNOSIS

In this case the symptoms were suggestive of enuresis, and for this condition the child was treated elsewhere. A rectal examination, which probably had not been previously made, but which is an important and essential procedure in the determination of the true significance of the urinary symptoms, disclosed a probable tangible cause for the symptoms. The distinct grating sensation elicited by the sound rendered the diagnosis of stone in the bladder most probable. The radiograph furnished conclusive evidence on this point. From the bimannual examination and the sounding alone it was evident that the calculus was of large size. This, taken in conjunction with the absence of a story of renal affection and the brevity of the period of suffering, made it probable, even before the radiograph disclosed the actual condition, that a foreign body was the nucleus for the calculus.

THE SUBMUCOUS RESECTION OF THE NASAL SEPTUM*

CLYDE E. PURCELL, M.D.
PADUCAH, KY.

The increased interest in the pathology and treatment, including operative procedures, of the nasal septum since 1902 seems to justify a review of the subject in order that erroneous conceptions then held can be righted, that the best advice for the patient's welfare can be given, and that the best operative procedures with fewest post-operative drawbacks, dangers and discomforts, can be promulgated. It is time, too, that absolutely impartial judgment be passed as to what is best and what is not best for the future of nasal surgery. Every operator, in the light of extended experience, has corrected faulty impressions and certain operative steps that have not stood the test of time.

Fig. 1.—Showing position of instruments within easy reach of the operator.

EVOLUTION OF THE RESECTION METHOD

It was formerly the custom to place a saw either above or below a sharp bend in the cartilaginous or bony septum, and cut it off, sacrificing the mucoperichondrium and leaving a bare surface. This was followed by annoying discharge, a dry condition of the nose, slow healing and a production of granulating tissue. Often the saw left a permanent perforation, and in few instances did free nasal breathing result. Only in very selected cases have any of the special methods named for the men who originated them proved of lasting benefit.

In talking to other otolaryngologists it was learned that the Asch procedure was disappointing both to the patient and operator, in that pain during convalescence was unrelieved. This has also been

my experience. Before the day of submucous resection, no doubt all of us tried the method of elevating the mucous membrane over a ridge or spur, followed by either sawing off the projection or cutting it away with a gouge. In common with the other methods, this nearly always failed to establish a patulous nostril.

These measures succeeding in few cases, and then in special and rare deformities, investigators began the search for a method that could be applied to any character of deviation or deformity. Like the locomotive, the submucous resection is not the acme of a single conception. Many have worked at it and each has added his mite.

IS THE DEVIATED OR DEFORMED SEPTUM INJURIOUS TO EYES, EARS OR THROAT?

At first thought it might seem extravagant to venture the statement that a bent septum could have any deleterious effect on the eyes, but clinical experience forces us to the conclusion that it has. Patients of my own are recalled who were able to lay aside glasses that had

Fig. 5.—View of interior nose. Dotted lines show the direction and extent of the initial incision. Acute angle of flap shows on floor of nose. The incision allows ample room to elevate around the obstruction. 1. The middle turbinate. 2. The inferior turbinate. 3. Overriding cartilage. 4. Septum.

been worn for years, after the remedying of a septal deformity, with complete relief. Asthenopia, and supra-orbital, unilateral, as well as general headaches, have been permanently relieved, apparently, by removing pressure contact of septum and turbinates or by straightening the septum. Stubborn cases of headache and eye pains that have resisted the usual ophthalmologic treatment have thus been explained, and the diagnosis later has been verified by correcting the pathologic condition in the upper anterior part of the nose.

The influence of nasal obstruction in causing deafness and inflammatory and suppurative processes in the ear is generally recognized. The narrowing of the nasal passages prevents ventilation and causes congestion and stasis of the turbinates, which reduces the hearing by interfering with the tympanic circulation. This can be

* Read in the Section on Laryngology and Otology of the American Medical Association, at the Sixty-first Annual Session, held at St. Louis, June, 1910.

demonstrated both from anatomic and clinical experience, and proper treatment of the nasal obstruction is usually followed by satisfactory hearing results.

It would seem that too little has been written on the influence of nasal insufficiency in relation to throat and larynx irritation. The origin of a large number of cases of chronic laryngitis can be traced to a nasal stenosis or disease in the nasal chambers. Following this enforced mouth breathing there is a lack of filtration, proper moisture is not maintained, and suitable temperature not established of the air supplied to the lungs. The arch enemy of free nasal ventilation—the deformed nasal septum—is thus indirectly responsible for much cough.

Fig. 2.—Author's forceps for removing the bony septum after the perpendicular plate has been cut through. A small pin in the lower blade fits into an opening of the upper, thus preventing the overriding of one blade. These forceps are small enough to be watched while in the nostril.

DO WE FEAR INFECTION TOO LITTLE?

Infection following surgery of the septum, turbinates or sinuses is such a rare occurrence that there is a disposition to fail to keep in mind its possibility. Infection of a mild type, no doubt, occurs in most cases. Streptococcal infection with fatal result has been reported. From the literature at hand, erysipelas infection has not been encountered. Therefore, the following case in my own practice would seem worth recording:

History.—Nov. 16, 1907, Mr. G., aged 37, farmer, complained of fulness in ears, tinnitus aurium and deafness. He had had trouble for some time but for the last few weeks had been worse with sense of fullness increasing. He was a mouth breather especially at night, and on the slightest exertion.

Examination.—Both drums were slightly atrophic and retracted. Hearing for watch was by contact; hearing for conversation was by approaching the patient, and speaking in a very loud tone. Tuning fork bone conduction was lengthened. Both inferior turbinates were enlarged and impinged on the nasal floor. An oblique bend and thickened maxillary crest extended in the direction of the sphenoid sinus pressing against the middle turbinate on the right side.

Treatment.—The lower portions of both inferior turbinates were resected. This procedure gave fair breathing capacity, and with canterization relieved the tinnitus and fullness.

Subsequent History.—The patient returned in January saying there was still some stopping up of the right nostril. It was decided to remove the crest to its posterior limits by resecting the nasal septum.

Second Operation.—The operation was done Jan. 19, 1908. A vertical incision anterior to the obstruction—flap seemed unnecessary in this case—was made and the bony obstruction was fully removed. Packing was removed in 16 hours when it was found that the wound had closed by first intention. In 30 hours after the operation the patient began to have fever, headache, nausea, pain in the nose and face, general malaise, and swelling of face and neck extending down on the body, especially the glands of the neck being involved. As there had been influenza in his family he therefore accordingly diagnosed his affliction as "grip."

Source of Infection.—Ten days previously Mrs. B. had been operated on in the office for a chronic frontal sinus suppuration by the intranasal route. Erysipelas developed, Jan. 22. The before-mentioned septum, no doubt, was infected from this case, though all instruments and hands were, as we thought, thoroughly disinfected. It is interesting to note that the new wound developed erysipelas 2 days before a diagnosis in the sinus case was made. The true nature of this septal infection remained obscure until the frontal sinus wound showed erysipelas.

The infection of the septum ran its course leaving a perforation the size of a pea two-thirds of the way back on the bony septum near the floor. This has caused no trouble whatsoever and the patient is utterly ignorant of its presence.

Too much stress cannot be laid on asepsis in all particulars on part of operator and assistants, though it is not wise to attempt to disinfect the nasal chambers of the patient where all scrubbing and douching are worse than useless. The fact that the septum can be resected without infection in the presence of a suppurating sinus disease shows this structure to be practically immune to pyogenic organisms.

DOES RESECTION AS NOW PRACTICED LEAVE ANYTHING TO BE DESIRED?

It would seem from the favorable reports of the investigators and workers in the field of septal surgery and from the enthusiasm aroused and maintained since the appearance of Freer's first article that in the majority of cases the method is almost ideal. Yet there remain several questions to be settled by the court of last resort—further experience and verification.

To operate on a patient in whom there is a suspicion of a constitutional taint is to invite danger and defeat. To operate on children yet in the formative period of life is a question not fully settled. Operators of wide experience argue for and against. I would not hesitate to operate on a child of 7 or over in whom there was an extreme deviation with nasal insufficiency, believing it safer to do so than to permit the little patient to suffer the inconvenience of mouth breathing and dangers of lack of facial development. To operate on patients of

Fig. 3.—Author's cartilage knife and hoe elevator. With this knife the primary incision through the mucous membrane—both vertical and horizontal—and cartilage may be made. It is also useful to begin the elevation on the opposite side through the cartilage cut. The whole cartilage may be removed under direct guidance of the eye with it. It aids greatly in the elevation of the flap.

Fig. 4.—Author's double chiselled elevator for elevating the flap. It is useful for working down in the acute angle on the floor of the nose, and around acute bends especially of the crista.

advanced age or those without the capacity to overcome the inconvenience of a somewhat long and tedious procedure is also questionable.

There is little liability of a permanent perforation of the septum if the submucous resection is carefully carried out by an experienced, painstaking operator. It is an operation applicable to any kind of deformity.

From my experience it would seem that the initial incision is the key to the successful termination. The crust formation following all the incisions, so far proposed in many cases, is objectionable. This is a point

which all the workers, it is hoped, will endeavor to improve and perfect.

THE DECISION TO OPERATE

It is a well-known and recognized fact that not all deformed septa need surgical intervention; insufficient breathing capacity is the indication. This is determined by stopping up one naris without interfering with the normal relation of the alae.

If sufficient air to supply the lungs for five minutes with lips closed without inconvenience to the patient is obtained the other naris is tested in the same way. This is the ideal nose, and one that will scarcely need be seen by a rhinologist. Of course, there are noses with difference in breathing capacity of the two chambers that do not require surgical treatment.

Before the day of our present method of operating much criticism was heard of nasal surgery and we had to admit its inefficiency. We have gone the gamut of crushing, cauterizing and sawing. But this is a period of evolution, and lucky is the man who can so plan and execute the condition of his environment as to escape criticism. Before accepting the responsibility of deciding that an operation should be done, let us take an inventory of present and past methods and their possibilities and see if we merit some of the criticism. Can we always say it is a trivial affair, free from danger and complications? Is it best and wise to inform the patient of a possible perforation even in the most experienced and skilled hands? Suppose a perforation occurs, with or without this advice, what of the legal aspect? Would the doctor be liable or has our experience been extensive enough to establish the impossibility of avoiding perforations?

COMPARATIVE STUDY OF NEGRO SEPTA

In a personal examination of 563 negroes in Paducah, of all ages, I have found the extreme deflected septum in not a single case. The work of the adult negroes was that of barbers, porters, roustabouts and the great army of loafers that frequent the dives. True, I did not find in every case a perfect plane, or absolutely vertical septum. The maxillary crest was prominent in 15 cases, but in only one case was it sufficient to cause nasal stenosis, which was not constant. This was associated with a vertical bend of the cartilage well up in the vestibule, and was found in a half-blood who had many American facial characteristics. Heredity, no doubt, is the most logical explanation of this case. One child, an octoroon, was found with adenoids, 18 had atrophic rhinitis, but altogether it was a fine lot of septa and nares free from disease.

One negro came to me in the early part of 1909 saying he could not get air through one nostril and giving a history of a blow on the nose several years before. Examination showed a bend in the perpendicular plate and quadrangular cartilage.

A SUMMARY OF ONE HUNDRED AND TWENTY-SIX CASES: ALL PRIVATE, ONE PERFORATION ONLY

In not a single case was it found that there was only a cartilaginous bend¹. Bony deformity was associated in all cases and therefore required rather extensive work. One patient was operated on twice as the removal of the cartilage did not result in full nasal patency. This was one of my very early cases. In no instance was there a

change in the nasal profile. This seems to be entirely preventable and its occurrence is inexcusable. There was one case, previously referred to, of infection from erysipelas which resulted in a permanent perforation the size of a pea—the only instance. In one case there was a circular absence of cartilage the size of a dime. This was attributed to ulceration from picking which the patient admitted doing. At time of operation there was no evidence of ulceration and no perforation was made, though for a few moments the condition was puzzling. Cocain and adrenalin had no effect on the bleeding in one case.

A large percentage—forty-seven patients, had previously had some other procedure—saw, turbinectomy, cautery, and Asch operation to give nasal respiration. One of these had a transcontinental experience of 12 attacks of these measures, including the Asch operation, with only temporary improvement. The submucous resection gave ample breathing room with no perforation. Seventeen operations were done to relieve hay fever when there was pressure contact of septum and turbinates, and so far relief has been complete, with the exception of one patient who was much improved.

THE INCISION THROUGH THE MUCOUS MEMBRANE

Whatever may be said or written of this operation, it would seem that the fulcrum of ultimate success is the primary incision. Objections to the Hajek incision are that it does not give access to the deeper parts and the elevation is difficult on the anterior free border; to the Killian operation the objections are the danger of a permanent perforation when the cartilage is cut through, limited room for instrumentation, and a tendency to scab formation. Of the incisions thus far described that of Freer is best planned. While ordinarily this gives ample operative interference, yet, in my experience, it is followed by rather extensive and prolonged scab formation. To overcome the inclination to scab formation and the tendency to retraction on healing of the flap, and in order to expose the crest more completely, I have used for the last year the following incision with ideal results (Fig. 5): Beginning well up on the septum with the ala nasi lifted, a vertical incision is carried down to and about half across the nasal floor. This incision has to be made, or at least finished, with an angular knife. From the lower end of this, a slightly curved incision in a horizontal direction is brought forward more in the cutaneous than in the muco-cutaneous structure (Fig. 5). This acute angle flap when elevated gives easy access to the crista. Two sutures are inserted in the vertical cut and if need be one in the horizontal. The two sutures prevent retraction of the flap in healing. Should the apex retract, the squamous epithelium is on the floor of the nose and therefore no scabs will form. The horizontal incision will not form crusts or scabs because it is in the skin. The incision is preceded by a few drops of cocain and adrenalin hypodermically.

In order to insure light for the operation, an extra rheostat and headlight should be in position; a storage battery is also in readiness. A fire in the neighborhood of the building or one destroying the current cannot then delay the operation, as happened to me before these precautions were taken.

THE PACKING

A piece of surgeon's gauze cut the proper size for the case in hand and coated on one side with suitable ointment, is then placed with this side next to the septum

1. Since reading this paper, I have had one case in which removal of the cartilage was sufficient for perfect breathing.

and smoothed out. "Strips of absorbent lint are then placed in, beginning on the floor" (Freer).

As soon as one strip is in and while patient is in the recumbent position liquid petrolatum is dropped in and continued after each piece, more petrolatum being used as the packing is built up.

It is the rule not to have a drop of bleeding following the removal of the packing in 20 hours. The piece of gauze may remain 2 or 3 days and does not interfere with breathing. This ointment does not melt at the temperature of the body and there is no displacement of flaps on removal of packing.

DEDUCTIONS FROM PERSONAL EXPERIENCE AND FROM THAT OF OTHERS

If it were possible for one to be liberal, and yet maintain that there is but one way to remedy septal deformities, radically through some form of mucous membrane incision, I should like to take this position. It is recognized, too, that to do good work one must have well-directed enthusiasm. It would seem from my experience—none of my 126 being clinic cases—that the operation is peculiarly fitted for private patients, all of whom are very grateful for the relief it brings.

Free access to the nose is essential. Therefore, the character of the incision is highly important, for here is the focus of success. At least two sutures are necessary (Fig. 5). No fear need be entertained of the sinking in of the bridge of the nose if the operation is well planned and executed. Perforation, with the flap method followed by suturing, need not occur, for it is hardly possible that two perforations opposite each other will happen. Should it happen, suture.

Spare the turbinates, cauterize little, and meddle seldom with the nose after the operation. A nose with stenosis, like a plugged-up pipe, has to be opened from end to end, therefore, to secure full breathing capacity sometimes requires extensive resection which uses up all one's attention, energy and judgment.

Fraternity Building.

THE RESULTS OF THE OPERATION OF SUBMUCOUS RESECTION OF THE SEPTUM IN PRIVATE PRACTICE*

FRANCIS P. EMERSON, M.D.
BOSTON

In order that we may reach definite conclusions in regard to the value of the submucous resection of the septum, it is necessary that we should know what indications, in the operator's opinion, justify its performance. These can be classified under two heads: first, the mechanical indications that lead to the selection of a particular operation in order that we may remove undue redundancy, correct displacement and overcome the resiliency of the septum; this division will not be discussed, as it is understood that all cases in this series were corrected by means of the window resection method; and second, the clinical indications.

It is obvious that not every deflected septum is necessarily pathologic, for we must bear in mind that the patient does not consult us for the deflection itself, but for conditions that have resulted from the unequal in-

gress of air, which has produced hypertrophies, contact, insufficient drainage or active infection of the functional tissues of the nasopharynx or the accessory sinuses. If this position is accepted, resection alone is seldom indicated, and, on the other hand, no operation which does not remedy the associated complications will relieve the patient. Statistics in regard to the success of the operation, gathered two, three or four years afterward and based on the judgment of the patient, presupposes that during this time there has been a normal function of the nasopharynx, for any deviation therefrom will, in his mind, be an incomplete result. When we consider the physiologic activity of the nasopharynx, its innumerable reflexes, its secretory activity, and its intimate relation with so many other highly specialized organs of the body, this is a severe test. For this reason, any results claimed for or against the operation must be based on the individual equation; that is, must depend on whether or not the particular operator not only has appreciated fully the mechanical details of the procedure, but also recognized and remedied the associated lesions which have resulted.

The genius of Killian, Jansen, Freer, Ballinger, Hajek and numerous other writers, who perfected the technic, and furnished explicit directions for each step, leaves no excuse for failure in our mechanical work on the septum, but the functional restoration of resulting abnormal conditions must be based on a study of each individual case. With a perfectly straight septum, the patient may be no better off than he was at first, while the partial or complete removal of a cystic second turbinate, whose function has been destroyed, may preclude the necessity of correcting its original cause. Again, many compensatory hypertrophies, particularly of the posterior ends of the turbinates, will disappear after being relieved of their over-activity by correcting the septum and equalizing the air current. Any indication for operation, therefore, must take into consideration the present functional activity of the mucous membrane, the glandular elements and the questions whether there is obstruction to the drainage of the accessory sinuses, or whether there are points of contact that interfere with breathing, over-stimulate by irritation the active tissues of the nose, or cause compensatory hypertrophies.

The fact that the center of development of the septum is situated so far forward in an area usually included in the operative field, has prevented me from advising any extensive resection in children under the age of twelve.

In the following series of cases the Killian incision was employed, and in no case was it sufficiently anterior to run the risk of a dropped nose. In my experience, more depends on ample space between the middle turbinal and the cushion of the septum for freedom in breathing than on a perfectly equal intake of air anteriorly. If, therefore, the deflected portion of the septum is straightened, so that there is not a recurrence of the compensatory hypertrophy of the anterior end of the middle turbinate after being once corrected, the functional results will be just as good as though we were able to make the anterior nares of equal diameter.

I did not believe in sacrificing the entire middle turbinal, but drained one or more cells or removed the anterior third as indicated. The inferior turbinate, also, was trimmed on its lower border, but not removed. The openings of the various sinuses were carefully explored, particularly that of the nasofrontal duct, to see that drainage was ample. Any pronounced difficulty in respiration was generally found to have some abnormal

* Read in the Section on Laryngology and Otology of the American Medical Association, at the Sixty-first Annual Session, held at St. Louis, June, 1910.

conditions within the "vicious circle of Ballenger." In any case with a history of attacks of vasomotor rhinitis, particular attention was paid to freeing the tissue under the cushion of the septum, together with a careful search for points of contact or pus irritation from a diseased sinus. Following the observations of Schadle, an overflow from the antrum was looked for particularly, but was not found as an exciting cause more often than a discharge of pus from the frontal sinns or ethmoid cells.

In this series of cases any deflection involving the lower half of the septum which needed surgical interference always included not only the triangular cartilage, but the maxillary ridge. Whatever freedom of breathing is obtained by resection can always be measured by the approximation to a central perpendicular line of the point of suspension and the base line of the new partition. It never bears any relation to the amount of tissue removed, for the intervening space is later filled with a fibrous exudate that will reproduce the old conditions, unless the two plane surfaces are approximated by throwing in of the base and suspension lines. In no case observed has there been a reproduction of cartilage or bone in the new septum.

Although a large percentage of the operations were performed under local anesthesia, that method, except in selected cases, is not recommended. The element of shock is of considerable importance and can be eliminated by general anesthesia and the operative time thereby materially shortened. Although physical pain can be eliminated by the use of local anesthesia, I believe that so-called cases of cocain intoxication are largely due to fright and should be considered in our selection of operative methods. One patient, a man of middle life, lay down five times, bathed in a clammy perspiration, with a slow and feeble pulse, simply from seeing the various instruments before any cocain had been used.

None of the patients developed sepsis or any alarming symptoms. The greatest discomfort was from pressure where the retention splints were too tight. In most of the early cases packing was done on one side; in the late ones, on both. Gauze splints covered with Cargile membrane were left in place forty-eight hours. In the early cases sutures were employed and then discarded, although more cases of primary union seem to follow their use. If the anterior end of the middle turbinate was removed, only the lower half of the vestibule was packed on that side.

In the series of sixty-two cases, from which the following data are drawn, thirty-six patients were males and twenty-six were females. Nineteen patients were operated on the right and twenty-five on the left side. The records in the other cases do not state which side was involved, or were sigmoid. Eight operations were performed under general and the remainder under local anesthesia. Letters were sent to the sixty-two patients and the deductions are based on the opinion of the patients as to their present condition and not on a reexamination. The replies also include the early operations, before experience had taught valuable lessons. On the other hand, more recent cases, in which the time limit has been too short for definite conclusions to be reached, have been omitted. Of these sixty-two letters, six were returned, the addresses not having been found, and eleven patients failed to reply, leaving forty-five answers for analysis. The circular questions and the answers were as follows:

1. Is the nasal breathing free? All but two of the forty-five had free nasal breathing.

2. What trouble have you had since the operation? Thirty-nine out of forty-five had none since the operation; two had nosebleed twice, and four still have some catarrh.

3. How much have you been relieved? Forty-three stated that they were greatly or completely relieved, one only partially relieved and the other not at all.

4. What ill effects, if any, have followed the operation? Forty-three had no ill effects; one reported a great deal of nervous reaction, and one had some scabbing from an anterior perforation.

5. What effect has it had on your general health? In one case the effect was unfavorable; in five there was no effect, and thirty-nine patients were improved.

6. What effect has it had on your hearing? The hearing of one patient had entirely returned; fifteen had improved, and the rest of the patients either had no impairment of hearing or the hearing was unchanged.

It is noteworthy that, in so extensive a surgical procedure in a region functionally active, no patient complained of any undesirable sequelæ, except in the one case of perforation. Only one stated that his condition had not been improved markedly. In three cases of perforation, two patients are not aware of the condition and, therefore, did not mention it in their replies, and in the third case due to an extreme anterior deflection, the patient is free from symptoms by the use of an ointment at night. (Other perforations were made, but healed by preserving the tissue opposite.)

In the correction of the abnormal septal and associated conditions there were marked cases of asthma, headaches, aprosexia, disturbance of vision, progressive otitis media, erysipelas (from infection of erosions), chronic eczema of the lip, recurrent bronchitis, chronic nasopharyngitis, redness of the external nose, aphonia, perversion of the sense of smell and taste, and dyspepsia, as well as the mechanical obstructions and chronic catarrhs.

Though I believe that, with proper modifications, the submucous resection of the septum is adaptable to all forms of deformity and that, according to the law of physics, a hollow cylinder is just as strong as a solid one containing the same amount of material, yet there is a possibility that, in an extensive resection in a debilitated subject, from injury of the perichondrium, there might result a sloughing of the cartilage wall, with resulting deformity. For this reason and because older methods have been the result of a careful evolution and adaptation to special deformities, we should become familiar with all and individualize our cases.

The window resection, when indicated, has stood the test of time and if the principle of the hollow cylinder be carefully preserved by leaving sufficient margin superiorly and anteriorly, there is no other procedure by which the rhinologist can obtain such satisfactory results in the whole field of nasal surgery.

484 Beacon Street.

ABSTRACT OF DISCUSSION

ON PAPERS OF DRs. EMERSON AND PURCELL

Dr. JOHN O. ROE, Rochester, N. Y.: In the correction of deviations of the septum it must be recognized that no one operation is adapted to or suitable for the correction of all the various forms of deviation which may be found, nor even for the different conditions that may, in many cases, be found in the same septum. Every case, therefore, must be studied independently, and the operative procedure selected which is best suited to that particular patient, regardless of any predilection that the operator may have for any special or favorite method.

Before attempting a submucous resection on the septum, its feasibility must be determined by the condition of the septum itself regarding its thickness as well as the location and degree of the deviation. Then too, we must take into consideration the etiology of the deviation, whether it be idiopathic or traumatic. Of course we recognize the fact that in nearly all cases there has been a traumatic cause, either of a recent or of a remote origin occurring perhaps in childhood; but the recent cases have to be dealt with differently from those that are due to a very remote cause, in which latter cases the submucous resection is best suited. In traumatic cases of recent origin, however, in which there has been more or less crushing of the nose, submucous resection must be undertaken very cautiously on account of the lack of support of the dorsum of the nose, and the liability of the sinking in of the bridge, thereby leaving a marked depression and a marked increase in whatever external deformity there may have been. I have seen a number of cases in which a marked deformity of the nose had resulted from the injudicious employment of the submucous method.

In those cases in which the thickening is confined to a limited area or to one side of the septum, associated with a spur, a limited resection of the thickened portion only should be performed. It is as unwarrantable in these cases to take out the whole framework of the septum as it would be to reset the whole femur to correct a limited deformity that had resulted from a fracture.

In the correction of other portions of the septum not requiring resection, the operation should be supplemented by other operations not requiring the removal of the bony or cartilaginous framework, such as may be accomplished by the use of my fenestrated fracturing forceps or other well-known methods sometimes employed for the correction of deviations of the septum. In all these cases it is important so to maintain the septum in its proper position that the passages are of equal size, and especially that no contact is left at any point, for no matter how free the passage may be, contact at any point will give the patient the sensation of an obstructed nostril.

If enlarged turbinates are in the way these should be dealt with before the operation on the septum is undertaken. I do not find it necessary in these cases to employ general anesthesia as the operation can be made completely painless by the local use of cocaine and adrenalin. In case of an idiosyncrasy against cocaine some of the substitutes may be employed. The disturbance from the cocaine, however, can usually be prevented by the previous use of digitalis and strychnin. In the case of nervous and apprehensive persons a hypodermic of morphin or other suitable hypnotic will remove the fears and render them most helpful and tractable patients.

DR. O. T. FREER, Chicago: The L flap, or open method of resecting deflections of the nasal septum, which I have gradually perfected since 1901, has nothing in common with the methods based on different principles brought out later. It was obvious to me that the promise which these other methods gave of an easy and speedy performance, with a simpler instrumentarium than mine would secure their immediate popularity and for this reason the procedures of Killian and of Hajek, advocated by Ballenger, soon became the most followed. But it was also obvious, from the insight into the complex structure of deviations of the septum given me by resections, that these methods, in which the submucous resection was described as a quick manipulation, easily accomplished through a slit at the front of the septum and with blunt or chisel-edged instrument for the elevation of the coverings, were based on superficial preconceptions of the task to be performed, rather than on a thorough understanding of its difficult nature.

An essential feature of my method is the preliminary incision creating the reversed L flap. It is this flap which uncovers to sight the entire deflection, thus leaving so small an amount of the mucous coverings on the convexity of the deviation to interfere with vision and instruments, that no obstructing long intranasal speculum is needed, a necessary instrument where the buttonhole cut is used; for this form

of incision leaves all of the mucous membrane on the side of the convexity in the way, in danger of being torn by forceps and other instruments.

In spite of the great advantages offered by the L flap, they seem to be but little understood except by those who have seen my operation, most surgeons having difficulty in making this flap and hence adopting the simple incision at the front of the septum. Certain improvements in the creation of the flap make a description of the later method of its production desirable here. The flap is begun by a horizontal incision, which follows the base of the septum from behind the deflection forward into the nasal vestibule along the junction of the septum and nasal floor, that is, along the very bottom of the septum. In almost all cases this extends forward into the cutaneous covering of the anterior part of the septum. I was glad to find that Dr. Purcell had independently arrived at the same conclusion in regard to the placing of the horizontal portion of the L. This part of the incision is made with the round-edge knife D of my septum set of instruments, and should, if possible, penetrate at once the perichondrium and periosteum to the cartilage and bone. The elevation of the flap is begun from this cut as shown in a accompanying illustration in the left naris with the round-bladed knife I. So soon as a little of the flap is loosened it is held up with a blunt elevator and the wound is wiped, that it may be seen whether the perichondrium be really divided or not. Usually it will be found that the mucosa alone has been severed and that a second cut is needed to reach the cartilage and bone. Then the perichondrium and periosteum are dissected up to where they may be readily lifted with a dull-edged instrument. The latter elevates the coverings backward on the septum so far as it can reach, regardless of an existing vertical angle of deflection, provided it can pass beyond it, as is usually the case. Then the keen elevator is introduced under the upflitted covering through the horizontal incision of the L as far as it can be made to go posteriorly and then made to cut through the coverings in a line at right angles to the base of the septum and from underneath, not from without, as the vertical cut of the L flap was formerly made. This method permits the elevation of so large an L flap that it includes two-thirds of the mucous coverings of the usual deviation and thus leaves the convex side of the deflection skeletonized and perfectly exposed to view without the use of a speculum. The flap is held forward by the assistant with one of the retractors which hold the nostril open in place of a speculum. An advantage of the L flap is a perfect exposure to view of the cartilage before making the first incision through it, which may thus be accurately placed at a sufficient distance behind the nasal bridge to insure its support. Hematoma cannot occur where the flap is used. I have found the submucous resection on children as satisfactory as for adults. Nine years, during which I have never refrained from operating on even very young children, have shown me that the objections to resecting deflections in childhood are purely theoretical.

DR. R. P. SCHOLZ, St. Louis: I agree that the submucous resection is applicable to all cases of septal deviation needing correction. If there be an exception, I take it to be in the correction of the septal deviation of very young children in whom the removal of cartilage might give rise to the fear of disturbing further development of the nose. I was surprised to hear Dr. Emerson say that he uses general anesthesia for this operation, for I have found the local anesthesia satisfactory. I make a simple incision along the anterior edge of the cartilage, beginning high up and extending down on to the floor of the nose. Gauze saturated with petrolatum makes a very desirable dressing, but paraffin gauze, as used by Williminski, makes the ideal tampon.

DR. BRYAN D. SHEEDY, New York: In the graduate institution with which I am connected, we average from fifteen to twenty submucous resections a week. A great many of the men present learn their submucous resection work at that institution. The operation performed is the regular one devised by Killian, the flap method as suggested by Freer occasionally being used. So far as infection is concerned,

I have seen in the last five years but two infections and practically no perforations. Our patients are operated on just as they come to the clinic without preliminary preparation. Children are operated on when they have a deflection of the cartilaginous septum sufficient to interfere with normal respiration and I have yet to see any bad results come through the submucous resection operation performed on children. Some one referred to deviation of the septum in colored people. The African skulls in the London Museum show very few deviations of the septum and I explain this condition through the fact that the colored and lower races seldom suffer from adenoids, the mouth-breathing in young children caused by adenoids being, to my mind, the principal cause for the many deviations we see.

As to deformity following the operation, many are familiar with the article I wrote four years ago, in which I gave photographs of six or seven patients, one in my own practice, who had appeared at the hospital with depression of the bridge of the nose following the resection operation. As we seldom see this deformity now, I have concluded that the sinking of the bridge was due to the removal of too much of the cartilage, the small amount of cartilage left under the bridge being weakened by inflammatory changes and therefore not sufficient to support the structures.

I usually depend on the Bernay sponge for after-packing, removing it the day following the operation, and my results have been most satisfactory. I have never used strips of gauze nor have I ever stitched the mucous membrane. I believe the stitches are an unnecessary hardship for the patients and I also believe that this operation should be done as quickly as possible, thus saving the patients unnecessary shock.

DR. W. L. BALLENGER, Chicago: We are not all expert operators, skilled as is Dr. Freer, and some of us get perforations and we are not going to quit operating because of that, but it is interesting to know how to remedy this condition if it occurs. I learned a very simple way recently from Dr. Goldsmith of Toronto. He places the cartilage removed into normal salt solution and if he happens to get opposite perforations he straightens the cartilage and reinserts it after finishing his resection between the mucous membranes and then by granulation the mucous membrane grows down over it, the cartilage becomes absorbed, being a foreign body, and a perforation is prevented. I think this is a very interesting thing to know.

In children whose septums are not yet wholly developed and who need the centers of development left undisturbed I follow the Sluder method. It is adapted to young children in whom there is extreme deviation from trauma. Sluder makes an incision above the deviation, one below, and one at the crest. Then he springs these two ribbons of cartilage together and they are held about 4 days until union takes place and the result is very good.

DR. O. TYDINGS, Chicago: I would protest against one class of operations. We all do the submucous operation and the sinking can be due only to encroaching too high up on the septal cartilage or to subsequent infection. In traumatic deformities in children, if a Gleason operation be done, and at the same time a proper splint put in, there is no reason for doing a submucous resection. It gives very beautiful and perfect results.

In packing the nose after a submucous resection I never leave the packing in more than ten or twelve hours. If I do the operation in the evening I remove the packing next morning. My packing consists of rubber tissue in which I have loosely placed cotton and I just use packing enough to keep the perichondria in contact. I have never found it necessary to use it very firmly.

DR. G. SLUDER, St. Louis: Since Dr. Ballenger has been good enough to mention the operation which I described in 1906, I should like to add a word in this connection. His description is accurate and comprehensive. There is nothing for me to add to that. I agree with his feelings concerning the development of the nose. My belief is that a rigid septum is necessary to prop the nose up during the developing years of life. I believe this because in cases in which a perforation of the septum has occurred in childhood—the

simple or traumatic perforation which occurs at the lower anterior portion of the cartilage—there is uniformly a greater or less depression in the profile of the nose opposite to it. At least this is true according to my observation extending over 12 years. I believe this disturbance in the nutrition of the septum to be responsible for the depression in the profile. If this be true then all the more would be necessary the septum itself. In one patient in whom the septum was straightened by this operation, and whom I was able to follow for 10 years, the double layer of cartilage shrunk until it had the thickness of only a single layer. It then appeared as a normal septum.

DR. FRANCIS P. EMERSON, Boston: We all admired the work of Dr. Roe and Dr. Freer in plastic nasal surgery and in perfecting the operation of the window resection of the septum. I am therefore particularly fortunate in having them discuss my paper. I do not want to be misunderstood about the reproduction of cartilage. In those cases examined it had not been reproduced. In children I have been conservative, preferring other methods. In developmental cases with moderate deflection, our dental friends are helping us materially. Some of the cases reported last year by Dr. Foster of New Bedford showed remarkable results. In regard to anesthesia, you will notice in my paper that a large percentage of operations were done under cocaine. I do not question but that all can be done that way. I have simply found that there are in Boston a large number of nervous women in whom the element of shock is of considerable importance and, for the comfort of the patient and my own convenience, I like general anesthesia.

DR. CLYDE E. PURCELL, Paducah, Ky.: I thank Dr. Freer for his endorsement of my incision and wish to bear him out in his statement that there are valid objections to the incisions so far offered. I am glad he stated before this body of laryngologists that we had practically reached the same conclusion working independently and I am also glad I read my paper here before he had a chance to describe this new incision or I might have been accused of stealing his thunder. I want to emphasize his position that perforations are preventable and should not occur. My experience in the cases herein reported bears him out. If the incision is placed well back in the nose and brought down on and partly across the nasal floor ample operative room is insured. It is easier in my experience to begin the elevation at the highest point of the incision on the septum, working down and not from the anterior free border. Getting down into the bottom of the acute angle seems essential, especially in the cases in which the crista is much involved. Unless there is a great deal of misplacement of the cartilage anteriorly, it is not necessary to bring the horizontally curved incision as far forward as I have represented in the drawing. I have had no personal experience with Dr. Sluder's method but it would seem that it has a very limited field of usefulness. When I get a suitable case I am going to try it. I want to commend the speaker who made a plea for more complete and thorough work in nasal surgery. It is a very easy matter to remove some cartilage but it is very difficult to remove the obstruction fully without injury to the integrity of the nose.

Now, in regard to sutures, it may be a little fad of mine, but I have had such fine results, with no retraction, that I shall continue to use them. I have also devised a little angular knife suitable for making incisions through the mucous membrane and also valuable for elevating the mucous membrane, cutting through and removing the cartilage. By using this I lessen the number of instruments employed. I think that we should not hesitate to give children the advantage of free nasal respiration. I understand that Dr. Killian operates on children and I certainly see no reason why we should not.

Diagnosis of Whooping-Cough.—During an epidemic, or with a history of exposure, whooping-cough should be diagnosed without special difficulty, but sporadic cases may hold many symptoms common to other diseases, e. g., acute bronchitis, influenza, tuberculosis, tonsillitis and adenoids.—C. Thorington, in *Gulf States Jour. of Med. and Surg.*

SURGERY OF CYSTIC DEGENERATION OF
THE KIDNEY *T. C. WITHERSPOON, M.D.
BUTTE, MONT.

The purpose of this paper is to direct attention to the practicability of giving surgical relief from certain symptoms or ill effects of cystic kidneys. The number of patients with cystic kidney for whom any given operator may render service is necessarily small; the majority are not aware of its existence until late in the course of the degeneration, and then it is impossible to stay the process or to relieve the symptoms.

The lack of individual experience necessarily leads to an uncertain surgical attitude toward the lesion, and when, during an operation, such a condition is discovered, the operator is unprepared to do the most appropriate thing to bring about a surcease of symptoms or to check the progress of the cystic degeneration.

For the purpose of getting directly to the subject, and before discussing the nature of the lesions and its relation to surgical treatment, I will relate briefly the case of a man who came to me just one year ago for treatment:

History.—June 5, 1909, the patient, S. S., a man aged 49, of rather thick build, of a muddy complexion but otherwise in seemingly good strength, came to the hospital to obtain relief from a bloody urine which began about June 1. There was nothing in his past history which shed light on the condition. He had not suffered from gonorrhoea or local injury to the genito-urinary tract, nor did he give a history of any general infection or body injury. At the time of his visit, the blood alone indicated to him that something was wrong, for otherwise he had not suffered, not even from frequency in urinating. His urine was examined and found to contain a large quantity of blood. On settling for several hours, fully one-half of its bulk was composed of a dark muddy deposit.

Physical Examination.—This revealed an enlarged left kidney which was slightly tender. On reflection the patient remembered that he had been conscious of the left side for months. This consciousness, however, was never of real pain nor even of discomfort sufficient to cause apprehension of disease. The patient was given internal medication, returning every day or two for observation. By June 10 he began to grow weaker and shorter of breath, and as the blood continued, the necessity arose for direct surgical intervention, if possible. On June 11, a cystoscopy revealed blood coming from the left kidney. On June 13, the patient came into the hospital for closer observation. He was restricted to a low diet and complete rest. During the first twenty-four hours in the hospital, he passed 42 ounces of very bloody urine; the next twenty-four hours, 34 ounces, the next only 30, but the next, 45 ounces. He was then prepared for operation, though a positive diagnosis had not been made, knowing only that the loss of blood continued and was from the left kidney.

Operation.—On June 18 a lumbar incision exposed a well-developed polycystic left kidney. The appearance was typical and needs no description. I opened the various cysts with scissors and forceps and removed their thin covering and partitions; only the bulkier, solid tissue was left. I spent about twenty minutes ridding the kidney of its cysts. I was greatly tempted to open the peritoneum and palpate the right kidney, but as the skiagram and external palpation indicated no increase in its size, I thought best not to do so. A large boiled gauze sponge was then packed snugly about the kidney and the wound closed at the upper end, leaving the lower open enough to freely drain the field of operation.

Subsequent Course.—The patient made an uneventful recovery. The urine cleared of blood entirely by June 21. The amount passed following the operation was slightly greater

than that passed while in the hospital prior to the operation. July 24 the wound was practically healed and the patient was discharged in apparently good condition. In March, 1910, I made an examination of him and found his condition very satisfactory. He says that he feels perfectly well. No recognizable blood has shown in the urine since the operation. The amount passed daily is normal. A sample sent to the laboratory gave the following: Color, light straw, clear, reaction, acid; sp. gr., 1018; no albumin, bile nor sugar. Microscopic findings, a few leukocytes, an occasional hyaline cast and a few large epithelial cells. To palpation of the side on which we operated there was no evidence of enlargement. There was also, we may note, no increase in size of the opposite kidney. He suffers no discomfort in the wound or along the genito-urinary tract. To all clinical means of ascertaining his condition, he is well.

This case fortunately presented a symptom which brought him to us early—the blood in the urine—and our effort to stop it has resulted in decided relief.

The questions naturally arise: What was actually accomplished? Will the relief be temporary or has the operation had a tendency to check the further progress of the trouble in the kidney operated on?

NATURE, ETIOLOGY AND COURSE

This brings us to a consideration of the nature of kidney cysts, their etiology and course.

R. L. Thompson in a recent review of the subject says:

The newer literature concerning kidney cyst-formation, especially the work of Ruckert, Busse, Dunger, Herxheimer and Braunwarth have shown that all cysts of the kidney are closely related—with the exception of a small group, they are due to a congenital malformation which seems to lead to this new growth.

He records a post-mortem finding, in an infant which died of an acute infection, of a faulty union of a lobule of cortex with its corresponding pyramid. In this portion of the kidney there was evidence of commencing cyst development.

The cysts which I wish to discuss in this paper are those which are included under the congenital type, whether they are found in the infant or developed later in life; whether single or multiple, in one kidney or both. A small class, which will not be considered, consists of those found in chronic indurative nephritis, the parasitic cysts, the dermoid cysts and those due to cystic degeneration in lymph-nodes and blood-clots.

Rayer, it will be remembered, was the first to separate the polycystically degenerated kidney clinically from those just mentioned. He presented no microscopic differentiation nor did he entertain an idea of the present-day conception of the development of the kidney, but based his opinion purely on the macroscopic appearance of the cystic organ.

Koster first accentuated the necessity for a recognition of two anlagen for kidney development and of a mal-union of the two for cyst formation. He, however, considered the anlagen as, on the one hand, the Wolffian duct, forming the ureter and pelvis, and on the other, a mesenchymatous cell-mass giving origin to the rest of the organ.

Hildebrand more clearly developed the theory of congenital cyst-formation, declaring, as Kupffer had demonstrated, that the pyramids and pelvis united with the cortex, and when a congenital failure of the union occurred, there was a disturbance at the location of the convoluted tubules next the pyramid with marked proliferative activity of certain cellular elements. This produced a draining back of the secretions and cyst formation.

* Read in the Section on Surgery of the American Medical Association, at the Sixty-first Annual Session, at St. Louis, June, 1910.

Ribbert later demonstrated that the obstruction played only a part, and that the cyst formation was to be accepted as a new growth.

Nauwerck, Hufschmid, Singer and others, look on the whole process as one of cystadenomatous formation—a new growth.

Wigand on the other hand, considered the cysts due to an abnormal spouting from the kidney anlage of canals which later become cystic.

The complete picture of a polycystic kidney must of necessity suggest a new growth, whether the basis of such a change lies in a congenital malunion of the cortex and pyramid, a congenital misplacement of certain cell elements, a congenital spouting of abnormal urinary tubes, an acquired epithelial proliferative process or an active connective tissue proliferation with obstruction of the urinary tubes.

Such a process may consist in the formation of one or several large cysts or may be characterized by a complete honeycombing of the kidney with a great number of cysts of all sizes, from those of microscopic dimensions to those as large as a walnut or even a hen's egg. When such a formation does occur in an individual, both kidneys are, as a rule, involved and not uncommonly the liver as well.

DIAGNOSIS

In making a diagnosis of cystic kidney, four symptoms may be considered: pain, hematuria, a recognizable growth in the side of the abdomen, and uremia. Pain, or perhaps discomfort, is not constantly present; in fact, all of the symptoms may fail until the end, when the greatly compromised kidney activity leads to the final uremia.

The presence of blood is much more common than either pain or discomfort or the discovery of a growth. In fact, it is the one symptom which most often calls for relief before the final uremic stage.

TREATMENT

The treatment of the condition is essentially surgical, for otherwise no treatment can be of any avail whatever. The first three symptoms are all amenable to surgery, at least, by this means alone can relief be offered, but for the last symptom, uremia, nothing can be done. It is true that in the uremic stage by cutting down the necessary kidney activity to the lowest possible degree through diet restriction, rest and by helping vicarious elimination, some short prolongation of life may be given, yet this is but temporary.

What surgical treatment should be resorted to in these cases? The majority of recorded operations were nephrectomies. I should like to offer this criticism of such a procedure. The removal of a kidney, especially as both are in the vast majority of instances involved in a like process, is a sacrifice too great to be permitted. The aim of any surgical procedure should be to save every grain of kidney tissue possible, while at the same time offering relief from the symptom complained of. In an organ of such vital necessity to the body as the kidney, but two conditions justify nephrectomy: first, the presence of an infectious process producing a serious general intoxication or the possibility of spreading a life-destroying infection; second, the presence of a malignant growth.

In cystic kidney neither of these conditions exist, for the final uremic state results purely from the loss of kidney tissue, rendering the condition analogous to that of

the contracted kidney. Some have recommended puncture of the cysts, others injections of cyst-destroying chemicals into the various sacs.

In the case reported I believe I have accomplished a satisfactory result by excising the non-functioning cyst coverings and septa and causing a healing of the wound through granulation, with union to the surrounding tissues.

This patient was bleeding freely and losing strength rapidly, yet within three days following the operation, all trace of blood ceased and has continued checked until the present time. The urine is apparently normal and his general health most excellent. What ultimate good has been done must be determined through time. Whether such a procedure will check further cyst-formation by diverting the blood in the engorged vessels through other vascular channels and thereby relieving congestion, cannot be determined short of a very considerable experience, but at least the patient still possesses his kidney and is able to care for the greatest possible amount of kidney work under the circumstance.

Dr. Ludwig Pick of Berlin, answering an inquiry as to the possible good of the operation, replies as follows:

I hasten to answer your question concerning the case of cystic kidney. According to my opinion, there is no differentiation possible between congenital cystic kidney of the newborn and of adults. I believe that all these cystic kidneys result from a congenital cause and that they do not have their beginning in middle life, and if they become manifest in middle life, they had their existence before. Why a stronger growth should develop at this time, there can be no theory offered and only a problematic answer may be given.

I personally believe that the kidney originates from two separateanlagen: first, the ureter pelvis and collecting tubes proximally out from the ureter anlage; secondly, the cortical portion of the kidney from a special blastema. When the twoanlagen do not meet exactly or normally and unite, then we have a formation for cystic kidney through an earlier or later development of an embryonic epithelium. Why in one case earlier and in another case later, is, as already said, not entirely clear. As you see, my opinion is that the kidney is developed from the twoanlagen and this explains the origin of the cystic kidney through mis-building.

Now, indeed, I believe that in your most interesting case, a final good result will not be obtained. But as the largest cysts were opened, it will last a certain time until the little ones, not yet opened by you, and not yet large enough, will make their appearance.

I have seen a case here in which a cystic kidney was removed entirely, and the other was, at the time, not apparently cystic. The patient lasted ten years until the other kidney became cystic and then the woman died.

ABSTRACT OF DISCUSSION

DR. DANIEL N. EISENDRATH, Chicago: I regret to dispel the rosy illusion under which Dr. Witherspoon is laboring with reference to the prognosis in his case, as he seems to think that his patient will recover. The consensus of opinion among pathologists and surgeons who have had occasion to see many of these cases of polycystic disease of the kidney is that in about 99.9 per cent. of the cases the condition is bilateral, and that it is only a question of time until both kidneys are so atrophied that no secreting tissue is left. Those cases present themselves practically in one of three ways. I have seen them in two of the three. In the first, the patient is brought into the hospital in uremic coma, with no previous history obtainable. At the autopsy we find that both kidneys are converted into a mass of cysts. Each kidney is three or four times as large as normal, and is a mass of cysts, with practically no kidney tissue left. So long as there is enough kidney tissue left between the cysts the patient will not have

a uremia, but as soon as there is less kidney tissue present than can take care of metabolism, uremia is inevitable.

In the second clinical picture the patient presents himself with severe, constant, almost uncontrollable hematuria. These are the patients for whom I believe that something can be done, and Dr. Witherspoon's case shows the benefit of surgical intervention. We might open a few of these cysts in the hope of establishing some collateral circulation, so as to diminish the vascularity, and I believe that it is in this way that the benefit seen in his case can be explained. But, so far as prognosis is concerned, the average experience is that within a definite period of years, owing to the progressive bilateral character of the disease, both kidneys will be involved to such an extent that a fatal termination is inevitable.

DR. C. M. NICHOLSON, St. Louis: I have had to deal with three cases of cystic kidney and all were unilateral. In each case the probable diagnosis was based on the presence of a tumor in the lumbar region, easily palpable and blood in the urine. In one of these cases there was marked pain. In the first case, the kidney being only about twice its proper size, nothing was done; in the second an incision was made, the diagnosis verified, eight or nine cysts punctured and the wound packed with gauze. The patient left the hospital apparently well four weeks later, but after nine months returned with a large lumbar abscess which was connected with the kidney. He has occasionally had abscesses form, though he declined to have an operation, further than drainage. The third case was the largest cystic kidney, with one exception, thus far reported (*Ann. Surg.*, xxxvii). It extended about twenty-two inches, occupying all the right side of the abdomen. There was not only a tumor and hematuria, but marked pain at times. A median incision was made, the diagnosis verified, the opposite kidney examined and found to be the proper size, thirty or forty cysts punctured through the loin and the entire mass removed. Dr. Ralph Thompson made an extensive study of this case and demonstrated that the mass was a cystic kidney, not of new formation, but due to dilatation of the uriniferous tubules. The patient made a perfect recovery and for the last few years has been entirely well, attending to all her duties. The treatment of these cases depends on the pathologic condition present. If all or most of the kidney substance has been destroyed, then the best interests of the patient are conserved by removing the mass.

DR. JAMES E. MOORE, Minneapolis: Inasmuch as this is a congenital condition which eventually ends with death, it seems to me that it is very rarely indeed that a nephrectomy is justifiable, because one is liable to have some kidney tissue left which is functioning. These are not surgical cases until such time as they begin to have complications that may be relieved by surgery. My experience is limited to two cases, in which I could not accomplish anything. In the first case I operated under a mistaken diagnosis, on a woman 50 years old, who was supposed to have an ovarian cyst. She was suffering from pressure symptoms and when I opened her up I was surprised to find that it was retroperitoneal, extending behind the kidney. I removed the cyst.

The second case was that of a man, between 40 and 50 years of age, who came with an obscure abdominal tumor, and was easy to diagnose congenital cyst. Both kidneys were large enough to map out the lobules. He came to me with fever and with a diagnosis of his own. He had lived in the south and said that he had had repeated abscesses of the liver. I did not question his diagnosis until I found the kidneys. His cysts were infected and he was becoming septic. He gave a history that Nature had opened some of his abscesses, and it seemed to me that I might help Nature this time, so I opened and drained three or four septic cysts. He was restored to health sufficiently so that he could attend to his business for about a year, when he developed uremia and died.

DR. T. C. WITHERSPOON, Butte, Mont.: The points I wish to bring out are these: First, we have fallen into the habit of accepting a statement as being authoritative and allowing it to become accepted generally without giving it careful scrutiny. That these cases are congenital we can, of course,

agree, if by that we mean that point at which the trouble occurs is the point of union between the two anlagen where we find active cell proliferation. But that this should be looked on as a congenital condition purely because it occurs at this anatomic point I cannot agree. It usually does not occur until the fifth decade of life, scarcely under the third, except in the type of cysts found in the infant, and it evidently comes from this proliferative cell activity. I do not know what induces the overgrowth of cells. I am not willing to look on this lesion as some Presbyterians do their future state, that is, as a matter unalterably fixed by predestination. I do not believe that it is. These patients may have a chance to recover. I am going to watch my cases and see what will happen and report later.

THE NUTRITION OF THE FEEBLE INFANT

HENRY DWIGHT CHAPIN, M.D.
NEW YORK

The proper nourishment of feeble infants is a problem that taxes the resources of the most skillful pediatrician. Digestion and assimilation may be poor either by inheritance or from faulty feeding, and when, from any cause, the general vitality of the infant is lowered, the digestive tract is usually the first to suffer and the last to recover tone. Whether the infant becomes feeble from errors in diet and hygiene, from illness or from poor inheritance, improved diet and hygiene form the only successful treatment. Drugs are of little or no avail. If these patients are not relieved, sooner or later some form of atrophy or marasmus will result—a condition in which a chronic digestive weakness is the principal evidence of the depressing symptom-complex. The large general death-rate of early infancy can be checked only by the most careful attention to the diet and care of this class of feeble infants. It must be confessed that thus far our results have not been very brilliant. The object of this paper is to discuss some of the factors that enter into this problem, with the idea of suggesting the lines along which improvement may take place.

The structure and function of the digestive tract, the form and quantity of the food elements that are given, especially in relation to the assimilative power of the individual, and the most improved hygiene must all enter into such a discussion. With reference to the ingestion of food, the stomach will naturally call for the first consideration.

I. THE MOTILITY OF THE STOMACH

Our knowledge of the general capacity and function of the stomach in early life has been fairly well worked out. In normal infants, during health, no great difficulty is encountered by competent feeders in reference to the kind and quantity of the food and the intervals of its administration. In feeble and badly nourished infants, however, the weak action of the stomach, especially in its muscular power, is the source of much trouble. The weakness and atrophy of the general musculature is exemplified in a marked degree in the motility of the stomach. At best, the musculature of the stomach and intestines is not highly developed during the first months of life, and in feeble infants, in whom the general muscular tone is below par, the digestive tract suffers very markedly from this cause. This will doubtless throw some light on those cases in which during life serious digestive symptoms have been noted but after death little pathologic change has been observed as far as the mucous membranes are concerned.

With this condition in mind, a series of twenty-one cases was carefully studied with regard to gastric motility, as in the case of the feeble infant it is important to make certain that the intervals of feeding are not too frequent. The ages of the patients were as follows: Two weeks, 1; three weeks, 1; six weeks, 1; two months, 1; three months, 6; four months, 4; five months, 3; six months, 1; seven months, 1; twelve months, 2. These infants were taken from the wards of the hospital and represent all grades of malnutrition from beginning cases to those in the last stages of atrophy. We may generally classify the cases as thirteen of marked feebleness, three cases of malnutrition in a milder form and five cases just at the beginning of faulty nutrition. It was, however, impossible to form any definite conclusions as to gastric motility based on the age of the child from these cases. The older children were brought to the hospital either suffering from some grave general disease, or because they had failed to gain weight and were becoming atrophic. They thus formed poor material from which to determine normal gastric motility.

Of nineteen patients that were examined at the end of three hours, only six could be shown to have approximately empty stomachs, and these six, with one exception, were holding their own and in no case could free hydrochloric acid be determined. In thirteen out of the nineteen cases, it was absolutely demonstrated that there was a considerable residual amount of food still remaining in the stomach. In all these cases there was a positive Fehling test, and curds and whey, either singly or together, were present. It is interesting to note that butyric acid fermentation was marked in six of the cases, and in two of the cases in which the stomach was apparently empty there was a faint trace of butyric acid. In five of the seven patients examined at the end of three and one-half or four hours, the stomachs were surely empty. Of the remaining two cases, one showed many curds at the end of four and one-half hours, while the other showed only a few small curds. These last two patients were losing weight rapidly and the butyric acid fermentation was marked.

In only two of the seventeen patients examined at the end of two or two and one-half hours, were the stomachs empty. In the other fifteen cases, a positive Fehling test was obtained with one exception, and in four there was a positive Gram test. In thirteen of these cases butyric acid fermentation could easily be demonstrated. Large tough curds, or many small curds with whey were present in all of these cases. In considering the above figures, it should be remembered that few, if any, of the children examined were entirely normal, and that deductions from these results have a value only as a study in the nourishment of the feeble child.

There can be little doubt that, in a large majority of cases, the feeble infant with digestive disturbances has been fed at too frequent intervals. Too often a second feeding is given before the previous meal has passed through the pylorus, with the result that each successive feeding has been contaminated. The process of butyric acid fermentation has thereby been set up and kept in operation until, at last, a condition analogous to that of myasthenia gastrica is present. In none of these cases could any great disturbance in acid secretions be made out. The condition of the enzymes was not carefully investigated, but, as it is a well-known fact that the enzymes are not affected until long after the acid secretions have become greatly diminished or disappeared, it may be taken for granted that the enzymes were present in a normal state. While free hydrochloric

acid could be demonstrated in only six cases, combined hydrochloric acid was invariably present in fairly large quantities. The average amount was about 30, the lowest being 12, and the highest 48. In nearly every case in which the stomach was not empty, fluid was present, and in a few cases the dilatation was marked. This state of affairs serves to emphasize the fact that in feeble infants gastric motility is greatly decreased, and that whatever may be the case in the normal healthy child, in these atrophic infants it is often necessary to increase the interval between the feedings.

According to Tobler and Bogen and Heubner, milk passes through the pylorus in the case of breast-fed infants in about two hours, and in those taking cow's milk in about three hours. Tobler has further shown as a result of experiments carried on in animals with variously colored milks that each subsequent feeding forms a sort of layer about the earlier one, and thus the food first ingested may be kept in the stomach indefinitely if the feedings are given at too frequent intervals. Granting the truth of these observations, it can be seen at once that it is of the utmost importance to have the meals properly spaced, as otherwise there remains a residuum of food in the stomach which contaminates each successive addition of food. This constantly recurring contamination and overburdening of the stomach results in fermentation, and in time gastric dilatation with a loss in tone of the muscular coats of the stomach may ensue. This explains how a chronic digestive disturbance may lead to the condition known as atrophy.

It is interesting to trace the analogy between this state in the infant and the condition known as myasthenia gastrica in the adult. Myasthenia gastrica is characterized by a loss of tone in the muscular coats of the stomach as a result of which there is a moderate dilatation. Its diagnosis depends on the finding of fluid in the stomach at the end of two hours or more, with a normal gastric secretion. Among the causes bringing about this condition may be mentioned the general debility following any disease and the habitual ingestion of excessive amounts of food. An important element in its treatment is to make certain that the stomach is never overloaded. In atrophic infants these conditions are reproduced and while it cannot be claimed that they are exactly parallel there is a good deal of similarity. Thus in atrophic infants a practically normal gastric secretion may be found with a marked loss of motility if our previous schedule of three-hour feedings be accepted as approximately correct. With few exceptions food and fluid remain in the stomach of these infants well over two hours—in most cases three hours or more—and as a consequence of this stagnation butyric acid fermentation begins and is passed along from one feeding to the next. Hence it should be expected, as in the myasthenia gastrica of the adult, that there should be a marked improvement in many of the symptoms if care is taken to make certain that the stomach is entirely empty for a short period before a future feeding. It is not only desirable that any fermenting material lying in the stomach be passed forward into the intestines to avoid contamination of an incoming meal, but there should also be an interval during which the stomach contents shall be strongly acid so that the growth of harmful bacteria may be inhibited.

14. THE FORM AND QUANTITY OF THE FOOD ELEMENTS

When percentage feeding was first developed, it was assumed that protein, fat, carbohydrates and mineral matter were well-defined entities, and the basis of teach-

ing was that scientific feeding consisted in merely changing the quantities of these ingredients in the food mixtures. Within the past few years an entirely different viewpoint has been taken, principally as the result of an increase in general knowledge of the subject of nutrition. "Protein," "fat," "carbohydrates" and "mineral matter" are now recognized as being generic terms and just about as definite as the terms "wood" or "stone." There may be few who realize that at least twelve different forms of protein, five different forms of carbohydrates and two different forms of fats are used successfully in infant-feeding and the digestive properties of these food elements are modified by the combinations in which they are offered.

To be most successful as a feeder one must be familiar with the uses and fields of these different forms of the food elements and must also realize that there is no fixed and absolute rule to follow in combining them. There are many feeble infants who seem to thrive when the food contains a high percentage of carbohydrates, while others do better if the carbohydrates are kept low and the quantity of protein is raised. Occasionally raising the fats will improve nutrition and this may appear to be what the infant needs and can digest; but most feeble infants seem to have difficulty when the fats are too high. Milk mixtures containing much cream pass more slowly through the pylorus than those low in their percentage of fat and higher in protein and carbohydrates, according to Tobler and Bogen. Many will remember that only a few years ago high fat in the food was looked on by many as the thing to be especially desired, but now low fats seem to have the field. There can be no universal rule with reference to the fats, however, any more than to any other of the food elements.

From the standpoint of nutrition infants need liberal quantities of protein for tissue formation, and enough fats and carbohydrates to supply heat and energy value or calories. But in the management of feeble infants the question of what is theoretically correct must be subordinated to what will practically work, or, in other words, what the infant will take and assimilate.

In some instances a very small quantity of protein, perhaps 0.5 per cent., is all that the young infant can take when the protein is in the form of the natural casein of milk. If the form of the casein is changed by the action of an acid, as in buttermilk feeding, in which the casein is precipitated in a finely divided state, as much as 1 or 2 per cent. of the casein may be digested easily. Lime-water, sodium bicarbonate, sodium citrate and other chemical additions for modifying the casein have been used with milk and all produce good results in some cases. No one method has succeeded in all instances, and it is not likely that any will ever be discovered that will be universally applicable, for the reason that infants are not all alike and conditions are not always the same. If oat gruel, or soy-bean gruel, with its very high protein content, is employed, several times as much protein may often be utilized as if the unmodified protein of cow's milk is used. These facts point out plainly that changing the form of the protein has frequently a very important place in the management of infants.

The changing of the form of the carbohydrates also frequently shows a marked effect in the progress of the infant. The carbohydrates used in infant-feeding are starch, dextrin, maltose, cane-sugar and milk-sugar, and it is often surprising what marked improvement will follow a change in the carbohydrates employed.

It has generally been thought that infants cannot take more than 7 per cent. of carbohydrates, but in Keller's malt soup, which has been advocated for atrophic infants, the carbohydrates, composed of starch, dextrin, maltose and milk-sugar amount to about 13 per cent., or almost double the accepted maximum quantity. The percentage of fat in the malt soup is about 1 per cent. and that of protein about 1.7 per cent. and each ounce yields about 22 calories or almost exactly the same as one ounce of good breast-milk. In many instances Keller's malt soup has given good results while in many others it has signally failed, like every other mixture. Its use proves only one thing; there are some patients who seem to thrive especially well when the fats are low and the carbohydrates high and consisting of a mixture of several forms.

I have long advocated the use of dextrinized gruels for this reason and for the practical results in many cases of difficult digestion. As usually employed, the carbohydrates exist in these gruels in the forms of soluble starch, dextrin and maltose in varying proportions, according to the degree to which the digestive change has been carried. Some atrophic patients, however, do better when the product is largely maltose. This can be attained by allowing an active diastase to remain in the gruel for a longer time at a comparatively low temperature.

The general method to be employed in feeding in difficult cases will have to be determined, to a certain extent, by experiment with the individual infant. If this fact is once firmly fixed in mind, much progress will have been made, as time spent in looking for a universally applicable food will then be used in learning how to make up mixtures of equal nutritive value in which the various food elements may be high or low in quantity and in a great variety of forms. Where the physician now has one or two formulas to draw on he may thus have many, and as he learns to use them he will find that the difference between success and failure often lies more in changing the form and even the flavor of the food than in a profound knowledge of calculating theoretically indicated mixtures. This is particularly the case in dealing with the difficult digestive problem of feeble infants.

III. FINKELSTEIN'S METHOD OF FEEDING

An interesting and somewhat unique contribution as to the cause and relief of nutritive disturbances in infancy has recently been made by Finkelstein, of the Berlin Kinderasyl. Instead of the fat or protein being the usual cause of trouble, most digestive disturbance is referred by him to the sugar of milk. He confirms¹ an earlier report of clinical observations at the Berlin Kinderasyl in reference to the pathogenesis of severe nutritional disturbances in the nursing. He there found that the ingredient in the food especially harmful to the sick infant was the sugar, and that in certain cases even the natural milk-sugar of cow's milk might cause the severest symptoms. He was thus led to hope that a method of nourishment based on a decrease in the milk-sugar would lead to cures that would be impossible with the ordinary methods. The report of improvement following this kind of diet has proved the correctness of the hypothesis and Finkelstein is convinced that a step in advance in the treatment of the nutritional disturbances of poorly nourished infants has been made. Not only may the lighter forms of nutri-

1. Finkelstein: Monatschr. f. Kinderh., April, 1909.

tional disorders be quickly and certainly improved, but patients can be cured that our previous experience has shown could be saved only by breast-milk. The earlier view of the harmfulness of casein is not confirmed and the opinion is advanced that casein in the intestinal canal is directly beneficial, as the intensity of the pathological sugar fermentation, with the ensuing dyspeptic symptoms, is lessened by increasing the amount of casein. A lowering of the sugar increases the tolerance of the intestines for fats and hence will allow an increase in the amount of fats which in the former mixtures, rich in milk sugar, only work harm. The principles of the new method of nourishment are summarized as follows: (1) the cutting down of the amount of milk-sugar and of the salts; (2) in place of this, casein is added and a not inconsiderable amount of fat; (3) a further bettering of the condition is sought by substituting other forms of carbohydrates for the milk sugar, which tends to an increased tolerance.

The food is prepared by separating the casein and fat from one liter of milk. The curds are pushed through a sieve to break them up and then added to half a liter of water. Half a liter of buttermilk without sugar is then added to the mixture. One liter of this food contains the whey and sugar from half a liter of milk, the

fied as follows: in good condition, 6; in fair condition, but a little below normal, 3; beginning atrophy, 4; with atrophy, 3; with marked atrophy, 4. Twelve patients died; eight of these began as atrophic infants and four started in good condition when the diet was instituted. Three patients, which began as atrophic infants, increased in weight, and five increased somewhat in weight who began in good condition. Altogether, eight patients gained slightly in weight and twelve lost in weight on the Finkelstein feeding.

It seems to me that when benefits follow this method of feeding, the results are due more to the form in which the protein is given, the casein being in a very finely divided state, than to the lessened amount of sugar in the mixture. The food appears in some cases to check the rapidity of atrophy temporarily and hence may have a restricted usefulness. Judging from the character of the stools it may also act well in certain forms of diarrhea.

IV. HYGIENIC MANAGEMENT

The hygienic surroundings have a most important effect on the nutrition of the feeble infant. If the environment is faulty the best care and feeding will usually prove ineffectual. These patients require an altered environment that will furnish plenty of fresh air, good

casein from one and a half liters and the fat from one liter. A small amount of fat and casein are lost in its preparation, but the following are estimated as the percentage ingredients: protein, 4.5 per cent.; fats, 2 to 3.5 per cent.; sugars, 1.5 per cent.; salts, 0.3 per cent.

This method of feeding was tried at the Babies' Wards of the New York Post-Graduate Hospital in a series of twenty cases. The infants, with a few exceptions, were not doing well on the ordinary food when they were changed to the new method. They were all hospital patients and presented the usual difficulties of infants previously badly fed and cared for, and finally sent to an institution for treatment. When the change was made the infants were fed every four hours, day and night, and the food was usually given in lesser bulk than in the previous feedings. Water was given freely between the feedings. The stools generally became gray and homogeneous with a putty-like consistency and dry appearance. There was usually then a tendency to constipation. The results are given in the tabulation above.

A study of this table will show that the results in this series of cases were not very promising. Before starting the new feeding the ordinary percentage method, with and without gruel diluents, had been employed with poor results. At the beginning of the new feeding the infants, as to their nutritional condition, may be classi-

general hygiene and individual care. For this reason they never do well in institutions, no matter how carefully and scientifically they are there fed. They cannot assimilate the best of food without plenty of good air to assist in its oxidation; oxygen is as necessary a food for them as protein or fat. It is only individual housing and care with constant oversight that can accomplish good results. Even an ignorant but kindly woman in a home can often get better results than a trained nurse in a hospital with a series of cases to look after and a stated routine to enforce. This is especially true in charitable work, where relief of feeble infants can be much better accomplished along the lines of family life with individual supervision instead of the collective life with institutional methods.

Acting on this idea, the Speedwell Society was started at Morristown, N. J., in 1902, and I have ever since boarded out my atrophic infants there under the supervision of a doctor and trained nurse, who watch and treat the cases under the care of the various foster-mothers. The results have been better than with any other method of treating this class of cases. Thus, among 121 infants under 3 months, 45 died; 95, from 3 to 6 months, had 29 deaths; 83, from 6 to 12 months, had 21 deaths, and 85 infants, from 1 to 2 years, had only 8 deaths. These infants were all poorly nourished

at the start, from bad hygienic surroundings, with various degrees of digestive disturbance from faulty feeding on the bottle, and stationary or losing weight. Although all had to be kept on bottle-feeding, a good proportion were not only saved but were restored to fair and even vigorous vitality. Under the old institutional methods nearly all would have died.

I would express my thanks to Dr. Pease and Dr. Leopold of my staff, to the former for undertaking the work on the motility of the stomach, and the latter for applying the technic in the Finkelstein trials.

THE PROGNOSIS IN CONGENITAL DISLOCATIONS OF THE HIP *

EDWARD H. OCHSNER, B.S., M.D.

Attending Surgeon Augustana Hospital, Adjunct Professor of Clinical Surgery in the Medical Department of the University of Illinois
CHICAGO

The subject of congenital dislocations of the hip has in recent years been so thoroughly covered in orthopedic text-books and monographs that most of its phases can be looked on as definitely settled. There are, however, a few problems that still remain open and require further observation and discussion. There is still considerable difference of opinion as to the ultimate prognosis in congenital dislocations of the hip, and, as is usual in such cases, only carefully compiled statistics can definitely settle the question. It is with the hope of aiding a little in the solution of this phase of the problem that I have decided to consider it and to add a report of the cases which I have myself treated, and to discuss briefly some of the factors which seem to me to have been most potent in producing the large percentage of complete or partial failures reported in the literature.

For the sake of clearness I wish to classify these cases under three headings: first, those cases in which no serious effort has been made to reduce the dislocation; second, those cases which have come to the surgeon too late for a successful bloodless reduction (while there is no hard and fast age limit, I think it is safe to say that after the sixth year in double and after the eighth year in single dislocations an attempt at bloodless reduction becomes more and more difficult and dangerous with less and less likelihood of successful accomplishment); third, cases of patients who come in time for the bloodless operation, in general before the age of 6 in double and 8 in single dislocations.

If untreated, or ineffectually treated by braces, Buck's extension, etc., the prognosis is always quite bad. At the very best there exists an unsightly deformity which persists through life and often becomes more pronounced as the patient grows older. Added to this we have a displeasing gait, which is either a limp or a waddling duck-like movement. These two factors alone are serious enough afflictions, especially for girls, who are the most frequent sufferers, but this is by no means all. The power of endurance is nearly always somewhat, often greatly reduced. Usually the older the patient grows the more the endurance suffers. Besides, there is no way of telling at the age of 3, for instance, which child will get along fairly well and which one will be a great suf-

ferer in later years. Some children manage to get along comfortably until the age of puberty or until they have some severe infectious disease or other great physical or mental strain, after which they seem never again to regain sufficient endurance to be able to carry this extra handicap.

Lorenz quotes Halsted as stating that 31 per cent. of all adult patients suffer pain, especially when fatigued. It may vary from slight discomfort to such a degree of severity as to incapacitate the patient from all work that requires walking or standing, and in extreme cases walking may become impossible.

Bradford reports five cases in women in his own practice who suffered severe pain when they exerted themselves to the equivalent of walking a mile at a stretch.

One of my own patients, a girl of 17, suffered great discomfort, even though her work was no more strenuous than is required of a general practitioner's office attendant. One patient, an unmarried woman, aged 35, whose pain simulated coxitis and who had been treated for coxitis for a considerable length of time, was found on careful examination to suffer from congenital dislocation of the left hip. Finally, one of the most serious consequences of untreated congenital dislocation of the hip is the resultant pelvic deformity, which in women may be the cause of dystocia.

By some the belief is still held that in a certain percentage of cases a spontaneous cure may take place, and that a new joint may be formed. This opinion is based on the fact that in traumatic dislocations this sometimes takes place. Those who take this position seem to forget, however, that a traumatic dislocation and a congenital dislocation are very different. In the former the head slips out of the capsule and can occasionally actually make for itself a pocket simulating a joint, while in the latter case the head remains within the capsule and cannot do this.

The old methods, such as supports to the dislocated hip by means of pelvic bands, corsets and braces of almost every conceivable description, are of course only palliative and have so far as known never secured a permanent reduction. That Paci secured some cures by his method is definitely proved, but nowhere, not even in his last article, have I been able to find any statement as to what percentage of cures he can effect by his method.

I believe we all agree that the operation of choice is the functional weight-bearing method, or so-called bloodless method of Lorenz. As stated above, after the age of 6 in double and 8 in single dislocations, successful reduction by this method becomes possible in a smaller and smaller percentage of cases the older the patient grows.

Thus, for instance, in my own cases, in three single and four double hip dislocations, or seven hip cases in all, I failed to secure satisfactory reduction every time. I secured anterior transposition with fair functional result once. When we add to this number a considerable number of cases of older patients, whom I have examined at various times at my office and elsewhere, but of whom I have kept no record, in whom the displacement was so marked and the muscles so shortened that an attempt at bloodless reduction was clearly out of the question, it becomes evident that the percentage of successful reductions in patients past the age limit is very small.

Unfortunately I am unable to find authentic figures in the literature which convey a clear idea as to the results obtained by other surgeons in cases of patients who have

* Read in the Section on Surgery of the American Medical Association, at the Sixty-first Annual Session, at St. Louis, June, 1910.

passed this arbitrarily established age limit, first, because most men do not recognize this limit in their statistics, or record only those cases in which a reduction has been attempted; and again, because others report only those cases in which they believe they have accomplished either a reduction or a transposition.

The bloodless operation is clearly not very promising where patients have passed this age limit, and, while reduction can be accomplished by the Hoffa-Lorenz open operation in practically every case, it has very serious objections, among which may be mentioned a considerable mortality, prolonged illness, a necessity for still longer after-treatment and a functional result which usually is very unsatisfactory.

Thus Hoffa in the fourth edition of his "Orthopedic Surgery" reports 250 cases treated by the open method. He secured reduction in every case, but had a mortality of six. Anatomically the results were good in all of his cases, no relaxation having taken place, but none of his cases were functionally perfect and a large percentage of them resulted in complete ankylosis. At the present time I believe that we are safe in saying that an attempt at reduction by open operation is never justifiable in double dislocation of the hip.

The late Prof. Julius Wolf of Berlin once expressed himself very tersely in regard to the Hoffa-Lorenz open operation in double dislocation of the hip. "Before the operation," he said, "the children walk like ducks and after the operation they walk like lame ducks."

In single dislocations the condition is somewhat different, however. If a patient has great trouble with a single dislocated hip and reduction cannot be secured by the bloodless method one is often justified in resorting to the open operation, because in this condition, even if ankylosis of one hip in good position results, the patient's endurance becomes greatly improved. Thus, for instance, I had two patients, each with double dislocations; in each I was able to reduce one hip by the bloodless method, but, failing to reduce the second hip by this method, I subsequently accomplished reduction by the open method. In one of these hips I secured an excellent anatomic result with very good motion and in the other a fair anatomic result with a fair degree of motion.

As stated above, statistics on this subject vary greatly, because different standards are adopted. Hoffa told me personally, shortly before his death, that he had treated over 600 patients by the functional weight-bearing method of Lorenz; that in single dislocations in patients between the ages of 2 and 8 he had satisfactory anatomic and functional results in 70 per cent. of his cases; that in double dislocations in patients between the ages of 2 and 6 he had, however, only 20 per cent. of permanent functional and anatomic results; that among those patients who came under treatment later in life the percentage of successful cases became rapidly less as the patients became older. It will be observed that this latter statement corresponds fully with my own experience.

Lorenz,¹ in the last report which I was able to obtain, gives the following statistics: In 364 cases of unilateral dislocation, 248 gave anatomically good results, 127 subspinal position, 19 showed lateral apposition. Of 158 bilateral dislocations, 70 showed good anatomic results, 19 showed subspinal position on both sides, 7 lateral apposition on both sides, 49 good results on one side, the other side subspinal, 4 cases one side anatomic replacement, the other side lateral apposition. Taking all hips

together, gives 680, with 358, or 53 per cent. of good results. Or in single dislocations, out of 364, 218, or 60 per cent. anatomically and functionally good results, and in the bilateral form of 158 cases, 70, or 44 per cent. gave anatomically and functionally good results. Of course, to these should be added the cases in which he accomplished lateral apposition or subspinal position. Unless the case is definitely reported, however, there is no way of telling whether such transpositions have actually benefited the patients.

Hoffa states definitely that some of his cases were worse after the transposition than before. This low percentage of satisfactory results may be accounted for in a measure by the fact that Lorenz gives his age limit as 9 to 10 years in unilateral and 7 to 8 years in bilateral dislocations. He gives it as his opinion that the third year is the most favorable.

TABLE SHOWING RESULTS OF TREATMENT OF HIP-JOINT DISLOCATIONS

Total Patients:		
Examined	37
Rejected	3
Declined treatment	3
Treated	31
Above Age Limit:		
Treated	5
With single dislocation, treated	3
With single dislocation, secured anterior transposition	1
With single dislocation, secured functional improvement	1
With single dislocation, failed in securing reduction	2
Condition unchanged	4
Double dislocation, treated	4
Double dislocation failed in securing reduction. Condition unchanged	1
Total Patients Below Age Limit:		
Treated	26
With single dislocation, treated	17
With single dislocation, secured reduction	17
With single dislocation, secured good anatomic result	16
With single dislocation secured good functional result	16
With single dislocation, secured good anatomic and functional result	16
Still in cast. Hip in position when last examined	1
With double dislocation. Total number of hips treated	18
With double dislocation, secured reduction by bloodless method in	14
With double dislocation, secured good anatomic result after bloodless reduction	9
With double dislocation, secured good functional result after bloodless reduction	9
With double dislocation, still in cast. Hips in position when last examined	4
With double dislocation, failed in securing reduction. Condition unchanged	2
Secured reduction by open operation	2
Secured good anatomic result with fair degree of motion. Following open operation	1
Secured fair anatomic result with fair degree of motion. Following open operation	1
Secured reduction position perfect when cast was removed 18 months after reduction. On examining 6 months later, relaxed. Reduced again. Has relaxed again	1

In this country Lorenz was evidently less successful. Thus Ridlon,² in 29 hips subsequently examined by him, gave it as his opinion that he found the following results: 2 perfect replacements, 1 apparent replacement, 6 supracondyloid displacements, 13 anterior transpositions and 7 complete failures, or perfect results in only one-tenth of the cases.

Blencke³ gives in 60 per cent. of all cases good functional results.

My own statistics are the following: I have treated 26 patients below the age limit. Of this number 17 had single dislocations. Reduction was secured in all of these. Sixteen have been out of their casts for a year or more and all of these have good, permanent anatomic and functional results, making 100 per cent. of permanent cures in cases with single dislocations of the hip below the age of 8 years. Nine cases, or 18 hips, with

2. Ridlon, J.: The Ultimate Results of the Bloodless Replacements of Congenitally Dislocated Hips. THE JOURNAL A. M. A., April 16 and 23, 1904, pp. 1011, 1063.

3. Blencke: Ztschr. Orthop., Chir., xv, Nos. 2-4.

1. Lorenz: Am. Jour. Orthop. Surg., 1904-5.

double dislocations in patients below the age of 6 were treated. Reduction was secured in 14 hips by the bloodless method. Ten of these hips have been out of the cast a year or more. Nine of the 10 have good functional, anatomic results. One relaxed after the cast was removed. I failed to secure reduction by the bloodless method four times: one patient both hips, two patients one hip each. The latter two were reduced by the open operation and good anatomic and functional results in one case and fair results in the other were secured. In other words, in 14 double hip dislocations below the age of 6, who have been discharged from treatment, good anatomic and functional results were secured in 10, or 71 per cent. The four still in casts were in good position when last examined. They have not, however, been counted in the percentage. The complete table will appear in the published paper.

While the number treated is relatively small, I believe I have had a sufficient number of them, and the time that has elapsed since their treatment was completed is long enough to justify some conclusions. The two assertions that can be made without fear of contradiction are fortunately the two that are of the greatest importance to the patient as well as to the general practitioner. They are, first, that no case should go undiagnosed beyond the age of 3; second, that if properly treated at this age the great majority of dislocations can be successfully reduced and can be given good anatomic and functional results. By a good anatomic and functional result I mean that the head should be permanently opposite the Y cartilage, that the patient should have normal endurance and that his gait should be so nearly perfect that the ordinary observer cannot even detect a peculiarity in the patient's walk.

I wish now briefly to call attention to a few errors that are commonly made in this work. They are extremely costly errors, as they are, I believe, the cause for the great number of serious traumatism, relaxations and anterior transpositions. It will be observed that in my statistics I have only one anterior transposition, and that in a girl 11 years of age. These errors can be avoided by observing the following directions:

1. Too great force should never be applied, especially not suddenly. In children below the age limit it is rarely necessary, and in children above the age limit there is very considerable danger of doing more harm than good. It is, however, possible that my failures in securing successful reductions in children above the age limit may be attributed to my unwillingness to use excessive force.

2. The reduction should be accomplished by bringing the head over the posterior rim of the acetabulum rather than bringing it around the lower border. This latter method is apt to be adopted if bringing it over the posterior rim proves to be difficult. I am sure it is one of the principal causes for the great number of anterior transpositions and also for the considerable number of failures in the hands of some operators. I believe that many of these hips have been considered reduced, when, as a matter of fact, the capsule has just been pushed in front of the head, resulting in a transposition without a reduction. If this takes place it is quite impossible for a new joint to be formed, because a portion of the capsule intervenes between the head and the acetabulum, preventing the development of the cotyloid ligament. These pseudoreductions are very deceiving, because the operator experiences the peculiar shock of the head slipping anteriorly, and because a fullness appears in the groin and the thigh becomes lengthened, as shown by the tenseness of the hamstring muscles.

3. When reduction is once accomplished, the hip should never be intentionally relaxed. This is an error that is very commonly made by even the most experienced operators. I

believe that it increases the difficulty of retaining the head very greatly, because it gives the hip relaxation habit. Any farmer would know better than to drive a cow over a fence twelve times, in order to teach her to stay in the pasture.

4. The hamstring tendons should not be stretched at the time of reduction. Their action is fully as important in holding the head opposite the Y cartilage as is the subsequent weight bearing. Besides, the tenseness of the hamstring muscles is a very valuable sign for the first couple of weeks, as it is almost positive proof that the hip has not relaxed. Besides this overstretching of the hamstring muscles is entirely unnecessary, and being an additional trauma, is dangerous and harmful. If these little patients are encouraged to use their limbs as soon as possible, they will always get their legs straight long before the casts are removed and there will be much less likelihood of injuring the vessels and nerves.

5. The cast should be applied over stockinette instead of glazed cotton. If the bony prominences are protected by a little felt or quilted gauze this will be much more comfortable than cotton padding. If stockinette is used the head can be held so firmly that it will not move even a quarter of an inch. It can thus be kept opposite the Y cartilage until the capsule has had time to shrink and until the cotyloid ligament has had time to develop. In my last twenty-five cases I have used this material and in not a single case did relaxation take place while the hip was thus encased.

6. The cast should be applied with the thighs abducted to a right angle and flexed to a right angle, and it should be left in place for a year from the time of reduction with only one change of cast. In recent years some of the best operators have been in the habit of removing the cast in a relatively short time. Thus Hoffa has advised immobilizing the joint from fourteen to sixteen weeks. I believe this accounts in a large measure for his small percentage of permanent cures in double dislocations of the hip. In a large percentage of cases this period is not sufficiently long to permit proper shrinkage of the capsule and proper development of the cotyloid cartilage. I believe that the development of the cotyloid cartilage is the most important factor in the permanency of the reduction.

I am confident that if these directions are followed the percentage of cures will be much greater in the future than it has been in the past.

2106 Sedgwick Street.

ABSTRACT OF DISCUSSION

DR. A. J. GILLETTE, St. Paul, Minn.: I think that the term functional result does not convey to one who has not treated these patients and followed them up the real benefit which is obtained. A functional result is one in which the patient is pretty well satisfied, but the doctor is not. In other words, the limbs are very useful, but anatomically they are not perfect. So that when you take into consideration the perfect results Dr. Ochsner has and then the functional result, he has done exceedingly well.

With regard to the amount of force to be used, I notice that he did not believe that we should resort to very severe manipulation. I am getting bolder and I am getting a little more enthusiastic each time, and I am sure I have put into place some hips lately which I would not have operated on a few years ago. Of course, it is possible to produce a fracture. It has occurred in the hands of very good men, and there may occur paralysis. Even if paralysis occurs after manipulation it is only traumatic and will soon clear up. At least, it has done so in my cases. I think that we should attempt to reduce these hips, and, if necessary, use a great deal of force.

I think we should perform the bloody operation on more patients than we do. There are so many reasons why we do not get the hip into position that I will not enumerate them now. If you can get the head of the bone into position, and there is a twist in the neck of the femur, reduce the dislocation and perform a subtrochanteric osteotomy to bring the thigh in a good position later. Supposing it is necessary to do a bloody operation, do so. If the result should happen to be an ankylosed hip, that is not so bad, if you have

the head in position. It is wonderful how much better these cases are than those which are not reduced. The patients can walk and get about better, look better and feel better. They are free from pain or discomfort of any kind, simply because there develops a tremendous amount of compensatory motion in the sacro-iliac joint.

Dr. Ochsner says that he does not believe in stretching the hamstring muscles, and he gets good anatomic results, yet practical experience tells me something else. Frequently when I get the head of the bone in the socket and then attempt to stretch the hamstring muscles, the head slips out. Therefore I do not see any reason why we should not stretch these muscles. I know I have made the mistake of using too much padding. Another thing about which I am pretty positive is that we are leaving these casts on too long. We all know that we immobilize a joint which is not diseased for a long time, say six or eight months, the muscles and ligaments about the joint become lax and loose and one can sometimes partially dislocate a knee without the use of an anesthetic after too long use of plaster of Paris. Nearly all the heads of the bones slip out after casts have been removed, and that reminds me that many times we see these cases complicated by rickets. I had one patient come to me, and I know that there was not a dislocation present. But as the patient had rickets, I treated that condition and after six months the people came to me with the child limping, and the limp was due to a dislocation which was not present at the first visits. I wondered whether in all these cases the dislocation might be due to an intrauterine rickets. Of course, rickets is due to malnutrition, intrauterine as well as extra-uterine, and therefore the after-treatment should include proper feeding. In several instances I had to treat the rickets before attempting reduction. Most of these cases of congenital dislocation of the hip present some evidences of rickets.

DR. J. P. LORD, Omaha: My experience in the treatment of congenital misplacements includes about thirty cases, and the time is commensurate with that of the history of this treatment, that is, since 1890. The treatment I employed has been all of the varieties that have been recommended. In several of my earlier cases, I think about six, I used the open treatment. My experience was that of others, and in the ten years following earlier experience, that method was abandoned. Then my methods were practically those used by Lorenz, with about the results that others reported who have used that method. For the last two years I have been using the method as recommended by Bradford, of Boston. He uses a mechanical device for applying direct force in effecting a reduction of the head of the bone, forcing it down into the acetabulum. I think this method preferable, because it does not produce the amount of traumatism that these more or less blind manipulative methods that are used for stretching the parts in every direction are liable to cause. Having reduced the head of the bone by this method, Dr. Bradford makes a strong point of applying the dressing with the limb not only in abduction, but also in inward rotation, so that the head rests more securely in the acetabulum. Bradford's results have been very much better than hitherto, often as high as 91 per cent. of good functional results. My results also have been confirmatory of Dr. Bradford's experience. This method in addition limits the time of the period of confinement: three months seem ample. I am so thoroughly convinced of the value of this particular procedure of Bradford's that little else seems to be desirable, except in those unusual cases in which there is little to be accomplished by a bloodless procedure and an operation must be performed.

DR. EDWARD H. OCHSNER, Chicago: We must always diagnose congenital dislocation of the hip by the *x*-ray. There is no reason why a diagnosis should not be made in all of these cases, and no patient should be allowed to go beyond the age of three or four without an effort having been made to effect reduction. If a proper effort is made at the proper time, we may be confident of getting much better results than the statistics of the past have led us to believe can be obtained. I believe that we can expect and have a right to expect 90 per cent. of cures in the single dislocations, and 70 per cent. of cures in the double dislocations.

RADIO-ACTIVITY INDUCED BY THE X-RAY

A PRELIMINARY REPORT *

HELIODOR SCHILLER, M.D.

AND

PATRICK S. O'DONNELL, M.D.

CHICAGO

Physicists know that certain metals used in experimental work become radio-active while under the direct influence of the *x*-rays. It has been asserted, however, that such activity ceases with the removal of such influence or shortly thereafter. The fact that emanations proceed from radium or radium-salts, by which substances exposed to them become radio-active, is well known.

The physical similarity between the rays emitted by the *x*-ray tube and the Becquerel rays, at least the similarity between the *x*-rays and the beta rays emitted from radium, their penetrating power, their phosphorescent action, their action on photographic plates in black paper and plate-holders, their action in causing air to become conductive for electricity—all these phenomena made the existence also of a similarity between the nature of these rays seem plausible to us, and therefore we began experiments by which we found that radio-activity could not only be induced in metals or other substances while under the influence of the *x*-rays, but could, like that from radium, be retained by these substances for a certain length of time, the induced activity gradually disappearing just as the induced radio-activity by radium and actinium disappears. We think we are able to demonstrate that we can store up *x*-rays or a part of them and make use of them after they have been long removed from the tube from which they were derived.

PHOTOGRAPHIC EXPERIMENTS

For our experiments we used uniformly 14½ amperes and 110 volts in the primary, 25 milliamperes in the secondary coil, a distance of 30 cm. from the substance to the tube and fifteen minutes' exposure. The tubes used were hard tubes and kept as nearly as possible of the same vacuum.

EXPERIMENT 1.—The following liquids were used: Liquid A, glycerin dilutions. Liquid B, quinin solutions. Liquid C, quinin and glycerin solutions. Liquid D, a suspension of platinum cyanid of barium in Liquid C.

These four substances were exposed in open Petri dishes to the direct influence of the rays and then put in a non-conductive material. After this they were exposed to highly sensitive trichromatic photographic plates in black paper, and as an object for the purpose we used safety razor blades. After three hours' exposure to the plate and one minute development in a normal developer, we found A negative; plate not affected; B gave clear definition of the razor blades; C and D gave very clear definition.

EXPERIMENT 2.—The same substances were again immediately exposed for twelve hours to photographic plates, which were developed for one minute, resulting in very good definition in all cases.

EXPERIMENT 3.—A portion of C and D were diluted in the proportion of 15 to 85, then exposed for fifteen minutes to the rays and for twelve hours to the plates. C gave very good definition; D had no effect on the plate.

* These experiments have been conducted in the *x*-ray laboratory of the Michael Reese Hospital and materials for the physiologic tests and experiments have been furnished by the kindness of the institution.

EXPERIMENT 4.—C and D were exposed to the x -rays and after exposure diluted, 15 to 85, then for twelve hours exposed to the plates. Both plates were unaffected.

EXPERIMENT 5.—A, B, C and D were, forty-eight hours after exposure to the x -rays, again exposed to the photographic plate and found negative.

EXPERIMENT 6.—Eight other substances were exposed to the x -rays under similar conditions, but all were found negative in respect to their photographic action.

EXPERIMENT 7.—B and C were exposed for thirty minutes to the x -rays, and twenty-four hours after removal from the influence of the x -rays were still found to possess positive action on the photographic plates; that is to say, the razor plates still had good visible definition.

A, B, C and D were examined concerning their action on the platinum cyanid of barium screen, and at least C and D had, after long observation, a phosphorescent action.

EXPERIMENT 8.—After exposure to x -rays, 20 minims of C were injected into a guinea-pig. The pig was then exposed for twelve hours to a photographic plate; the trunk and skeleton parts of the feet were to be seen in a good outline on the plate and the plate as a whole was affected. The pig was found dead and already rigid. This experiment proves the penetrating power of the induced rays.

CONCLUSIONS

1. By exposing certain substances to the direct rays we are able to induce in these substances:

A. Rays which have a decided action on the photographic plate held in black paper and plate-holder.

B. Rays which have a penetrating power.

C. Rays which have a fluorescent action on the barium-platino cyanid screen.

2. These properties remain in these substances at least twenty-four to thirty hours and gradually disappear.

3. These properties have greater strength in B, C and D than in A.

4. These properties are present in a degree when these substances undergo dilution before their exposure to the x -rays.

5. These properties disappear at once if the substance is diluted after exposure to the rays.

ANIMAL EXPERIMENTS

Of equally great interest, revealing still other unknown peculiarities of x -rays, were our animal experiments made with the substances after they were exposed to the x -rays, or, as we prefer to say, after we made them active. It has been long known to one of us that x -rays are able to increase the toxicity of certain drugs and alter their physiologic action. A report of this phenomenon will appear in a later contribution; this knowledge helped us to understand the results of our experiments.

The injections were made in the mid-region of the back subcutaneously.

We injected 20 minims of substance A into a guinea-pig prior to its exposure to the x -rays; 20 minims into a second pig immediately after direct exposure of the substance to the x -rays; 20 minims into a third animal forty-eight hours after exposure of the substance to the x -rays or after the substance had lost its activity. This was controlled by the photographic plate. We found that the control Pig 1 remained healthy and began to feed five hours after injection.

Guinea-pig 2 was found to be hypersensitive to touch immediately after injection. A few hours afterward it acted as if sick and refused food and dragged the rear legs; the dragging finally approached a degree of paralysis. After four days the condition gradually improved, the paralysis disappeared and the animal got well.

Guinea-pig 3 died the fourth day. We experienced similar results after injecting other guinea-pigs with 10 minims of B and C before exposure to the x -rays, 10 drops after exposure and again 10 drops of the substance which had lost its activity. The control animals remained well whereas the animals injected with the active substances became temporarily sick and paralyzed in the legs, while the animals injected with

the substances which had lost their activity died between the third and fourth day.

Pathologic or histologic examination of the place of injection has not yet been made. We have left a great many examinations for the future, but we felt justified in reporting our findings even in this premature stage.

In estimating the value of our findings, importance must be attached to the fact that those rays induced by us may prove of value in combating disease in conditions in which radium or radium emanations have hitherto been of service.

The comparative ease with which we are able to activate great quantities of substances which are at once easy to obtain and cheap, whose activity we shall be able to regulate and graduate in accordance with the length of exposure to x -rays and by their known susceptibility, and which we shall be able to use internally by mouth, in baths, in the form of compresses, or possibly hypodermically—all these possibilities give rise to the hope that we may enlarge our armamentarium against sickness, not overlooking the value of the discovery in the chemical field.

We have found that many other chemical substances have a tendency to become radio-active for a few minutes, others hold the radio-activity for considerable time, although this activity is scarcely perceptible with the most sensitive plates.

BITES FROM COPPERHEAD SNAKES

GILMAN R. DAVIS, M.D., PRICE HILL, W. VA.

In response to the suggestion of Dr. Prentiss Willson,¹ that physicians should report cases of poisoning by copperhead snakes, I will report three cases. The mountains of West Virginia are full of copperhead snakes, and bites by them are frequent, many of which are treated by domestic remedies without calling a physician. The fact that patients generally recover indicates that the wounds are not serious.

To be efficacious, the prophylactic treatment of a snake bite must be immediate. The first thing to do is to grasp the limb on the proximal side, close to the wound and substitute constriction by a handkerchief or cord for the pressure of the fingers as soon as possible. Rapid and shallow stabs with a sharp-pointed penknife should then be made in and about the wound and strong suction applied by the mouth. This method involves the risk of sepsis, not only from the knife, but also from the mouth, which is never aseptic. But it is well to follow the maxim "in a choice between two evils take the less." Free bleeding may be expected to wash the poison from the wound. Snake poison taken into the stomach, even in considerable quantity, is destroyed by the gastric juice, and the amount injected into the tissue by the snake bite is about what would adhere to the point of a needle.

If I can reach the patient very soon after the infliction of the injury, I inject a solution of permanganate of potassium hypodermically in and about the wound. This quickly destroys the virus by its rapid oxidizing action. I avoid the use of whisky, but give full doses of strychnin and aromatic spirits of ammonia.

During the last two summers, I have personally treated three cases of copperhead snake bites. Two were in boys of 3 and 12 years respectively, and one in a girl of 10 years. The boys were bitten on the instep and the girl on the side of the bare ankle by snakes which proved to be of the copperhead species. In the older boy, there was swelling of the foot and leg extending to the knee. In the younger boy and in the girl, the entire leg was swollen to the body. In no case was there any constitutional disturbance. The pulse and temperature were approximately normal. Recovery was rapid, the boys being able to run about as usual in from 3 to 5 days. The girl was in bed for 4 days and on crutches for 10 days.

SYMPOSIUM ON THE TREATMENT OF ACUTE ANTERIOR POLIOMYELITIS

1. TREATMENT OF THE ACUTE STAGE

H. M. McCLANAHAN, A.M., M.D.
OMAHA

The recent literature of this disease has shed much valuable light on its nature, pathology, and clinical manifestations. The treatment of the acute stage has received scant consideration. If we can do nothing to modify the disease, certainly we can do something for the patient, and until specific treatment is discovered it is the duty of the physician to institute proper treatment to meet the indications in the average case. It is now recognized that this disease is caused by some living poison developed without the body. Evidence is rapidly accumulating that it is not only infectious, but to some degree contagious. Like other infectious diseases—for example, scarlet fever—it varies widely in its clinical manifestations. Some cases are so light during the acute stage that the parents give it no serious thought until paralysis develops. Others are so severe as to simulate cerebrospinal meningitis, or terminate in early fatality by involvement of centers in the medulla. In sporadic cases the nature of the malady is frequently not recognized until the manifestation of paralysis. During an epidemic the nature of the disease may at least be suspected. I firmly believe that if its nature is recognized with the beginning of symptoms, treatment is of value, and I base this statement on the evidence of physicians in this state who have had large experience.

I shall first discuss the subject of treatment in general and then the treatment of certain varieties.

TREATMENT IN GENERAL

Isolation of the patient can do no harm to the individual and may protect others in the family. To my mind it is more important than rigid quarantine. The advice of the family physician is usually accepted, hence if he advises the mother to at once isolate the patient he has adopted the best measure to prevent the extension of the disease to others. If a mistake in diagnosis is made no harm can possibly result. If during local epidemics of this disease, such as prevailed in 1909 in Nebraska and during 1910 in Iowa, physicians everywhere would adopt this course many cases might be saved from exposure.

The physician should realize that he is dealing with a general infection involving all organs, as well as the nervous system, and apply the same general principle of treatment as in other infectious diseases; hence the important principle of treatment is elimination. This includes thorough depurative action on the bowels, the ingestion of a liberal amount of fluid to promote excretion from the kidneys, the use of remedies to stimulate diaphoresis, a liquid nourishing diet and proper temperature and ventilation of the room.

How are we to meet these indications? In the Nebraska epidemic constipation was the rule, diarrhea the rare exception. Strictly speaking this was obstipation, and undoubtedly due to the disturbance of the motor function of the bowels. Men of large experience, as Anderson of Stromsburg, Shidler of York, Shaw of Osceola, and many others with whom I have had correspondence, found this a very difficult symptom to overcome, especially in those cases where vomiting was a

symptom. The best remedy is calomel in broken doses, given at frequent intervals, combined with soda. This should be followed by castor oil. It is a clinical fact worth remembering that when a child is vomiting, frequently it will retain castor oil. Even should it vomit, it will not expel all of the remedy. I clearly recall a case in which the child vomited the first two doses of castor oil and retained two subsequent doses.

Enemas are useful and often necessary, but the success of an enema depends in a large measure on the cooperation of the patient. First, an enema of 4 ounces of warm olive oil should be given, and the child encouraged to retain this for an hour or more, then an enema of one quart of soapy water should be given. This is best made by putting one-quarter of a cake of good soap in a pitcher, pouring over it a quart of boiling water and stirring until the water is cooled to body temperature. If this fails it may be followed by an enema of epsom salts, 2 ounces; glycerin, 2 ounces, and warm water sufficient to make 1 pint. After the bowels have been freely moved, they should be kept moving at least twice a day during the acute stage. If the child refuses to drink enough liquid to keep up free elimination from the kidneys, then warm salines by the bowels should be given. To stimulate the skin nothing equals a hot pack. This is also of benefit in the polynenritic type. Dr. LeGrand Kerr of Brooklyn recommends this as a routine treatment. If properly applied this is agreeable to the child, and it is always important to have the child's voluntary cooperation. A soft, white blanket, lightly wrung out of hot water (if there is evidence of stupor, it should be wrung out of mustard water), is wrapped snugly about the child. A dry blanket should be wrapped over this—not a muslin sheet which absorbs water. The child should be encouraged to drink while in the pack. I have found that some children will drink freely of grape-juice when they will not take water. When removed from the pack they should be gently rubbed dry and placed between blankets until perspiration has ceased.

The diet during the acute stage includes milk, plain, diluted or modified; buttermilk, broths, and, if there is much gas, some of the modified cereals, sometimes a poached egg, toast when properly made and fruit juices. Toast to be easily digested should be made from bread well dried, slices cut thin and heated through.

The fever seldom requires special attention, and when it does, sponging or a cool enema most safely meets the indication. Coal-tar derivatives should be avoided entirely.

As a routine treatment, I wish to recommend the use of hexamethylenamin (urotropin). This was suggested by Dr. Dana in an article appearing in *THE JOURNAL* about two years ago, based on the fact that Cushing of Baltimore had determined that this remedy when administered could be detected in the cerebrospinal fluid. I know of no objection to its use. It is generally well tolerated by the stomach. I have used it in a few cases and recommended it in a number. Dr. Adams of Florence, Nebraska, has employed this in twelve consecutive cases without mortality. I personally saw some of these patients. The rule was to give two grains every two hours during the acute stage, or, more definitely, during the first two or three days.

TREATMENT OF CERTAIN TYPES

Certain types of the disease require special consideration; first, the cerebral type. By this I mean cases beginning in a stormy way with fever, delirium or stupor,

muscular rigidity, etc. It usually happens that these symptoms subside in two or three days, and if the physician has called it cerebrospinal meningitis he begins to doubt his diagnosis. Lumbar puncture is now recognized as the only positive method of early diagnosis, but I wish to speak of it here as a therapeutic measure. Dr. Adams has had four of these cases and in every one there was relief of symptoms following the puncture. I saw two of them and can verify his statement. In these cases, also, the ice-cap is undoubtedly of benefit.

The polyneuritic type certainly requires special attention. Therapeutic nihilism will not do; the patient must be relieved. I have known of instances in which the screams of the child could be heard across the street. The pain is usually most intense in the back and legs. There is usually cutaneous hyperesthesia, so that even the weight of the bed-clothes gives pain and the walking of the attendant in the room hurts the child. A limited number will require the hypodermic use of morphin, but this is recommended only in the severe cases. Relief can often be attained by the use of a suppository. The one that has served my purpose best is as follows: Powdered opium gr. 1/2, extract of belladonna gr. 1/8, sodium salicylate gr. 5, oil of theobroma enough for one suppository. One suppository is to be inserted every three hours until relief is attained. Here again the hot pack, as above described, will sometimes give relief. When the stomach will retain it, sodium salicylate is of benefit. In some cases the pain continues beyond the acute stage. In one little girl the severe pain in the back persisted for about three weeks. Dr. Shidler of York has reported two cases in which lumbar puncture gave notable relief.

MANAGEMENT OF COMPLICATIONS

The mortality in this disease is chiefly from the involvement on the medulla, leading to respiratory failure. I think it is well to remember that this complication will occur in any type of the disease; hence such symptoms as shortness of breath, pallor of the skin with slight cyanosis of the lips, unwillingness to talk and an anxious countenance, should warn the attendant of approaching danger. In the presence of these symptoms what can be done? I have personally seen two cases that terminated fatally in spite of every effort. In all these cases the physician should be on the alert. It has occurred to me that oxygen might be of benefit, although I have no personal experience in its use in these cases. If I should again see a case of this type, however, I would do a lumbar puncture, on the theory that the bulbar paralysis might be due to pressure and that the withdrawal of fluid would tend to relieve this pressure. One case was reported to me, in which the child was taken out of doors on a cot with benefit. There is no evidence that strychnin, nitroglycerin or digitalis are of benefit.

2. TREATMENT FROM THE NEUROLOGIST'S VIEWPOINT

B. SACHS, M.D.
NEW YORK

The study of recent epidemics of infantile spinal paralysis, particularly of the New York epidemic of 1907, has led to a modification of the prevailing conception of the disease. Its infectious origin has been known for the past fifteen years or more¹ but not until recently have we realized that the infectious process may involve (in

some instances) the greater part of the central nervous system from the cortex of the brain to the lumbar ganglia. In the majority of cases we may still consider it an anterior poliomyelitis; in other instances it will be more correct to speak of it as an infectious meningo-encephalomyelitis.²

Our views as to the treatment of the disease have also undergone a radical change. It will not do for the physician to sit by idly and state that there is "little to be done"—as was the fashion not so many years ago. The disease calls for patient and intelligent treatment with a certain prospect of reward. After the subsidence of the acute stage³ the practitioner is face to face with the problem of what to do for the paralyzed limbs or muscles. Although this paralysis is due to an affection of the spinal cord, it is well not to attempt treatment of this organ. So far as we are at all able to influence the spinal lesion itself, the enforced rest in bed, and, in the earlier stages, the application of an ice-bag, will help as much or as little as any other measure. It is at least certain that these simple measures will do no harm. Counter-irritation is both painful and unnecessary, and the avoidance of pain in the case of a disease that is of itself painful and distressing is a point that we ought not to overlook. Counter-irritation over the spine is contraindicated because it will interfere with the quiet rest of the patient on the back; because of the danger of the formation of bedsores; and, lastly, because it is more than doubtful whether it can do any good. Galvanization of the spine in the hands of a careful practitioner may do no harm. It is more than doubtful whether it can do any good, and no one as yet has shown that if a current be applied to the skin over the spine any of it actually reaches the spinal cord substance itself. All therapeutic efforts should be concentrated on the treatment of the paralyzed groups of muscles, and in order to treat these with some show of intelligence it is above all necessary to determine which muscles or groups of muscles are especially involved. The entire aim of treatment is mildly to stimulate the nerves and to exercise in one way or another muscles which cannot be exercised by the will. This can be done by electricity, by massage, and by active and passive exercises.

ELECTRIC TREATMENT

First, as to the proper form of electric treatment: It is the rule in paralysis due to poliomyelitis that the nerves and muscles exhibit some form of the reaction of degeneration. This implies that in all but the mildest cases the nerves and muscles will not respond to the faradic current but will contract on galvanic stimulation. Muscular exercise is the chief aim in treatment, and for that reason one must follow the simple rule that in treating the paralyzed muscles that form of current is to be used which gives the best contraction with currents of moderate strength. Thus, if it is found that the contraction with the negative pole (KCC) is obtained with weaker currents than is the contraction with the positive pole (ACC), then the attempt should be made to exercise the muscles by the use of the negative pole, the other pole being placed at some distance from the paralyzed group of muscles. Currents of moderate strength should be employed, and the making

2. The Report of the Collective Investigation Committee on the New York Epidemic of 1907, Jour. Nerv. and Ment. Dis., Monograph Series VI. I recommend a careful study of the entire report to all physicians interested in the subject. The final section on treatment is full of helpful suggestions. The German translation of the report has just been published.

3. Let me hope that my colleague in this symposium has recommended that during this stage the treatment be similar to that employed at the onset of other acute infectious diseases.

1. Sachs: Nervous Diseases of Children, ed. 1, 1895.

and breaking of the current should be done slowly, so as to give the muscle time for deliberate contraction. Moreover, it is well in the majority of instances to apply the stimulating pole over the belly of the muscle unless it has been previously determined that the muscles can be excited from a motor nerve point. Do not merely pass the pole up and down the limb, but determine exactly how the muscles can be properly moved and apply the pole to those points. It is needless to say that this cannot be properly done unless the person doing it has had some satisfactory training in the use of electric instruments. If at all possible, the physician or his assistant should give this treatment, particularly in the earlier stages of poliomyelitis, and it should not be left in the hands of a trained nurse unless that person is specially qualified to give that treatment. In almost every case of poliomyelitis some groups of muscles are more completely paralyzed than others; some of them can be excited from the motor nerve point, others cannot. Whenever an entire group of muscles can be moved by applying the current over a motor-nerve point—the peroneal, for instance—advantage should be taken of this for the simple reason that a number of muscles can be exercised at one and the same time. Whether the paralysis has involved the muscles of the upper or the lower extremities, or of the abdomen or of the back, the same rules as to electric treatment obtain in all cases. The faradic current, except as a mild nerve stimulant, is of little benefit, particularly in the graver cases in which both nerves and muscles give no faradic response. It may be suggested, however, that an examination for diagnostic purposes with the faradic current be made from time to time, and as soon as the muscles and nerves in the process of recovery begin to respond to the faradic current, this current may be used conjointly with the galvanic.

In those rarer instances in which the lesion is so slight that the faradic response of nerves and muscles has never been entirely lost, the faradic and galvanic currents may be employed at alternate sittings. The matter of electric treatment can hardly be overdone. It should be begun about one week after the subsidence of the febrile period and should be continued daily until full recovery has set in or a chronic stage has been reached, during which exercising of the muscles no longer results in further improvement.

MASSAGE

The paralyzed limbs of a poliomyelitic patient exhibit a distinct tendency to wasting and to an impairment of the peripheral circulation. These conditions can be improved, if not overcome, by proper massage. A thorough kneading of the muscles will help to improve the circulation in the peripheral parts and at the same time will serve to counteract the tendency to contracture which is developed at an early period of the disease in many instances. A deep massage of the parts is in order, but the person giving the treatment should be cautioned not to add insult to injury by bearing down too heavily on the nerves in exposed areas. Thus the ulnar and musculospiral nerves, the sciatic, the peroneal and the posterior tibial, should not be manipulated with too much force. In the earlier stages of poliomyelitis these nerves are apt to be sensitive and I have known much harm to be done by violent massage. I would urge that every practitioner arrange to witness the massage as given by the person intrusted with it, and to caution against any excessive measures. Many a case of sciatic and peroneal neuritis might have been avoided if this precaution had been taken.

PASSIVE AND ACTIVE EXERCISE

I wish to lay especial stress on the importance of passive and active exercises. In the earlier paralytic stage passive exercises are of the greatest importance because in this way, and perhaps in this way only, can a tolerable nutrition of the paralyzed muscles be maintained. Moreover, early contractures can be partially counteracted. This tendency to contractures is in many instances the most serious feature of the disease and is responsible for subsequent deformities. In the investigation committee's report¹ Dr. Jelliffe has specially urged the value of hot baths (100 F.), and of giving the first passive exercises when the patient is lying in the tub. I fully subscribe to this suggestion and would insist that the nurse or attendant in charge of the patient be asked to carry the child carefully into the bath, and to have the passive exercises given in the tub.

Directly the paralysis has begun to recede, the time has come for active exercises. While the paralysis comes on with great suddenness, the improvement in the use of the muscles as a rule sets in very slowly and deliberately. There is no task more important for the physician in charge of poliomyelitis cases than to recognize the return of power to one or the other muscles or groups of muscles at the earliest possible moment, to fasten on this return, and to encourage from small beginnings the further development of muscular power. In the case of paralysis of the upper extremities, finger exercises, the grasping movements of the hands, raising of the shoulders, raising of the arms, etc., should be encouraged, and definite periods of the day should be set aside for such movements.² If the deep spinal and abdominal muscles are involved the patient should be encouraged to rise from the recumbent posture. At first only one or two attempts of this sort should be made; as the child grows stronger the same movements may be repeated four, five and six times up to the point of fatigue. In the case of the lower extremities, the movement of the toes, the bending of the knee, the raising of the entire leg, may be practiced while the child is still confined to its bed or couch, and as the improvement continues it should be encouraged, first with assistance, and held firmly under the arms, to stand on its feet, to make a few careful steps, and as power returns to the limbs to walk from its bed to a couch, to a chair, finally across the room; but it should not be allowed to walk unsupported until the physician has satisfied himself that the legs will actually carry the body.³ The tact and good judgment of a physician will be displayed in determining when it is safe to allow such a patient to use its limb or limbs unsupported. Children beyond the age of five, and older persons, may be encouraged to use crutches in getting about. Smaller children may be placed in go-carts, and other devices may be resorted to, in order that weakened muscles may be exerted without detriment to the patient; but unless the muscles are wholly inadequate to the performance of their duties they should not be entirely replaced by mechanical devices.⁴ It goes without saying that active exercises can be employed only in those cases in which some groups of muscles have retained considerable power, and I feel satisfied that we shall see a much smaller number of deformed and helplessly paralyzed limbs if these active exercises are properly prescribed in the earlier periods of the disease.

1. No physician would be in danger of following the example of an Eddyite practitioner who insisted that a child with a poliomyelitic leg be put in the middle of the room and be made to stand, with the result of its falling in a heap and fracturing its thigh.

5. It is most important to guard against the development of pes equinus and of genu recurvatum.

ORTHOPEDIC MEASURES

If permanently paralyzed or deformed limbs are the result of an attack of poliomyelitis, orthopedic measures should be freely resorted to. Simple contractures may, no doubt, be overcome by tenotomies, possibly by suitable apparatus, but I would particularly urge that the transplantation of tendons and the shortening of tendons be practiced in those cases in which an improved position of one or both legs could be brought about by such procedures. To a neurologist, the problem of transplantation of tendons is a very simple one. It merely amounts to implanting the tendon of an under-acting muscle into the tendon of an over-acting opponent. Much time is wasted, as a rule, in hoping for a return of tolerably normal conditions. If six months or a year after the onset of poliomyelitis a group of muscles shows considerable wasting, an absolute reaction of degeneration and no return of muscular power, it is useless to hope for spontaneous improvement. The orthopedist should then step in and attempt to correct the mischief done by the disease.

MEDICINAL TREATMENT

No reference has been made to medicinal treatment, for the simple reason that I know of no drug which has the slightest effect on the spinal lesion or on the paralyzed muscles after the acute stage has been passed. While salicylates and mild narcotics will have to be employed in the earlier period of the disease, and even iodids and ergot may be administered in the earlier stages, there is no sufficient reason to administer these drugs in the paralytic and post-paralytic periods. For the relief of neuritic and muscular pains, give a combination of pyramidon, citrate of caffeine and aspirin, or aspirin alone, varying the quantities according to the age of the patient. If necessary, codein may be added. I am very certain that injections of strychnin or of arsenic are absolutely useless, though there can be no objection to the use of the ordinary blood and nerve tonics, provided the practitioner keep in mind that he is attempting to improve the general condition of the patient and is not endeavoring directly to effect a change either in the spinal cord lesion or in the paralyzed nerves and muscles.

CONCLUSION

In conclusion, let me insist that intelligent gymnastic exercise of the paralyzed or weakened limbs is the method to which one should pin one's faith, and from personal experience I can state that the physician who directs these exercises intelligently, and who will direct them patiently, will have no reason to regret the time devoted to this good cause. In recent epidemics the disease has been of such varying intensity that we have no right to claim that any case is a hopeless one, and much can be done by properly directed therapeutic efforts.

135 Central Park West.

3. THE ORTHOPEDIC TREATMENT

JOHN RIDLON, M.D.
CHICAGO

The treatment of anterior poliomyelitis consists of massage, movements, braces and surgery. Massage is used to maintain and restore, at least to some extent, the nutrition of the paralyzed muscles. Electricity is employed for the same purpose, but is in my opinion of very doubtful value.

MOVEMENTS

Passive movements of the joints of the paralyzed part are made by the operator to maintain the normal range of motion and thereby prevent contraction of the unopposed or weakly opposed muscles, and to stretch already contracted muscles and correct recent and mild deformities. Assisted movements are made use of where some strength remains in the paralyzed muscles, but too little for the patient unassisted to put the joint through its full range of motion. Active movements performed by the patient himself have positive curative value, probably greater than any other remedy. Resisted movements are normal active movements of the patient resisted by the operator just sufficiently to bring out the full strength of the patient as he performs each movement.

BRACES AND SPLINTS

Such mechanical appliances as splints and braces are used to prevent the development of contraction deformities, and to enable the patient to use the paralyzed limb more and more normally than in many cases it is possible for him to do without this aid.

SURGERY AND MASSAGE

Surgery is used to correct deformities, to maintain that correction and to assist in the restoration of function and in some cases to eliminate the necessity of braces.

Gentle massage and gentle passive movements may be employed from the time that the diagnosis is made. More vigorous massage and movements should be employed as soon as the sensitiveness of the limbs has passed off, and should be continued daily for years. When it is possible to have a skilled masseur, one should be employed. When it is not possible to have the service of a skilled masseur for a long time, some member of the family should receive from some competent operator at least a few lessons.

Osteopathic treatment, as such, is useless; for osteopathic treatment is to massage what homeopathy once was to regular medicine, a pretense to a reality. Real massage is a real aid. Osteopathy in the treatment of infantile paralysis is a pretense; it is useless, and the employment of the osteopath means the loss of much valuable time.

CONTRACTION DEFORMITIES

In nearly all cases of anterior poliomyelitis contraction deformities develop sooner or later. In most cases, fortunately, it is later, some months after the acute attack with its usual accompaniment of sensitiveness and soreness of the limbs has passed, and when it is comparatively easy with splints or braces to prevent it. But in a few cases contraction deformities, even of severe degree, develop during the first eight or ten days, while the sensitiveness is still so great that it seems a positive cruelty to move the child at all. But if the attending physician allows contraction deformities to develop, whether it be early or late, he should realize fully the responsibility he is taking, and should stand ready to admit that to his neglect of a simple precaution the child must have all the rest of his life more useless limbs than he needed to have. For no orthopedic or surgical treatment can ever make these contracted muscles as good as they might have been had he prevented the development of deformity.

Obviously, then, the first thing to do in the orthopedic treatment of a case of anterior poliomyelitis is to prevent contraction deformity by daily passive movements, if they are sufficient; if they are not sufficient, to put the limb in a plaster cast, or some equally efficient splint,

with all joints in the normal position for standing erect; and to maintain them so until all tendency to contraction deformity has passed, or an efficient brace can be applied.

DETAILS OF BRACES

No practitioner should prescribe a brace unless he can make it himself and modify it from time to time as may be necessary. To require an instrument-maker to measure for, make, fit and apply a brace is equivalent to asking a druggist to put up a bottle of medicine for the treatment of a patient suffering from the diagnosis of pneumonia. If the physician in charge of the case can not measure and make the drawings for the brace he wants, so that any competent mechanic can construct the brace, and then fit and modify the brace without the assistance of the mechanic, he is not competent to carry on the brace treatment and should not attempt to do it.

Here and there an orthopedist can be found sufficiently competent to correct some slight contraction deformities by braces constructed to stretch the shortened muscles, but of these there are few, for in these days most young orthopedists seem to have a greater ambition to perfect themselves in surgery than in mechanics.

As a rule braces should be used only to prevent the development of deformities at joints where the tendency is not great, in joints where the deformity has been fully corrected, and to enable the patient to use the limb more and better than he can use it without the brace.

CONTRAINDICATIONS TO BRACES

If there is no deformity and no tendency to deformity and the patient can use the limb without a brace, then a brace should never be used. A brace should be a help, not a burden. It is greatly to be regretted that the cupidity of some physicians leads them to order braces from surgical instrument makers who give a commission of 25 per cent. on the cost of the brace, for this usually means a costly brace that the physician can neither measure for, fit to the patient nor use intelligently.

INDICATIONS FOR SURGERY

Surgery in the treatment of anterior poliomyelitis may be either "bloodless surgery," that is, the correction of the deformities by great force, stretching and tearing all shortened soft parts that produce joint deformity, the patient of course being fully anesthetized, or operative (bloody) surgery. There is a certain risk, not often appreciated, in the use of great force in the correction of paralytic deformities. For both from non-use and from deficient nutrition arising from the paralysis, the bones grow thin and friable and may be broken before the deformity can be overcome.

These bones when broken sometimes are the source of fat emboli, not infrequently the cause of death. But when a deformity can be safely corrected without a cutting operation it should be so corrected. Then it should be put up in a well-padded and heavy plaster splint and kept in the splint and used for from four to eight months. After that an efficient brace should be worn for years.

When a paralytic deformity cannot be corrected by force alone, it can generally be fully corrected by simple tenotomies and force. When this is done the after treatment should be as before indicated, namely, a well-padded and heavy plaster splint, worn for months

while the limb is being used, followed by a brace, for years in most cases, massage and movements. I have seen no better results than this uniformly gives.

TENDON SURGERY

During the past fifteen or twenty years a great many patients with infantile paralysis have been operated on by various and changing methods of tendon-splicing, tendon transplantation, and tendon lengthening. The present view of this work is that the tendon-splicing of fifteen years ago is useless; that the tendon-transplantation of ten years ago is useful in a small and carefully selected lot of cases; that the tendon-lengthening and joint-fixation with permanently buried silk ligatures as practiced during the past five years holds out as yet a promise of better results when well done in carefully selected cases. Yet hardly a week passes that we do not see utter failures as results of operations done by others. As yet it is too soon to say what the ultimate results will be after ten or fifteen years have passed in the cases that now seem to be entirely satisfactory.

Treatment of these patients by nerve grafting is useless.

The resection of flail joints in complete paralysis in order to obtain ankylosis and escape the burden and cost of braces for life is sometimes a success, and sometimes a failure through failure of bone union, probably owing to the impaired nutrition.

PROGNOSIS

Finally, let me say that occasionally a patient with anterior poliomyelitis recovers without paralysis; occasionally a patient but slightly paralyzed recovers from the paralysis; most patients gain from six to eighteen months after the acute attack has passed, and never gain after that in real strength, but may gain in ability to use the limb through orthopedic treatment. In at least a third of the cases there is arrest of the growth of the length of the limb during the whole of the growing period of the child. It has been asserted by Heather Bigg of London that in some cases which have shown a progressive difference in growth of the limbs for several years the paralyzed and shorter limb in a measure overtakes the well limb by a more rapid growth, but this I have not seen, nor has it been mentioned by other writers.

72 Madison Street.

THE HOME OF THE ASSOCIATION
A BRIEF HISTORY OF ITS MATERIAL PROGRESS AND OF
THE GROWTH OF THE ASSOCIATION BUILDING

CHAPTER I. THE FIRST BUILDING
INTRODUCTION

This story, which will be a continued one, relates to the establishment and equipment of a permanent home for the American Medical Association and its JOURNAL. It is a good

Transactions practically exhausted the revenues of the organization, and often more than exhausted them, the Association had no headquarters, except under the Permanent Secretary's hat. Except during the four days of the annual session the Association was practically non-existent. References were made occasionally in presidential addresses to the desirability of a permanent home and headquarters, but for a long time it ended in a desire and a hope.

THE START OF THE JOURNAL

When in 1883 the Association decided to publish a journal, some kind of editorial offices became a necessity, and the establishment and development of a home dates from that period. Dr. N. S. Davis, who was the leader in the establishment of THE JOURNAL, became its first editor, and editorial quarters were opened in his office. And here they remained from the first issue of THE JOURNAL, July 4, 1883, until November 24, 1888, when they were removed to 68 Wabash Avenue. September 1, 1894, in that early wandering period, THE JOURNAL moved to 86 Fifth Avenue, and May 1, 1896, to 61 Market Street. Each of these removes was made necessary by the growth of THE JOURNAL, which necessitated increased space and facilities. The circulation at the latter date had reached nearly 8,000 copies weekly. In 1902 the circulation had leaped to over 25,000 copies weekly.

At the session of that year the trustees reported that the lease on the Market Street property would soon expire, and that sufficient room could not be secured in the building to accommodate the rapidly growing needs of THE JOURNAL. The increasing prosperity of the Association and the enlarged earning capacity of THE JOURNAL justified the trustees in considering the purchase of real estate for a permanent home for the Association, and they were authorized to do so.

THE FIRST BUILDING ERECTED

Accordingly in March, 1902, property was purchased on the northeast corner of Dearborn Avenue and Indiana Street, a few blocks north of the Chicago river and close to the "loop" district, the business center of Chicago. This property, 100 feet on Dearborn Avenue by 80 feet on Indiana street, contained at that time five two-story and basement houses, and

Fig. 2.—The three-story and basement building originally erected, and occupied in December, 1903.

story and we feel that every reader of THE JOURNAL will be interested in it.

A short time ago we printed a series of editorial articles detailing certain facts in the history of the Association, its aims and purposes, its progress in organization, and what it has done and is doing for the benefit of the medical profession and for the people. The present series of articles constitutes a brief record of the triumphs of the Association on the material side, and particularly of its efforts to found a permanent home for its material activities.

THE DAYS OF THE TRANSACTIONS

Without a home, an organization, like a man, is not only a wanderer, but is also greatly hampered in usefulness. During the early years of the American Medical Association, when the membership was small and the cost of publishing the

Fig. 3.—The old home of the Association as it is at present, with the added fourth story erected in 1905, together with the remaining houses of the original purchase and the two three-story houses on the east (right side of picture) later purchased to secure additional ground space.

cost \$42,000. The property as originally purchased is shown in Figure 1. Two of these houses—those on the north—were torn down and the erection begun of a three-story building, 40 by 80 feet, with high basement, of brick with stone trimmings. This building was completed, equipped and occupied December 1, 1902, and is shown in Figure 2. The cost was about \$35,000. In the first four months of 1903 the circulation had reached over 27,000 and before the year was out, on account of the phenomenal growth of THE JOURNAL and its business, it was again crowded for room, and it was necessary to extend the building. An opportunity was given about this time to purchase at an extremely low price—approximately \$15,000—the adjoining property on the east, consisting of a lot 40 by 100 feet, containing two three-story and basement houses. The purchase was made in June, 1903. This made the entire ground space owned by the Association 100 by 120 feet. In 1905 the old building was enlarged by the addition of another story and by extending it back 40 feet, completing the building as at present occupied. Thus it had become a four-story building, with a high basement 40 by 120 feet in dimension. It is shown in Figure 3 with the houses on the south and the two last purchased on the east.

THE FIRST BUILDING OUTGROWN

But the circulation of THE JOURNAL did not remain at 27,000. Far from it. In 1909 the number printed had mounted to 55,000 weekly, and the collateral printing and publishing business and the work of the Directory Department, and of the Councils on Medical Education and on Pharmacy and Chemistry, with its chemical laboratory, which had been established meanwhile, had grown in a corresponding manner, and again there was not room enough. And so, bursting through its walls, the business oozed out into one of the adjoining houses. The tenants moved out, additional presses were placed in the basement and the other floors of the house were occupied as offices and by the mailing department. But this was only a temporary makeshift. The cry was still, MORE ROOM!

How that cry was answered will be told in succeeding issues.

THE VALUE OF EHRlich'S NEW DISCOVERY "606" (DIOXYDIAMIDO-ARSENOBENZOL)

A PRELIMINARY REPORT FROM PERSONAL OBSERVATIONS

B. C. CORBUS, M.D.

Adjunct Professor of Genito-Urinary Diseases, College of Physicians and Surgeons, Medical Department, University of Illinois

CHICAGO

Originally the expression, "specific therapy" was understood in a purely chemical sense, which is evident from the fact that from olden times the administration of mercury, iodine, etc., was designated as specific therapy. More recently immunotherapy has laid claim to the same designation and has pushed the chemical into the background.

The two forms of treatment may come together in important points, since chemotherapy may also lead to the formation of antibodies, but there are very great differences. In immunotherapy the various antibodies are formed as products of complicated reactions on the part of the animal organism. These antibodies are strictly specific in nature and act exclusively on the respective bacteria or their toxic products. They do not of themselves exert any injurious action on the organism. For this reason the serum therapy represents the ideal of all forms of treatment, in that the protective substances kill the parasites without injur-

ing the body, and therefore every thinking person will give preference to immunotherapy (whether active or passive) whenever it is applicable.

Unfortunately, in contrast to diseases due to bacterial action, in a whole series of infectious diseases the successful formation of antibodies in the required manner is impossible. This is particularly true for diseases produced by protozoa, malarial plasmodia, trypanosomes, piroplasmas and the pathogenic spirochetes. In these diseases the clinical course indicates that the healing reaction of the organism is seriously hindered by peculiarities characteristic of the parasites. In such cases we must attempt to kill the parasites chemically; the possibility of doing this is known. I need only refer to the use of quinine in malaria, mercury and iodine in syphilis and atoxyl in trypanosomiasis.

The substances employed, however, are poisons, and do not, like the antibodies, leave the body unharmed. Hence the importance of the careful, detailed study to which Ehrlich¹ has devoted himself for a number of years. Ehrlich has found that certain chemical substances are particularly attracted to certain parasites; they are parasitotropic. Being poisons and capable of injuring the cells of organs, these substances are also organotropic, and their curative value in parasitic diseases depends on the existence of a proper relation between the parasitotropic and organotropic properties.

After many experiments in various directions, Ehrlich has finally succeeded in preparing a substance for the cure of syphilis in which, if it is used in proper dosage, the parasitotropic power sufficiently overshadows the organotropic to make the latter a negligible quantity. He has come to the conclusion, after years of animal experimentation that the most effective treatment consists in administering a single dose of such strength that it sterilizes the animal completely by destroying all the parasites in the organs, and thus produces a complete healing or cure. This act of sterilization with one dose Ehrlich designates as "therapia sterilisans magna."

The chemical "606" was first tried in Professor Doctor Konrad Alt's² clinic in Uchtspringe (Altmark) in September, 1909, by Dr. Hoppe. Twenty-three patients were treated, mostly syphilitic paralytics. The dose employed was 0.3 gm. The arsenic was eliminated slowly and found in the urine as late as the tenth day. Professor Alt asked Schrieber of the Altstädtische Krankenhaus in Magdeburg to try the remedy in recent syphilitics; twenty-seven patients so treated improved with astounding rapidity; the dose used, however, was still only 0.3 gm., half the quantity now given. Wechselmann³ was the next to report, June 22, 1910. He gave 0.15 gm. to women and 0.6 gm. to men. At present Wechselmann has a record of the largest number of patients treated, something over 900.

The Virchow Krankenhaus in Berlin offers the largest field for experimentation. I can testify to the authenticity of the statement of Dr. Siesskind,⁴ Wechselmann's first assistant, that spirochetes begin to disappear in from eighteen to twenty-four hours after injection. Here I saw at least seven babies that had been treated; the average age was ten days; the patients had macular eruptions, fissures and mucous patches. All showed a wonderful improvement in four or five

4. Personal observation.

days. Taegé⁵ has treated a syphilitic infant by injecting the mother; both improved. In 100 gm. of the mother's milk no trace of organic arsenic and only a trace of inorganic arsenic could be found. He concludes that the infant was influenced, not by arsenobenzol, but by endotoxins. The substance has been given to mothers while the fetus was yet in utero without either producing death or causing abortion.

The results in secondary and tertiary lesions were equally brilliant. Wechselmann asserts that there is an increase in body weight. This is certainly true of the old cases in which there were tertiary manifestations; however, it was necessary in some refractory cases to give a second injection, which may have been due in part to the method of administration. He offers the explanation that the spirochetes may be stored up in the cutaneous, glandular, muscular or osseous tissues, and later find their way into the blood-stream. He showed several patients with syphilitic periostitis in whom the pain disappeared over night by crisis, as it were.

Lesser⁴ in the Charité, while not having such an abundance of material, has handled his cases excellently. Up to the present time, he has treated 160 cases. I saw one baby three weeks old in which the cutaneous lesions disappeared in five days. Here also a large gumma of the tongue had completely healed in a remarkably short time. One patient with malignant syphilis with cerebral symptoms, in whom no cure was possible, nevertheless improved visibly. In each of his cases, Lesser has resorted to only one injection. This, I think, is due in a large measure to the technic that is used. It is a modification of Alt's, and was judged to be the best by the numerous physicians who were in daily attendance. It is the technic that I am employing, not only on my patients, but also on the patients who were referred to me by Dr. Ehrlich for treatment. A detailed description of the technic will be found below.

A. Neisser⁶ has treated 126 patients. He asserts that in the total of 2,500 patients treated with "606," at the time of his writing, not a single serious organic disturbance occurred which could be definitely attributed to the remedy. Its effect surpasses anything that has been used, even mercury and iodine. Like Lesser, he uses a solution that is as nearly neutral as possible; hence he never saw instances of severe pain. He says that the action of a neutral solution seems to be slower and more prolonged. H. Isaac⁷ from the old Lassar clinic says that there is an incomparable, often rapid, and thorough action of the remedy on spirochetes observable and a prompt absorption of pathologic-anatomic changes produced by them; he finds that lesions on the mucous membrane are most rapidly benefited. From all the prominent clinics in Europe, most astonishing reports are published.

The specific has been tried only in a few cases of parasyphilis. In a limited number of tabetic cases with girdle pains, etc., the relief has been prompt, but this, in the absence of a positive Wassermann, may have been due more or less to suggestion.

TECHNIC

The surprisingly large number of different technics is indeed confusing, as each clinician seems to be endeavoring to attach his own special method to Ehrlich's dis-

covery. The following are references to a few methods, all of which I have seen used: those of Alt and Hoppe,² Wechselmann and Lange,³ Michaelis,⁵ Kromayer,⁹ and the intravenous method of E. Schreiber and J. Hoppe,¹⁰ I shall describe, however, only the technic of Lesser for the following reasons: 1. The substance is the most easily kept sterile. 2. The method is the simplest to carry out. 3. It is the most lasting in its effects and most efficient in its results.

LESSER'S METHOD

Take a graduated cylinder with ground glass stopper, in which there are about one dozen glass pearls to assist in mixing. Add "606" salt; immediately add 15 c.c. hot water, shake vigorously until every particle of the salt is dissolved; then add 2 c.c. normal sodium hydrate (NaOH) solution; a precipitate occurs. Then continue to add sodium hydrate solution in very small quantity, shaking vigorously after each addition, until the solution begins to clear; then drop by drop, until we have a clear solution. This should be neutral; if the cylinder does not contain 20 c.c. of solution, sterile water is added up to that amount. Then 10 c.c. of this solution is injected deep into the buttocks on either side, always taking care to cleanse the parts with soap, water and iodine.

In every instance patients should be sent to the hospital for treatment, and care should be taken that they rest for one-half hour after the injection.

Ehrlich lays great stress on the fact that no patient who has ocular disease involving the fundus, cardiac or kidney disease, should receive any of the specific.

Neisser⁶ reports that the injection did not produce fever in non-syphilitics; the temperature rise in syphilitics (general reaction) is attributed to endotoxins liberated from the killed spirochetes. Vomiting occurred during fever occasionally. The vomitus was examined in four cases and never contained arsenic.

In three cases Neisser⁶ saw erythematous eruptions, which disappeared rapidly.

All investigators report an increase of leukocytes immediately following the injection.

Neisser⁶ advises local treatment of syphilitic lesions, either excision or local treatment with calomel in addition to "606."

THE CURATIVE EFFECTS OF "606"

The idea that Ehrlich's new substance will prove a panacea for every case of syphilis is a mistake, notwithstanding the fact that after a single injection the spirochetes disappear from primary lesions, in from twenty-four to forty-eight hours, and that old indolent lesions heal with remarkable rapidity.

The results are best divided into two classes: (1) immediate; (2) remote.

1. *Immediate Effects.*—In all primary lesions in which the sore is of the erosive type, if taken before a positive Wassermann is present, one dose containing 0.6 gm. seems to destroy all the spirochetes. This is confirmed by Neisser.

Excision of the primary lesion, while fraught with some danger to the surgeon, accomplishes a great deal, as a large number of spirochetes are thus removed. This permits the specific to act in excess on any that may still be in the system.

In the cases in which the initial lesion is marked by extensive sclerosis a second dose has been necessary.

because the substance in the circulation was not able to permeate the chancre on account of the extensive endarteritis present; so in this class of cases, whenever it is possible without undue loss of tissue, excision is demanded if we expect one injection to have its maximum effect.

The immediate results in secondary lues, if occurring early in the infection, are good so far as external manifestations are concerned, but in late secondaries it has been necessary to repeat the injection in some instances.

It may be possible in the future to give a preliminary treatment of potassium iodid in this class of cases, and clean house, as it were, thus bringing the spirochetes into the blood-stream. Previous treatment with mercury and potassium iodid does not, however, seem to have any effect on the efficiency of the treatment.

Tertiary lesions show the most marked improvement. This is due, as suggested by Ehrlich, to the fact that there are a large number of antibodies in the circulation and one injection stimulates the organism in a wonderful manner. It may also be explained on the hypothesis that the strain of spirochetes is well-nigh exhausted in virulence and that a little of the specific acts in a far-reaching manner.

I have intentionally omitted mentioning any of the other forms of syphilis, as the experiments were carried out in a large measure only in cases in which there were active, visible lesions.

Dr. Ehrlich¹¹ does not wish the specific tried at first on any except the most suitable cases, knowing full well the danger of complications in patients who are already debilitated by disease.

2. *Remote Effects.*—We have now been treating syphilis many hundreds of years with mercury, and our knowledge in regard to its efficiency or inefficiency is well established. All reports that are published on the new discovery must be regarded as preliminary, because in syphilis, more than in any other disease, freedom from relapses for years is necessary before a cure can be established.

At present our success in healing syphilis with mercury has been obtained by an extremely energetic treatment, begun early, our aim being to get a negative Wassermann and to keep it negative throughout the whole time.

If we have in "606" a specific that in one or two doses will kill all the spirochetes in the system, then we have indeed a wonderful remedy.

But how can we tell?

THE WASSERMANN REACTION

In the light of our present knowledge, our only hope lies in the Wassermann reaction. With the Wassermann reaction, under mercury treatment, it was possible with a fair degree of certainty to tell when we had the disease under control, but unfortunately after the administration of "606" we have a different picture. Here we have a large number of dead spirochetes in the system and a hyperleukocytosis, and we may have a persistent positive reaction; on the other hand, a few spirochetes may be living and later be so insignificant as to permit a negative reaction, and still later a positive one.

If we are to make use of the Wassermann test—and this seems to be the only method now at hand—we shall

have to wait until numerous statistics are available before we can draw definite conclusions.

On the continent every well-regulated clinic has at least one or two Wassermann laboratories, and reports are beginning to appear. Professors Alt and Hoppe² were the first to report Wassermann findings. Of the original twenty-three patients, mostly paralytics, out of eighteen cases with a positive Wassermann, two became negative after one injection of 0.3 gm. "606." There was strong diminution in two others, and noticeable diminution in three.

Neisser⁶ reports on primary lesions treated soon after infection that only 10 per cent. of patients with positive Wassermann became negative, but the dose was only 0.4 gm.

Schreiber⁹ and Hoppe report that of fifty-two patients treated and observed for fifty days or longer, 84.6 per cent. lost a positive Wassermann. Four other patients lost the reaction later, making 92.3 per cent. The earliest change from positive to negative occurred in four days, the longest after seventy days. In one patient treated intravenously the Wassermann became negative in forty hours.

M. Meyer¹² reports sixteen cases, of which twelve were cases of paralysis. In four of the twelve the Wassermann was not affected (dose too small); in four it became less decided for a while; in four treated intravenously it became at once negative. There was no marked improvement of the paralysis.

Karl Lange¹³ reports 268 patients treated.

In 153 cases in which the Wassermann was first positive, it became negative four or five weeks after treatment; nine negative cases treated with mercury before "606" was injected, remained negative; two cases of primary syphilis previously negative, treated with the substance remained negative; five cases of tertiary syphilis became positive after injection; two changed to negative, and one died with positive, two were still positive; two cases in which Wassermann had appeared negative became positive; one later became negative, the other one partially positive; ninety-seven cases remained positive.

We can see from the foregoing that the results of the Wassermann test up to the present time are very variable.

For a Wassermann test to be of value in a given patient it must become negative and remain so for at least one and one-half years; without this we are justified in not accepting any case as an absolute cure without the lapse of a long period of freedom from the disease.

CONCLUSIONS

Looking into the future, it seems hard to prophecy what we are to expect from a single injection. In order that our results may fulfil the theory of Ehrlich's "therapia sterilisans magna," the following conditions are necessary: first, one must not administer "606" in any condition that is not of spirochetal origin. Second, there must be absolute certainty of diagnosis by means of the Wassermann reaction or by examination for spirochetes. Third, the most careful and painstaking technique in preparing the substance for injection and in the injection itself must be observed.

Therapeutics

PREVENTION OF ACCIDENTAL VENEREAL INFECTION IN SCHOOLS

In comparatively recent years the medical profession has succeeded in securing tangible results in promoting public health by means of medical inspection of the children in the public schools. The most striking of these results have been obtained chiefly in diseases which are readily recognized by moderately trained observers such as imperfections of the eyes, ears, nose, throat, skin, bones and joints. The frequency of the occurrence of venereal diseases among school children has in but few instances been noted, and the prevention of these diseases has but rarely been attempted.

The necessity for studying this subject more carefully and for the inauguration of more effort to prevent these diseases among school children is evidenced by the paper which Dr. Ira S. Wile, of New York, has recently presented (*New York Medical Journal*, Sept. 10, 1910). To show the necessity for this study he gives us the statistical facts that 20 per cent. of all venereal diseases is acquired before the twenty-first birthday; that the annual average of deaths from syphilis has increased from 4.1 per cent. in 1901 to 5.4 per cent. in 1908 in every 100,000. The recorded number of deaths ascribed to gonorrhoea has remained unchanged during these years, but this does not take into consideration deaths due indirectly to the gonococcus. He quotes Dr. Morrow that it is a "conservative estimate that in this country the morbidity from gonorrhoea would represent 60 per cent. of the adult male population, and that of syphilis from 10 to 15 per cent." while it has been stated that in France 20,000 children die yearly from syphilis. It is probable that many deaths of children not ascribed to these diseases are really caused by secondary consequences of them. The primary cause of death may be concealed, if known; or may not have been diagnosed, so that deaths from various inflammations, peritonitis, and brain tumors may rightly be due to these diseases.

Probably there is no practicing physician who could not relate one instance, and perhaps a large number of instances, where he knew of some individual who came in more or less close relationship to one or more children while he was suffering from syphilis or gonorrhoea. We therefore should not be surprised that many school attendants, such as janitors, scrub-women, or other adjuncts to the school, are infected with one or other of these diseases, instances of which are mentioned by Wile.

A study of school children has shown that the occurrence of syphilis and gonorrhoea, generally accidentally acquired, between the ages of 4 and 16 is not infrequent. Though some schools and at least one city compel examination of the sexual organs of children before their admittance, this examination cannot be urged. Such examination is of little value unless careful microscopic examinations of secretions are made. It is, however, perfectly possible that the teacher of each room should note if a child requires too frequently to leave the room for urination, and should have the school inspector or the family physician decide the cause of such irritation or disturbance. The teacher should be urged especially to note evidences of sore mouth, sore eyes, enlarged glands, and eruptions ever so simple, and should call the school inspector's attention to such instances. The laboratory departments of the various boards of health

should be as ready to examine, without charge, slides and secretions for gonococci and for the *Spirochæta pallida* as they are to make typhoid, malaria, diphtheria, and tuberculosis examinations. In other words, there can be no excuse for not having every suspected child thoroughly and properly examined, and if the findings are positive such a child should be as surely removed from school as though he had a distinctly recognized contagious disease.

The various methods of acquiring these diseases accidentally and innocently are summed up by Wile as: "by fondling, kissing, using infected glasses and infected eating utensils, from the use of common towels, pencils, sponges, and polluted toilet seats." Occasionally there was more direct contact, as "by exchanging chewing gum, interchange of mouth toys, and sexual contact."

The obvious conclusions to draw from these facts and investigations are that the toilet seats should be daily cleansed with strong antiseptic solutions. Small, individual towels should always be ready for use at the school basins. Drinking fountains must be substituted for the common drinking cup. There must be personal desk articles for each child. Short, hygienic talks should be given the children as to the danger from exchanging and putting into the mouth articles that belong to other children. They should also be taught cleanliness of their own mouths, hands, and persons. Such talks should not be given once or twice, but repeatedly, at least once every term in every room.

EXTRA-UTERINE PREGNANCY

A correct and prompt diagnosis and an immediate operation in this condition are necessities for the preservation of the life of the mother. It is not intended in this note to discuss the data obtained by physical examination, but the symptoms of suspicion of such pregnancy are so well brought out in a carefully prepared table of ten cases of this condition by Dr. H. M. Lee, of New London, Conn. (*International Journal of Surgery*, March, 1910) that it is worth while to present them again here.

These ten patients, varying in age from 26 to 43, all missed the proper date for the menstrual period from a week to more than a month. All, however, had a menstrual flow from a week late to a month late. The character of the flow in all of these patients was scanty and dark. There was sharp abdominal pain in every instance, even in the one of the nine that did not rupture. The duration of the pregnancy before the pain and rupture averaged 8 weeks. The hemorrhage was into the broad ligament twice and into the peritoneal cavity 7 times. After rupture the pulse varied from 100 to 140, while the temperature in every instance after rupture was above 99 F., but in only one instance as much as 100 F. The time of operation after rupture varied from 3 hours to 48 hours. In each of the 10 instances the patient recovered, and 6 of these women have since again been pregnant.

Uses of Glycerin.—No substance is equal in power to glycerin in disguising nauseous medicines. Castor oil, turpentine, solutions of iron and various other medicines can be diluted and at the same time almost completely disguised by glycerin. As Wood says: "It seems to envelop the medicinal substance and prevent its action on the palate."—G. D. Lind, in *West Virginia Medical Journal*.

SATURDAY, OCTOBER 22, 1910

A SANER VIEW OF CHOLERA

The constant reader of the daily newspaper, if he reflects on the difference between our national attitude respecting the cholera menace in 1892 and that almost universally exhibited at the present day in regard to a similar situation, will be tempted to conclude that the American nation has progressed toward a greater self-control. The attempted "quarantine" at Fire Island eighteen years ago cannot have been forgotten by many of our readers. Recollections of the barbarities there practiced in the name of sanitary protection may even yet cause a feeling of shame in the citizen jealous of his country's reputation for sanity and soberness of judgment. To be sure, the panic of 1892 was quickly over, so that the New York papers could soon speak reprovingly of "the savagery that has lately disgraced our shores," but while it lasted it was acute and to all appearances amazingly general. As a matter of fact, cholera did get into New York in spite of the brutal quarantine measures that were employed. Perhaps more would have got in with a less barbaric quarantine, but it could probably have been suppressed quite as readily as the smaller quantity.

How different it all is at present! Cholera is now being brought to our shores, but there is little or no newspaper hysteria, little or no general alarm. National and local authorities are active in the employment of proper measures of diagnosis and exclusion, but no tendency has been displayed to revert to barbarism. The cholera danger, such as it is, is viewed soberly and calmly without hysterics and without belittlement of the real peril.

The actual situation has been fully set forth in our news-columns of the last few weeks. Cholera has been more prevalent in parts of Europe the past season than for many years. The disease, furthermore, is widely distributed and many ports having important commercial relations with this country have been infected. It does not seem improbable that in 1911 a still further extension of the disease will occur. More cases may reach our Atlantic ports and it is by no means unlikely that some healthy "carriers" may escape detection and introduce the disease into the United States. But even

so, does anyone believe that a "pandemic" of cholera is probable in this country under present conditions? If we consider simply the matter of public water-supply, the situation throughout the nation is highly reassuring. The majority of our large cities now have supplies into which little or no sewage enters or which are effectively purified by sand-filtration. In the absence or relative scarcity of sewage-polluted water-supplies, there is no likelihood of any general spread of cholera. Even in Russia at the present time the city of Moscow, which is the fortunate possessor of a good water-supply, is practically exempt from cholera, while St. Petersburg, with its badly contaminated river-water, has suffered severely. As an illustration of the changed conditions in this country compared with eighteen years ago we may cite the following sentence from a paper written by an eminent sanitarian in 1892, who calls attention to the fact that cities with a good drinking-water have nothing to fear from cholera, and continues: "The citizens of Philadelphia, Chicago, Lowell, Lawrence and Albany, on the other hand, may reasonably feel much concern about cholera." To-day the five cities which were then thus singled out for sanitary opprobrium—and justly so—all have good supplies of drinking-water obtained either by sand filtration, by substitution of ground-water for contaminated river-water, or by exclusion of sewage from the source of supply. The improvement brought about in these instances is, we believe, fairly typical of the improvement that has occurred in the country at large.

It is not possible nor is it especially important to determine to what degree the relatively slight alarm over cholera shown at the present time is due to just confidence in the increased wholesomeness of our public water-supplies. Other factors, such as the increased efficiency of the national and local public health service and our more complete knowledge of the ways and means by which cholera is spread, certainly are taken into consideration or at all events should be. The fact remains that we can now soberly face the possibility that a person harboring cholera vibrios may land in a seaboard city. We have no reason to show either unconcern or hysterical fear at the event.

THE OXYDONOR AND SIMILAR FAKES

It is sometimes hard to decide which is the greater—the impudence of the quack or the credulity of his victims. The comparative ease with which the medical faker is able, by the most preposterous of claims, to separate the fool from his money indicates the enormous potentialities in advertising. It might be supposed that an individual who set out to sell, as a panacea for most fleshly ills, a piece of brass pipe with one or two wires attached to it, would have a hard and rocky road before him. But such a supposition would be incorrect. Not only would the enterprising faker find customers for his

gas-pipe, but there would be such a demand for this most inane of "therapeutic" devices, that two or three imitators would immediately enter the market.

The original exploiter of what may be called "gas-pipe therapy" was one Hercules Sanche, who modestly described himself as the "Discoverer of the Laws of Spontaneous Cure of Disease." Of course, Sanche did not "discover" this long-known truth at all, but he did appreciate its commercial value. Starting with the premise that a certain proportion of sick people—and of those who think they are sick—will get well without treatment, or in spite of it, he cast about to devise a means of reaping a pecuniary reward from the operation of this natural law. Sanche might, of course, have used some harmless or unmediated tablets and after describing at great length the marvelous properties inherent in them, have sold them with substantial profit to himself. This method of fleecing the public, however, besides being old and threadbare, was not altogether free from the probability of legal complications. He might have offered to sell "absent treatment" and have discoursed learnedly on the benefits and virtues of this wonderful therapeutic force. But "absent treatment" does not appeal to the average man who wants a tangible something in exchange for his dollars. Sanche finally hit on a device that was perfectly harmless—and worthless—and yet theatrical enough to make the purchaser feel that he was getting something for his money. He called it the "Electropoise," and it consisted, as described elsewhere¹ in this issue, of a piece of metal pipe closed at each end and with a flexible wire attached. That was all. It sold for ten dollars.

So popular did this humbug become that Mr. Sanche extended his operations by putting on the market a modification of the "Electropoise"—the "Oxydonor." This differed from the "Electropoise": It was shorter; it contained a stick of carbon instead of being empty; and it sold for thirty-five dollars instead of ten dollars. Coincident with his invention of the "Oxydonor," Sanche also invented a "force" or "power" which he christened "Diaduction." The "Oxydonor" was the instrument by which this "force" was supposed to be created. To operate the "Oxydonor," the distal end of the wire attached to it was applied to the wrist or ankle of the fool—we may be excused for using this term—who used it; the "Oxydonor" itself was placed in cold water and the "diaductive force" was expected to be thus generated.

The commercial success attending the exploitation of this fake was such that an imitation appeared under the name "Oxygenor" or the "Oxygenor King." This fraud also, is described in detail elsewhere¹ in this issue. It differs but little from the "Oxydonor"—so little, in fact, that Sanche brought suit against the "Oxygenor" concern for infringement of patent. The court held, however, that such a palpable humbug as the "Oxydonor" was not entitled to legal protection.

More recently still, another fake of the same nature has been foisted on the public. It is called the "Oxygenator" and selling depots have been established in many cities. An elaborate booklet describes the virtues of this latest exponent of "gas-pipe therapy" and another new "force" has been invented to aid in selling it, *viz.*, "Oxyopathy." In many ways the latest type of this form of charlatanry is the worst, inasmuch as claims are made for it that are not only absurd but dangerous. For instance, the following statements occur:

DIPHTHERIA: This overwhelming child's disease finds its supreme master in the *Oxygenator*. No earthly power except the *Oxygenator* can take the slowly choking child, and with speed, simplicity and safety, bring it back to health.

Don't jeopardize the health and life of your children by allowing to be injected into their veins and blood the often fearfully contaminated and death-dealing serum of an animal, otherwise known as antitoxin.

It is difficult to restrain one's indignation at the thought that such viciously cruel lies as these are permitted to be scattered broadcast. Let the neurotic and neurasthenic adult, if he can convince himself that a nickel-plated piece of gas-pipe possesses curative properties, experiment with it on his own person if he wishes. But that a helpless child in the throes of a fearfully dangerous—and yet, rightly treated, curable—disease, should be allowed to suffer and die because ignorant parents have been persuaded to rely on these mechanical frauds, is no less than criminal. As for the miserable harpies who for a few filthy dollars will write such cold-blooded untruths as those quoted above, the safety of society demands that they be put with thieves and murderers, where they can do no further harm.

To sum up: The "Electropoise," the "Oxydonor," the "Oxygenor" and the "Oxygenator" are utterly worthless except as a means of enriching their exploiters. Their therapeutic value, aside from the element of suggestion that may be induced in those simpletons who are willing to pay from ten to thirty dollars for a piece of nickel-plated tubing, is absolutely *nil*. As already said, if adults wish to squander their money on such foolishness and are content to confine the "treatment" to their own persons, well and good. If they have nothing much the matter with them they may believe they have received benefit; if they are dangerously ill, Nature will probably exterminate them as unfit. But let no person try to "cure" the helpless child with such frauds; as soon as that is attempted, such an individual ceases to be a harmless idiot and becomes a dangerous one.

POLIOMYELITIS

The disease long known as infantile spinal paralysis, or acute anterior poliomyelitis, has acquired of late a new and vital interest for many physicians. This interest has been aroused by the numerous and wide-spread epidemics, especially in this country, and by the gratifying contributions to our knowledge of the disease, nota-

1. Pharmacology department, page 1486.

bly those of Flexner and Lewis from the Rockefeller Institute. Within three or four years, upward of five thousand cases have been reported in the United States, and it is quite certain that many more have escaped detection and record. Extensive epidemics have occurred in Massachusetts, New York, Vermont, Pennsylvania, Virginia, Michigan, Wisconsin, Minnesota, Iowa, Nebraska and Kansas. No community or family, at least in the northern states, is exempt from the possibility of its invasion, and, while the approach of cold weather will diminish its incidence this year, the advent of next summer may bring this dread invader to the door of any physician.

It is of the utmost importance, therefore, that every practitioner should acquaint himself with the recent advances in our knowledge of this disease, should be alert to detect its first appearance in his practice, and should prepare himself to cope with it effectively.

The causative agent has been shown by Flexner and Lewis to be an ultramicroscopic organism of great potency, resistant to freezing, drying and glycerinization, infectious and quite certainly contagious. It is resident in the body of the afflicted person—in the cerebrospinal axis, the cerebrospinal fluid (at least in certain stages), the mesenteric and other lymph-glands, the nasal mucous membrane, the saliva and possibly elsewhere. It is discharged from the body chiefly by way of the nasal mucous membrane and probably finds its principal avenue of entrance by the same route, though it has been successfully inoculated in several other ways. Whether or not the virus is ever conveyed by insects is undetermined, but the possibility of such conveyance warrants the most thorough precautions to prevent it.

The numerous opportunities afforded of late for autopsies on patients dying in the early stages have made it possible to study much more exhaustively than heretofore the pathogenesis of the disease, and to set at rest former controversies in reference thereto. There is a striking unanimity in the reports of these recent pathologic observations and deductions from all quarters. The alterations found are those of a specific general infection, expending its destructive energy chiefly on the gray matter of the cord and brain. The vascular changes are primary, but changes are found also in the posterior root-ganglia, the nerve fibers, heart, liver, kidney, lymph-glands and elsewhere. The pathology of the disease has been concisely summarized by Robertson and Chesley.¹

The disease is characterized by a sudden onset, marked prostration, headache, pain and rigidity in the back of the neck and along the spine, tenderness and pain on motion of the extremities, giving rise to a modified Kernig sign, fever—usually moderate in degree—rapid pulse, sometimes vomiting, and usually obstinate constipation,

rarely diarrhea. Involvement of the encephalon is characterized by delirium, convulsions and stupor. The characteristic paralyses, in both the spinal and encephalic types, constitute the most convincing diagnostic sign, but these are sometimes delayed for several days, and are often absent in the abortive cases, which are as capable of transmitting the infection as are those of severer type.

The diagnosis should not be difficult, even in the early stages. On the prompt recognition of the disease at this period depends the physician's ability to check the advance of the epidemic and to safeguard his community. The diseases with which poliomyelitis is most likely to be confounded are influenza, typhoid and paratyphoid, rheumatism, auto-intoxication with meningism, possibly some one of the exanthemata (a rash is not an infrequent accompaniment of poliomyelitis) and finally epidemic meningitis. None of these should present serious difficulty to the careful observer, except meningitis; and here the lumbar puncture of Quincke affords a reasonably certain means of differentiation. Flexner has described the characteristic appearance of the cerebrospinal fluid in poliomyelitis at various intervals after its inception, and the persistent absence of the *Diplococcus intracellularis* in three or four specimens almost negatives the possibility of epidemic meningitis. The meningitides due to other organisms are usually secondary to their invasion of other organs. Every practitioner should have always at hand the appliances requisite for this simple procedure, which involves little more difficulty, pain or danger than a hypodermatic injection.

The first duty of the physician, after a diagnosis of possible poliomyelitis has been made, is to endeavor to protect the family and the community by the prompt isolation of the patient and the scrupulous disinfection of all articles which may have become contaminated with the discharges, especially those from the nose and mouth. If such complete isolation cannot be secured in a suitable room in the house, or by the removal of the patient to an isolation hospital, the erection of a tent with a board floor, to accommodate the patient with nurse or mother, offers an admirable solution of the difficulty. In the city a suitable site can be found in a vacant lot or on the porch or roof of house or apartment. The experience of many physicians in the treatment of tuberculous patients, and of Northrup and others with the open-air treatment of infants and children, has demonstrated that such an environment is not only safe but advantageous even in severely cold weather. Fortunately the season of prevalence of poliomyelitis is the summer when the prejudice of the laity is not likely to obtain against the consignment of a child to a properly constructed tent. If every case of suspected poliomyelitis or of any other infectious disease, were to be promptly isolated by some such arrangement many virulent epidemics might be nipped in the bud, drastic

1. Robertson, B. E., and Chesley, A. J.: Pathology and Bacteriology of Acute Anterior Poliomyelitis, THE JOURNAL A. M. A., Sept. 17, 1910, p. 1013

quarantine measures avoided, and an enormous saving of illness, death and wretchedness effected. Early diagnosis, prompt isolation and thorough disinfection afford at present the only effective measures for the suppression of infectious poliomyelitis, as of most other infectious diseases.

The curative treatment of the individual patient is fully discussed in the articles by McClanahan, Sachs and Ridlon, prepared at the request of THE JOURNAL, which appear elsewhere in this issue.

Current Comment

TEACH THE TEACHERS

The September number of the *Bulletin of the North Carolina Board of Health* is a teachers' edition, specially prepared for the instruction of the public school teachers of the state. It contains articles on the importance of the recognition of physically defective children, the movement for oral hygiene in the public schools and its importance, the medical inspection of public school children, the value of science teaching in the grades and high schools, and the relation of childhood and youth to public health. Illustrations show the dangers of the common drinking-cup. Such bulletins issued under the authority of the state board of health and distributed to school teachers, parents, and pupils of the high schools are a most valuable means of public instruction on sanitary and hygienic questions.

CONTAMINATED WATER-SUPPLIES AND SENSITIVE OFFICIALS

In one of the most important reports of recent years on typhoid fever in a large city, Dr. C. Hampson Jones, assistant commissioner of health of Baltimore, comments very justly on a common official, not to say commercial, attitude toward any criticism of a public water-supply. "Last of all, we will consider as a possible source of some of the typhoid fever infection our drinking-water. Of all the ten alleged possible sources of typhoid fever in our city, this one must be mentioned with caution. The other nine possible sources may be heralded throughout the land, and no dissenting voice will be heard; no one will feel himself personally aggrieved. But it is not so when the tenth source, water, is even hinted at as a possible source of some of the cases of the fever." It is possible to say hard words about lack of sewer connection, abundance of opportunity for fly-breeding and uncleanness in general, but the water-supply must be approached with reverent touch and not lightly condemned or even suspected. The reason for this feeling is plain. A water-supply exposed to contamination is now generally recognized as a commercial disadvantage, as an item against the interests of the city. "Conventions" are apt to give a wide berth to a city with bad drinking-water and in some cases are transferred to a rival community, as has recently happened at Rutland, Vt. The mildest censure or most friendly warning may be made to seem bitterly offensive. At the recent meeting of the Central States

Water Works Association at Indianapolis, Mr. Paul Hansen made a strong plea for a change in this particular. The attitude of some officials is stated very frankly: "We find otherwise competent and reliable water-works superintendents zealously defending water-supplies known to be polluted or subjected to the possibility of pollution. The argument used in nine cases out of ten is that the water cannot be harmful since no cases of typhoid fever or other diseases have been definitely traced to its use. This argument is sometimes used in the face of the presence of an abnormally high death-rate from typhoid fever." It is, however, an encouraging sign to find sensitiveness displayed at all. It is well to have a pure water-supply considered as a municipal asset.

ILLEGIBLE PRESCRIPTIONS

Many of us indulge in hasty penmanship, especially in such important matters as the writing of prescriptions, thereby giving the profession a reputation for carelessness in this respect which, on the whole, is undeserved. The excuse frequently given is that the physician is too busy to spend time over such a trivial matter as chirography. It is just possible that when one considers one's time too valuable to permit the doing of good work, the valuation placed on that time is too high. The writing of a prescription or a certificate is as essential a part of a physician's work as the making of a diagnosis or an examination; and neglect to write a prescription legibly may entail as serious consequences as neglect of other branches of professional duty. If there is any vocation in which there are no trifles—in which there is no excuse for negligence at any point—it is the practice of medicine.

MEDICAL RESEARCH AND CANCER

Through medical research many problems relating to the etiology, diagnosis and treatment of disease have already been solved, and so much has been added to the positively known facts of medicine as to place that branch of learning among the sciences. Each discovery usually leads directly to the solution of numerous other related problems. For example, the discovery of bacteria not only revealed the specific causes of several diseases but led to positive methods of identifying different forms of bacteria and to effective methods of treatment by antitoxins, serums and otherwise. Each discovery has given added impetus to research along other lines, and has encouraged the belief that many other diseases, such as cancer and tuberculosis, will sooner or later be shorn of some of their terrors. Most of all, however, these successes have attracted the attention of men of wealth to the value of medical investigation, so they are now giving liberally toward the furtherance of this research. Not only do we hear frequently of gifts for our research medical schools, but funds especially for research are also being provided. In Great Britain the Imperial Research Fund has recently held its annual meeting, at which Mr. Arthur J. Balfour was a speaker. In this address, as reported by the *London Times*, Mr. Balfour shows how all great therapeutic problems must

be dealt with as a part of the great biologic whole. He shows also that most if not all of the discoveries have resulted from a broad scientific outlook which has produced unexpected conclusions and results in very different fields apart even from human pathology. For example, he shows how the investigation of microbic organisms led to finding in bacteria a common cause in the production of such utterly different things as alcohol, pearls and whooping-cough. At any rate, modern medical research requires not only the use of every variety of specialized apparatus, such as the microscope and the spectroscope, but also of the known facts and precise methods of physics, chemistry, physiology and biology, as well as of the more recent sciences of bacteriology, pathology and pharmacology. It will be interesting to know, if that time ever comes, through which of these sciences or what combination of these sciences the secret of the cause or treatment of cancer shall have been discovered.

Medical News

COLORADO

Sanatorium for Hollanders.—The Christian Benevolent Society for Consumptives has been incorporated to establish a sanatorium for the care of those suffering from tuberculosis. The institution will be located in South Denver and will receive Hollanders from all parts of the United States. The secretary of the institution is Rev. I. Van Dollen, Denver.

Women Elect Officers.—The Women's Colorado State Medical Society, at its third annual meeting held in Colorado City, October 11, elected the following officers: president Dr. Mary Hawes, Denver; vice-presidents, Drs. N. Eugenia Barney, Sterling, and Emogene P. Sherman, Idaho Springs; secretary-treasurer, Dr. Kate E. Geiger Yont, Denver, and auditor, Dr. Alice B. Guthrie, Denver.

Personal.—Dr. Horace G. Wetherill, Denver, was elected honorary president of the fifth International Congress on Gynecology at St. Petersburg. —Dr. Luke MacLean, Pueblo, has been appointed a member of the State Board of Medical Examiners, vice Dr. Carey K. Fleming, Denver, deceased. —Dr. Frank N. Carrier, Canon City, has been appointed surgeon in chief of the Chino Copper Company, Santa Rita, N. M. —Dr. Francis A. Sutorius, Florence, fell, October 3, and dislocated his right shoulder.

ILLINOIS

Personal.—Dr. Harry C. Bill, Streator, has returned from abroad. —Dr. William Lorenz, formerly a member of the staff of the Kankakee State Hospital, has been made assistant medical superintendent of the Wisconsin State Hospital, Mendota. —Dr. Walter G. Bain has been elected director of the pathologic laboratory of St. John's Hospital, Springfield. —Dr. Sidney G. Pratt, Buda, has returned after a year's absence greatly improved in health. —Dr. Joseph De Silva, Rock Island, has been elected secretary of the National Association of Penal and Reformatory Institutions. —The damage suit instituted by Dr. Jessie Bulkeley Ogden, Wankegan, against the *Waukegan Gazette* for damages arising from a criminal action inaugurated by the state against Dr. Ogden, following the death of a patient, is said to have been taken from the docket by her attorney, October 5.

Chicago

Personal.—Dr. Robert Dodds was thrown from his automobile in a collision with a trolley car October 10, and sustained painful injuries. — Dr. and Mrs. Joseph Zeiber and daughter, Dr. and Mrs. Cassius C. Rogers, and Dr. Norval H. Pierce have returned from Europe. — Prof. Carl S. N. H. H. Berg, for several years secretary of the Section on Pharmacology and Therapeutics of the American Medical Association, and a member of the Council on Pharmacy and Chemistry, is critically ill at his home in Chicago.

Cornerstone Laid.—The cornerstone of the Iroquois Memorial Emergency Hospital at 87 Market Street was laid October 15, in the presence of more than one hundred relatives of the victims of the Iroquois Theater calamity. Dr. William A. Evans, health commissioner, received the hospital on behalf of the city.

Scandinavian Physicians Meet.—The annual dinner and election of officers of the Scandinavian Medical Society of Chicago was held October 13. Dr. Alfred C. Cotton, president of the Illinois State Medical Society, was guest of honor. Dr. Andreas Klövstad was elected president, and Dr. William J. Anderson, secretary-treasurer.

Health League Formed.—The Chicago Health League was organized October 12, at the rooms of the Visiting Nurses' Association, with Dr. Sydney Kuh, president, and Miss Harriet Fulmer, secretary. The organization is composed of representatives from eighty different clubs, civic associations, and labor unions, and its object is the promotion of the general health of the city. Legislation for better sanitation and health regulation of factories and all places of employment will be demanded by the league.

INDIANA

New Medical Chapter.—A chapter of the Phi Chi Medical Fraternity has been established at the University of Indiana, Bloomington, under the name Alpha Mu.

Personal.—Dr. Chauncey W. Dowden, medical director of the West Baden Hotel, has returned from Europe. —Dr. Samuel M. Ried, Muncie, is recovering after being seriously ill at his home for several months.

Antituberculosis Camp Open During Winter.—The directors of the Antituberculosis Colony, Pottowatomie Park, South Bend, have decided to make the cottages habitable for cold weather, and to keep the camp open during the winter months.

Medicine Vendor Fined.—William Hoop, Indianapolis, a vendor of nostrums and mineral water, has been fined for selling medicines without a license. The sentence was suspended on the promise of the defendant to leave the city at once.

Verdict for Physician.—A jury in the circuit court at Bluffton, on September 21, is said to have returned a verdict in favor of the defendant in the suit of Mrs. Cora Vore against Dr. James W. McKinney, in which damages of \$5,000 were sought for alleged malpractice.

IDAHO

Home from Europe.—Dr. James L. Stewart, Boise, has returned after a three-months' trip abroad.

State Association Session.—The eighteenth annual meeting of the Idaho State Medical Association was held in Boise, October 6 and 7, under the presidency of Dr. John M. Taylor, Boise. The following officers were elected: president, Dr. John W. Givens, Orofino; vice-president, Dr. George O. A. Kellogg, Nampa; delegate to the American Medical Association, Dr. Ayer A. Higgs, Soldiers; alternate, Dr. C. L. Dutton, Meridian; Dr. George H. Coulthard, Idaho Falls, chief of the committee on public health, and Dr. William T. Drysdale, New Plymouth, Idaho member of the board of trustees of *Northwest Medicine*.

IOWA

Tuberculosis Census.—The State Board of Control on October 11, began taking a census of tuberculosis sufferers of the state. More than 3,500 letters were sent out to physicians of the state asking each to make a report to the board of cases in his community, the age of patients, stage of the disease, and whether or not health rules were being observed.

Personal.—Dr. Benjamin R. McAllister, assistant physician at the Cherokee State Hospital, has been appointed superintendent of the State Insane Hospital, Jamestown, N. D. —Dr. George Donahue, the new superintendent of the State Inebriate Hospital, Knoxville, assumed charge of the institution October 7. —Dr. Max E. Witte, superintendent of the Clarinda Insane Hospital, has been reappointed for a fourth term of four years by the board of control. —Dr. Willis E. Keith, Lost Nation, sailed for Europe October 1. —Dr. Thomas C. Gorman, Anamosa, began work as medical superintendent of the state reformatory October 2. —Dr. Harry E. Kirschner, superintendent of the Tuberculosis Sanatorium, Iowa City, has returned after three months abroad.

KENTUCKY

Personal.—The degree of master of arts has been conferred on Dr. Archibald H. Barkley, Lexington, by Transylvania University.—Dr. Bernard Asman, Louisville, has removed to Hot Springs, Ark.

Sanatorium Opened.—Waverly Hill Sanatorium for Persons Suffering from Tuberculosis was formally opened to the public October 6. The institution has been established at a cost of about \$150,000 and is maintained jointly by the city of Louisville and county of Jefferson.

License to Practice Refused.—The governor, on September 30, refused to take action on the appeal of James S. Calvert of Caldwell county, who was refused a license by the State Board of Health, and who appealed from its decision. The governor, after reviewing the record, stated that he was not convinced that he should disapprove of the action of the board, as the record did not show that the appellant had been properly educated.

Poison Law Upheld.—The court of appeal has rendered a decision upholding the law regulating the sale of poisons. A druggist was indicted on information from the State Board of Pharmacy for selling morphin without a prescription from a physician, and without satisfying himself that the poison was to be used for legitimate purposes. The defendant's attorney contended that the words "retail" and "legitimate purposes" as used in section 2630 of the Kentucky Statutes were too indefinite and uncertain and that therefore the statute is invalid. The court holds that the statute is sufficiently specific and confirms the imposition of the fine.

LOUISIANA

New Maternity.—The New Orleans Lying-in-Clinic has been founded by Drs. Jacob W. Newman and Edith Loeber-Ballard. A building at Howard Avenue and Lee Circle has been leased for headquarters, and the clinic is open for consultation and general advice every day between ten and eleven, and at all hours for emergency calls.

The Cocain Evil.—The Orleans Parish grand jury has taken a strong stand regarding the cocain traffic in New Orleans. Fortified with facts from retail and wholesale druggists and physicians, the grand jury not only has recommended the continued rigid enforcement of the provisions against the illegal sale of cocain, but that the judges of inferior criminal courts sentence such law violators, when convicted, to a jail term instead of imposing a fine, and that a drastic state law be drafted increasing the penalties and limiting the quantities of cocain sold by wholesale dealers, and prohibiting and penalizing the importation by retailers and wholesalers of cocain into the state in larger quantities than are required for legitimate medicinal purposes. Fifteen cocain vendors have been arrested, and several have already been fined the maximum penalty allowed under the present law.

Personal.—Dr. George Doek has removed from New Orleans to 1906 Locust Street, St. Louis.—Dr. John B. Elliott, Jr., has been made chief of the department of medicine of Tulane University, vice Dr. George Doek, resigned, and Dr. J. Birney Guthrie has been made professor of clinical medicine.—Dr. Joseph A. Dama, New Orleans, has returned from Europe.—Dr. George S. Kreeger has been elected president of the Lake Charles Board of Health, vice Dr. Temple B. Smith, deceased.—Dr. Louis A. Murdock, St. Joseph, has been elected president of the Tensas Parish Board of Health.—Dr. R. Clyde Lynch, New Orleans, has been elected acting surgeon in charge of the ear, nose and throat department of the Eye, Ear, Nose and Throat Hospital. He has also been made professor of oto-rhino-laryngology in the postgraduate department of Tulane University, vice Dr. Gordon King, deceased.—Dr. James A. Anderson has been elected a member of the board of health of New Orleans, vice Dr. William H. Robin, resigned.

MARYLAND

Fixes Minimum Fee.—Anne Arundel County Medical Society, at its meeting October 11, adopted resolutions fixing the minimum fee for examination of insane persons at \$10. The county has persistently refused to pay more than \$5 for this class of examination.

Baltimore

Department Asks Increased Appropriation.—The health department has asked for an increased appropriation of \$45,555 for the coming year.

Cottage at Sanatorium Dedicated.—The Mayer Cottage, a three-story building with accommodation for 20 patients, was

dedicated at the Jewish Home for Consumptives in the suburbs of the city, October 16.

Grawitz in Baltimore.—Dr. Ernst Grawitz of the University of Berlin lectured at Johns Hopkins Hospital October 11 on "Diseases of the Blood." During his stay in Baltimore, Dr. Grawitz was the guest of Dr. Lewellys F. Barker.

Asks Appropriation for Hospital.—Dr. Warren P. Morrill, resident physician, Dr. Joseph W. Schereschewsky, U. S. P. H. and M.-H. Service, and others appeared before the Board of Estimates October 11 and urged an appropriation for an additional building and also for an administration building for Sydenham Hospital for Infectious Diseases, to cost \$55,000.

Personal.—Dr. John W. Chambers, who has been suffering from septicemia due to an infected wound of the hand, is reported much improved.—Dr. Barrett C. Catlin, who was operated on in September, is reported to be convalescent.—Dr. Martin F. Sloan, resident physician at Endowment Hospital for Tuberculosis, has gone to Johns Hopkins Hospital with suspected typhoid fever.

Lectures to Medical Students.—Prof. Alexander C. Abbott, of the University of Pennsylvania, will deliver two lectures at the University of Maryland, November 9 and 10, on "The Functions of the Municipality in Public Preventive Medicine" and "The Interdependence between the Laboratory and the Clinical Investigator."—Dr. Charles Wardell Stiles, U. S. P. H. and M.-H. Service, began a course of lectures at Johns Hopkins University October 12 on "Medical Zoology and Animal Parasites."

MICHIGAN

Sanitary Work of Railroad Company.—Dr. Arthur M. Hume, Owosso, chief surgeon of the Ann Arbor Railroad, announces that all passenger cars are fumigated each month; that individual drinking cups have been installed; that water tanks are being reconstructed so that ice does not come in contact with the water; that anti-spitting cards are being placed in coaches and stations, and that all smoking cars are being provided with cuspidors which are cleaned with an anti-septic solution at the end of each trip.

Accused Go Free.—In the case of A. W. Stewart, Mount Clemens, charged with illegal practice of medicine, which came up in circuit court, September 19, proceedings were dropped and an order secured for discontinuance of the suit on the declaration of the defendant that he had ceased practice and would qualify under the state law before resuming.—In the case of Mrs. Annie Daniels, living near Twining, charged with criminal abortion, causing death, on Miss Mary Lyle, the jury, on September 14, brought in a verdict of not guilty.

Hospital Staff Organized.—The House of Providence Hospital, Detroit, organized the following physicians into its staff October 10: radiographer, Dr. George C. Chene; obstetrics, Drs. Nathan Jenks, Charles H. Judd, Walter E. Welz, F. J. A. McDonnell, William H. Morley and W. E. Tyson; diseases of children, Drs. Guy L. Kiefer, Francis Duffield and Thomas B. Cooley; medicine, Drs. Edwin G. Knill, Hugo A. Freund, George A. Trizisky and Victor C. Vaughan, Jr.; eye and ear, Drs. Eugene Smith and Robert W. Gillman; nose and throat, Drs. Burt R. Shurly and Richard E. Mercer; skin, Drs. Henry R. Varney and R. A. C. Wollenberg; nervous diseases, Drs. Augustus W. Ives, Raymond L. Clark and David R. Clark; pathologist, Dr. George C. Chene; visiting staff, Drs. David H. O'Donnell, John V. White, Frank T. F. Stephenson, Eugene Robb, Isaac L. Polozker, Christopher Campbell and Edwin B. Forbes; consulting physicians, Drs. Edmund A. Chapoton, J. Henry Carstens, Theodore A. McGraw, Max Ballin, Charles Douglas and David Inglis; general surgery, Drs. Frank B. Walker and William A. Spitzley; associates, Drs. Allen W. McDonald, Robert T. Tapert, William J. Seymour, Claude M. Stafford and William E. Keane; gynecology, Drs. Howard W. Longyear and H. Wellington Yates; associates, Drs. Theodore A. McGraw, Jr., and Benjamin R. Schenek; proctology, Drs. James A. McVeigh and D. T. Kirschner; orthopedies, Drs. Daniel LaFerte and William E. Blodgett, and gastroenterology, Drs. James E. Davis and William M. Harvey.

MINNESOTA

Academy Election.—The Minnesota Academy of Medicine, at its annual meeting in Minneapolis, October 5, elected Dr. S. Marx White, Minneapolis, president; Dr. John L. Rothrock, St. Paul, vice-president, and Dr. Arthur W. Dunning, St. Paul, secretary-treasurer.

Sanitariums in Conference.—At the meeting of the Minnesota State Sanitary Conference in Minneapolis, October 6 and

7. Dr. Harry A. Tomlinson, superintendent of the State Hospital for the Insane, St. Peter, was elected president and J. T. Gerould, of the University of Minnesota, vice-president.

Auxiliary Organized.—A permanent organization of the Woman's Auxiliary of the Hennepin County Medical Society was effected at Minneapolis, October 10. Mrs. W. J. Burns was elected president; Mrs. J. W. Little, vice-president; Mrs. Frank J. Corbett, secretary, and Mrs. C. Nootnagle, treasurer.

Personal.—Dr. Thomas C. Clark, Stillwater, has gone to the district recently devastated by forest fires and is in charge of the hospital arrangements, and of the details for the care and relief of the sufferers.—Dr. George F. Beachler, Minneapolis, is reported to have been missing from his office and home since September 5.—Dr. Gustavus A. Newman, New London, has been appointed physician at the State Penitentiary. Stillwater, vice Dr. Burton J. Merrill, resigned.

New Dispensary Staff.—Dr. Henry C. Knight, Minneapolis, has been elected chief of the staff of the Wells Memorial Dispensary, and Dr. James S. Reynolds, secretary. The following department heads have been appointed: diseases of the stomach and intestines, Dr. Henry L. Knight; eye, ear, nose and throat, Drs. Howard McMorton and James S. Reynolds; surgery, Drs. William M. Chowning and James E. O'Donnell; internal medicine, Dr. Henry W. Cook and Kemlin J. Lee, and obstetrics and diseases of children, Dr. Charles B. Wright.

Combating Tuberculosis.—At the annual meeting of the Goodhue County Medical Society, held in Red Wing, October 4, the establishment of a county sanatorium for consumptives was earnestly favored. The building fund at present is only \$2,000 but the society decided to raise \$2,500 by subscription for the establishment of a suitable hospital.—The new plans for the new St. Louis County Tuberculosis Sanatorium are being prepared by architects of Saranac Lake, N. Y. The sanatorium will be located on an eighty-acre site at Midway and will include an administration building and several cottages.

State Society Meeting.—At the forty-second annual meeting of the Minnesota State Medical Association, held in Minneapolis, Oct. 6 and 7, the following officers were elected: president, Dr. James W. Robertson, Litchfield; vice-presidents, Drs. Frank W. Dimmitt, Red Wing, and Charles L. Schofield, Benson; secretary, Dr. Thomas McDavitt, St. Paul (reelected); treasurer, Dr. Richard J. Hill, Minneapolis; councilors, Dr. Charles E. Dampier, Crookston, First District; Dr. Joseph G. Millsbaugh, Little Falls, Second District, and Dr. John L. Rothrock, St. Paul, Fifth District; delegate to the American Medical Association, Dr. George Douglas Head, Minneapolis, and alternate, Dr. Max P. Vander Horck, Minneapolis. The next meeting will be held in St. Paul on the first Thursday and Friday of October, 1911. The association adopted resolutions endorsing the Owen Bill for a national department of health, commending the work of Dr. Harvey W. Wiley, and condemning the use of benzoate of soda and like substances as food preservatives. The association decided to continue the *Journal of the Minnesota State Medical Association* as its official organ, with the understanding that the subtitle *Northwestern Lancet* should be removed from the cover.

MISSOURI

Silver Day for Hospital.—On Silver Day at Kansas City, more than \$6,300 was collected for Mercy Hospital.

Colored Physicians Organize.—The negro practitioners of Missouri met in Sedalia October 8, and organized the Pan-Medical Association of Missouri, and elected the following officers: president, Dr. J. Mayo Harris, Sedalia; secretary, Dr. James F. Shannon, Kansas City, and treasurer, Dr. John R. A. Crossland, St. Joseph.

Personal. Dr. D. B. McHenry, Princeton, has recently returned from Europe and has located in Oklahoma City.—Dr. D. Everett Standard, Springfield, fractured his arm in attempting to crank an automobile September 25.—Dr. T. J. McAllister has been elected treasurer of the St. Joseph Colored Antituberculosis Society.

St. Louis

Old Buildings Used for Consumptives.—The city quarantine hospital has been converted into a sanatorium for the treatment of tuberculosis and 74 patients are at present under treatment.

Violators of Milk Law Fined.—Fifty milkmen, charged with selling milk under the standard required by the city, or containing formaldehyd as a preservative, were arraigned in police court October 5, and 49 were either fined or ordered to pay costs.

NEW YORK

Clinical Lectures.—Dr. L. Duncan Bulkley will give the twelfth series of clinical lectures on diseases of the skin at the out-patient hall of the New York Skin and Cancer Hospital, Wednesday afternoons at 4:15, from November 2 to December 21. The medical profession is invited.

Typhoid Fever.—The epidemic of typhoid fever in Westchester County has not assumed the proportions recently reported, there being at present only about 25 cases under treatment. The epidemic has been traced to a small brook running through White Plains, and is not due to the public water supply. In view of the prevalence of typhoid throughout the state, Governor White has asked Dr. Eugene H. Porter, State Commissioner of Health, to investigate and report on the actual facts. It is intended to follow up this investigation with steps to prevent the further spread of the disease at threatened points.

PENNSYLVANIA

Personal.—Drs. Henry W. Sweigart, Lewistown, and William A. Tower, Millintown, were seriously injured, October 9, in an automobile wreck.—Drs. Lawrence Litchfield, Irwin J. Moyer, John W. Boyce, Thomas D. Davis, Percival J. Eaton, James H. McClelland and Walter F. Edmundson have been appointed by the Pittsburg Civil Service Commission examining board for medical examiners of the public schools.—Dr. Daniel D. Heilman, Northumberland, is reported to be critically ill with tetanus in a Philadelphia hospital.

The Status of Poliomyelitis.—Owing to the large number of cases of poliomyelitis in this state, a special meeting was held at the College of Physicians on October 14 to discuss the situation. Dr. George L. de Schweinitz presided and papers by the following were read: Dr. Paul A. Lewis, of the Rockefeller Institute; Dr. Allen J. Smith, professor of pathology in the University of Pennsylvania; Dr. Charles K. Mills, professor of nervous diseases in the University of Pennsylvania; Dr. Joseph S. Neff, director of the Department of Health, and State Health Commissioner Dixon. That anterior poliomyelitis flourishes in those parts of Pennsylvania which are liberally watered but have poor drainage, even in high altitude and that there have been very few cases over gravel formations where perfect drainage of the subsoil obtained, was the interesting point brought out in the paper by Dr. Dixon. Some of the most important charts were shown that have ever been tabulated by his department. These charts were made out in columns showing the geologic formations, water distribution and elevations. The number of cases of poliomyelitis that have appeared were put down on the charts in the districts in which they occurred. Elevation apparently has no influence on the disease. To these charts will be added the distribution of vegetable and insect life in order that it may be observed whether any peculiar insect or vegetable is found in places where the disease has been most prevalent. A total of 920 cases of poliomyelitis have been reported from 50 different counties in the state during the present epidemic. Of this number there were only two cases among the colored race. Males showed a greater tendency to contract the disease than females. The outbreak began about the end of May almost simultaneously in the Lehigh Valley, in Lancaster county, in Potter county and in Philadelphia. The epidemic reached its height the latter part of August. A total of 332 cases was reported during that month. It has tended to subside in October. Out of 920 cases, 600 occurred before the fifth year of age, 163 contracting the disease before the end of the eighteenth month of life. That the studies made by the department show that the disease is not badly contagious is indicated from the following statistics: In the rural districts out of 66 households having 2 school children but one contracted the disease. In 41 households with 3 children but one contracted the disease. In 37 with 4 children only one sickened. In 33 with 5 children one sickened. In 20, with 6 children, and in 8 households with more than 6 school children, only one contracted the disease. It will thus be seen what exhaustive study the State Health Commissioner and his assistants are making to find the cause of this disease. The work will be continued vigorously both in the field and in the laboratories.

Philadelphia

Society Elects.—The Philadelphia Pathological Society at its annual meeting, October 13, reelected Dr. David Riesman, president, and elected the following officers: vice-presidents, Drs. Aloysius O. J. Kelly, Allen J. Smith, Joseph Sailer and Hobart A. Hare; secretary, Dr. Edward H. Goodman; treas-

urer, Dr. Courtland Y. White; recorder, Dr. Frederick H. Klaer, and curator, Dr. Howard T. Karsner.

Personal.—Drs. Edward P. Davis and W. Reynolds Wilson have returned from Europe.—Dr. John A. McKenna, Lansdowne, sailed for Europe October 8.—Dr. Thomas C. Stellwagon has been appointed chief of the surgical clinic of Jefferson Medical College Hospital.—Drs. George J. Schwartz and Thomas J. Buchanan have resigned from the visiting surgical staff of the Jefferson Medical College Hospital.—Dr. James B. Walker is dangerously ill at his home.

WEST VIRGINIA

Petition for State Sanatorium.—The West Virginia Fraternal Association, in session at Weston, October 6, adopted resolutions asking the state legislature to establish a state tuberculosis sanatorium, and appointed a committee to circulate petitions and to bring the matter before the legislature at its coming session.

County Medical Society Election.—The first meeting for the season of the Ohio County Medical Society was held in Wheeling, September 12, and the following officers were elected: president, Dr. William S. Fulton; vice-president, Dr. D. Bigger Best; secretary, Dr. Randolph J. Hersey; treasurer, Dr. Reed McC. Baird; censors, Drs. James G. Walden, Albertus Nichols, and Samuel L. S. Sprague; delegates to the state association, Drs. Charles A. Wingerter, Edward L. Armbricht, and David H. Taylor, and alternates, Drs. Andrew J. P. Wilson, James G. Walden, and John J. Osborn, all of Wheeling.

State Society Meeting.—The forty-third annual meeting of the West Virginia State Medical Association was held in Parkersburg, October 5-7, under the presidency of Dr. Thomas W. Moore, Huntington. The following officers were elected: president, Dr. Charles A. Wingerter, Wheeling; vice-presidents, Drs. John E. Camaday, Charleston, Glenn Moorman, Parkersburg, and George D. Jeffers, Parkersburg; secretary, Dr. Arthur P. Butt, Davis; treasurer, Dr. Hugh G. Nicholson, Charleston, and councilors, First District, Dr. Henry B. Linsz, Wheeling; Second District, Dr. W. Holmes Yeakley, Keyser; Third District, Dr. Peter A. Haley, Charleston; Fourth District, Dr. Walter S. Link, Parkersburg, and Fifth District, Dr. Samuel R. Holroyd, Athens. White Sulphur Springs was selected as the meeting place for 1911.

GENERAL NEWS

Personal.—Dr. William Colby Rucker, U. S. P. H. and M.-H. Service, formerly health commissioner of Milwaukee, has been detailed for duty in connection with the cholera situation.—Dr. Charles E. Ruth and family, Ponce, Porto Rico, who have been spending the summer in northern Michigan, have returned home.

Railway Surgeons in Session.—The annual meeting of the Society of Surgeons of the St. Joseph and Grand Island Railway was held in St. Joseph, Mo., October 6. A clinic was held in St. Joseph Hospital in the morning, under the direction of the chief surgeon, Dr. Charles W. Wallace, St. Joseph. The following officers were elected: president, Dr. Barton Pitts, St. Joseph; vice-president, Dr. William M. Boone, Highland, Kan., and secretary, Dr. Charles H. Wallace, St. Joseph.

National Precautions Against Cholera.—At the request of Surgeon General Walter Wyman, every American village, town and city that recently has received, or until further notice receives, any Russian or Italian immigrant will be directed to isolate him if he develops any symptoms whatever of cholera. Of 15,000 steerage passengers who have landed in the last seven days, more than half have been from Italian ports or are Russians. The two cholera patients at Swinburne Island are improving.

Health of Canal Zone.—The report of the sanitary department of the Isthmian Canal Commission for August shows 55 deaths, 31 from disease and 24 from external causes, equivalent to an annual mortality per 1,000 of 13.04, an increase as compared with 1908 when the mortality was 11.39, and 1909 when the mortality was 10.28 per 1,000. No reason for this increase is assigned. No cases of yellow fever, small-pox or plague were brought to the isthmus or originated on it during the month.

Higher Preliminary Requirements in Colorado.—Dr. S. D. VanMeter, secretary, states that the Colorado State Board of Medical Examiners, at its October meeting, adopted a resolution providing that applicants for license to practice in Colorado, graduating after January 1, 1914, will be required to furnish satisfactory evidence that, before matriculation, they

had completed two years' study without conditions in an accredited college of liberal arts. The requirement of one year of collegiate work, as previously announced, becomes effective January 1, 1912.

Infant Mortality.—The American Association for the Study and Prevention of Infant Mortality will hold its first annual meeting in Baltimore November 9-11. At the opening session, addresses will be made by Hon. Jules Jusserand, the French ambassador, and by Dr. William H. Welch. The second session will be devoted to philanthropic prevention of infant mortality; the third to municipal, state and federal prevention; the fourth to medical prevention, and the fifth to educational prevention. An exhibition will be held devoted to the milk work of departments of health, medical milk commissions, the influence of feeding on infant mortality, contagious diseases conveyed by milk, and specific causes of infant mortality.

Fraternity Meeting.—The Phi Beta Pi Medical Fraternity held its twelfth annual meeting in Philadelphia October 4-7, and elected the following officers: supreme archon, Dr. Albert H. Parks, Minneapolis; supreme vice-archon, Dr. Ned O. Lewis, Kansas City, Mo.; supreme secretary, Dr. George M. Kline, Ann Arbor, Mich.; supreme treasurer, Dr. Marcel J. de Mahy, New Orleans; supreme editor, Dr. George G. Zochrlaut, Chicago; supreme eastern pretor, Dr. John W. Holmes, Philadelphia; supreme western pretor, Dr. David S. Long, Kansas City, Mo.; supreme southern pretor, Dr. Covert B. Cooper, New Orleans, and supreme northern pretor, Dr. David D. Todd, Ida Grove, Iowa. The fraternity will convene in Detroit next year.

Meetings to Come.—The twenty-sixth annual session of the New York and New England Association of Railway Surgeons will be held at Hotel Astor, Broadway and Forty-fourth street, New York City, November 3 and 4, under the presidency of Dr. Leroy M. Bingham, Burlington, Vt. Dr. John B. Deaver, Philadelphia, will deliver the address on surgery.—The twelfth annual meeting of the Ohio Valley Medical Association will be held in Evansville, November 9 and 10, under the presidency of Dr. Albert E. Sterne, Indianapolis. The subject of his address will be "The Question of Exercise."—The International Medical Society, consisting of representatives from Mexico, United States and foreign countries will meet in El Paso, Texas, October 27-29. Drs. von Ehrlich, Berlin, and Charles Wardell Stiles and Claude H. Lavinder of the U. S. P. H. and M.-H. Service, will deliver addresses.

Meeting of Southwestern Physicians.—The fifth annual meeting of the Medical Association of the Southwest was held in Wichita, Kan., October 11 and 12, under the presidency of Dr. George H. Moody, San Antonio, Texas. The following officers were elected: president, Dr. Middleton L. Perry, Parsons, Kan.; vice-presidents, Drs. John M. Griffin, Sulphur Springs, Ark.; William H. Stauffer, St. Louis; Everett S. Lain, Oklahoma City, Okla., and Wilmer L. Allison, Fort Worth, Texas, and secretary-treasurer, Dr. Fred H. Clark, El Reno, Okla. (reelected), and executive committee, Drs. William A. Wood, Hubbard, Texas; Samuel S. Glasscock, Kansas City, Kan.; St. Cloud Cooper, Fort Smith, Ark., and Jefferson D. Griffith, Kansas City, Mo. Oklahoma City was selected as next meeting place. A state department of health, as suggested by the Owen bill, was endorsed by the association.

Millions for Medical Research.—At the meeting of the board of trustees of the Rockefeller Institute for Medical Research, in New York City, October 17, the occasion of the celebration of the opening of the new hospital described below, it was announced that Mr. Rockefeller had given \$3,820,000 additional to the institute, thereby making his total gifts to this institution \$8,240,000. The institute property has been placed absolutely in the hands of the board of trustees, consisting of John D. Rockefeller, Jr., Frederick T. Gates, William E. Welch, Starr J. Murphy and Dr. Simon Flexner. The function of the trustees is to hold and care for the property of the institute, including investment of endowment funds, and to hold the entire income under the control of the board of scientific directors, composed as follows: Dr. William H. Welch, Baltimore, president; Dr. L. Emmett Holt, New York City, secretary-treasurer; Dr. Simon Flexner, New York City, director of laboratories, and Drs. T. Mitchell Prudden, Christian A. Herter and Hermann M. Biggs, New York City, and Theobald Smith, Boston.

New Methods of Instruction at Syracuse.—A number of important changes made in the arrangement of courses at the College of Medicine of Syracuse University will be interesting to those who are trying to solve the problems of medical

education. These changes provide for the completion of the course in anatomy during the first year. This work will hereafter be in charge of Professor Henry W. Stiles, who comes to Syracuse University from Tulane University. He will be assisted by Dr. Robert H. Haskell, formerly of the University of Michigan. Physiologic chemistry is planned for the second semester of the first year and the first semester of the second year. As a prerequisite, a review course in general chemistry will be given during the first semester of the first year. Although the course in physiology is not to be changed during the present session, it is intended in the near future to provide for the completion of all work in this subject during the second year. The course in obstetrics has been arranged so that all the work in that subject may be completed during the third year. The rearrangement in surgery provides that all clinical work for the third and fourth year students will be taken in the forenoons. Provision has been made so that hereafter students in medicine will be assigned to cases in hospitals thereby having the opportunity for clinical investigation under the supervision of the attending staff. The students will also be given clinical laboratory work in a hospital, will act as clinical clerks and attend numerous section clinics. It is planned to correlate clinical work with that of the department of pathology and bacteriology. With this object in view an additional course has been provided in the bacteriologic examination of patients in hospitals and a second course in post-mortem examinations. Furthermore, a clinical and pathologic conference including one hour per week for the third and fourth year classes has been scheduled. At this conference it is intended that medical and surgical cases on which autopsies have been held during the preceding week are to be discussed. Clinical histories and records as well as the laboratory findings will be shown, the object being to present in a clear and concise manner all data having a bearing on a clinical diagnosis.

The New Hospital of the Rockefeller Institute.—The opening of the new hospital of the Rockefeller Institute for Medical Research in New York marks an advance in the organization and scope of this institution of noteworthy significance to practice as well as to research in medicine. The hospital is located on the grounds of the institute near the laboratory buildings but separate from them and is open on all sides to light and air. There is a separate building for the isolation and care of cases of communicable diseases. This building with its eight stories and an isolation pavilion, and with so complete an equipment, provides accommodations for only seventy. The reason for this is that the hospital was built not to add seventy beds to the facilities in New York for caring for the sick or injured, but to undertake a work which is not largely carried on in existing institutions. Their purpose is essentially philanthropic and educational, and only secondarily scientific. The primary purpose of the institution, however, is to advance the knowledge of clinical medicine, especially in the nature, diagnosis and treatment of disease. This can best be accomplished by the closest possible study of a very few patients, and the object sought can best be reached by attacking different medical problems singly and concentrating the entire energies of the institution on one or two or three of them. The problems to be taken up are not likely to be those of a rare or unusual nature, however interesting, but some of the most pressing problems of the day. Thus it is proposed to take up at first acute pneumonia and certain forms of heart disease, and of affections of disturbed metabolism, and infantile paralysis; the purpose being to determine by the most minute observations in the care and treatment of these few the best means of caring for the great majority of those who are suffering from these diseases. It has a medical and nursing staff which is relatively large in comparison with those of most other hospitals. One entire floor of the building is devoted to clinical laboratories, chemical, biologic, physiologic and photographic, for more accurate diagnosis and observation and the development of exact methods of treatment. The endeavor has been made to secure the best environment for persons under treatment—space and air and agreeable surroundings. The most ample provision has been made for the open-air treatment for patients suffering from both acute and chronic disease. There is a special diet kitchen in which all food can be prepared with scientific precision when this is required. There is a department of hydrotherapy and electricity. Another unique feature in the organization of the hospital is that the members of the medical staff will devote their entire time to the work of the hospital. They will receive salaries and will not be allowed to practice outside of the hospital or to receive any fees from patients. They will, therefore, have no other interest than

the welfare of the patients under their care and the securing of such new knowledge of disease and its treatment as the exact observation and methods now made practicable promise to afford. The hospital contains few large wards, the largest holding but eight beds, but there are numerous single rooms for special cases where the best environment can be secured. Many of these single rooms have private baths connected with them. No fees are to be charged to any patients. The isolation pavilion provided for infectious diseases is entirely separate from the main hospital and has been planned in such a way that it will be possible to treat any form of infection with entire safety to the other occupants of the hospital. This makes it possible at any time for the institute to study any new phase of infectious disease which may appear in the city or in the community and greatly adds to the possibility of the usefulness of the institute.

Memorial to Finsen.—A monument to Finsen, the pioneer in scientific phototherapy, was recently unveiled at Copenhagen, erected by subscriptions from members of the profession, former patients and others at home and abroad. It stands on a prominent open corner with the large new public hospital in the background. The base of the monument is a huge, rough boulder, bearing the simple inscription, "To the Memory of N. R. Finsen, 1860-1904." It is surmounted by a group of three colossal figures representing Finsen standing, apparently invoking the light, and two female figures at his feet. Finsen's career reads like a romance; from the Faroe Islands, near Iceland, where he was born, to a Nobel prize and funeral with international honors, all in 43 years, most of them handicapped with severe heart disease!

CANADA

Seeks Reciprocity.—New Brunswick is making an effort to secure reciprocity with Great Britain, and has made application to the General Medical Council for this purpose. Nova Scotia and Prince Edward Island have already reciprocal arrangements with Great Britain.

Personal.—Drs. George A. Armstrong, and Frederick G. Finley, Montreal, and John A. McCollum and Samuel Cummings, Toronto, have gone abroad.—Dr. Charles Sheard, medical health officer of Toronto, has resigned.—The class of 1892, Toronto University, has elected Dr. Henry J. Way, Chicago, president.

McGill College Opens.—The opening lecture of the session of the McGill Medical Faculty was delivered October 3, by Dr. William Hunter, London, who spoke on "Antisepsis in Medicine." The new Medical building is in use for the first time. It contains the departments of anatomy, pathology, and bacteriology, a medical museum, and medical library.

Hospital Notes.—A new hospital is to be erected at New Westminster, B. C., at a cost of \$200,000. The present hospital accommodates only forty-five patients, but as many as eighty-five have been in residence at one time.—The tuberculosis Dispensary at St. John, N. B., is to be opened Thursday afternoons for children, and parents are advised to take to the dispensary for examination all children who have been exposed to the disease.

Association Meetings.—The following officers were elected at the meeting of the Alberta Medical Association: president, Dr. L. S. Mackid, Calgary; vice-presidents, Drs. John Park, Edmonton, Walter S. Galbraith, Lethbridge, and Andrew W. Park, Cochrane, and secretary-treasurer, Dr. Thomas H. Whitelaw, Edmonton.—The College of Physicians and Surgeons of Quebec has elected the following officers: president, Dr. Louis P. Normand, Trois Rivières; vice-presidents, Drs. Art A. Simard, Quebec, Henry A. LaFleur, Montreal, and L. Arthur Lessard, Granby, and registrar, A. P. Gauvreau, Montreal.

LONDON LETTER

(From Our Regular Correspondent)

LONDON, OCT. 8, 1910.

Coroner's Jury Comments on an Unsuccessful Operation

The verdict of the coroner's jury, usually composed of persons uninitiated on medical questions, is sometimes far from enlightened and may be harmful, as the following case shows. A man died three hours after an operation for intestinal obstruction at the Preston Infirmary. For some reason, the coroner thought that it was his duty to hold an inquest, although that is not necessary in cases of the kind. The medical evidence was to the effect that the man could not have lived more than a few hours if the operation had not

been performed, and that it gave him his only chance of life. The house surgeon stated that during the three years he had been at the infirmary there had been a dozen such cases which he had not reported to the coroner. If inquests were held in all such cases the result would be that physicians would not undertake the responsibility of performing operations and the odium attached to them. They had to consider their own reputation. However, the coroner rejoined that he failed to see why the operation should not be done "because there was a certain amount of publicity attached to it." Another surgeon gave evidence to the effect that he had operated in nine similar desperate cases in three years and that 5 of the patients were living today. "Whatever was said outside doctors must do their best." The verdict was that the man "died about three hours after an operation for obstruction of the bowels, and that his death was accelerated by the operation." One jurymen had the sense to protest against the latter portion of the verdict, because it might frighten the public into not allowing their relatives to undergo operations. There does not seem to have been any evidence that life was shortened in this case by the operation and therefore the latter part of the verdict was speculative and unjustified.

Medical Literature for China

Professor Osler's "Principles and Practice of Medicine" has been translated into Chinese by Dr. P. B. Cousland, president of the China Medical Missionary Association, Shanghai. This undertaking has engaged Dr. Cousland for several years. The book is the only first-class work on medicine that has so far been translated into Chinese. Other translations are in progress. Dr. Cochrane, of Peking, is translating Heath's "Anatomy;" Dr. McAll, of Han-kau, Stengel's "Pathology;" Dr. Cormack, of Peking, Hutchinson and Rainey's "Clinical Methods;" and Dr. Neal, of Tsi-nan, Fuch's "Ophthalmology." A new and compact "Systematic Anatomy" is also passing through the press. An atlas of beautiful anatomic plates has just been printed for the China Medical Missionary Association by the Oxford Press at a cost apart from the letter-press of \$2,500, a part of which has been contributed by the China Emergency Appeal Committee. As dissection of the human body is not yet allowed in China such plates are of great importance.

Yellow Fever in West Africa

Sir Robert Boyce, of the Liverpool School of Tropical Medicine, who has just returned from an expedition to West Africa, at the Liverpool Chamber of Commerce made an important report on yellow fever in that country. He states that in a short time we shall be in possession of facts which will throw great light on the diseases of the West African coast. He has come to the conclusion, as a result of his own observations, reading and inquiries, that yellow fever is endemic to the west coast of Africa and that for years it has been mistaken for malaria. In Sierra Leone, yellow fever has never been absent since 1806, and it always attacks those who have most recently arrived. It is even described by the natives as "the disease of the newcomers." But the mortality of Sierra Leone has greatly improved. One cause is the use of mosquito nets and greater care in living generally. It is the *Stegomyia calopus* which is the cause of the trouble. It has been said that this mosquito is difficult to tackle, but it is the easiest to get rid of. If the attacks on this mosquito were kept up, soon nothing more would be heard of yellow fever and the death-rate on the coast would go down with a run and many other diseases would disappear.

PARIS LETTER

(From Our Regular Correspondent)

PARIS, Oct. 7, 1910.

Twenty-Third Meeting of the French Surgical Association

The Association française de chirurgie held the opening session of its twenty-third meeting on October 3, under the presidency of Dr. H. Delagenière, surgeon of the hospitals of Le Mans and corresponding member of the Académie de médecine. None of our medical meetings is more interesting than this one. The proof is not only in the number of the members of the association, which increases each year, but in the number and high standing of the foreign surgeons who attend it. This year they were particularly numerous. Among them were Sir Victor Horsley of London, Professors Czerny of Heidelberg, Kocher of Geneva, von Eiselsberg of Vienna, Tavel of Berne, Girard of Geneva, Ceci of Pisa, Jonnesco of Bucarest and Phoocas of Athens.

Dr. Delagenière opened the meeting with an interesting paper on a very practical subject, "The Surgical Hour in Visceral Pathology or the Surgical Period in Certain Internal Diseases." For a long time, he said, surgeons have been accusing physicians of sending patients to them too late, to the loss of the patient and of surgery. Is not excessive specialization one of the causes of this condition? Specialization ought to exist only in practice, for the medical sciences form a whole whose complete knowledge is indispensable to every practitioner. The resources of surgery are incompletely and imperfectly known to most physicians. And yet, almost all visceral diseases present a period in their evolution during which surgical intervention may be tried with success, either for re-establishing the physical function of the organ or arresting the morbid process. This period passed, either the organ is destroyed from the physiologic point of view or the disease can no longer be arrested and the operation cannot cure the patient radically. Each visceral disease has its surgical hour, so to speak, and it is when this hour has struck that operation presents both the greatest simplicity and the greatest security.

Hostility to Ehrlich's "606"

Some French professors have been very skeptical in regard to the new remedy for syphilis and have gone so far as to carry the discussion, which ought to have remained on a purely scientific ground, into the lay papers. An interview which Professor Bouchard gave on the subject to a morning paper appeared under headings derisive of the remedy. It is extremely probable that Professor Bouchard did not say all that is attributed to him in the paper, and this seems to be well understood even in Germany, where the *Medizinische Klinik* of September 25 published a note blaming the Paris correspondent of a German lay paper for speaking unpleasantly of Bouchard. These squabbles are altogether out of place and it is to be regretted that Dr. Ehrlich himself did not hesitate to write to one of our lay journals, which naturally hastened to publish his letter.

Among us "606" has found a particularly bitter and violent opponent in Dr. Hallopeau, former physician of the Saint-Louis Hospital, who, after having published a criticism of "606" in a number of political journals, attacked it at the Académie de médecine October 4. According to him "606" does not fulfil the conditions of harmlessness and of constancy of effect which alone would justify the interest taken in it. There have been, he says, fourteen deaths from its use, two in Paris, besides cases of blindness.

These criticisms, circulated by the lay press, aroused active objections in the academy. Dr. Netter, *agrégé* professor at the Paris medical college, expressed surprise at hearing Hallopeau denounce systematically a drug which Ehrlich studied with so much care before putting it in general use. The deaths mentioned by Hallopeau could not be considered as due to the drug; as for the cases of blindness, Netter had heard of none. He believed that one should give credit to a man of such high standing and great scientific probity as Professor Ehrlich.

BERLIN LETTER

(From Our Regular Correspondent)

BERLIN, Sept. 29, 1910.

Personal

Professor Payr of Greifswald has been called to Königsberg as director of the surgical clinic to succeed Professor Lexer, who goes to Jena. Payr's successor is Prof. Fritz König of Altona, a son of the noted Berlin surgeon.

Ehrlich on His "606"

At the eighty-second session of German scientists and physicians, the Naturforscher Congress, just held at Königsberg, one meeting was devoted to the discussion of Ehrlich's new remedy and he made the following interesting statements with reference to "606."

The specific action of the remedy was recognized in animal experiments and is shown especially by the fact that on the application of a sufficient dose the spirochetes disappear in from 24 to 48 hours. If the time required is longer, either the dose was too small or the spirochetes in question are immune to arsenic. The second fact which has developed is that specific antibodies are produced. It appears that treatment with "606" furnishes an unusually favorable opportunity for the demonstration of these antibodies. The first important observation was that the milk of a mother who was nursing a syphilitic child and was herself treated and cured with "606," had a remarkably favorable action on the child. A similar result has been noticed in a large number of nursing women.

The arsenic content of the milk is extraordinarily small, so that it is evident that the milk must contain antibodies which are received into the stomach of the child and absorbed. From other sources it is known that if the serum of such patients is injected into syphilitic children the symptoms of the disease disappear. While it is evident that specific antibodies are formed, Ehrlich is of the opinion that the serum treatment alone is not sufficient for a positive cure. For if of a thousand spirochetes only a few survive, they are sufficient to prevent a complete cure. If children are injected with serum an extraordinarily prompt curative action is observed at first; the exanthemata very promptly disappear. But after 6 or 7 days other disturbances develop testifying that the antibodies were insufficient to destroy all the spirilla. It is therefore best to give such a child, soon after, a sufficient injection of "606" to kill the rest of the spirochetes.

The second specific action is on the Wassermann reaction which is certainly connected with the presence and growth of the spirilla. The very interesting observation has been made, that in certain affections a negative Wassermann reaction becomes at first positive under the influence of the injections. For instance, in chancres at an early period, the number of spirochetes is so small that they are not capable of producing a positive reaction. If now the previously negative reaction is at once converted into a positive one, evidence is furnished for the actual syphilitic nature of the disease. The importance of this reaction in the treatment with "606" cannot be sufficiently emphasized, he declared. If by the therapeutic action, only 100 out of 1,000,000 spirochetes survive, no reaction will occur, but every positive reaction is to be regarded as analogous to a relapse and is therefore an indication for the repetition of the treatment with "606." Such cases should be examined at sufficient intervals and kept under observation. It would be very desirable if a modification of the Wassermann reaction could be made so that the practitioner could apply this important test to his patients.

A third action which is very hard to explain consists in the fact that the remedy often works with wonderful rapidity. The statement has been made from many sources that patients, for instance, who had not been able for months to swallow any solid food on account of disease of the fauces or tonsils could do so immediately after an injection. This remarkable rapidity of action is not to be explained by anatomic changes but depends on the removal of the pain, which was due to the action of the products of the secretion of the spirochetes; "606" acts in this case as an antineuralgic. On the other hand, it has been occasionally observed that increased sensitiveness occurs in some patients similar to what has been observed after mercurial injections. The first observations in this line come from Italy where extraordinary caution was at first used and doses of from 0.025 to 0.05 gm. ($\frac{1}{2}$ to 1 grain) were employed. The spirochetes recovered themselves after a short time; they were not destroyed by the weak remedy but stimulated so that the result was a greater secretion of toxin. Ehrlich has always regarded the remedy as an arsenical and a dangerous remedy and has therefore insisted on the necessity of a thorough preliminary testing of it. No one can expect complete harmlessness in a remedy which is to kill parasites. The mortality as a result of the remedy depends exclusively on the constitution of the patient, a law which holds for all dangerous remedies, even for chloroform. Ehrlich has now reports of the use of "606" in 10,000 cases. The results have shown that "606" is not especially dangerous. In this large number of cases there is only one in which death immediately followed the administration of the remedy, and this was the case of a female patient whose disease, tertiary syphilis, must have eventually resulted fatally. In this case the injection was made with the acid solution and there was a certain shock which would be avoided with the newer preparation. All other fatalities, of which the number might reach a dozen, occurred in cases of severe nervous disease, tabes and the like, in which the prognosis at least was very doubtful. If in such desperate cases unfavorable results ensue, it must not be said that the remedy is dangerous. Such extremely dangerous experiments must be undertaken if one has the conviction that he can save the patients in that way. Ehrlich does not consider the remedy indicated in cases of severe paralysis, for even if a cure resulted the patients could not be expected to become useful members of human society. A second contraindication is furnished by diseases of the heart and blood vessels in which one must be very cautious. As to the technic, the alkaline solution which was first introduced by Alt and Iversen has the slight disadvantage of being somewhat painful while the neutral injection has the advantage of lessened painfulness. For that reason

the neutral emulsion should be preferred in neurasthenic and alcoholic persons and in patients sensitive to pain. Probably in future a combination of both methods with the use of both intravenous and subcutaneous injections may be adopted. The dose depends on the nature of the disease. A general dosage cannot be given. In nervous affections 0.4 gm. (6 grains) should not be exceeded for these oversensitive individuals react very unpleasantly on the part of the heart and central nervous system. Moreover in these central nervous affections the number of spirochetes is very small and a smaller amount of the remedy is probably sufficient for their destruction. It has been established that from 16 to 20 per cent. of the paralytics have lost their Wassermann reaction. These patients have not regained the reaction in a period of two years and this fact gives a most hopeful outlook for the future. In general Ehrlich agrees with Neisser that one should try to give doses large enough to secure a cure by the first injection. In a relatively healthy person a dose as high as 0.8 to 1.0 gm. (12 to 15 grains) or even higher can be given without danger. Finally Ehrlich notes that the remedy is also active in other diseases. Among these the most prominent is frambesia which is very nearly related to syphilis, next chicken cholera and certain forms of malaria. The fact has been independently established from various sources that a single subcutaneous dose was sufficient for the removal of fever in malaria. Also in two small-pox cases the remedy had an apparently favorable effect.

Marriages

- G. M. WYATT, M.D., to Miss Elam, both of Dewey, Okla., September 28.
- HENRY B. KOLB, M.D., to Miss Mary Cookran, both of Baltimore, October 5.
- ELVA C. MACER, M.D., to Miss Rena Rust, both of Evansville, Ind., October 5.
- LEWIS E. MISSIMORE, M.D., to Mrs. Lucille Alexander, both of St. Louis, October 5.
- HERBERT W. HEWITT, M.D., to Miss Sila M. Hovey, both of Detroit, October 1.
- HARRY ISAAC WIEL, M.D., to Miss Sarah Lilienthal, both of San Francisco, October 2.
- CARL TILLMANN, M.D., to Miss Lucy Bakehouse, both of Gourney, Iowa, July 13.
- CHARLES W. RILEY, M. D., Baltimore, to Miss Helen Cruikshank, at Baltimore, October 4.
- JOHN CROCKETT EASTON, M.D., to Miss Mabel Prince, both of Springfield, Ohio, October 11.
- SILAS MERCER MOORMAN, M.D., to Miss Frances Ditweiler, both of New York City, recently.
- ROZELL MCGLATHERY, M.D., Oil City, La., to Miss Margery Frances Lloyd of Chicago, October 12.
- CLARENCE LE R. COLE, M.D., U. S. Army, to Miss Hoff, at Whipple Barracks, Ariz., September 21.
- PHILIP HENRY WEBER, M.D., Elmhurst, Cal., to Miss Ruby Hughes of San Francisco, recently.
- JAMES A. BOND, M.D., Parkersburg, W. Va., to Miss Bertha George, at Glen Marcy, Md., October 1.
- LEMUEL BYRD SHORT, M.D., East St. Louis, Ill., to Miss Josephine Hill of Fillmore, Ill., recently.
- JAMES H. BOUTLER, M.D., Detroit, to Miss Evaline Crawford of Denver, at Hamilton, Ont., October 12.
- JOHN A. DUNCAN, M.D., Upham, N. D., to Miss Grace Margaret Kinghorn of Toronto, Ont., September 21.
- HOLLAND TODD GROUND, M.D., Aberdeen, S. D., to Miss Martha Grace McDonnell of Chicago, October 15.
- BERNARD HAMLIN GLENN, M.D., Fowlerville, Mich., to Miss Nellie Deborah Lansing of Howell, Mich., September 7.
- FRED WARREN McCAW, M.D., Mount Union, Iowa, to Miss Myra Russell Patterson of Winfield, Iowa, September 29.
- WILLIAM HENRY CASTLE, M.D., Manaroneck, N. Y., to Miss Mary Elizabeth Cullen of Middletown, Conn., September 30.
- THOMAS P. GUILFOYLE, M.D., Cherry, Ill., to Miss Kathleen Helen Dwyer of Arlington, Ill., at Peoria, Ill., September 29.
- JOSEPH HOWARD HODGES, M.D., Harpers Ferry, W. Va., to Miss Edna Bell Hendricks, at Shenandoah Junction, W. Va., October 12.

Deaths

DeForest Willard, M.D. University of Pennsylvania, Philadelphia, 1867; died at his home in Lansdowne, Philadelphia, October 14, from double pneumonia complicating acute multiple neuritis, aged 64. He was a member, and in 1902 chairman, of the Section on Surgery of the American Medical Association; president of the American Orthopedic Association in 1890; of the Philadelphia County Medical Society in 1892, and of the American Surgical Association, and the Philadelphia Academy of Surgery in 1902, and a fellow of the Philadelphia College of Physicians; professor of orthopedic surgery in the University of Pennsylvania since 1889; surgeon to the Presbyterian and University hospitals; consulting surgeon to the Germantown, Jewish, Atlantic City and Phe-nixville hospitals, and surgeon in chief of the Widener Training School for Crippled Children.

Dr. Willard was author of a text-book on "Artificial Anesthesia," published in 1891; and of a work on "Surgery of Childhood, Including Orthopedic Surgery," published in 1909; and numerous monographs on surgical and orthopedic subjects; acting assistant surgeon under the auspices of the United States Sanitary Commission at the Second Corps Base Hospital, City Point, and at the Fair-grounds Hospital, Petersburg, Va., and attending medical officer of the Centennial Exposition in 1876.

Dr. Willard was progressive. He was not only one of the leading orthopedists of the country but also a most notable surgeon. He was a man with hosts of friends and without an enemy.

John Veitch Shoemaker, M.D. Jefferson Medical College, 1874; died at his home in Philadelphia, October 11, from acute nephritis, aged 52. He was a member of the American Medical Association and trustee from 1890 to 1893; American Academy of Medicine; Association of Military Surgeons of the United States; British Medical Association and London Medical Society; formerly secretary, vice-president and president of the American Medical Editors' Association and president of the American Therapeutic Association; demonstrator and lecturer on anatomy and lecturer on cutaneous affections in Jefferson Medical College from 1874 to 1886; professor of cutaneous diseases and materia medica and therapeutics since 1886 in the Medico-Chirurgical College, and president of the institution since 1890; senior physician to the Medico-Chirurgical Hospital; founder of the *Medical Bulletin* in 1879, and *Medical Register* in 1887; and editor of the *Medical Times and Register*.

He was surgeon-general of the State of Pennsylvania from 1898 to 1902; and during the Spanish-American War raised the necessary funds and presented to the State of Pennsylvania a fully-equipped hospital train for the transportation of its sick soldiers from Camp Alger, Va. He was commissioned first lieutenant, Medical Reserve Corps, U. S. Army, in 1908.

Dr. Shoemaker was a prolific contributor to the literature of dermatology, materia medica and therapeutics and served as president of the Board of Charities and Corrections of the City and County of Philadelphia since 1901.

Benjamin Franklin Dixon, M.D. Medical College of the State of South Carolina, Charleston, 1874; of Raleigh, N. C.; a veteran of the Civil War and major of the Second North Carolina Infantry, U. S. V., during the Spanish-American War; formerly superintendent of the Masonic Orphan Asylum, Oxford; later president of the Greensboro Female College, and since 1900, state auditor; died at Rex Hospital, Raleigh, North Carolina, September 26, from angina pectoris, aged 65.

T. Floyd Woodworth, M.D. Ohio Wesleyan University, Cleveland, 1869; formerly a member of the American Medical Association; a member of the Medical Society of the State of New York and president and secretary and treasurer of the Columbia County Medical Society; for several terms coroner of Columbia county; health officer of Kinderhook, and local United States pension examiner; local surgeon of the New York and New England and Albany and Hudson Railways; died recently at the Ann May Hospital, Spring Lake, N. J., from heart disease, aged 78.

Gustavus Lincoln Simmons, M.D. Harvard Medical School, Boston, 1856; a member of the American Medical Association; formerly physician of Sacramento county; president of the Medical Society of the State of California in 1893; secretary and president of the Sacramento Board of Education; a member of the local board of pension examiners; surgeon of the Fourth Infantry, N. G. Cal.; for more than twenty years a commissioner in lunacy and a member of the local board of health; died at his home, October 4, aged 78.

Samuel Dutton Gilbert, M.D. Yale University, New Haven, Conn., 1871; of

New Haven, Conn.; a member of the American Medical Association; president of the Connecticut State Medical Society; attending physician to New Haven Hospital; died between Dover, England, and New York on board steamer *Lapland*, September 27, from pneumonia, aged 62. The New Haven Medical Association, at its meeting October 3, adopted suitable resolutions regarding the death of Dr. Gilbert and appointed honorary pallbearers.

Patrick Henry Jameson, M.D. Jefferson Medical College, 1849; a charter member of the Indiana State Medical Association; founder of the Indianapolis City Hospital; during the Civil War in charge of the Military Hospital, Indianapolis; a member of the city council from 1863 to 1869; a member of the board of trustees of the Indiana Hospital for the Insane from 1861 to 1868; physician to the Indiana Institute for Deaf and Dumb from 1861 to 1869; from 1869 to 1879 president of the boards in charge of the benevolent institutions of the state; for thirty years a trustee of Butler College; died at his home in Indianapolis, October 7, from senile debility, aged 86.

DeForest Willard, 1846-1910

J. V. Shoemaker, 1858-1910

TWO PROMINENT PHILADELPHIANS

Temple B. Smith, M.D. Marion Sims College of Medicine, St. Louis, 1892; a member of the Louisiana State Medical Society; president of the Lake Charles Board of Health; local surgeon for the Southern Pacific and Kansas City Southern railways; died in St. Patrick's Sanitarium, Lake Charles, October 3, from the effects of a gunshot wound of the abdomen inflicted by his wife during a quarrel a week before, aged 46.

Charles Edwin Miles, M.D. Worcester (Mass.) Medical College, 1859; vice-president of the National Eclectic Medical Association; for several years chairman of the Massachusetts Board of Registration in Medicine; and assistant editor of the *Massachusetts Medical Journal*; a member of the Boston School Committee; died at his home in Roxbury, October 1, from pneumonia, aged 79.

George U. Runcie, M.D. Northwestern University Medical School, 1880; University of Louisville, 1890; a member of the Indiana State Medical Association; from 1880 to 1893 physician to the Indiana State Prison South, Jeffersonville; local surgeon to the Evansville and Terre Haute Railroad; died at his home in Poseyville, October 2, from cerebral hemorrhage, aged 52.

William W. Hamilton, M.D. Hospital College of Medicine, Louisville, 1879; of Meridian, Miss.; a member of the American Medical Association; one of the founders, and secretary, and professor of obstetrics in the Mississippi Medical College, Meridian; health officer of Lauderdale county; local surgeon of the Southern Railway; died on a Southern Pacific train in Lafayette, La., October 8, from cerebral hemorrhage, aged 52.

Jacob Miller Hinson, M.D. Hahnemann Medical College, Philadelphia, 1886; of Brookline, Mass.; for many years ophthalmic surgeon to the Massachusetts Homeopathic Dispensary and Burrage Hospital; assistant in the Massachusetts Homeopathic Hospital; died suddenly in Saratoga, N. Y., October 4, from heart disease, aged 45.

Cornelius Gilman Trow, M.D. College of Physicians and Surgeons, New York City, 1872; of Sunderland and South Deerfield, Mass.; a member of the Massachusetts Medical Society; chairman of the school committee of Sunderland and trustee of the public library; died at his home in Sunderland, October 7, from laryngitis, aged 63.

George F. Cook, M.D. Medical College of Ohio, Cincinnati, 1872; a member of the Ohio State Medical Association and American Medico-Psychological Association; founder and physician-in-charge of the Oxford Retreat; president of the Oxford National Bank; died at his home, September 21, from chronic bronchitis, aged 64.

William Watson Gailey, M.D. Philadelphia College of Medicine and Surgery, 1863; of Ashland, Ill.; for many years a member of the Illinois State Medical Society; a medical cadet during the Civil War; died in Maplewood Sanitarium, Jacksonville, Ill., September 27, from uremia, following chronic nephritis, aged 68.

Frank Blair Olhausen, M.D. University College of Medicine, Richmond, 1898; a member of the Medical Society of Virginia; for several years local surgeon for the Baltimore and Ohio and Southern railways at Harrisonburg, Va.; died at his home in that city, October 8, from cirrhosis of the liver, aged 34.

Milo Wakely Scott, M.D. Rush Medical College, Chicago, 1877; for several years a practitioner of Grand Forks, N. D., and county physician and coroner; a member and treasurer of the first capitol commission which located the state capital at Bismarck; died at his home in Los Angeles, September 4.

Joseph Janney Hull, M.D. New York University, New York City, 1858; a member of the New York Pathologic Society; and for many years consulting surgeon to the Nursery and Children's Hospital; died at his home in New York City, August 26, from arterio-sclerosis and myocarditis, aged 76.

Henry Jayne, M.D. University of Michigan, Ann Arbor, 1865; a veteran of the Civil War; mayor of Taylorville, Ill., from 1891 to 1893, and for four years postmaster of that city; died at his home, September 10, from nephritis, aged 73.

George A. E. Carey, M.D. Cincinnati College of Medicine and Surgery, 1864; assistant surgeon of the First Ohio Volunteer Heavy Artillery during the Civil War; died at his home in Indianapolis, October 11, from arterio-sclerosis, aged 77.

Frank Horace Lower, M.D. Cleveland Medical College, 1894; of Cleveland; a member of the staff of the Huron Road Hospital; died at Lakeside Hospital, Cleveland, September 28, from general paresis, aged 42.

Pharmacology

[CONTRIBUTION FROM THE CHEMICAL LABORATORY OF THE AMERICAN MEDICAL ASSOCIATION]

PERFECTED OXYGENOR KING*

W. A. Puckner and L. E. Warren

A decade ago Dr. N. C. Morse of Eldora, Iowa, called attention¹ to three mechanical frauds which he had investigated and which were being exploited for the cure of disease. These instruments were known, respectively, as the "Electropoise," the "Oxydonor Victory" (Fig. 1), and the "Oxygenor King" (Fig. 2).

The "Electropoise" consisted of a metallic cylinder, called "Polizer," 3½ inches in length and weighing about 5 ounces, to which an un-insulated cord was attached. To the distal end of the cord a small disc was attached and by means of an elastic band and buckle the disc could be fastened to the wrist or ankle of the patient. On sawing into the "Polizer" it was found to be hollow and empty. The price of this instrument was \$10.00.

The "Oxydonor Victory" resembled the "Electropoise" very closely. Its cylinder, called the "Vocor" was composed of brass, was 2½ inches in length and its weight was about 5 ounces. Inside the cylinder a stick of carbon, such as is used by electricians, was found sealed at either end by sealing wax. The price of this appliance was originally \$35.00, but at the time of Dr. Morse's investigation it could be purchased for \$10.00.

The "Oxygenor King," while similar in a general way to the other instruments, was somewhat more complex. It consisted of a brass cylinder 5½ inches in length and weighed 24 ounces from each end of which an insulated cord extended, one terminating in a copper disc and the other in a disc of zinc, the discs being intended to be fastened to the limbs of the patient. On cutting into the cylinder of the "Oxygenor King," it was found to be filled with a mixture of powdered charcoal and sulphur. The price of "Oxygenor King" was \$25.00 net cash.

WHAT THE COURTS SAID

Nothing in the composition of any of these instruments could possibly generate the smallest quantity of oxygen, ozone or electricity. Other than their influence as "faith healers" Dr. Morse concluded that none of them could have any "more medical virtue than a copper wire attached to a stove lid or a tin can filled with brimstone and charcoal." Dr. Morse also called attention to the fact that Dr. Hercules Sanche, the promoter of "Oxydonor Victory," had attempted to invoke the power of the courts to prevent the sale of the "Oxygenor King" but that the United States courts had decided that his instrument was not of sufficient value to entitle it to the protection of a court of equity. The matter was in the courts for sometime and when the case was finally disposed of, THE JOURNAL commented on the matter editorially in part as follows:²

"The court stated that these and similar fakes can not have the indorsement of the courts when the pretended inventor can not make or refuses to make an explanation. The court admitted that reputable witnesses testified that when sick they used some of these devices, and that they were restored to health; but the court goes on to say that there is nothing to prove that this sequence of events is in the nature of cause and effect. He remarks: 'It would be just as reasonable for an Iowa farmer to say his barn was not destroyed by the last thunderstorm because there was a lightning rod on Mount Pisgah, as for a man to say that his restoration to health was brought about by the use of an Oxydonor or an Oxygenor.'"

THE OXYGENOR KING

The "Oxygenor" is now called the "Perfected Oxygenor King." One of these instruments was recently examined in

* This and similar fakes are commented on editorially in this issue.

1. THE JOURNAL A. M. A., Dec. 1, 1900, p. 1464.
2. THE JOURNAL A. M. A., Jan. 11, 1902, p. 333.

the Association Laboratory. In an advertising circular this apparatus is thus described:

The Perfected Oxygenor King is a scientifically constructed instrument capable of curing all curable diseases without drugs, employing only the oxygen of the air.

It consists of a metal cylinder, especially charged with a delicately adjusted but permanent combination of rare and costly metals, chemical agents and conductive elements, and called a generator.

From the description given in the circular it appears that the "generator" is a small nickel-plated cylinder, closed at each end by means of a screw cap. To each of the two caps an insulated wire several feet in length is fastened, terminating in a metallic plate—one a zinc plate to be fastened to the ankle of the patient, the other a copper plate for the wrist. A third wire called a "force-controlling cord" joins the two others at a short distance from the cylinder and may be attached to the cylinder at one of the several points by means of a screw connection.

HOW IT IS SUPPOSED TO WORK

The method of applying this instrument is simplicity itself. There is but one requirement, namely, that the generator be placed in a temperature thirty to sixty degrees below that of the body. This is done by placing it on a window-sill, on the floor, or in a basin of cool water.

The patient then attaches the green cord to his ankle, the red cord to his wrist, and sits down, reclines on a couch or retires to bed.

The instrument produces its curative effects without further notice or effort on the part of the patient, and usually without any

In contrast to the above the following statements are also found in the circular:

One of the most noteworthy features of the Oxygenor treatment is that the patient cannot possibly be injured or acquire a "habit" by its use. It is not only simple, durable . . . and manageable even by a child, but innocent . . . It cannot injure or distress even the most delicate infant.

While the circular advertising the "Perfected Oxygenor King" is on the whole, a jumble of distorted facts, meaningless phrases and baseless assertions it still seemed worth while in view of the absurd claims made to examine the contents of one of the instruments.

WHAT IT CONTAINS

The material examined (taken from the "generator") was a dull, bluish-green, odorless powder. It was made up of irregular sized particles, ranging from coarse to fine. Qualitative tests demonstrated the presence of sulphur in the free state and of sand, both in considerable quantities. Small quantities of lead carbonate (white lead), free carbon (charcoal), a few particles of brass, and traces of iron were also present.

Quantitative examination indicated³ that the composition of the material is essentially as follows:

	Per cent.		Per cent.
Sulphur	66.85	Moisture	0.12
Sand	29.82	Brass	0.19
Lead carbonate	1.64	Iron	trace
Charcoal	0.50		
Total	99.52		

Figure 1

Figure 2

Figure 3

Fig. 1.—This depicts the piece of metal tubing "invented" by Hercules Sanche and named the "Oxydonor." The claim was made that "it causes the human organism to thirst for and absorb the oxygen of the air." It was advertised to "quickly and infallibly cure" a list of diseases ranging from "headache" to "hydrophobia" and from "twitchings" to "tetanus." This fake sold for from \$10 to \$35.

Fig. 2.—The "Oxygenor" is an elaboration of the "Oxydonor" fake. It, also, is supposed to "oxygenate" the simpletons who use it. Twenty-five dollars (\$25.00) is asked for this piece of metal pipe filled with sand and sulphur.

Fig. 3.—The "Oxygenator" is the latest imitation of Sanche's original fake. It is just as worthless as the others and the claims made for it are even more viciously false. Twenty-five dollars (\$25.00) and thirty-five dollars (\$35.00) are asked for it.

sensation of any kind whatever except the diffused, pleasurable feeling that comes with an increase in bodily vitality.

Under certain circumstances, however, the patient will break out into a gentle perspiration, and for this reason he should be careful to avoid a draught.

It is possible, also, that with the force-controlling cord at "strong" he may experience some inconvenience. This can be remedied by attaching it to the weak connection, or "G" post.

According to one portion of the circular the "instrument has been designed "to control and adapt. . . . the force governing change," whatever that may be, and its curative properties are claimed to reside in this power. In another part of the circular the reader is led to believe that disease is caused by imperfect power to absorb ozone through the skin (!) and that the use of the "Perfected Oxygenor King" restores this deficiency, thereby enabling the organism to regain its normality. A list comprising the names of 121 diseases which the "Perfected Oxygenor King" is claimed to cure is given in the circular. Among these are epilepsy, heart disease, locomotor ataxia, scarlet fever, yellow fever, and pneumonia.

TESTIMONIALS—AS USUAL

We can furnish proof that its range of cures is from Headache to Paralysis, from Blood Poison to Change of Life, from Chick-pox to Varicose Veins, from Colic to Bright's Disease, from Malaria to Dyspepsia. In fact, practically the entire list of prevalent ailments is embraced in the record of cures.

The examination shows that the "rare and costly metals" consist of none more expensive than copper, lead or zinc, and that the other "chemical agents" (which comprise 97 per cent. of the whole) consist of sulphur and sand in the proportion of 2 to 1.

An examination of the cylinder from which the sulphur-sand mixture was taken reveals a curious situation. While all of the wires connected with the instrument are carefully insulated these wires and the screw posts are all attached to the surface of the brass cylinder without insulation from each other. The cylinder then, with its complex of three screw posts and "force-controlling cord," amounts to nothing more than an enlargement in a conductor. In effect it is as though insulated wires were soldered on opposite sides of a tin pail or, to use Dr. Morse's illustration, on opposite sides of a stove lid.

The examination of the "Perfected Oxygenor King" shows that it could not possibly generate the smallest quantity of oxygen or ozone and that it could not produce or induce any electric or magnetic phenomena whatever. Despite the emphatic statements of the exploiters (in the advertising circular) to the contrary the only possible therapeutic effects are those easily referable to the element of suggestion.

3. The details of the analysis will be published in the annual report of the Chemical Laboratory.

Correspondence

Typhoid Fever in Detroit

To the Editor:—The article in THE JOURNAL, October 8, on our water-supply, coming from the chief organ of the physicians of the United States, demands attention. From such an authority one would expect the most careful consideration and conclusions drawn, not from analogy or hypothesis but from scientific examinations of the water, its source and surroundings and the vital statistics affected by its supply. In other words, it is essential to make a careful and thorough "sanitary survey."

May I be permitted to doubt the thoroughness with which this has been accomplished by the commissioner of THE JOURNAL? The general tenor of his article is a condemnation of Detroit's water-supply and an intimation that we are in immediate danger of a typhoid epidemic. The belief in this menace to our health is not based on the health of the city, the results of a chemical and bacteriologic examination of the water, or positive evidence that there is danger of pollution.

The United States census bureau of statistics has just reported thirty-four large cities with a general death-rate of 15 per thousand, and well near the top comes Detroit with but 14. It is an accepted fact that an impure water-supply is one of the chief factors in determining mortality. Though it may not contain a specific disease germ, an impure water lowers vitality and renders consumers more liable to disease.

In the article referred to, the commissioner fails to mention any chemical examination made by him of the water, but states that the results of the local examinations "in general appear to be satisfactory." In other words, he indorses local analyses, which have invariably demonstrated the purity of our supply. It is fair to presume that his chemical examinations served to confirm our reports, or the contrary would assuredly have been proclaimed. Bacterial examinations he says "do not afford any marked evidence of contamination at the time the samples were collected. On the other hand, their generally negative character does not necessarily imply that the water is at all times and all conditions safe."

Here again he indorses the numerous examinations made by the local board of health and implies that it may be possible that at times when the examinations are not being made the supply may be contaminated. The bare possibility may be granted, but if a present contamination is not detected in a long series of examinations extending over a number of years, does it not seem worse than sensational to startle and alarm a large city with a hypothetical possibility?

As to danger of pollution in future: it is admitted that Conner's Creek furnishes nearly the only menace to the water-supply, and that the exit of this creek is opposite although removed nearly three-quarters of a mile (3,700 feet) from the intake pipe; a deep and moving stream (three miles an hour) separates the two points. It is clearly impossible for a sluggish creek to project its contents through a huge volume of quickly moving water to our source of supply. The extension of the city takes in Conner's Creek, and the projected sewerage will soon remove even this assumed danger.

To confirm his opinion of the danger of an epidemic somewhere in the future, the commissioner gives several tables of vital statistics among which is that of the average death-rates per thousand population by five-year periods since 1886 as follows:

1886-9.....	4.52	1900-4.....	1.74
1890-4.....	4.35	1905-9.....	2.05
1895-9.....	1.91		

Twenty-five years ago (five-year period) we had more than double the deaths we have at present. The same is true of the next five year period twenty years ago. This tremendous decrease in mortality assuredly points to anything rather than a gradual increase of contamination of our water-supply, the result of "Detroit's increased population." Nor does it seem to confirm the commissioner's statement that "if present conditions are allowed to govern Detroit's water-supply a much more serious outbreak of typhoid is but a question of time."

Assuming that the deaths from typhoid in Detroit are due to water contamination, the decidedly lessened mortality would seem to indicate an improvement in watershed sanitation.

I agree with the commissioner that a thorough, intensive and exhaustive examination of the whole situation, similar to that carried out in Washington and Pittsburg, should be undertaken to settle once and for all this vital question and to allay public apprehension created by these frequent attacks on the purity of our water-supply.

JOHN E. CLARK, M.D., Detroit.

[COMMENT: Dr. Clark says he has offered the above reply to the Detroit newspapers. One of these, the *Free Press*, states that Dr. Clark "has written a letter to the editors of the magazine which will make interesting reading for them and for the medical fraternity of the country."

It ought not to be necessary to state that in publishing this study of the water-supply of Detroit and the typhoid situation THE JOURNAL did not intend "to startle and alarm a large city with a hypothetical possibility" in a way "worse than sensational;" but the investigation, as in the case of Milwaukee, was an incident in the thorough study which THE JOURNAL is making of typhoid conditions in the cities of the United States. Municipal water-supplies and sewage disposal present serious problems for the immediate future; and the prevalence of typhoid fever is a pretty good indication that conditions in any city are not what they should be.

With reference to the particular situation in the city of Detroit, Dr. Clark ignores the chief facts and misinterprets the tenor of the article in question. The facts are briefly these: One extensive epidemic of typhoid fever in Detroit has been definitely traced to the public water-supply; the source of supply is at present as much if not more exposed to contamination than it was when this epidemic occurred; for fifteen years the typhoid fever rate in Detroit has shown no diminution. These facts have not been and cannot be questioned. There is nothing novel or sensational about them. It is generally recognized among sanitarians that Detroit's water-supply is not what it should be. Hazen, for example ("Clean Water and How to Get It," p. 29), says: "Detroit is sixty miles below the outlet of Lake Huron, and in that distance there is opportunity for much pollution. This pollution comes both from the drainage of the considerable area reaching the river in this distance and from the discharge of sewage from the cities directly upon its banks. And this pollution by sewage is an important matter even with a dilution as great as that in the Detroit River." The statement that in some years Detroit has had a lower death-rate than some other cities is beside the point. If other American cities have a higher typhoid rate than they should, that is no reason why Detroit citizens should clamor for the same privilege. The *tu quoque* argument is nowhere more out of place than in sanitary matters. Would Dr. Clark maintain (1) that no sewage ever finds its way into the Detroit water-intake; (2) that there is at no time more typhoid in Detroit than would be expected in a city with a pure water-supply?

We would suggest to the Detroit newspapers, and to those officials who are supposed to represent the people as regards health matters, that it is better to know the facts and act on them, than ostrich-like, to refuse to see danger and to say there is none. See editorial comment, page 1477.—Ed.]

A Restricted Materia Medica List

To the Editor:—The action of the National Confederation of State Medical Examining and Licensing Boards in advising the restriction of materia medica examinations to a comparatively small number of drugs is to be highly commended. It is certainly better to know one hundred drugs well than to know one thousand badly. You are of course right in your assumption that the list will hardly please everybody. I cannot truthfully say that it pleases me absolutely; for in my opinion it contains some drugs which in a restricted

list might as well be omitted, and it does not contain some drugs which are of sufficient importance to be contained even in a select list. But this is not the point of this letter. The point is a mild criticism of the classification of the drugs. Emanating from such a high body greater care should have been taken in classifying the drugs properly. Or perhaps it would have been better to give them simply in alphabetic order. For instance, I cannot see why aqua hydrogenii dioxidii, oleum santali, aloe and aloinum should be classed among local irritants (THE JOURNAL, Oct. 8, 1910, p. 1302). One is an antiseptic, another is a diuretic and antibleorrhagic (demulcent in character) and the last two are cathartics; to bunch them all together as local irritants is in my opinion rather unscientific. Nor is it right to class oleum morrhuae and pepsinum among the protectives and emollients. I am not aware that carbon monoxid is a drug, official in any pharmacopeia, but still it is classified twice, as a hydrocarbon narcotic (hydrocarbon without any hydrogen!) and among "sundry." To classify potassium permanganate as a saline is not quite right, but to do so with saccharum lactis is rather ludicrous.

WILLIAM J. ROBINSON, M.D., New York.

Queries and Minor Notes

ANONYMOUS COMMUNICATIONS will not be noticed. Every letter must contain the writer's name and address, but these will be omitted, on request.

ARSENO-BENZOL—"606"—ARSEN-PHENOL-AMIN

To the Editor:—Where can I learn more about the Ehrlich-Hata remedy for syphilis? A. D. G.

ANSWER.—The above is a sample of the frequent inquiries that are received in this office. THE JOURNAL has endeavored to keep its readers informed on every phase of this subject, as soon as arsenophenol-amin seemed to be a practical addition to our therapy of syphilis, but, naturally these abstracts and editorials made no particular impression on many of our readers; now that the importance of the remedy is more apparent to them, however, they seek for additional information and write to us without looking back over the previous issues of THE JOURNAL. For their benefit, we give below the issues of THE JOURNAL in which the principal references have appeared. August 13, September 10 and October 8 and 22 are the most important issues.

THE JOURNAL has published the following original articles and editorials on this subject:

- Nichols, H. J.: Preliminary Note on Action of Ehrlich's Substance "606" on *Spirinchata pertenuis* in Animals, THE JOURNAL, July 16, p. 216.
 Murphy, J. B.: Arsenical Treatment of Syphilis, THE JOURNAL, September 24, p. 1113.
 Nichols, H. J., and Fordyce, J. A.: Treatment of Syphilis with Ehrlich's "606," THE JOURNAL, October 1, p. 1171.
 Corbus, B. C.: The Value of Ehrlich's New Discovery; A Preliminary Report from Personal Observation, THE JOURNAL, October 22, p. 1470.
 Ehrlich's New Remedy for Syphilis, editorial, THE JOURNAL, August 13, p. 601.
 Organic Arsenic Preparations—Ehrlich's "606," Editorial, THE JOURNAL, September 10, p. 949.
 Ehrlich's Syphilis Remedy Not Yet on the Market, editorial, THE JOURNAL, September 10, p. 951.
 "606"—Arseno-Phenol-Amin, editorial, THE JOURNAL, October 1, p. 1204.

The following articles have been abstracted in THE JOURNAL:

- Wechselmann, W.: *Berl. klin. Wehnschr.*, July 4; abstracted in THE JOURNAL, August 13, p. 617. *New York Med. Jour.*, September 3; abstracted in THE JOURNAL, September 17, p. 1051.
 Neisser, A.: *Deutsch. med. Wehnschr.*, June 30; abstracted in Berlin Letter in THE JOURNAL, July 23, p. 326.
 Schreiber, E., and Hoppe, J.: *Munch. med. Wehnschr.*, July 5; abstracted in THE JOURNAL, August 13, p. 617.
 Loch, H.: *Munch. med. Wehnschr.*, July 26; abstracted in THE JOURNAL, August 13, p. 617.
 Trempel, G.: *Deutsch. med. Wehnschr.*, July 28; abstracted in THE JOURNAL, August 13, p. 617.
 Fischer, P., and Hoppe, J.: *Munch. med. Wehnschr.*, July 19; abstracted in THE JOURNAL, August 13, p. 617.
 Ehrlich, P.: *Wien. klin. Wehnschr.*, August 4; abstracted in THE JOURNAL, September 10, p. 976. *Munch. med. Wehnschr.*, August 30; abstracted in THE JOURNAL, October 8, p. 1331.

- Bobac, K., and Sobotka, P.: *Wien. klin. Wehnschr.*, July 28; abstracted in THE JOURNAL, September 3, p. 898. *Wien. klin. Wehnschr.*, August 4; abstracted in THE JOURNAL, September 10, p. 976. *Wien. klin. Wehnschr.*, August 25; abstracted in THE JOURNAL, October 1, p. 1239.
 Herxheimer, K., and Schonefeld, B.: *Medizinische Klinik*, September 4; abstracted in THE JOURNAL, October 8, p. 1331.
 Spiethoff, B.: *Munch. med. Wehnschr.*, August 30; abstracted in THE JOURNAL, October 8, p. 1331.
 Dubot, R.: *Ibid.*
 Martin, A. P.: *Siglo med.*, September 10; abstracted in THE JOURNAL, October 1, p. 1209.
 Braendle and Clingstein: *Med. Klin.*, August 21; abstracted in THE JOURNAL, September 24, p. 1155.
 Iversen, J.: *Munch. med. Wehnschr.*, August 16; abstracted in THE JOURNAL, September 24, p. 1154.
 Taeg, K.: *Ibid.*
 McDonagh, J. E. R.: *Lancet*, September 3; abstracted in THE JOURNAL, October 1, p. 1234.
 Hoffmann, E.: *Med. Klin.*, August 14; abstracted in THE JOURNAL, September 17, p. 1062.
 Ptek, W.: *Wien. klin. Wehnschr.*, August 18; abstracted in THE JOURNAL, September 24, p. 1153.
 Heubner, W.: *Therap. Monats.*, August; abstracted in THE JOURNAL, September 24, p. 1155.
 Isaac, H.: *Berl. klin. Wehnschr.*, August 15; abstracted in THE JOURNAL, October 1, p. 1236.
 Michaelis, L.: *Ibid.*
 Junkermann, K.: *Med. Klin.*, August 28; abstracted in THE JOURNAL, October 1, p. 1237.
 Fraenkel, C., and Gronven, C.: *Munch. med. Wehnschr.*, August 23; abstracted in THE JOURNAL, October 1, p. 1238.
 Kromayer, E.: *Berl. klin. Wehnschr.*, August 22; abstracted in THE JOURNAL, October 8, p. 1329.

In addition THE JOURNAL'S foreign correspondents have reported from Paris, Berlin, Budapest and Vienna the results obtained with this remedy (THE JOURNAL, August 13, pp. 609 and 610; August 27, p. 791; October 22, p. 1483, etc.).

A letter from Dr. B. C. Corbus in THE JOURNAL, October 8, describes a visit to Ehrlich and his method of administering this remedy, and his article in this issue (October 22) gives a careful description of the Lesser technic, which Corbus thinks is the best.

The Public Service

Medical Department, U. S. Army

Changes for the week ended Oct. 15, 1910.

- Bowman, M. H., M.R.C., granted leave of absence for 2 months and 24 days, to take effect about October 15.
 Slater, Ernest F., M.R.C., par. 27, special orders No. 224, Sept. 24, 1910, W. D., announcing his honorable discharge from the service of the United States on Oct. 13, 1910, is suspended for the present.
 Voorhies, Hugh G., dental surgeon, granted leave of absence for 1 month, to take effect about October 24.
 Hefebower, Roy C., lt., will proceed to Fort Totten, N. Y., about October 19, for temporary duty, during the absence of Major Charles Wilcox.
 Strong, Francis X.; Carter, Henry P., and Gantt, Robert H., M.R.C., ordered to active duty in the service of the United States, and to the Army Medical School for a course of instruction.
 Ragan, Charles A., captain, ordered to the Walter Reed General Hospital, District of Columbia, for observation and treatment.
 Williamson, L. P., lt., ordered to Fort D. A. Russell, Wyo., for duty.
 Roberts, William M., major, leave of absence granted in S. O. 140, June 16, 1910, extended one month.
 Straub, Paul F., major, granted leave of absence for 1 month and 15 days, about November 1.
 Eastman, William R., captain, granted leave of absence to include Nov. 5, 1910, on account of sickness.
 Wiggin, D. C., M.R.C., resignation accepted, to take effect Nov. 1, 1910.
 Moncrief, William H., captain, granted leave of absence for 1 month, with permission to visit China and Japan.

Medical Corps, U. S. Navy

Changes for the week ended Oct. 15, 1910.

- Wise, J. C., medical director, transferred to the retired list from Oct. 7, 1910.
 May, H. A., passed asst.-surgeon, detached from the naval hospital, Mare Island, Cal., and ordered to the bureau of medicine and surgery, Navy Department, temporarily.
 Morris, L., surgeon, detached from the *Georgia* and directed to await orders.
 Howard, J. V.; Omelvena, J. G.; Halsey, W. H.; Eaton, W. E.; Jacoby, A. L.; Pratt, L. L., and Halton, E. P., asst.-surgeons, commissioned asst.-surgeons from Oct. 1, 1910.
 Stuart, D. D. V., Jr., asst.-surgeon, commissioned asst.-surgeon from Oct. 5, 1910.

Medical Economics

THIS DEPARTMENT EMBODIES THE SUBJECTS OF ORGANIZATION, POSTGRADUATE WORK, CONTRACT PRACTICE, INSURANCE FEES, LEGISLATION, ETC.

UNQUALIFIED DOCTORS VS. UNQUALIFIED LAWYERS

The newspapers are showing a marked tendency toward a broader view of the relations of the medical profession to the public. This tendency is increasing and has been frequently commented on. In a recent number of the *Denver Times*, the editorial writer gives a sudden and somewhat unexpected turn to the efforts which are evidently being made in Denver to enlist support for the National League of Medical Freedom. No better method could be devised for exposing the specious nature of the claims made by this organization.

Why, as the *Times* pertinently inquires, do we not have a National League for Legal Freedom? One might also ask why do we not have a national league to free us from the persecutions of licensed engineers and pilots, or from any of the other safeguards and protections which civilization has thrown around the life and health of the individual? If the citizen is to be allowed to spread typhoid fever, diphtheria or tuberculosis among his acquaintances and associates, if any man who claims to be a prophet of a new sect or cult is to be allowed to treat the sick, why should not any man who feels called on to do so, be allowed to practice law before the courts, to run an engine, or to steer a steamboat? If we are to have "medical freedom," why should we not have freedom of every other kind such as is enjoyed by the savage who recognizes no restraints either for his own good or that of others? With these considerations in mind, the extracts from the *Times* editorial are especially interesting:

"Why should not the Hon. Charles Spalding Thomas and his friends of the 'Medical Freedom League' expand their efforts in behalf of professional incompetency by including in their latest movement the emancipation of the people from the impositions of qualified, legal practitioners. Is not this city, is not every city crowded already with confident citizens who, though they know not Coke, nor Blackstone, nor Chitty, are yet ready to 'give an opinion' on the abstrusest of legal problems, and who will give you that opinion free and without the asking? Why should it not be the inalienable right of every citizen to 'practice law' without the tedious botheration of first studying its principles? . . . Why shouldn't there be osteopathic lawyers; and absent-treatment lawyers; and eclectic lawyers; and fasting-cure lawyers; and lawyers who are not lawyers? This lawyers' trust opens a new and enticing field for the energies of patriotism, the enthusiasm of folly and the sweets of advertisement; and we confess astonishment that Mr. Thomas—who surely knows more of law than he knows of medicine—has not seized the occasion sooner. To be an honorary vice-president of a 'League of Medical Freedom' is an empty honor because there are so many of them already; to be president of the 'League of Legal Liberty' would be a distinction that a man could hold alone and uncoveted."

After paying a truly beautiful tribute to the old-fashioned family doctor, the editorial continues:

"We are discussing this question of physician and patient at some length to-day because it is essentially a 'domestic' theme. It concerns in an intimate way our common lives and well-being. If the law permits a man to call himself a doctor of medicine who is not a doctor of medicine—learned in medicine the law is permitting a fraud, and a hazardous fraud, on the public. If the law permits a man to practice surgery who has no sound knowledge of that science, the law is abusing itself before a counterfeit. We confess to a secret admiration for certain kinds of 'patent medicines.' We know of no reading that equals in its imaginative sweep the 'literature' which accompanies those artistically wrapped bottles of 'reliable, household remedies.' But the harmless 'patent medicine' is a soothing, if useless, thing that works no harm if it produces no benefits; while the living man who professes a skill that he has not is responsible for innumerable maimed bodies and poisoned lives. We feel that we are conservative in estimating that 80 per cent. of the people are attended by physicians of the 'regular' allopathic and homeopathic

schools; and yet many newspapers are careful to keep silence on the subject because of a fear of offending the adherents of some cult or other who are supposed to regard even honest criticism as an offense. And we believe that fear to be ill-founded. . . .

"The men who make 'proprietary' medicines and sell them, not as 'patent' but authentic; and the unqualified 'quacks' who seek to practice under a title to which they have no just and qualified claim, are humbugs of an inimical kind with whom we can negotiate no truce. And we may as well make our attitude on that matter quite plain at this inception of the Medical Freedom 'League.' Because that 'league' is a contradiction in terms and it ought to have something very heavy and very hard hurled at it with great frequency."

POSTGRADUATE COURSE FOR COUNTY SOCIETIES

DR. JOHN H. BLACKBURN, DIRECTOR
BOWLING GREEN, KENTUCKY

[The Director will be glad to furnish further information and literature to any county society desiring to take up the course.]

Third Month—Second Weekly Meeting

SURGERY OF THE KIDNEY

INJURIES OF THE KIDNEY

PATHOLOGY: 1. Penetrating, gunshot and stab wounds. Injury to kidney, ureter, blood-vessels, peritoneum. 2. Sub-parietal injury, rupture of kidney. Extent, structures injured, hemorrhage, extravasation of urine.

SYMPTOMS: Local injury. Hematuria. Prostration or shock, sweating, vomiting, pain.

TREATMENT: 1. Gunshot wounds. 2. Incised wounds. 3. Sub-parietal injury.

MOVABLE KIDNEY

ETIOLOGY: Pregnancy, lacing, loss of flesh, traumatism, association with enteroptosis, configuration of renal fossa.

SYMPTOMS: Digestive and abdominal symptoms, neurasthenia, Diet's crisis. Physical examination.

TREATMENT: Palliative. Operative, indications, technic of nephrorrhaphy.

HYDRONEPHROSIS

VARIETIES: 1. Congenital. 2. Acquired, from traumatism, ureteritis, stricture, calculus, pyelitis, floating kidney, malignancy, prostatic enlargement.

PATHOLOGY.

DIAGNOSIS: Differentiate from cystic kidney, enlarged gall-bladder, tumor of liver or ovary.

TREATMENT: 1. Removal of obstruction. 2. Treatment of kidney.

Society Proceedings

COMING MEETINGS

Am. Assn. for Study and Prev. Infant Mort., Baltimore, Nov. 9-11.
Hawaiian Territorial Med. Assn., Honolulu, November 26-28.
Ohio Valley Med. Assn., Evansville, Ind., Nov. 9-10.
Southern Medical Assn., Nashville, November 8-10.
Virginia, Medical Society of, Norfolk, October 25-28.

AMERICAN ROENTGEN-RAY SOCIETY

Eleventh Annual Meeting, held at Detroit, Sept. 29-Oct. 1, 1910

The President, Dr. GEORGE E. PFAHLER, Philadelphia, in the Chair

The officers elected were given in THE JOURNAL, Oct. 15, 1910, p. 1390. Richmond, Va., was selected as the place for holding the next annual meeting, the time to be decided later.

Tuberculosis of the Lungs as Seen and Heard

DR. HENRY HULST, Grand Rapids, Mich.: The work I wish to report on was done in the Grand Rapids Tuberculosis Sanitarium for the purpose of determining the value of roentgenographic diagnosis in tuberculosis of the lung. The results were secured by physical examination, skiagrams and

autopsy, each observer working independently of the other, making an individual diagnosis, and then comparing his findings with the other two. Cavities, especially deep ones, are generally missed by physical diagnosis, but they are always shown on the plates, some of them even showing structural lung detail. Their depth is best determined stereographically. They always appear as dark spots, and in most cases are corroborated at necropsy. The skiagram never fails to show the disease in the presence of clinical evidence or physical signs; in fact, it shows better the extent of the disease than do the other methods. A diagnosis should not be made on the strength of physical diagnosis alone, nor on the tuberculin test, nor on the skiagram, although the latter is the best single method of diagnosis. In some plates, the healing process is graphically shown. The great advantage of the roentgenographic method is that it furnishes a correct, though incomplete, graphic reproduction of the microscopic anatomic-pathologic changes in the lung. These pictures must be read, however, in the terms of post-mortem findings, and not of auscultation and percussion.

DISCUSSION

DR. K. DUNHAM, Cincinnati: I wish to emphasize the value of stereoscopic plates in making a diagnosis of tuberculosis of the lung. They are an absolute necessity. This work is showing us that we must look, not to the apices of the lungs, but to the hilus for the first evidence of tuberculosis. The difference in density from the normal is very apparent and is easily recognized by the expert.

DR. L. G. COLE, New York: In New York, I asked the board to have three independent physical examinations made of these patients before I made a skiagram. When those three men agreed on the physical signs, the process in the lungs was so extensive that it could not be considered incipient. The most interesting part of that was that it occurred in about 75 per cent. of the early cases, whereas in the other 25 per cent. these 3 men located the disease in different parts of the lung, but the skiagrams would definitely locate the disease—and it was not always the same man whose physical findings were corroborated by the skiagram.

Primary Lymphangiosarcoma of the Lungs

DR. ALFRED L. GRAY, Richmond, Va.: The appearance of the skiagram in this case was typical of an extensive miliary tuberculosis of both lungs. The patient had been bothered every summer and winter for the past six years with what he considered to be a severe cold, which would finally settle on his chest. His last attack was of three months' duration. There was loss of appetite, lassitude, loss in weight, and a very annoying and hacking cough, occurring in paroxysms and accompanied by intense pain in the chest. Expectoration was scanty and frothy. The heart was normal. There was slight impairment of resonance in the left supraclavicular region, with numerous dry râles in the left interseapular and subseapular regions. Temperature and pulse were normal. There were one or two enlarged glands in the right supraclavicular region. Histologic examination of one of these gave a picture of a typical lymphangiosarcoma. The patient died, but a necropsy was not permitted.

DISCUSSION

DR. H. K. PANCOAST, Philadelphia: I had a similar case last winter. The first radiograph I made showed the same picture as Dr. Gray saw in his plate, and had I not known something of the clinical history of the patient and the suspected diagnosis, I would not have known that it was not a case of pulmonary tuberculosis. A week or two later, I made a second plate, and found an effusion into the pleural cavity on the side most affected. It caused considerable confusion in the mind of the clinician, who could not understand the reason for these shadows when the case was undoubtedly one of growth in the lung. It is difficult to make a diagnosis between a growth of this kind and pulmonary tuberculosis, and it emphasizes the fact that an effusion in the pleural cavity may occur in these cases.

DR. K. DUNHAM, Cincinnati: In a case of carcinoma of the lung, the stereoscope saved us from making a diagnosis of tuberculosis. The question arises in Dr. Gray's case, whether it is not really a case of tuberculosis in the lung and lymphosarcoma in the gland removed from the neck. Unfortunately, a necropsy was not permitted; it might have cleared up the diagnosis.

DR. F. H. BAETJER, Baltimore: About six months ago, I saw a patient who apparently had an esophageal stricture. Bismuth was given and the skiagram showed that the esophagus was drawn over to the right side, and that both lungs were studded with tuberculous nodules, some being of good size. I made a diagnosis of tuberculosis, and gave it as my opinion that the stricture was caused by it. An operation was done and a carcinoma of the esophagus was found. The patient died, and at the necropsy we found the carcinoma, and on the edge of it a lot of tuberculous tissue. The lungs were studded with tuberculosis and carcinoma. The skiagram did not show the difference between the two.

DR. HENRY HULST, Grand Rapids, Mich.: I think that it is a mistake to base an absolute diagnosis of miliary tuberculosis or lymphosarcoma on plates alone, even when viewed stereoscopically. We must not base a diagnosis on insufficient data, because that will discredit our work.

DR. FEDOR HAENTISCH, Hamburg, Germany: If no necropsy was made in this case, we should not be so very sure that the plate shows a lymphosarcoma of the lung. I think it is a case of miliary tuberculosis with a thickened pleura.

DR. L. G. COLE, New York: One point against the tuberculous nature of this case is the even distribution of the spots. It is rare to see tuberculosis affecting the entire chest in that way. There are always areas in which the disease is more extensive than elsewhere. The picture might correspond with a diffuse acute miliary tuberculosis. Of course, the clinical symptoms did not correspond with this.

DR. G. C. JOHNSTON, Pittsburg, Pa.: I have skiagraphed about 40 cases of carcinoma of the lung, and 12 or 13 of these were referred to me merely because of some slight affection, a little paralysis, of the vocal cord. The majority of these patients gave a history of previous operation for carcinoma, one patient had a breast amputated 20 years previously. There was no recurrence in the scar, but examination showed carcinoma or tuberculosis involving both lungs. I could not differentiate which was present from an examination of the plate alone. I inclined to a diagnosis of carcinoma, and in every case, time proved the correctness of that diagnosis.

DR. W. F. MANGES, Philadelphia: A more or less distinct outline of the growth is characteristic of sarcoma. I saw that shown distinctly in a case I had last winter. I think Dr. Gray's case was one of tuberculosis.

(To be continued)

MICHIGAN STATE MEDICAL SOCIETY

Forty-Fifth Annual Meeting, held at Bay City, Sept. 28-29, 1910

The President, Dr. J. H. CARSTENS, Detroit, in the Chair

The officers elected were noted in THE JOURNAL, October 15, page 1388.

President's Address: Medical Organization, Education, and Legislation

DR. J. H. CARSTENS, Detroit: Medical societies enable practitioners to keep up to date. Physicians should study the great question of eugenics, which is especially a medical question, and also place themselves in the front ranks for social purity. Medical laws are made for the benefit of the public, and the State of Michigan should appropriate money for the medical examining board, and not let the latter depend on the fees for medical certificates.

Expert medical testimony has been a blot on the medical profession. Laws should be enacted which would require every county medical society to select from its own ranks, say three men of every branch of medicine, who would be

considered experts in those branches. Large medical societies could select ten or twenty in each branch. If a case occurs in the courts for expert medical testimony, the judge should select the three men so designated, who are to examine the patients at their leisure, discuss the case among themselves, arrive at some conclusion, and bring in their report and testify to the findings. Even as the law now stands this would not prevent the other side from having other expert testimony, but few of the latter experts would be found who would testify contrary to the experts designated. By having such experts we would get more justice and shorter law suits, with less expense to the county. In other professions like pharmacy, dentistry, architecture and engineering the same method might be carried out, and so greater justice would be done in all law suits, and the work of the professional expert would be at an end.

Interpretation of Gross Findings in the Urine

DR. WILLIAM E. KEANE, Detroit: The gross observation of the urine will prove of most value in the management of gonorrhoeal patients. Vigilance here will sometimes anticipate a beginning epididymitis by noting the peculiar cloud of exudate that appears in the second tube, before any other objective or subjective symptom appears. The purulent urine of acute gonorrhoeal inflammation is, as a rule, free from shreds, but as the inflammation subsides and becomes localized, little scabs are formed that wash down with the streams of urine. As the pus decreases and the shreds appear, improvement will be daily more marked. Each and every shred has its story to tell. The thick pieces of irregular size are generally indicative of stricture or chronic inflammation. The thread-like strings that quickly settle, weighed down with pus, are from the anterior urethra. The so-called tadpole shred has a globular head, with a long cotton-like tail, and arises from a follicle of the deep urethra. The fleecy film which suspends near the top originates in the prostatic sinus and may contain prostatic cells, bacteria, spermatozoa and mucus. The heavier mucus is seen only in the first tube with an absolutely clear second tube, indicating trouble in the anterior urethral glands. Epithelium appears floating in the urine as a dark or light-colored dust, depending on the amount present. Besides the recognition of the individual shreds, one soon learns to note other changes in its character. Whether the urine is sparkling or flat, whether it is of high or low specific gravity will be determined at a glance. Bacteria, when present, will be found in both tubes. The gonococcus produces a dirty color, with an odor that offers confirmatory evidence. A patient suffering from chyluria will pass a urine that is distinctively indicative of his trouble. The milky-looking mixture is seldom, if ever, seen in any other urinary condition.

Pellagra

DR. E. L. EGGLESTON, Battle Creek, read a paper in which he presented a report of two cases of this disease with the diagnosis and treatment. He also reported the necropsy findings in one case, together with the etiology and pathology of the disease.

DISCUSSION

DR. JOHANN FLINTERMAN, Detroit: Did pain running along the course of the nerve trunks appear, and was it manifested by skin and internal symptoms? Were there other symptoms? Cases have been described in which there was a manifestation of some skin affection, combined with severe diarrhea and perspiration.

DR. CHURCH, Adrian: Did any of the patients recover?

DR. FRANK SMITHIES, Ann Arbor: Was the Wassermann reaction used in any of these cases, or was a blood examination made?

DR. E. L. EGGLESTON, Battle Creek: In one case which ran a very short course and terminated fatally, the patient complained of no pain whatever, and there was no rise of temperature any time; but there was a subnormal temperature during the course of the disease. The clinical manifestations are different in different cases. Frequently, when the nervous

system seems to be particularly affected, there may be a great deal of pain. In the case reported as originating in Michigan, the patient had a great deal of pain in the back and head and neck, and complained considerably of headaches. Two of the patients died. Of the other three patients, one seems to be in very good condition, although there have been two recurrences of the disease. The other two are certainly getting worse and will not live very long. The mortality at present is considered to be about 35 per cent. The Wassermann reaction was not tried in any of these cases. The blood was examined frequently, a blood count made, and there was a moderate degree of anemia in each of the cases. I want to emphasize the point that if a patient, from the south or not, complains each spring of a feeling of great debility, loss of appetite, stomach disturbance and diarrhea, he should be watched very carefully. Many such cases appear in the north, many of them in Illinois; they are not limited to the south, and by keeping these points in mind one will not miss the diagnosis very often.

(To be continued)

KENTUCKY STATE MEDICAL ASSOCIATION

Fifty-fifth Annual Meeting, held at Lexington, Sept. 27-29, 1910

(Concluded from page 1492)

Diagnosis and Medical Treatment of Cirrhosis of the Liver

DR. G. W. PAYNE, Bardwell: Atrophic cirrhosis of the liver is incurable. So far as we know, there is no drug that can remove the cicatricial connective tissue; on the other hand, we know that these conditions can exist for years when compensatory circulation exists. The patient should abstain entirely from alcohol and live on a milk diet as nearly as possible. The diet should be nutritious, but not too rich. The gastric intestinal catarrh should be reduced, if possible, and the patient should lead a quiet outdoor life. Skin must be kept active and bowels open, and the patient should pass plenty of urine. For the ascites at its onset, or to prevent reaccumulation after tapping, such cathartics as magnesium sulphate, compound jalap powder or minute doses of calomel may be used. As a diuretic, I give bitartrate of potassium, combination of calomel, digitalis and squills, or infusion of digitalis. Lavage is useful in most cases, bitter tonics and acids may increase the appetite. If hemorrhage takes place from stomach or intestine, ice to the abdomen, morphin hypodermically and rest are indicated. If profuse diarrhea is present bismuth subnitrate, tincture of krameria or tincture of catechu may be used. In the syphilitic cases, or when syphilis is suspected, potassium iodid and mercury should be given in large doses.

Diagnosis and Treatment of Cholecystitis

DR. IRVIN ABELL, Louisville: Acute suppurative and gangrenous involvements of the gall-bladder are, as a rule, easily recognized; the local pain, tenderness and swelling, due either to distention of the gall-bladder or to surrounding adhesions, point unmistakably to the cause of fever and gastric distress. In such instances, an attempt at medical treatment is but to invite further disaster. Resort should be had to immediate drainage. In cases of the fulminating type, the diagnosis is not always easy; the sharp onset, violent pain, which is not always localized, vomiting, distention of the abdomen, rapid pulse, are seen with other lesions— notably of the appendix, or a beginning of peritonitis, from rupture of some of the hollow viscera. In such cases, the history is of value in making a diagnosis, particularly pain or discomfort in the gall-bladder area, immediately preceding the onset of symptoms. Such cases usually pursue a rapid course, leading to abscess formation, gangrene or rupture, and only prompt recognition and early operation give promise of saving life and restoring the diseased viscus to such a condition as to permit it to carry out its physiologic function. The indications for surgical treatment embody two principles: (1) removal of obstruction;

(2) institution of drainage. In some cases no abdominal operation is easier; in advanced and complicated cases, no abdominal operation is more difficult. The removal of obstruction may mean the removal of stones from the gall-bladder, cystic, hepatic, or common duct. It may mean that the operator must remove, or mechanically overcome, the effects of stricture of either of the ducts; in the case of the cystic duct, this may necessitate the removal of the gall-bladder; in the case of stricture of the common duct, it may mean a plastic operation on the duct or its junction with the intestine. Obstruction is frequently caused by adhesion and inflammatory deposit; thorough separation may be easy or may present difficulties which tax the most skillful. Drainage may be required in the gall-bladder, or in the common or hepatic ducts, and has to be made by means of rubber tubing, which is stitched into the ducts or bladder. The drainage should be continued long enough to overcome the infection. No operative procedure is complete unless a thorough examination of all the bile passages, demonstrating their potency, is made. With the elimination of obstruction and the institution of free drainage, we may safely promise a patient not only relief but permanent cure with a minimum exposure to danger.

State Care of the Insane

DR. CURRAN POPE, Louisville: Real investigation into the condition of those who enter state hospitals for the insane is either never made, or is at best superficial and never scientific. The time has come when the importance of treating the insane should receive the same intelligent consideration and care as is now given to the treatment of tuberculosis. The wave of public sentiment that has lifted tuberculosis to its present position should be duplicated with the mentally afflicted, and we should no longer hear of an unfortunate being classed as the "accused," needing prosecution on the one hand and defense on the other, both of which, in truth, are purely nominal and largely automatic. Our legislatures must awaken to the dangers of such a system and be prepared to accept all that modern psychologic work has done in its practical application to the mentally sick.

We should have no "asylums" for the insane; we need modern hospitals. The aim should be not to herd mentally unsound people in corridors flanked by rooms, to give them three meals a day, a few medicines, and control by attendants, but to use every manner of means known to medical science to cure them. There is a prevalent and wide-spread belief that, in the vast majority of instances, insanity is incurable; this is not true. The majority of insane patients do not recover because they do not receive proper diagnosis, and practically have no treatment. As a result, insane hospitals are truly and properly named "asylums," in which are kept hundreds of chronic insane, who live and die an "asylum life," simply because they have been subjected to custodial care alone. With a modern psychopathic state hospital, the patient could be quietly and without publicity sent for treatment on the recommendation of a commission of psychiatrists, whose report should be subject to supervision in chambers by the county judge. For the future care of Kentucky's mentally unsound, I would suggest a central hospital, modern in its equipment, located near a large city, with every facility for diagnosis, investigation and treatment. Through this hospital, every patient would first have to pass, and when it was found that the unfortunate sufferer was condemned to permanent loss of mind, he could be removed to one of the present hospitals for custodial care. Such a hospital would be incomplete without a psychologic laboratory, equipped with modern instruments of precision, in the hands of a trained expert, with a corps of assistants, who could test and study and relieve many cases by well directed psychologic work alone. Modern psychiatry has advanced with rapid strides toward the more thorough and complete understanding of the intellectual mechanism of the insane, and any modern, up-to-date hospital that does not possess a full equipment of psychologic apparatus, with experts in charge, who devote their time and attention solely to the investigation and study of the ailments and afflictions of its patients, falls far short of the modern conception of hospital work.

Chronic Nephritis

DR. S. L. BEARD, Shelbyville: There are many causes for chronic nephritis—alcoholism, long exposure to cold and dampness. The gonococcus plays an important part in the cause of the disease, the germ may have been lurking in the joints or the prostate, and after all other symptoms of gonorrhoea have disappeared, even years after the disease has been apparently cured, may give rise to acute or chronic inflammation of the kidneys. Other causes are acute infectious diseases, such as scarlet fever, which often produces the acute form, and maybe the chronic form of the disease. The disease is very slow to develop. Possibly the first symptoms to be noticed will be a slight edema of the eyelid or of the legs, then a listless feeling, the patient being restless at night and unable to sleep, with loss of appetite. Edema is always a prominent symptom, and will eventually give the patient a great deal of discomfort. As the disease develops, the legs may swell to an enormous size, with rupture of the skin and oozing of serum. The amount of urine in a case of chronic nephritis is very much diminished. Frequently the quantity will be diminished 40 per cent., some days a larger quantity may be voided. In the later stages of the disease, the volume of urine increases to some extent; the specific gravity is often below normal, it may possibly be normal or above. Little can be done in treating these patients, for we rarely see the case until it is well developed. We may advise the chronic alcoholic to stop drinking. The treatment of the chronic form of the disease is about the same as that of the acute. The first essential is to insist on absolute rest in bed for a period of time at least; of course, the patient should not be kept in bed indefinitely; a little sunshine and very moderate exercise will be beneficial, but for a time at least we should insist on rest and quiet.

Intracranial Complications of Otitis Media

DR. G. C. HALL, Louisville: The study of the intracranial complications of otitis media has been extensive enough, and over a sufficient period of time, to permit us to draw certain conclusions regarding the cause and effects of suppuration within the temporal bone, and for the most part the method to be applied to stop it and guard against its extension. As in other regions of the body, prophylaxis is of chief importance. It is much easier to prevent these conditions than to cure them when once developed. "Cure every case of otitis media," should be the watchword of the profession. In this way alone we would eliminate at least 90 per cent. of the complications of temporal bone suppuration, for, as a general proposition, it may be stated that primary acute otitis media with mastoiditis offers but few instances of intracranial involvement, and in them the infection is overwhelming. In dealing with this subject we practically presuppose the existence of mastoiditis, and in whatever light we view it the mastoid portion of the temporal bone becomes the object of our first concern. From a pathologic standpoint, the route of infection is nearly always through the mastoid cells, whether it be sinus thrombosis, brain abscess or meningitis. The symptoms are those primarily of mastoiditis with the symptoms of the complication added, and the treatment in all cases is directed to the thorough eradication of all diseased bone in the mastoid, as a preliminary to attacking the lesions of the deeper structures. In cases of suspected intracranial involvement, the organisms present in the discharge have an important bearing on the gravity of the lesion. It has been shown that the streptococcus is responsible in over 50 per cent. of these severe infections. In cases of sinus thrombosis, it can often be obtained from the general circulation. Prophylaxis is most important in dealing with these conditions. It is worth all the remedial measures we possess, and the truest and surest prophylaxis is obtained by putting every running ear under careful and intelligent treatment, and the correction of those diseases of the nose and throat that render the ear so liable to infection.

Acute Nephritis

DR. W. R. THOMPSON, Mount Sterling: All three forms of the disease are included under this heading, as it is impossible to differentiate the anatomic varieties from a clinical standpoint. Nearly every known disease has at some time been

shown to be accompanied or followed by acute nephritis. Acute infectious diseases are the most prolific causes, and scarlet fever heads the list; the specific organism of the disease, or its toxin, is responsible for the lesion of the kidney. The severity of the scarlatina or other infection bears no relation whatever to the occurrence of nephritis. Those suffering from the most malignant forms of the disease may entirely escape, while a patient with the mildest attack, and one which has perhaps been entirely overlooked, may have a most severe lesion of the kidney. It is important to bear in mind that a comparatively insignificant angina, mild rheumatism, or a slight attack of influenza, may be the forerunner of acute nephritis. The causative influence of cold in acute nephritis has been largely overestimated. In a majority of the cases, if the history is carefully and thoroughly investigated, the underlying cause will be discovered, and the exposure to cold will be found to be merely incidental.

Fracture of the Base of the Skull

DR. D. C. DONAN, JR., Horse Cave: Surgery of the skull is undergoing an evolution similar to stomach surgery in recent years. A source of error formerly was mistaken diagnosis. Fracture by *contre-coup* is a rare thing, according to Treves. The theory of Arran, as Archibald observes, merely states the fact. Rawlings' idea of a splitting force will explain some cases. Most cases can be explained by the law of von Wahl, namely, a fracture by bursting is due to bilateral compression, and the fissure runs parallel with the violence. The factors are velocity and momentum of the wounding object, as well as the shape or area of contact. The principal lesion is nearly always situated in the sella turcica, the petrous portion of the temporal bone, the greater wing of the sphenoid and the orbital plates. In nearly all cases, we are dealing with a compound fracture, and the high mortality is partly due to infection. Most cases with non-reacting pupils are fatal. Unconsciousness is not a reliable index of the severity. Under expectant treatment may be mentioned rest, restricted diet, purgation and the application of the ice coil. Hexamethylcyanin has been recommended as a preventive of infection. Lumbar puncture has its advocates in selected cases. Decompression is a new addition to the list of operations for the relief of compression. Severe injuries, such as bursting fractures, with extensive laceration of the brain, are nearly always fatal, and these should be left to the inclination of the surgeon. Patients with immediate symptoms of compression and no laceration should be operated on. Cases in which there are late symptoms of compression and beginning optic neuritis, nearly always demand operation. In simple cases, in which there is no laceration and no compression, expectant treatment may be resorted to. In punctured fractures, we should explore all doubtful cases, and then follow the indications.

The Diagnosis and Treatment of Cancer of the Gastro-Intestinal Tract

DR. J. H. BLACKBURN, Bowling Green: The cure of cancer in the gastro-intestinal tract depends entirely on surgical treatment, hence it became necessary and imperative that the diagnosis should be made early, if we are to give more than temporary relief. The difficulty of the early clinical recognition of cancer in any portion of the gastro-intestinal tract is generally conceded, since a relatively large number of the patients do not present symptoms until late in the disease, often only after the involvement of adjacent structures. With the marked advances in the surgical treatment of the disorders of digestion during the last decade the history of cancer of the stomach has been entirely re-written. The classical symptoms of this condition, as found in all text-books on practice of medicine are anorexia, pain, vomiting, hemorrhage, humor and cachexia, the subjective symptoms varying somewhat with the location of the growth in the stomach. From the standpoint of the surgeon, these are late symptoms, for, if we wait for their development, the percentage of cures from operation will be very small. The surgical treatment may be divided into palliative and radical. The experience of both surgeons and physicians in the early diagnosis of gastric cancer is that the only way in which a positive diagnosis may be made is in

the inspection of the parts when the abdomen is opened; therefore, exploratory laparotomy may be classed as one of the surgical procedures in the treatment of this condition. After passing the ileocecal junction cancer becomes a rather frequent lesion, increasing in frequency from the cecum through the colon and sigmoid to the rectum. In a large percentage of the cases of cancer of the large intestine the lesion is primary. It may be completely eradicated, and there are several factors which make the surgical treatment when instituted early a curative one, the most important of these being the slow rate of growth, the limited lymphatic drainage, the tendency to local extension rather than by metastasis. However, if we wait for the development of an acute or chronic obstruction, or for the presence of a distinctly palpable tumor, both of which may be called ancient symptoms, the time for complete removal of all the tumor and involved tissues may have passed.

Neurasthenia

DR. W. F. BOGESS, Louisville: In every case of neurasthenia, ocular reflexes should be looked into and relieved by practical fitting glasses. For various mental conditions, fear, etc., exercise is the best remedy that can be used, and when the patient is able to do so he should do the things he fears most.

To sum up the treatment of neurasthenia:

1. Obtain control of your patient in every way possible, remembering that the attitude of the physician has much to do with the cure.
2. Find the cause, whatever it is, in the patient's habits, method and mode of living, past and present life; ascertain what physical defect may be present and remove it.
3. Determine whether the patient does or does not need the rest treatment, or intelligent supervision of exercise, work, rest and sleep.
4. Employ electricity, hydrotherapy, massage, psychotherapy, etc.
5. Include under general medicinal treatment the use of nuxvomica, arsenic and the glycerophosphates, intelligently and physiologically administered.
6. Treat the various symptoms as they arise intelligently, always remembering that by paying too much attention to any one symptom you accentuate the trouble and thereby do your patient injury.

Cancer of the Uterus

DR. W. H. WATHEN, Louisville: Cancer arising in the cylindrical epithelium of the cervical canal is of the adenocarcinoma variety, and rapidly extends to adjacent structures, especially the parametrium and the bladder wall, quickly involving the lymph glands, and is often followed by metastasis in other organs. Hence, it is less amenable to treatment than cancer of the infravaginal cervix. Cancer arising from the endometrium, while it is from cylindrical epithelium and usually of the adenocarcinoma type, does not invade adjacent structures rapidly and seldom in the operable stage involves the parametrium, or by metastasis extends to other organs of the body. This variety, if seen in time, is more amenable to radical treatment than cancer of the cervical canal. All varieties of cancer of the uterus extend more rapidly to local structures, and is followed more quickly by metastasis in young, vigorous people than in old people. While many millions of dollars have been expended in research work to discover the cause of cancer, there is no positive evidence that the real cause is known. Special study has been along the lines of the parasitic theory, the cell autonomy and the biologic and biochemical nature of tumors. While no parasite has been discovered by any experimentation, this does not negative the fact that a specific germ is the cause, for the germ may be in the protoplasm of the cell and too small to be discovered by any power of the microscope yet devised. While cancer of the uterus does not usually appear until after the age of 30, and is more frequent between the ages of 35 and 55, it may develop in a girl of 15 or in a woman of 75. Cancer of the cervix is nearly always seen in women who have borne children, but I have often seen it in women who have had no children, and who probably never had sexual connection. If diagnosed and operated on in the early stages, the end results of cancer of the infravaginal cervix or the endometrium are far more encouraging than in cancer arising in the cervical canal, and the operation need not be so extensive, and may be performed in nearly every instance *per vaginam*. This is not true, however, in most cases of the

adenocarcinoma arising in the cervical canal, which so quickly invades the adjacent structures and must be widely removed in order to give the woman the best chances for recovery. Uterine myomata, with cancer of the uterus or cancerous involvement of the myomata, should be operated on by the suprapubic method. This association or involvement is rare. Cancerous involvement may result from continuity of cancer in the cervical canal or endometrium by metastasis from cancer in other parts of the body, or by the development of cancer in the epithelium of the glands of an adenomyoma. I recently removed a uterus with malignant involvement of myomatous tumors, caused by the extension of an adenocarcinoma in the cervical canal.

My experience in curettage, followed by the application of phenol and alcohol, encourages me in the belief that such treatment may often relieve pain and other symptoms, prolong life, and sometimes so change local conditions as to make operable a case that before such time was inoperable, in the sense that all involved structures could not be removed. In conclusion, let me repeat that until we know more about the cause and history of cancer, our success must depend on early diagnosis and prompt and thorough surgical treatment, being governed in the choice of operation by local conditions.

Expert Testimony

MR. EDWARD J. McDERMOTT, Louisville: What are our remedies? First, each profession—especially the medical profession, which is called on most for expert testimony—must try to create a strong opinion, in its ranks and in its public associations, in favor of higher ethical standards, and must frown down its weak or corrupt members who allow themselves to be misused or besmirched as false or foolish witnesses. Second, the courts must be induced to inquire more fully into the qualifications of experts, and to handle, with more care and strictness, this clause of evidence which is often useful, and which can sometimes be corruptly used with success and impunity. This part of the reform must be accomplished by the lawyers and the courts. Third, legislation must be devised to strengthen the court's control of opinion-witnesses, and to prevent selfish and unscrupulous litigants from getting much benefit by hiring charlatans or cranks or dishonest, but shrewd and plausible men, of sufficient learning and experience, to enable them all the better to deceive a jury. It seems clear to me that the legislature has the power (1) to regulate the selection or calling of experts or opinion-witnesses, and (2) to regulate their compensation. It also seems clear to me that the legislature, in the interest of truth and for the protection of both the medical and the legal professions, should regulate both the selection and the compensation of such witnesses. The disreputable physician and the disreputable lawyer and their client now have such an unfair advantage of their reputable adversaries, that truth and justice are too often trampled down. As litigants with most money at their command may get the greatest number of experts, and the most expensive experts, the court should have the right (1) to prescribe a list of eligible men, (2) to limit the number to be called, and (3) to fix the compensation. No witness in any case should have a contingent fee. He should not have his compensation depend on the success of his testimony or his side. This is too great a temptation to partisanship. It may be wise (in the interest of the poor) to allow a lawyer to be employed on a contingent fee, for he is not a witness—he is not swearing to the right of his side—but there is no excuse for allowing a witness to be so tempted by self-interest to deviate from the truth where a deviation is so easy, and is never punishable, in an expression of a mere theory or opinion. Even contingent fees of lawyers, in damage suits and perhaps in other cases, should be subject to the scrutiny and control of the courts to prevent hardship and injustice to the poor in whose interest such fees are supposed to be allowed.

Inguinal Hernia

DR. B. F. VAN METER, Lexington: The simplest operation that focuses all effort on the complete removal and high ligation of the sac is the successful operation. The sac is not

always recognized and identified by the occasional operator; sometimes it is never ligated at all, and then nothing but failure can result. Every hernia patient has the right to have laid before him, on the one hand, the comparative risk, the percentage of recurrences, the time of disability; on the other, the everlasting semidisability, and the danger of strangulation, with its enormous increased risk to life. There is small, but very definite danger from the anesthetic, when general anesthesia is used; when local anesthesia is used this danger is eliminated—a zero mortality in a hundred consecutive cases, two weeks' complete disability, two weeks of partial disability, with 95 per cent. of permanent cures.

Indications and Technic of Cerebral Decompression

DR. E. S. ALLEN, Louisville: The dominating factor in cerebral surgery is the effect of compression on brain tissue. While any other tissue may be compressed with comparative impunity, nerve tissue is compressed only at the cost of immediate loss of function, with slow restoration if pressure be relieved, and atrophy without regeneration if pressure be not relieved. Its high degree of differentiation makes it an easy prey to insignificant trauma, and its injury is frequently attended by early and easily recognizable symptoms. Local pressure and death of other tissue may pass unnoticed, but nerve fiber gives unmistakable sign and gives it regularly. The compression of nerve tissue, except in silent areas of the brain, will produce definite symptoms. Many of the lesions which affect the brain, and especially those which have a surgical bearing, do so by reducing the available space inside the skull. The symptoms of hemorrhage, tumor, etc., depend in the main on the compression which these various lesions exert directly on the brain. Realizing that cerebral compression results, ultimately, in medullary anemia, and medullary anemia in vasomotor paralysis, and vasomotor paralysis in bulbar starvation, with cardiac and respiratory paralysis, and that our principal guide in this intracranial pathology is arterial tension as recorded by the manometer, then I believe the chief indication for decompression must be when the tension reading reveals the fact that the struggle between the intracranial compressing force and the vasomotor center is becoming a life and death effort, and that it is best to interfere when the vasomotor strength is high and not wait until the compressing force is victorious and the arterial tension is dropping or undulating.

Acute Gastro-Intestinal Infection in Infants

DR. J. M. REES, Cynthiana: Since less than 10 per cent. of deaths due to intestinal disease occur in breast-fed infants, we should urge and encourage maternal nursing. While this is necessary in all classes, it should be especially insisted on among the ignorant and negligent. It requires but little experience, and may be done by those of very little intelligence and among the very poor, while artificial feeding is not successful unless carried on intelligently, and, at the same time, a certain amount of money is available to obtain reliable nourishment, especially pure milk. Too frequently, babies are taken from the breast when, with a little care and patience, lactation could be continued. We should point out the great danger a mother assumes when she undertakes artificial feeding without the necessary means or preparation. Mothers too often, in order to escape the hardships of breast feeding, remove the child from the breast, not seeming to understand that the puny, fretful, bottle-fed infant is infinitely more troublesome than the well-nourished, breast-fed baby that spends most of its time in sleep. The first feeding is always an experiment, and we should endeavor to begin with a mixture slightly weaker in fats and proteins than mother's milk, and increase in a gradual manner, until at the end of the first year the child is receiving plain cow's milk. Carefully fed infants, whose digestion is normal and whose feeding mixtures are prepared from fresh and clean milk, acquire an almost clock-like regularity in their habits, vomiting never occurs, and the bowel movements are yellow and come at regular intervals. Any change from this regularity is a signal of disturbance, which should be promptly investigated.

Colonic irrigation is, in many cases, as important as the initial purgation. By it any residue of feces or irritating secretions in the colon or rectum is removed, and, as it stimulates peristalsis, it assists in evacuating the small intestine. It also adds to the body an amount of fluid to compensate for the waste cause by the diarrhea. For the best results, the physician must personally attend to the irrigation, unless he has a competent nurse. This should be done two or three times during the first twenty-four or forty-eight hours; later, once daily is sufficient. Saline solution, at a temperature of 100 F., may be used, with a long rectal tube or catheter of sufficient caliber and stiffness to prevent it from kinking. The other local methods are the application of heat and counter irritation to the abdomen for their soothing effect; the use of cold for its antipyretic effect, and the application of heat when there is depression of the vital forces.

Other Papers Read

The following papers were also read: "The Present Status of Serum and Vaccine Therapy," by Dr. F. H. Montgomery, Danville; "Cancer of the Breast: Diagnosis and Treatment," by Dr. J. T. Reddick, Paducah; "Prophylaxis and Treatment of Scarlet Fever," by Dr. J. S. Lock, Barbourville; "Measles," by Dr. F. A. Frazer, Marion; "Prophylaxis and Treatment of Pneumonia," by Dr. J. C. S. Brice, Flemingsburg; "Abdominal Crises Caused by Pathologic Changes in Meckel's Diverticulum Other Than the Strangulation by Band," by Dr. George A. Headon, Louisville; "Abscess of the Liver: Diagnosis and Treatment," by Dr. J. J. Rathbun, Russell; "Electricity in Diagnosis and Treatment of Disease," by Dr. J. J. Rodman, Owensboro; "Something Old and Something New in Medicine," by Dr. D. O. Hancock, Henderson; "Popliteal Aneurism. With Report of Matas Operation," by Dr. J. R. Nurnan, Covington; "Diagnosis and Treatment of Enterocolitis in the Adult," by Dr. E. A. Stevens, Mayfield.

State Boards of Registration

COMING EXAMINATIONS

- ARKANSAS: Regular, Little Rock, November 8-9. Sec., Dr. F. T. Murphy, Brinkley; Homeopathic, Little Rock, November 11. Sec., Dr. P. C. Williams, Texarkana; Eclectic, Little Rock, November 8-9. Sec., Dr. G. A. Hinton, Hot Springs.
- CONNECTICUT: Regular, City Hall, New Haven, November 8-9. Sec., Dr. Charles A. Tuttle; Homeopathic, Grace Hospital, New Haven, November 8. Sec., Dr. Edwin C. M. Hall, 82 Grand Ave.; Eclectic, Hotel Garde, New Haven, November 8. Sec., Dr. Thomas S. Hodge, 19 Main St., Torrington.
- FLORIDA: Palatka, November 9-10. Sec., Dr. J. D. Fernandez, Jacksonville.
- LOUISIANA: Homeopathic, New Orleans, November 7. Sec., Dr. John T. Crebbin, 1207 Maison Blanche Building.
- MAINE: City Council Rooms, Portland, November 8-9. Sec., Dr. Frank W. Searle, 806 Congress Street.
- MASSACHUSETTS: State House, Boston, November 8-9. Sec., Dr. Edwin B. Harvey.
- NEBRASKA: State Capitol, Lincoln, November 9-10. Sec., Dr. E. Arthur Carr, 141 S. Twelfth Street.
- NEVADA: Carson City, November 7-9. Sec., Dr. S. L. Lee.
- TEXAS: Palestine, November 22-24. Sec., Dr. R. H. McLeod.
- WEST VIRGINIA: Morgantown, November 14-16. Sec., Dr. H. A. Barbee, Point Pleasant.

Wyoming June Report

Dr. S. B. Miller, secretary of the Wyoming State Board of Medical Examiners, reports the written examination held at Laramie, June 22-24, 1910. The number of subjects examined in was 10; total number of questions asked, 100; percentage required to pass, 75. The total number of candidates examined was 10, all of whom passed, including one osteopath. Sixteen candidates were licensed through reciprocity. The following colleges were represented:

College	PASSED	Year Grad.	Per Cent.
Rush Medical College	(1910)	88.4
Atlanta School of Medicine	(1908)	76.4
State University of Iowa, College of Medicine	(1910)	88.7
University Medical College, Kansas City	(1904)	83
Creighton Medical College	(1909)	86.4, 87.3
Lincoln Medical College	(1910)	79.3, 90.5
Columbus Medical College	(1886)	75.9

LICENSED THROUGH RECIPROCITY

College	Year Grad.	Reciprocity with
George Washington University	(1897)	Dist. Colum.
Northwestern University Medical School	(1909)	Illinois
College of Phys. and Surgeons, Chicago	(1904) (1907)	Illinois
Rush Medical College	(1902)	Iowa
Drake University	(1907)	Iowa
Sioux City College of Medicine	(1903)	Iowa
Louisville Medical College	(1902)	Indiana
Baltimore Medical College	(1907)	Vermont
Maryland Medical College	(1904)	W. Virginia
University of Michigan, Homeopathic College	(1903)	Minnesota
Barnes Medical College	(1902) (1909)	Missouri
Eclectic Medical Institute, Cincinnati	(1908)	Iowa
Staring Medical College, Columbus	(1904)	Ohio
Medical College of the State of South Carolina	(1898)	S. Carolina

New Mexico July Report

Dr. J. A. Massie, secretary of the New Mexico Board of Health and Medical Examiners, reports the written examination held at Sante Fé, July 11-12, 1910. The number of subjects examined in was 10; total number of questions asked, 100; percentage required to pass, 75. The total number of candidates examined was 3, all of whom passed. Twenty-one candidates were licensed to practice on presentation of satisfactory credentials. The following colleges were represented:

College	PASSED	Year Grad.	Per Cent.
North Carolina Medical College	(1906)	77
Epworth College of Medicine	(1910)	87.2
Memphis Hospital Medical College	(1894)	75.1

LICENSED ON CREDENTIALS

College	Year Grad.
Gross Medical College	(1893)
Hahneman Med. Coll. and Hospital, Chicago	(1880)
College of Physicians and Surgeons, Chicago	(1906)
Keokuk Med. Coll., Coll. of Phys. and Surg.	(1906)
College of Physicians and Surgeons, Keokuk	(1890)
University of Louisville	(1901) (1909) (1910)
Louisville Medical College	(1903)
Hospital College of Medicine, Louisville	(1898)

Book Notices

LEHRBUCH DER KINDERHEILKUNDE FÜR AERZTE UND STUDIERENDE. Von Dr. med. Bernhard Bendix, Privatdozent für Kinderheilkunde dirigierender Arzt der Charlottenburger Säuglingsklinik. Sechste, Durchgesehene und Verbesserte Auflage. Paper. Price, 15 marks. Pp. 671, with 83 illustrations. Wien: Urban & Schwarzenberg, 1910.

Professor Bendix has for many years held a foremost place as an authority on diseases of children. The present edition of this work, the sixth, has been extensively revised and much of it wholly rewritten to include the latest advances in every department of pediatrics. This is especially true of the chapters on nutritional disorders in infancy. The book everywhere gives the mature observations of one of Germany's greatest pediatricians, and is highly commended to every physician who is interested in diseases of children.

THE VEGETABLE PROTEINS. By Thomas B. Osborne, Ph.D., Research Chemist in the Connecticut Agricultural Experiment Station, New Haven. Price, \$1.20 net. Cloth. Pp. 125. New York: Longmans, Green & Co., 1909

Until the appearance of this monograph, one of a series on biochemistry, the data on the chemistry of plant proteins had not been collected and presented in a systematic way. It was not until recent years that the importance and the practical value of knowledge regarding vegetable proteins were appreciated and then largely through the well-known researches of the author himself. As a large portion of this monograph is in reality an abstract of the author's investigations, it is very accurate and covers the most recent work in this field.

The chemistry of plant proteins is considered historically, beginning with the study of gluten in wheat and covering the more recent discoveries of other proteins in various plants.

The book is not intended as a laboratory guide or hand-book, but is a complete collection of descriptions of the various plant proteins, which have been investigated. Aside from the complete descriptive matter, the monograph contains tables and a very complete and valuable bibliography of the protein chemistry literature.

PHYSICAL EXAMINATION AND DIAGNOSTIC ANATOMY. By Charles B. Slade, M.D., Chief of Clinic in General Medicine and Instructor in Physical Diagnosis in the University and Bellevue Hospital Medical College, New York. Cloth. Price, \$1.25. Pp. 146, with 36 illustrations. Philadelphia: W. B. Saunders Co., 1910.

The author has attempted to give in a concise manner practical points and definitions in the technic of physical examination, chiefly of the thorax and abdomen, with some reference to information that may be obtained by general inspection. The book, intended for students, is elementary in character, deals chiefly with the normal subject, and does not pretend to enter into the diagnosis of specific pathologic conditions, making reference to them only to illustrate the application and object of the different methods employed to elicit information. The topography of the chest and abdomen and the various anatomic structures within is well shown by numerous diagrams, and a few photographs are used to illustrate certain points. It is a practical and useful elementary exposition of the subject of physical diagnosis.

CLINICAL TREATISES ON THE PATHOLOGY AND THERAPY OF DISORDERS OF METABOLISM AND NUTRITION. By Dr. Carl von Noorden, Professor of the First Medical Clinic, Vienna. Part VIII, Inanition and Fattening Cures. Part IX, Technic of Reduction Cures and Gout. Cloth. Price, \$1.50 each. Pp. 103 and 112. New York: E. B. Treat & Company, 1910.

The scientific considerations which are involved in the attempt to restore the nutrition to normal in emaciated individuals are first explained in chapters dealing with the phenomena of inanition and undernutrition and then the practical application of these principles in the treatment of these cases is explained. The exposition of the calculations necessary to determine the individual's nutritive requirements and the addition of several important tables make this part (Part VIII) of the book a very valuable guide. The important fact that a mere increase of adipose tissue does not always secure the highest grade of nutrition is particularly emphasized and the inability of the organism in certain conditions to avail itself of the increased pabulum furnished is clearly brought out. Incidentally the author exposes the fallacy of attempting to restore a normal condition of nutrition in certain tissues by supplying merely the component elements of the tissue. The use of calcium in rickets on this principle is shown to be fallacious. In a similar way the absurdity of the claims for the use of lecithin in nervous disorders is shown. It is a defect of the work that so much prominence is given to a much-advertised American breakfast food.

Part IX treats of reduction cures and puts a method of treatment which began in empiricism on a scientific basis. For the specific plans such as the Banting cure, etc. the author substitutes exact calculations of the needs of the patient based on his body weight and the calorific value of the different classes of food. The uric acid theory of gout and renal lithiasis is discussed with a frank admission of the paucity of our actual knowledge. The dietetic treatment is based on the principle of excluding exogenous purins and determining by experiment the degree of tolerance of the individual patient for purins on the same principle as we determine the power of the individual diabetic to metabolize sugar. The purin content of various articles of diet is described. The author makes no distinction between white and dark meats, as his own experience as well as the results of chemical analysis has taught him that the white meats present no advantage over the red in this respect. The uselessness of the so-called uric acid eliminants for the treatment of gouty arthritis is emphasized, although the author admits that we can influence to some extent the solubility of uratic deposits in the genito-urinary tract. This volume will form a useful and suggestive manual for those who treat this class of cases which is undoubtedly more numerous in this country than commonly supposed.

Medicolegal

Corporations Cannot Practice Medicine

The Court of Appeals of New York says: In re Co-operative Law Company (92 N. E. R. 15), where it holds that a corporation can neither practice law nor hire lawyers to carry on the business of practicing law for it, that it cannot do so any more than it can practice medicine or dentistry by hiring physicians or dentists to act for it. The legislature, in authorizing the formation of corporations to carry on "any lawful business," did not intend to include the work of the learned professions. Such an innovation, with the evil results that might follow, would require the use of specific language clearly indicating the intention. Business in its ordinary sense was aimed at, not the business or calling of members of the great professions, which for time out of mind have been given exclusive rights and subjected to peculiar responsibilities.

Salary of County Health Officer

The Supreme Court of Mississippi says, in Adams County vs. Aikman (52 So. R. 513), that the latter-named party had been for several years health officer for Adams County. In July, 1907, the board, by order on its minutes, fixed his salary for the 12 months next thereafter at \$50 per month. No further order was entered with reference to his salary, but he continued to receive as such the sum of \$50 per month until the expiration of his term, on April 30, 1909. On May 15, 1909, he was reappointed as such health officer. At its June, 1909, meeting, the board of supervisors, by order duly entered on its minutes, over his objection, fixed his salary at \$300 per annum. At the August meeting of the board he filed his claim for an allowance of \$50 per month, which claim was rejected by the board and a warrant directed to be issued to him for \$75, or \$25 per month, which he declined, and shortly afterwards brought suit for \$150 for the months of May, June and July. In the justice court, where he brought suit, he recovered judgment, and also in the circuit court, to which an appeal was taken. But the judgment of the Circuit Court is reversed by the Supreme Court, which holds that he was entitled to recover from the county only the sum of \$25 per month, the salary fixed by the board, and that, if dissatisfied with that allowance, he should have appealed from the order of the board fixing the same. Under section 2,509 of the Mississippi Code of 1906, it is the duty of the board of supervisors to fix the salary of a county health officer in advance of his appointment; but, in the event it fails to do so, it may fix his salary at a later date. To hold otherwise would result in depriving such officer of any compensation for services which he might have rendered after his appointment and before his salary was fixed, for the reason that he can receive no compensation except a salary fixed by the board. There is no conflict herewith in the prior decision that, where a salary of a health officer has been fixed by order of the board, it cannot be subsequently reduced to such an amount as virtually to abolish the office.

Titles marked with an asterisk (*) are abstracted below.

Medical Record, New York

October 8

1. *The Carbohydrate Diathesis. W. E. Deeks, Canal Zone.
2. *Treatment of Diabetes Mellitus. T. S. Hart, New York City.
3. Anesthesia. J. T. Gwathmey, New York City.
4. *Residual Appendix. O. C. Smith, Hartford, Conn.
5. *Treatment of Typhoid with Vaccine. A. W. Hollis, New York City.
6. Hemophilia Treated by Transfusion. M. Habn, Washington, D. C.
7. *Typhoid Fever. A. K. Sallom, Philadelphia.

1. **Carbohydrate Diathesis.**—Deeks maintains that patients suffering from one or more of the following disorders are consumers of an excess of carbohydrate food: indigestion, gastric ulcer, decaying teeth, stomatitis, constipation, chronic

pharyngitis, true rheumatic bronchitis, anemia, most dysmenorrhoeas, enuresis, etc. He believes the diet to be indirectly responsible for appendicitis, and frequently for tuberculosis. He does not state what the exact nature of the products of carbohydrate fermentation is, but he contends that his statements can be verified clinically, and from a humanitarian standpoint the results are worthy of a further investigation. In the tropics, unless engaged in active physical exercise, the nearer men keep to a diet consisting of meat, fish, poultry, milk, green vegetables and fruit, the less they suffer. In this combination is found an energizing, tissue-forming, low heat-producing food, free from fermentative properties and containing enough of the indigestible vegetable cellulose to stimulate intestinal peristalsis and elimination. Sugars should not be consumed at all, except in solution, on an empty stomach, and then sparingly. The amount of starch ingested should be proportionate to the physical exertion involved.

2. **Treatment of Diabetes Mellitus.**—Hart emphasizes the importance of taking proper care of diabetes with the mild type of the disease, and of subjecting them to suitable restrictions early in its course. By the painstaking control of the diet, under the guidance of accurate records based on careful observation, the progress of diabetes, in the majority of instances, may be so checked that it will never reach the most severe form. In other instances, although the disease becomes more severe in spite of our best efforts, we are nevertheless able materially to hinder the progress of the malady, and we may save our patients much suffering and lengthen their lives by a number of years.

4. **Residual Appendix.**—Smith believes that from our knowledge of the pathology of appendicitis and the comparative frequency with which appendicitis recurs sooner or later following an appendiceal abscess or general peritonitis caused by appendicitis, we must conclude that the residual appendix—that is, the appendix left after abscess and drainage—is much more subject to inflammation than the appendix which has not been diseased. If its mucosa is continuous with the cavity of the cecum it is still exposed to infection. In addition to that, its circulation has usually been partially destroyed, it has become adherent to the abdominal wall, or some other organ, and is in a position to be strained or traumatized. Moreover, there may be residual concretions and residual pockets of pus within the lumen which did not escape at the primary attack. If these deductions are correct there can be no doubt of our duty in advising a secondary operation, and explaining thoroughly to the patient the reasons for, and the advantages of, this procedure.

5. **Typhoid Fever.**—In the series reported by Hollis, 21 patients were treated by the older method of hydrotherapy, either by the tub bath or by sponging; 11 patients were treated with vaccine without hydrotherapy. In the remaining 5 cases the patients were too short a time under treatment to make any comparisons. The diet, in general, was of the high caloric variety. No drugs were employed, but strychnin and whiskey were used as stimulants in the severe cases. The bowels were moved by enemata. The patients who were treated by hydrotherapy, barring a few who were given sponge baths because of poor response to tubbing, had a tub bath at a temperature of from 80 to 90 F. for 15 minutes, with friction, every 4 hours from noon until midnight inclusive if the rectal temperature was 103 F. or higher. At 8 a. m. all received a warm soap and water sponge. Those treated by vaccination received no baths other than a daily warm soap and water sponge. In a very few cases 250,000,000 bacilli were employed but no different clinical or laboratory effect could be noticed between the smaller and larger doses. No fever reaction was obtained. No case ended by crisis. No death occurred among the vaccinated patients; 4 occurred in the other series, one from hemorrhage, one from toxemia, one from perforation and one from pulmonary thrombosis with necrosis of the whole left upper lobe of the lung. Headache, gastrointestinal symptoms and toxemia were far less frequent in the vaccinated series than in the other cases, and the absence of discomfort seemed striking, while convalescence was more rapid.

7. **Typhoid Fever.**—Sallom gives charts of the mortality curve of morbidity of 68,943 cases of typhoid observed in Philadelphia, from January, 1898, to June, 1909. Of this number 8,012 died, a mortality of slightly over 11.75 per cent. Mortality rises in February and March, falls in April and rises again in May, reaching its acme in July. It then falls again and rises toward October. The relationship of morbidity to mortality is striking. Morbidity reaches its lowest ebb in July, and is highest in September. The maximum of morbidity coincides with the minimum of mortality. The author believes that season has an important effect on mortality. With the maximum morbidity a minimum percentage of mortality is present, and vice versa, as morbidity falls mortality rises.

- 19 *Types of Exophthalmic Goiter. J. G. Mumford, Boston.
- 20 Hysteria, with Necropsy. W. R. Woodbury and C. Reed, Boston.

19. **Exophthalmic Goiter.**—The first case reported by Mumford was that of a woman, aged 42. At the age of 37 she consulted her physician for what appeared to be a trifling heart lesion, for she found herself troubled with occasional dyspnea on exertion. Her physician discovered a slight mitral leak and some dilatation of the heart. Careful treatment and prolonged rest resulted in no benefit; gradually there developed further a constant distressing dyspepsia, pain and nausea after eating and a state of continual apprehension. These symptoms persisted for two years, when there developed further a mild, bilateral tremor of the fingers. At this stage she consulted Mumford and he suggested the diagnosis of exophthalmic goiter. Within a month there developed a series of characteristic symptoms: the thyroid became enlarged, with a typical thrill; the eyes gradually became prominent, with lagging of both lids and widening of the palpebral fissure; and the tachycardia became pronounced, the rate of the heart ranging between 110 and 130. Mumford instituted the use of hydrobromate of quinin, neutral, in 5-grain capsules, 3 times a day, and continued the medication without intermission for 15 months. During the early months of treatment the patient experienced great relief.

Twelve months after the beginning of the quinin treatment, through the accident of a serious grief, all her discomforts reappeared; the eyes became prominent and anxious, with their associated abnormal lid phenomena; her tachycardia returned; the heart became irregular; dyspnea became extreme; she was troubled with a constant diarrhea and distaste for food; profuse sweating became pronounced; the tremor returned in force; and the right lobe of the thyroid rapidly doubled in size. Thyroidectomy was done, and 8 months after the operation the patient appeared to be well, except for a slight exophthalmus.

The second patient, a vigorous young woman, of active habits, about 32 years of age, and the mother of 4 children, suddenly became extremely nervous; within a week she took on symptoms that suggested to her physician a rapid neurotic breakdown; she was sleepless, fretful, irritable and almost impossible to live with, as her friends asserted. Within a week after the surprising development of these symptoms her physician discovered a marked tumor of the thyroid gland. There was no other evidence of hyperthyroidism, with the

exception of the nervousness; there was no exophthalmos, no tachycardia or palpitation, no tremor, no digestive disturbance, no sweating; in fact, the diagnosis was founded almost solely on the nervousness and the rapidly enlarging thyroid.

This patient's physician, Mumford states, had the courage of his convictions, and his convictions were sound and accurate. Without stopping to employ drugs, and without waiting to see the development of the case, he proceeded at once to a surgical operation, and his activity seems to have been justified by the results. He removed the whole of the left lobe of the thyroid, leaving, however, the isthmus, with a considerable pyramidal lobe, and the whole of the right lobe. The lobe removed was the most affected; those parts which were left seemed to be but slightly hypertrophied. The patient promptly recovered from the operation and regained her normal health. Her symptoms of hyperthyroidism gradually returned after a year and became more settled and more pronounced than before. A second operation was decided on. Every reasonable operative precaution was taken to avoid increasing the hyperthyroidism. The operation occupied about 35 minutes and was extremely tedious, but the patient bore it well. Trouble began immediately after the patient was put to bed, however; she sank rapidly and died of acute hyperthyroidism about 36 hours after the operation.

24. **Dilatation of the Aorta.**—McCrae claims that dilatation of the aorta, considered apart from aneurysm, is relatively common and probably occurs more frequently than aneurysm. Two main etiologic factors stand out: (a) acute infections, notably rheumatic fever, and (b) those which cause general sclerotic changes. The symptoms often suggest disease of the heart itself. The physical signs are often very definite, of which visible pulsations in the upper interspaces, dullness over the upper sternum and adjoining interspaces, and the fluoroscopic examinations are the most important. Pressure signs are comparatively common, but are rarely severe. The diagnosis, as a rule, can be readily made from aneurysm. The outlook as regards dilatation is good.

25. **Heart-Block.**—The case of heart-block which furnished the basis for the observations made by Stengel and Pepper is said not to have been of such exceptional character that a separate publication of the clinical features would be of value, but the numerous tracings which were obtained furnished some interesting information and one of these proved of unusual importance in throwing some light on the possibility of true hemisystole. Although for a time complete heart-block existed and later partial heart-block, during the patient's stay in the hospital no Stokes-Adams syndrome

was present. The complete block, after the administration of atropin, promptly changed to an incomplete block with a 3 to 1 rhythm, then to a 2 to 1 rhythm, and later to a normal rhythm. The 2 to 1 rhythm and the normal rhythm for a time alternated one with the other, and a number of tracings were obtained showing this change while the tracings were actually being made. It furnished indications of genuine hemisystole during the transition of the normal rhythm to a 2 to 1 rhythm. From this same tracing it could be demonstrated that the origin of the *c* wave is the right ventricular contraction, rather than the carotid pulsation. The *a-c* interval is longer in such cases as this during normal rhythm, while it may be normal in length during partial block. The auricular rate becomes faster when the normal rhythm changes to a 2 to 1 rhythm, and slower when the opposite change occurs.

In attempting to determine the cause of greater auricular rate during 2 to 1 or 3 to 1 rhythm than when no dissociation existed, it occurred to the authors as reasonable that the interference with auricular outflow, which is present at each alternate or third auricular contraction, would necessarily leave the auricle relatively unemptied and would thus occasion an earlier stimulus to contraction, which would result in a more rapid rate. When a change from normal to 2 to 1 rhythm occurs the quickening of auricular rate is less prompt than is the showing when a 2 to 1 rhythm changes to the normal. An explanation for this circumstance may be found in the fact that resumption of normal rhythm after a 2 to 1 rhythm at once relieves the auricle of back pressure and the consequent stimulus to increased rate. Such a sudden relief is followed by prompt re-adjustment of auricular activity, whereas the effect of the change from normal to a 2 to 1 rhythm and the consequent gradual overfilling of ventricle and auricle would be met by a slower response. In this case, during the time of complete block, the ventricle rhythm was not at all times regular, although the ventricle usually contracted about 20 times to the minute, or about every three seconds; at other times there were irregular pauses, the longest being 5.4 seconds. There were, however, no extrasystoles at any time. It is known from physiologic experiment that, owing to poorly developed or retained independent rhythmicity, a portion of the ventricle, as, for example, the severed apex of the ventricle, tends to cease contracting after a time and will resume regular contractions only after an external stimulation. It is possible, therefore, that the continued action of the ventricle sometimes for long periods and despite occasional long pauses in cases of complete block may be due to the stimulus of distention with blood resulting from the continued auricular action.

26. **Aneurysm of the Aorta.**—Eshner concludes that aneurysm of the aorta is essentially a fatal disorder, although exceptionally spontaneous cure takes place. Accordingly, treatment can, as a rule, be only palliative, relieving symptoms and prolonging life. Deligation is inapplicable from anatomic considerations. Rest, ergot, iodids, gelatin, calcium chlorid, adrenalin chlorid, and introduction of foreign substances, with or without the passage of a galvanic current, have been employed. Horsehair, catgut, needles, watchspring and wire of various kinds have been introduced, with varying results, and a galvanic curve has been passed through conducting substances. Wiring with electrolysis has been employed in a moderate number of instances, with satisfactory results in the majority. The procedure has proved simple and safe, but it is applicable only to sacculated and not to fusiform aneurysms.

27. **Orthodiagraphy.**—According to Clayton and Merrill the orthodiagraph is of real value to the clinician, and as it becomes more commonly used we may be able to formulate some useful facts which as yet it is unwise to attempt. The instrument is by no means necessary in all cases, but may be an aid to diagnosis in many more or less obscure pathologic conditions of the heart and aorta.

28. Abstracted in *THE JOURNAL*, May 28, 1910, p. 1806.

31. **Medical Uses of Rectal Infusions.**—Sewall believes that it must be admitted that the favorable results accompanying the use of proctoclysis in appropriate medical cases indicate that this method of quasi-internal hydrotherapy deserves such a thoroughly detailed study as will accurately establish its indications and limitations in medical therapeutics.

32. **Status Lymphaticus.**—A study of the two cases mentioned by Rachford indicate that the disappearance of the lymphocytosis under the roentgen-ray treatment of the thymus in status lymphaticus is so marked that a careful study of the blood state in this condition will give important information not only as to the efficacy of the treatment, but as to the length of time this treatment should be continued. It will be wise, perhaps, to discontinue treatment when the lymphocytosis disappears, even though there still be left some cough and stridor. The chloro-anemia which is not improved under the roentgen-ray treatment may be aggravated if it be continued too long. Following the roentgen-ray treatment in these cases, hypodermic injections of iron, with careful feeding and fresh air, may be necessary to restore the blood state to a normal condition. In both of the cases here reported slight cough and stridor were present when the roentgen-ray treatments were discontinued, but disappeared entirely a few weeks later.

In the roentgen-ray treatment of status lymphaticus in infants and young children, although no portion of the body is exposed to the influence of the rays except that which directly holds the thymus, there are the following results of this treatment:

1. The hyperplastic thymus decreases in size and the cough, stridor and asthma disappear.
2. The enlarged spleen and lymph nodes decrease in size.
3. The exhaustion and general feebleness of constitution gives place to normal conditions of health and strength, and physical and intellectual growth are greatly stimulated.
4. There is rapid disappearance of the marked lymphocytosis which characterizes this disease.
5. Excessive physiologic action of the thymus gland is controlled.

The slight return of the symptoms, stridor, cough, etc., at intervals of three or four months in one of the cases, and the quick control of these symptoms by one or two exposures to the roentgen-ray, indicate that the gradual regeneration of the thymus following the roentgen-ray treatment may be accomplished by a gradual reproduction of the same pathologic conditions, hypersecretion, etc., which were present before the treatment was begun.

33. **Splenomegaly.**—The blood-picture in the case suggested a diagnosis of pernicious anemia; the marked number of nucleated red cells (13,000), and especially the great proportion of megaloblasts (29 per cent.), making it probable that it was the plastic form of this disease. The splenomegaly present, although being unusual in pernicious anemia, would by no means exclude it, as cases are on record in which the spleen was quite large and in which the disease was undoubtedly of the pernicious type. Osler records such a case, which was at first taken to be one of splenic anemia, but subsequently came to necropsy and proved to be one of pernicious anemia, and in something like 1 per cent. of all cases of pernicious anemia the spleen is so large as to reach to the umbilicus. But assuming that the case be one of pernicious anemia, even then it presents several most unusual features. In the first place the disease commenced at the age of 8 years, if not earlier, which is very unusual. Again, it has lasted for at least 20 years, and the patient is still in comparatively good health; and yet the longest cases recorded, apart from 6 cases of apparent recovery, only lasted between 14 and 15 years. Further, according to the patient's history, he was so well between the ages of 14 and 28 that he was never laid up nor did he require any medical advice, that is, he seemed to have a remission of 14 years, and yet the longest recorded remission from prostrating symptoms on record is 6 years, although McPhedran recently reported a case in which there was a remission for 17 years.

As regards splenic anemia, the enormous size of the spleen with the marked anemia and anormal differential white blood-count would superficially suggest such a diagnosis, but

the very profoundness of the anemia would be against this conclusion, and further, the fact that the anemia was always of the pernicious form with a high color index would seem to exclude this diagnosis. Other forms of splenomegaly with anemia, such as congenital syphilis, tumor, malaria, and even a possibility of filaria were all carefully weighed and excluded. The case would appear to be one either of pernicious anemia of an exceptionally prolonged type, commencing at an exceptionally early age, and associated with an exceptionally large spleen, or one of splenic anemia with an exceptional blood-picture.

34. **Cord Lesions in Pernicious Anemia.**—These two cases illustrate two of the types of nervous-system involvement occurring in the course of pernicious anemia. In the first case, which had the longest and more pronounced history of anemia, the nervous symptoms were at a minimum and the posterior columns of the cord, particularly in the cervical region, alone showed degeneration, characteristically patchy in distribution. In the second case, the nervous involvement, particularly in the later stages, overshadowed the anemia. Here the spinal cord presented very extensive, yet incomplete degeneration with slight replacement gliosis in the posterior columns, and also a similarly irregular but more diffuse degeneration in the lateral tracts, which, however, was a rather less complete and apparently somewhat more recent process.

44. Abstract of this appears in department of society proceedings this issue.

46. **Fecal Incontinence.**—Hirschman says that if one is familiar with the anatomy of the sphincter muscles, avoids the use of the actual cautery or the injection of escharotics, is careful not to injure the muscular layers of the bowel in excising hemorrhoids, incises the sphincters at right angles in excising fissures or fistulas, and uses common sense in his after-care—avoiding packing and using drainage—there is no reason why incontinence of feces should ever be held up as a reproach to those who are doing honest and conscientious work in rectal surgery.

50. **Varicose Ulcers.**—The formula most frequently used by Roos in the treatment of these ulcers is the following:

R		gm. or e.c.
Gelatin	ʒi	30
Zinc oxid	ʒss	15
Glycerin	ʒxlv	55
Water	ʒiij	90

Mix and prepare over a vapor or hot-water bath.

The amount of any of these ingredients may be varied, the other medicants, such as ichthyol or boric acid, may be added. This is spread, while quite warm, over the entire surface of the cleansed and disinfected leg by means of a brush. When the paste begins to harden, a muslin bandage is placed around the leg, and a second coating applied, and this is fol-

lowed by a second muslin bandage. A window must then be cut through the dressing directly over the ulcer, through which dusting powder and absorbent material may be applied daily. This dressing may remain for from 3 to 7 days and is easily removed with hot water. Later, it may remain 2, 3 and even 4 weeks. It exerts a gentle elastic pressure, and is much more comfortable than an elastic bandage or stocking. Roos says that this dressing will also be found of good value as a prophylactic during pregnancy, when these veins sometimes become engorged and extremely painful.

59. **Employment of Patients.**—Winterode in summarizing his paper states that the remedial benefit from a therapeutic standpoint is as follows:

To the Curable Cases.—When instituted in the incipency of psychoses it offers an opportunity for early mental restitution, thereby affording facilities for the treatment of new cases.

To the Incurable Cases.—It is a means of re-education, transforming those of filthy and vicious habits with destructive inclinations into tidy, contented and useful members of the household.

To Alcoholic Psychoses and Drug Habitués.—It acts as a prophylactic, lessening the predisposition to relapse by creating new habits, instruction in new vocations, which will encourage inclination along different paths having more favorable environments and different associates.

Farm Colony.—It relieves congestion, admitting of classification, with home environments and greater amount of freedom.

Economic Value.—This consists in utilization of products in the hospital, manufacture of which has been the means of restoring the patients to health. The saving is in cost of furniture, clothes and other articles which may be destroyed; also in extra supervision of patients to prevent assaults, to say nothing of the quantities of hypnotics which would be necessary were they not kept busy.

Cooperation of state industries, Winterode says, provides a market free from competition with organized labor; produces, by means of the hospital, articles cheaper and better suited for their needs at sufficient profit than can be purchased on the open market; encourages development of other industries, and also acts as an incentive to instruct patients in skilled labor, which will come in good stead when discharged. This will take place as follows:

To the State.—Relief of burden of taxation, the necessary consequence were they to become charges for life.

Farm Colony.—The most economical plan of caring for the insane, with rational reduction of accommodations as well as maintenance, without reducing essential comforts.

Ethical Value.—Placing in homelike surroundings, with supervision, where pernicious habits are corrected, provides a disciplinary agent and reorganizes habits, or, in other words, prepares the individual for competition with his fellow-men.

64. **Insanity in the Navy.**—In the Government Hospital for the Insane, Washington, D. C., are gathered together more than 2,900 mental and nervous bankrupts. During the period January 1, 1899, to June 1, 1910, Butts found that there were 634 admissions of insane men of the Navy and Marine Corps to this institution. Of this number, 34 have been readmissions and 72 have been retired officers, naval beneficiaries, and supernumeraries who could not properly be considered in the same statistical tables with those men who just prior to their admission into the hospital were performing active service in the Navy or Marine Corps. There remain then 528 cases of insanity from the active lists of the service during the period named which have on one or more occasions been admitted to the hospital. The conspicuous features of Butts' study are the large number of recoveries—49.24 per cent.—and the very small number of deaths—6.64 per cent. He found also that 67.24 per cent. of the insanity of the navy occurs in men under the age of 30.

Of the foreign-born, Ireland has furnished a conspicuously large number of insane men, while her average annual percentage of enlistments has been relatively small, the ratio being 7.95 per cent. insane men to 1.91 per cent. enlistments. Germany, on the other hand, has furnished a much larger average annual percentage of enlisted men than any other foreign country, and a relatively small percentage of those men have become insane—very much smaller than Ireland—the ratio being 2.65 per cent. insane men to 2.22 per cent. enlistments. The Government Hospital for the Insane was opened in 1855; from that date up to and including June 30, 1909, there have been admitted into the institution 5,865 foreign-born insane patients. Of this number 2,282 were born in Ireland and 1,614 were born in Germany. Only one insane Filipino, a musician, has thus far found his way into the hospital. Next in importance to alcohol, had heredity and syphilis, heat or sunstroke, seems to have been the most frequent etiologic factors.

From his examination of the insane men of the Navy and Marine Corps now undergoing treatment at the Government Hospital for the Insane, and the case records of those who have been discharged from the hospital, Butts has been impressed with the great desirability of inquiring into the family and personal histories of candidates of enlistment before accepting them as recruits. He feels sure that if more care were exercised in this respect by recruiting officers that an immense amount of money could be saved the department, as well as extra work for other medical officers, and there would be great diminution in the number of admissions of insane men of the Navy into hospitals for their care.

67. **Helminthologic Technic.**—The essential steps of the methods employed by the U. S. Naval Medical School Laboratories in the collecting, killing, preserving, clearing, staining, mounting, and sectioning of flatworms, roundworms, and ova, respectively, are given by Garrison as follows:

Collecting: Wash in warm water, or, preferably, salt solution; in case of ova wash thoroughly by repeated sedimentations in water.

Killing: Flatworms.—Kill in following solution: Saturated aqueous solution of bichlorid of mercury, 70 per cent. alcohol, equal parts; mix and add 1 per cent. glacial acetic acid; use heated to about 70 C.; wash in running water; remove residue of bichlorid with iodine alcohol.

Roundworms.—Kill in 70 per cent. alcohol heated to about 80 C. Allow to cool.

Ova.—Kill as for roundworms, or add 5 per cent. formalin.

Preserving: Transfer to 70 per cent. alcohol—5 per cent. glycerin mixture. (Except formalized ova.)

Clearing Without Staining: Roundworms and Ova.—Clear on the slide with caustic-potash solution (30 per cent.) or with glycerin, or first with the caustic, followed by glycerin. Clear in bulk by allowing the alcohol to evaporate from a glycerin-alcohol mixture, leaving sufficient glycerin to cover the specimen.

Flatworms.—May be treated as for roundworms, but are usually stained (q. v.).

Mounting from Glycerin: Either mount directly in glycerin, ringing cover glass heavily with cement or balsam or (for more durable preparations) transfer to glycerin jelly, mount, and ring cover glass.

Staining and Mounting in Toto: Flatworms.—Flatten between two slides held by a rubber band and stain in carmine from one or two to twenty-four hours or longer. Remove from between slides and decolorize in alcohol or in acid alcohol, watching progress of decolorization under microscope. Replace between slides and pass through dehydrating alcohols to xylol and mount in balsam. (If aqueous carmin is used the specimen need not be compressed until after decolorization.)

Roundworms and Ova.—Little or nothing can be gained by attempting to stain ova or roundworms except when the latter are first sectioned.

Sections: Flatworms.—Usually stained in bulk before sectioning. Dehydrate, clear, and imbed in paraffin, carefully orienting the specimen. Cut sections thick.

Roundworms:—Sections seldom needed. Cut worm in pieces to allow fluid to penetrate from the ends. Impregnate thoroughly with a hard paraffin. Cut thick sections and stain on the slide in alcoholic carmin.

81. **Freezing Microtome.**—The apparatus described by Roberts is identical in principle with the ordinary carbon dioxide operated freezing microtome, except that the cold is applied by a slow current of brine at a minimum temperature of about 12 C. instead of by a rapid current of carbon dioxide gas at 30 C. or lower. In fact, with a few easily made alterations, the same instrument might be used for carbon dioxide and brine alternately. The brine is usually made by the interaction of fine ice and salt in a slightly elevated reservoir, and is run into and away from the microtome by rubber or metal tubing. The flow is regulated by a cock of some sort; a brass stop-cock mounted on the base of the instrument is best, but a simple screw-cock compressing the rubber tubing answers every purpose. To secure an even distribution of the cold, the brine, on entering the drum of the instrument, should first strike the center of the freezing plate and then radiate equally in all directions and be drained off below. This is brought about without difficulty by a suitable arrangement of entrance and exit tubes and a baffle plate. The advantages of this apparatus are said to be: simplicity, cheapness in the first cost and operation, wide availability (it can be used wherever ice and salt are to be had), and rapidity combined with great steadiness and regularity of operation, due to the high capacity for heat of the brine as compared with that of the gases used in other forms. Moreover, the brine can easily be prepared of any temperature desired down to -12 C., which is plenty low enough, and maintained at exactly the desired temperature. The freezing being under perfect control, much better sections can be cut than with carbon dioxide freezing, where the temperature and rate of flow of the freezing medium are subject to wide and only partially controllable variations.

- 87 *Personal Experiences in Renal Surgery. G. N. J. Sommer, Trenton, N. J.
88 *Stomach Surgery. E. Stachlin, Newark.

87. **Renal Surgery.**—Briefly, Sommer's cases were as follows: Case 1.—Abdominal section and drainage for tumor in lower abdomen mistaken for mesenteric cyst. Second abdom-

inal operation and removal of an ectopic kidney. Recovery. Case 2.—Acute septic infarction of the kidney; nephrectomy. Recovery. Case 3.—Acute infection in hydronephrosis; nephrectomy. Recovery. Case 4.—Chronic pyonephrosis; nephrectomy. Recovery. Case 5.—Hypernephroma; nephrectomy. Recovery from operation; death later from recurrence. Case 6.—Carcinoma; nephrectomy and appendectomy; operative recovery. Death from recurrence later. Case 7.—Stone in the pelvis of the kidney; pyelotomy. Recovery. Case 8.—Calculus in pelvis of the kidney; pyelotomy. Recovery. Case 9.—Calculus in hydronephrosis; nephrectomy. Recovery. Case 10.—Calculus pyonephrosis; nephrectomy. Recovery.

The skin preparation of these patients has been of two kinds, the first being the usual hot water and soap, alcohol and 1 to 1,000 solution of biclorid; the second, the iodine method, which consisted in painting the operative area with an 8 per cent. solution of iodine crystals in 95 per cent. alcohol. This is applied twice just before operation and covered with a sterile dressing. Both methods have been satisfactory. The kidney has usually been exposed by an incision beginning at the outer border of the erector spinae muscle, 2 c. m. below the last rib. It runs downward and forward parallel with the last rib toward the inner side of the anterior superior spine of the ilium. If necessary to secure room the incision is made to the outer border of the rectus. The perirenal fat is torn through or removed with the diseased organ when necessary, as in malignant disease or severe perinephritis.

In removal of the kidney the ureter is tied off as low down as possible with chromic catgut and the stump sterilized with carbolic acid and alcohol. The vessels are usually tied with silk. When the pelvis of the kidney has been opened the wound has usually been closed with plain catgut interrupted sutures and a cigarette drain placed down to the suture line. No leakage has been noted in cases in which this was done. In nephrectomy the wound has usually been drained with gauze or rubber tubes. The wound is closed with chromic catgut for the deep layer and interrupted silkworm gut sutures which are removed on the tenth day. The drain comes out on the third day and is not replaced. The patient is usually permitted to drink freely of water after the operation, and when the urinary secretion is deficient, spartein sulphate, 2 grains hypodermically, is given every 3 hours.

93. **Relation of Nasal Disease to Hay Fever and Asthma.**—Crane reports five cases which he believes support his view that hay fever and asthma are reflex neuroses caused in many instances by nasal disease. Therefore treatment of the nasal condition is indicated.

94. **Administration of the Public Health.**—The establishment of bureaus of health is advocated by Hoag. He would have each bureau with its own building and its corps of physicians be the administrative health bureau for the particular neighborhood in which it was located. One or more experienced physicians would be in charge with a dozen or more assistants according to the needs of the locality. These would all be under municipal pay, as the whole system would be under the municipal control and supported from the city's funds.

The duties of the assistant municipal physicians would be to visit from time to time, daily or tri-weekly, every family within their district, attend cases of illness when needed, advise regarding sanitation and infection, and report cases of violation of law. Conditions and circumstances or cases of illness which they were incompetent to handle would be reported to their superior officers, whose duty it would then be to direct and take charge of them. A system of promotion according to time of service and ability would also be a part of the system. The admission into the ranks of the physicians attached to the Bureau of Public Health would be by competitive examination.

The whole system would be a valuable clinic for the physician before entering private practice, for he would get actual experience in visiting families in their homes which is never obtained either in the dispensary or the hospital. This would in nowise affect the private practitioner or his livelihood. There would always be a demand for the private physician by the better classes just as we have private tutors, although there is a public school system, or have private detective septic methods are concerned. Young physicians on graduating would elect whether they should wish to enter on private practice at once or enter the ranks of municipal health officers.

95. **Friedreich's Ataxia in a Child.**—A boy, aged 5½ years, family history negative as to tuberculosis, alcoholism or syphilis, born after normal labor, a breast-fed baby, was well nourished and robust up to the age of 3 years. At that time, vomiting without apparent cause at the rate of once in two or three months after drinking a cup of tea. Two and a half years ago his vomiting came on once every week, soon after rising in the morning, stomach being empty. After a few weeks the vomiting became more frequent, three times a week for two weeks, and then once every day, always in the morning soon after rising. This continued for six months, at the end of which time he was vomiting a few times a day. No medication could stop it. During these six months, the father noticed that his gait began to be slightly unsteady and that he could not run about as heretofore. During these six months he also complained of severe headache, then vomiting suddenly ceased and the headache left the patient when he was taken ill with fever which left him after three days, but he was unable to rise or walk without being supported, and that condition is present to-day. Six months after the onset of this fever he began to show an ataxia in the upper extremities which is fully developed to-day.

The musculature of the body is in a decidedly hypotonic state; patellar reflexes absent. Argyll-Robertson pupil present. The gait is that of typical tabes; speech is rather slow. Examination of the fundi of the eyes showed negative results. There is no nystagmus and hearing is normal. There is marked ataxia in the upper extremities; no disturbance of sensation, sphincters normal. The intelligence of the child is absolutely intact. Noguchi's modification of Wassermann's reaction of the blood is positive. The child is unable to walk or stand without being supported; deep muscular sense is gone; otherwise, he is doing very well.

2. **Treatment of Cholera.**—Feeling convinced that a careful study of the changes in the blood would yield valuable indications for treatment, Rogers has carried out a long series of researches on these lines, especially during the past three years. The first result was the reduction of the death-rate to barely one-half by the use of hypertonic saline intravenous injections in the collapse stage, and blood-pressure-raising measures as a preventative of later uremia. From 1895 to 1905, the death-rate was 59 per cent. In 1906, when normal salines were used intravenously, it fell slightly to 51 per cent., but on these being given up once more in 1907, as of little use, it rose again to 59.5 per cent. The hypertonic solutions were commenced early in 1908, and during two years' observations the mortality among 294 cases was only 32.6 per cent., or but little more than one-half the previous rate, thus affording conclusive evidence of the great life-saving value of the new method. However, an effectual cure of cholera is most likely to result from some simple method of destroying or rendering harmless the toxins within the bowel itself, thus preventing their absorption in fatal doses. Rogers therefore set to work to find such an agent of a non-poisonous nature, and this agent he believes to be permanganate salts. The permanganates are given in two different ways. First, in solution, to drink *ad libitum* in the place of water. Beginning with from one-half to one grain to the

pint, on account of the unpleasant astringent taste, the strength is rapidly increased up to from 4 to 6 grains in 1 pint, or even stronger if the patient will swallow it. Fortunately, in severe cases the thirst is so great that no difficulty is usually experienced in pushing the drug in this way. Vomiting may occur, but does no harm. On the contrary, it probably helps to remove some toxin. Calcium permanganate is the best salt for this purpose, Rogers believes, being somewhat less astringent than the potassium salt, while as it is divalent it will exert a greater oxidizing action. The calcium element may also possibly lessen the effusion through the bowel wall. The other method of administration is in pill form, for which purpose the potassium salt is more easily dispensed on account of the hygroscopic properties of the calcium and sodium compounds. The simplest method is to mix two grains of potassium permanganate with a little kaolin powder and vaselin, and make as small a pill as possible. It is then coated so as to dissolve only on reaching the alkaline small intestine, where its action is wanted. It is important to see that the pills dissolve readily as they sometimes become hard and inefficient after being kept some time, and may then pass through the bowel unchanged. Rogers now gives one pill every quarter of an hour for the first two hours, and then every half-hour until the stools are colored green and become less copious, which usually occurs in about twelve hours. In mild cases they need only be given during alternate four-hour periods. Barley water may also be administered to maintain the strength, as it is not readily acted on by the permanganates. At the beginning of the second day eight more pills are given, and in severe cases this is repeated on the third day in order to avoid relapses, which have occurred in three cases. They all promptly yielded to a renewal of the permanganate treatment, however, thus furnishing an additional reason for believing its action to be directly curative. The internal administration of permanganates in cholera for the purpose of destroying the specific toxins within the alimentary tract was commenced by Rogers in August, 1909. By the end of the year 17 cases, including 10 severe attacks requiring transfusion, had been treated, with only 1 death.

4. **Diagnosis and Treatment of Syphilis.**—For a thorough mercurialization, Feibes is of the opinion that the method of "Schmierkur" (rubbings) is the most efficient; with no other treatment, he says, can we so thoroughly regulate the admission of mercury; we can stop it at a moment's notice, and easily prevent the discomforts and dangers of acute mercurial poisoning. If for any reason the "Schmierkur" is inapplicable, injections of calomel may be recommended as being of equal value; their disadvantages are the painfulness, the risk of abscesses, and their dangers in cases of idiosyncrasy. They are undoubtedly of great efficacy, especially as regards producing an effect quickly.

5. **Pityriasis Rubra Pilaris.**—Sixteen years ago, after commencing work as a lithographic stone polisher, the palms of the patient's hands became red and thickened. Recently, follicular papules appeared on the proximal phalanges of the fingers of both hands, later on the middle phalanges of the third and fourth fingers, and subsequently on the back of the hands, affecting in the main the skin over the first, second and fifth metacarpal bones. Later, the fronts of the wrists, the outer aspects of the forearms, and the backs of the elbows became affected. On examination, in addition to the lesions already mentioned, isolated follicular papules were seen on the lower abdomen. Large horny, dark gray follicular papules were conspicuous over the dorsal convexity of the spine, extending laterally. In the summit of the intergluteal fold—namely, over the sacrum—the papules were closely aggregated, presenting a somewhat verrucose appearance, and a similar condition was present over both ischial tuberosities. The knees were similarly but not so markedly affected, and there were some hyperkeratoses where the boot is laced. The soles were erythematous, the neighborhood of the heels was markedly hyperkeratotic, as was also the center of the right sole. The forehead was slightly erythematous, but no scaling was observed. The upper half of the bridge of the nose showed telangiectases. A few comedones were present on

the face, and also on the back of the neck. The scalp was scaly but not markedly so. The affected areas of the hands, fingers, intergluteal fold, and ischial tuberosities were slightly but definitely erythematous, and there was a suspicion of erythema on the mid-dorsal region of the trunk. The erythema appeared to begin perifollicularly and spread laterally until neighboring specific centers of origin coalesced into one continued patch. The finger nails were longitudinally striated. The papules throughout are distinctly follicular and contain a central horny cone. According to the patient's story, the first evidence of the disease was on the palms after commencing work as a lithographic stone polisher. Tomkinson suggests that these clinical signs doubtless point to pressure as a determining or accessory agent in the development at least of some of the lesions in this and, perhaps, on closer observation, in other cases, but nothing more, otherwise pityriasis rubra pilaris could be by no means a rare affection. Doubtless the actual cause must be sought for internally.

16. **Cutaneous Diphtheria.**—Of the 10 recent cases Dawson has seen 4, and in 9 of them there was no membrane or other usual manifestation of diphtheria. All but 2 of these cases occurred in children; 4 of them ended fatally, 7 of them were of an impetiginous eczematous type, and in 3 of them there were vesicles and bullæ which gave rise to a profuse discharge. In 4 there was severe conjunctivitis, with copious serous and purulent discharge. The commonest and therefore most typical form occurs in children, and has the appearance of an impetiginous eczema, nearly always affecting the head and face, and associated with severe conjunctivitis, sometimes with otorrhea and rhinitis, the whole forming a clinical entity from which a diagnosis may be deducted with some degree of confidence.

18. **Treatment of Roentgen-Ray Burns.**—The chief object of Eddowes' paper is to call attention to an operation which he has introduced for the relief of bad cases in which painful ulceration has occurred and proved rebellious to ordinary treatment. Slight cases can be easily managed by the application of fomentations, lotions, and pastes of various kinds, and Unna's zinc-gelatin. For some of the chronic cases, particularly those commonly involving the backs of the hands in x-ray workers, he has found few remedies to equal compound tincture of benzoin. In severe cases in which there is pain, rigidity and ulceration, it sometimes happens that the ulcers heal but slowly, if they heal at all; and, if healed, easily break down again. In these cases Eddowes resorts to nerve section. He says that not only do incisions relieve pain and tension, and cure the ulcers, but they also, by bringing in extra new tissue, increase the mobility of the parts.

20. **Tuberculosis in India.**—Roberts attempts to show that tuberculosis manifests itself in India rather differently than in Europe, not at all in the tuberculous lesions of organs but in the beginning of the disease, and that it adds another prolonged fever to the many fevers encountered in that country. There are three forms in which early tuberculosis shows itself. They differ, curiously enough, and for some unexplainable reason, from the early signs seen here in Europe: (1) An acute febrile form resembling a typical typhoid, which Roberts calls "acute tuberculous fever," and encountered principally in young adults; (2) an irregular fever with enlargement of the cervical glands, the carotid chain, and those under the jaw, and seen principally among children; (3) a debility associated with dyspepsia and constipation, resembling tropical debility. Even here the thermometer shows afternoon or evening rises to about 100 F., very easily overlooked.

28. **Clinical Surgery in Japan.**—The number of patients operated on by Takaki for hemorrhoids by the Whitehead method is 176—124 males and 52 females. They were all treated by the same method and completely cured, except in 7 cases—3 cases of stricture, 2 cases of ulcer on the mucous membrane, 1 case of paralysis of the sphincter, and 1 case of pulmonary embolism. Of 3 cases with stricture 2 were patients in the Charity Hospital. They left the hospital a few days after operation and did not return to the hospital for some time. So the stricture was due to the early discharge and their carelessness. The other case was due to the early opening of the bowels before the wound had had time to unite properly. Two cases of ulcer were due to leaving the mucous membrane too long, so that after the wound healed a portion of mucous membrane appeared outside the anus and the ulcer was formed by the rubbing of the trousers. This could have been prevented by removing the mucous membrane at the time of operation. One patient complained of the inability to retain the feces, especially when suffering from diarrhea. This patient had had prolapse of the rectum for 8 years and even before the operation he was unable to retain the feces. So Takaki does not consider this patient to have been paralyzed by the operation. Three of these operations were done under local anesthesia. Of course, it was more difficult owing to the rigidity of the sphincter, but it can be done without much pain. In one case of prolapse it was fairly easy.

Takaki treated 7 cases of carcinoma with thymus gland. For making the powder he used the fresh calf's thymus gland. It was dried under low temperature and ground into powder. It was given by the mouth and the doses were from 0.01 to 0.05 gram twice a day between meals. After a few trials it was Takaki's habit to give sodium sulphate combined with it. He says that it is wonderful how the pain disappears. The thymus powder seems to have some power of disintegrating the tissues of the malignant tumor by suppuration or necrotic changes. The size of the tumor was in one case diminished, and in two cases became smaller by disintegration. It seemed to retard the growth of the tumor. It has more effect on carcinoma than on sarcoma. Ludigestion is liable to occur.

32. **Pneumonia.**—It is McKechnie's practice to give morphin in the early stages of pneumonia if there is pain preventing sleep, or if there is much restlessness, or if the amplitude of the respiration appears to be sufficiently diminished to cause an accumulation of carbon dioxide. The diminution in amplitude of respiration is no doubt a protective process which gives rest to the inflamed lung. On the one hand, he says, we have the diseased lung for which rest and repair is the best thing; on the other hand, we have the patient, the owner of the lung, to whom a certain continued respiratory activity is essential. The physician must try to hold a judicious balance between these more or less temporarily conflicting interests, always remembering that he must ease the amount of physiologic work the lungs have to do as much as possible, and at the same time enable the patient to live over the crisis. The first dose of morphin McKechnie gives is usually 0.008 gm., and, he says, one seldom needs to give more than 0.016 gm. He invariably gives morphin hypodermically; as he considers this to be the only sound and safe way, as the effect of the dose becomes apparent in a few minutes and there is no danger of unabsorbed doses causing unexpected poisoning.

During the last ten years he has given morphin to between 200 and 300 adults suffering with acute lobar pneumonia, usually giving it during the first three days of the attack, most frequently on the evening of the first or second day. Out of all these cases he can not recollect a single instance in which there appeared to be any harmful effect. On the contrary, the benefits have usually been marked. The breathing becomes easier, the pain is relieved, the circulation improved, and the patient gets some of that rest and sleep which is such an important element in conserving the energy and in

diminishing the manufacture of carbon dioxide. The use of ice, hot compresses, poultices, etc., may be dispensed with, and the patient need no longer battle with a gigantic poultice on his already overtaxed and overheated chest; morphin relieves the pain and gives sleep far more efficiently. McKechnie's experience causes him to doubt the soundness of those warnings against the use of morphin which are indulged in at present. It seems to him probable that the fear of using morphin has been based on some unfortunate results, possibly really unconnected with its administration, perhaps due to its employment in an injudicious way, as, for instance, by oral administration.

33. **Radical Cure of Hemorrhoids.**—After proper preparation for the operation, about one minute is spent in placing four of Lane's artery forceps to the four cardinal points of the anal circle; these, irrespective of rugosities, are applied exactly at the junction of the mucous membrane and the skin. The forceps, say, on the north and east are seized, the intervening portion is rendered taut, and with a good scissors the mucodermal line is rapidly divided; the same process is repeated with the remaining three segments, and thus the circular dissection is effected. The depth of this primary cut includes skin and some subcutaneous tissue. In the next stage the left index finger is introduced into the anal canal to act as a guide, and the tissues are snipped carefully with scissors—right round and straight down to the submucosa; as the external sphincter comes into view it is pushed upward with a blunt dissector. This process of defining the submucosa and pushing the sphincter up out of harm's way must be carried out thoroughly all round, and on no account must any advance be made until the adit level is struck—the submucous coat. During this process of freeing the mucous cuff it is necessary to apply six or eight pressure forceps to the cut edge of the mucous membrane for traction purposes; the latter, by the way, must be done gently, for the forceps are liable to slip off or tear their way out. The cuff having been freed up to the transverse fold of the mucous membrane which indicates the site of the internal sphincter, a vertical slit is made in the former up to this point, and immediately the apex is sutured to the skin, a series of small transverse snips are then made through it at this level, and sutures applied. If any vessel spurts it is seized and ligated. When concluded the area of sutured circle ought not to exceed the size of a half dollar, unless there has been considerable previous prolapse. A morphin suppository is inserted, the part is thoroughly cleaned and dried, and a dry gauze sponge is applied and is kept in position by a pad of wool and a T-bandage. On the third evening 5 grains of calomel are given, followed by a tablespoonful of oil on the fourth morning. As often as the bowels act the dresser cleanses and dries the part, and reapplies dry gauze dressing. On the tenth day the patient is allowed out of bed and is discharged a few days later with a pot of carbolyzed petroleum, which he is instructed to apply into the rectum three times a week for a month.

42 Iodoform and Thyroidism. A. R. Short.

42. **Iodoform and Thyroidism.**—A middle-aged woman was treated for a carbuncle in the perineum, which was dressed by a medical practitioner and a nurse with very ordinary quantities of iodoform. During three weeks, about half an ounce of the powder was dusted on, and altogether about 40 inches of narrow iodoform gauze packing were used. The carbuncle healed well under this dressing. For weeks after the cessation of treatment she continually complained that she could smell and taste iodoform, though there was in reality none in the house. She went to the South of England to reconquer her strength three or four weeks later, and stayed ten days. On her return she was noticeably ill; there was great emaciation, she was nearly 28 pounds below her normal

weight, the pulse was always 120 or more, the thyroid was moderately enlarged, tremor was marked, and she was exceedingly nervous and restless. Short considered it a case of exophthalmic goiter. The onset of the present illness was in January, 1909. There has been very slow but decided improvement, and now, April 1910, she is almost well, but has to lead a very quiet life.

Short connects this case with the use of iodoform because the trouble followed soon after the application of the drug, although it was not diagnosed for about a month. She undoubtedly suffered from iodoform poisoning, because the smell haunted her long after the drug was omitted. Iodoform is proved to cause hyperthyroidism of the acute type, and it is therefore reasonable to suppose that in a susceptible person chronic thyroidism might be produced. Iodoform should be used sparingly on absorbing surfaces, especially in adults. It should be avoided if there is any reason to suspect a tendency to exophthalmic goiter. The treatment of early cases of parenchymatous goiter should be directed to altering the drinking water and to introducing iodine. It would appear, since iodoform causes thyroidism more readily than iodids, that iodine ought to be given to such patients in organic combination. In the treatment of exophthalmic goiter, iodine starvation should be worth a trial. This could be effected by a meat diet.

51 Effect of Ipecacuanha on the Leukocyte Curve in Amebic Hepatitis. E. D. W. Greig.

52 Report for 1909 of Medical College Hospital, Calcutta. F. J. Drury.

47. **Ipecacuanha Treatment of Acute Hepatitis.**—The treatment of the acute hepatitis preceding the formation of liver abscess is described by Pilgrim as follows: When not associated with loose stools and the bowels are inclined to be costive, a mild mercurial purge is first given; otherwise the ipecacuanha treatment is begun on the evening of admission or diagnosis of the disease. It is necessary that the patient should have nothing to eat or drink for at least two hours before or after the giving of ipecacuanha. Twenty minutes before taking the ipecacuanha, Pilgrim gives 20 grains of chloral, and then in average cases he gives 25 grains of ipecacuanha. In severe cases in which the full influence of the drug is immediately required, he gives 30 grains for the first 3 or 4 nights, after that reducing it to 25 and 20 grains gradually. He has occasionally given 40 grains, but he believes that this is seldom necessary, and the cases treated by him have responded very favorably to 30-grain doses and less. As a rule he finds one dose daily suffices, but in severe cases he does not hesitate to give it night and morning, and also in cases not apparently severe, but in which the leukocytosis does not rapidly reduce. The ipecacuanha is given in keratine capsules, 5 grains in each; given in capsules both the nausea and vomiting are greatly reduced. Many patients do not vomit at all, but only suffer for a short time from nausea, while some few are absolutely free from any unpleasant or abnormal sensation; it is all a question of whether the capsule breaks or comes undone before it has passed through the pylorus. After swallowing the ipecac, the patient is enjoined to lie absolutely still in bed, when under the influence of chloral, he usually soon drops to sleep, and if he wakes up 2 or 3 hours later, feeling uncomfortable, the drug will at all events have largely exerted its influence. Pilgrim thinks it a mistake to put on mustard plasters or other local applications to the stomach, which only attract attention to that

organ and interfere with the drowsy feeling which begins to steal over the patient ending soon in sleep. The daily dose of ipecac. is continued till the leukocytosis falls to 10,000 or less, and the temperature has become normal, and the pain or discomfort in the region of the liver has gone, this latter being among the first symptoms that disappear under this treatment. Then the ipecac. is continued for another week in daily doses of 20 grains, for by this time even in cases in which the drug has proved obnoxious, toleration is usually established, and the patient seeing the result obtained is seldom refractory. Other important accessories, such as diet and rest are very carefully arranged for. At the end of about two weeks such patients are allowed up, and after a few days are sent away cured for a change, and urgently advised never to touch alcohol in any form, no matter how moderately, so long as they have to reside in India.

54 *Diabetes in Children. P. Maurel.

55 *Radiotherapy of Suppurating and Fistulous Glands. F. Barjon.

54. **Diabetes in Children.**—Maurel found that the diabetes in his child patients generally assumed the form of the severe pancreatic diabetes of adults. He thinks that children will be found to have diabetes much more commonly than is generally supposed if it is sought for more systematically. The disease usually develops insidiously until the rapid falling off in weight, the polydipsia and polyuria attract attention. Arrived at this stage, the disease runs a rapidly fatal course as a rule; the younger the child the more rapid the course. Infants with this disease should be given a teaspoonful of Vichy water with each meal; older children should be dieted like adult diabetics—measuring the amount of urine every day and weighing the child every three or four days, limiting him to milk in case of accidents, in other respects following the principles of treatment of adults, with possibly a course of saline and arsenical mineral waters.

55. **Radiotherapy of Glandular Lesions.**—Barjon found that radiotherapy gave good results in treatment of inflammatory glandular lesions, and he has recently been applying it in suppurative processes in glands and their complications, and the results have surpassed his anticipations. He describes his experiences with 56 patients. With closed lesions a minute puncture followed by radiotherapy gave perfect cosmetic results. Radiotherapy is most effectual, he states, after the suppuration has ceased under the influence of repeated punctures. If the suppurative process has opened a way outward the cosmetic results naturally are not so good, but even then they surpass those obtained by other measures. In one case suppurating glands in the inguinal region had been removed some time before but the wounds had not healed and they suppurated anew, until there were six large ulcerations extending down on the thigh and around on the buttocks and showing no tendency to heal. Four days after the first application of radiotherapy a turn for the better was apparent, and after the sixth sitting, in as many weeks, healing was complete, the new skin being thin and supple.

60 *Absence of Pause between Expiration and Inspiration. (La respiration continue.) R. Pla y Armengol.

57. **Prophylaxis of Compressed-Air Disease.**—Langlois discusses the bases for international regulation, remarking that the French law may serve as a model. One of the provisions

of this law insists on safeguards for workmen coming out of the compressed-air chamber so that if they should become dizzy there is no chance for a dangerous fall. The public authorities also post in the pay office a placard warning the workmen that it is imprudent to stay for more than 8 out of the 24 hours in air at a pressure of 2 kg. (8.8 pounds); 7 hours, of 2.5; 6 hours, of 3; 5 hours, of 3 or 3.5, and 4 hours, of 3.5 and 4. The law further insists on ventilation to insure that the proportion of carbon dioxide does not surpass 1 per thousand.

60. Continuous Respiration.—Play Armengol has encountered this peculiarity of the respiration only in patients with tuberculous infiltration of the lungs during the first stage of infection. There is no pause between expiration and inspiration; they follow close on each other so that respiration is continuous.

66. Treatment of Tuberculous Hip-Joint Disease.—Neuber advocates earlier application of operative measures, before extensive caries has developed and in all cases when caries is under way if the general health permits and severe lesions of internal organs are not evident. He gives an illustrated description of the technic which he has found gives best results in his experience at Kiel. The ultimate favorable position of the joint depends mostly on the energy, perseverance and care of the patient, himself, after the operation, and Neuber keeps him under supervision for several years to encourage and influence him in this direction. Neuber seeks to avoid the use of complicated walking apparatus as it prevents the functional strengthening of the muscles which is such an important factor in the final outcome. He incises from the front, severing the sartorius and rectus femoris, which permits ample access to the joint and inguinal glands and revision of the wound without moving the patient. The final result is that the patient can sit comfortably, move his limb actively sideways, bend it and twist it a little; the shortening is counteracted by the dropping of the pelvis. The gait with a cane is approximately normal; without it there is a slight limp.

68. Ileocecal Tuberculosis.—The great difficulty in treatment is that the affection is not differentiated until so late that extensive operations are necessary. Eschenbach has had 27 cases in his service, it being thus shown to be the most frequent of all tuberculous abdominal affections with the excep-

tion of peritonitis. Fourteen of the patients survived the operation and the first few months afterward, and with the exception of a tendency to hernia in a few the 11 patients recently examined were free from all disturbances. In 4 cases 3 and 4 years have elapsed since and the patients are in the best of health although the operation was very extensive.

69. Puncture of the Brain and Lumbar Puncture for Intracranial Hemorrhage.—In the case reported by Hesse the patient was still unconscious two hours after a fall on the head; breathing was stertorous, pulse 64, and a small hematoma was evident in the right orbit and temple. Within the next half hour the pulse dropped to 48 and the patient seemed moribund. A Neisser-Pollack puncture was then made back of the right Krönlein point and 8 or 10 c.c. of black blood released. The breathing ceased to be stertorous at once and the pulse increased to 68; the condition improved rapidly to such an extent that osteoplastic trephining became possible; 35 c.c. of blood were evacuated from the hematoma, and recovery was soon complete. Punctures in another case revealed multiple hematomas, the patient improving wonderfully while 70 c.c. of fluid was being evacuated from the right posterior Krönlein point, opening his eyes and asking questions during the operation. This was the third puncture.

72. The Balance Sheet to Date of Spinal Anesthesia.—Hohmeier and König have examined the records of 2,400 cases in which spinal anesthesia was applied in 41 well-known institutions, and they state that the idea that this is a harmless procedure will have to be abandoned. There are 12 fatalities for which it seems to have been directly responsible. The list includes 4 cases of death from paralysis of the respiration center; in 7 of the fatal cases the patients were over 70, but one patient was only 32. In rather a large proportion of cases the patients years after seem to suffer to an unusual extent from paresthesias, neuralgia, weakness, headache or vertigo, suggesting possibly a tardy effect of the spinal anesthesia. They urge physicians and surgeons to re-examine now anew patients to whom the spinal anesthesia technic was applied at any time. This may reveal an unexpectedly large number of cases of late injuries of the central nervous system from the spinal anesthesia years before. Their conclusions are that the method should be reserved for the exceptional cases.

- 86 The Problems and Achievements of Recent Research in Zoology. O. Kuttner.

78. Explanation of Action of Oatmeal in Diabetes. Klotz has found, he states, that wheat flour becomes transformed to sugar and the transformation stops there, while oatmeal is transformed a step further and is assimilated as an aglyco-genic, anhepatic carbohydrate, and has thus an antiaetoneuric action.

85. Early Symptoms of Tetanus.—Evler bases his study of the early symptoms of tetanus and the effects of serotherapy on thirteen cases, one in his own person. The feature of the early symptoms, he states, is that they appear transiently and are slight at first. Sometimes there are only traces of symptoms which the patient does not think of connecting with his often slight and rapidly healing lesion. A day or so after the infection there may be restlessness, sleeplessness, distressing dreams, difficulty in urination and more frequent impulses, oppression in the chest, violent headache, drawn features.

no-bleed, sweating, fatigue, excessive yawning, vertigo, darting pains at various points and chilliness. Sometimes the local disturbances are more prominent; swelling of the injured limb, notwithstanding the limb is raised, is suspicious of tetanus; it feels hot but is not red, and the local arterial pressure is unduly high. There may be occasional local pains and in a day or so the lymph cords show red and the region is very tender. Single groups of muscles may be tonically contracted and cannot be voluntarily relaxed; the contraction at first causes no pain but merely hinders moving the limb a little. Contracture and tremor may be observed in the injured limb, sometimes clonic twitching, but they are not painful and do not attract the patient's attention; more and more muscles gradually become involved and fibrillary movements may be evident at times. If the wound is on the hand, on grasping the forearm twitchings in the different flexor tendons may be felt, and the fingers tremble and twitch. One of the first signs, the third day, is a persisting pain after the involuntary contractions of the muscles induced by effort; nothing is to be seen at the spot at first but later the muscles contract to form a painful lump which disappears after a time but returns anew if the part is touched again. The lymph glands were swollen in several of his cases, the inguinal glands in some resembling the findings with syphilis. In one case the ulnar gland was so swollen and painful that it was excised under local anesthesia. Vertigo is an especially important early sign; it is often so severe that this is what first brings the patient to the physician. Ocular symptoms are also important, and there may be a spasmodic cough. The pulse is generally tense, slow and full. The hearing at first may be unusually acute but later there is more or less deafness. Speech is slow, probably from disturbances in the cortex and tongue. The benefits of serotherapy are apparent from the detailed history of his patients and of his own case. He was infected in operating on one of the patients and early symptoms developed within 24 hours, but he continued his practice for 9 days notwithstanding he presented nearly all the symptoms enumerated above. Serotherapy was commenced on the fifth day. Nutrient enemas became necessary on the seventeenth and the following day but by the nineteenth day the teeth could be opened a little and recovery then progressed although insomnia and headache persisted for some time and the gait was stumbling for weeks. Chilliness and occasional sharp pains were noted for months with muscular twitchings. Two of the 12 patients died. In one of the fatal cases no portal of entry for the germs could be discovered.

88 *Public Hygiene and Infectious Diseases. W. Kolle.

88. **Public Hygiene and Infectious Diseases.**—Kolle's historical and critical review of this subject concludes with the remark that the infectious diseases have nothing to do with the evolution of the species by survival of the fittest, as those best equipped for the struggle for existence, both physically and mentally, are the very ones who are carried off by the infectious diseases. The aim should be, he reiterates, to impress on every citizen, high and low alike, the duty of being healthy as a patriotic duty he owes his country. Prophylactic hygiene, he added, is not merely an index of the degree of external civilization to which a state has attained, it is also an index of the internal culture, and nothing can compare with it as a factor for culture in general. He delivered the address at the recent dedication of the Institute for Infectious Diseases at Berne.

89. **Cosmetics.**—Paschki urges physicians to pay greater attention to the correction of minor disfigurements and advising patients how to attain the aspect of well-groomed health. He states that he was the first, years ago, to urge physicians to study this branch of medicine from the scientific and active standpoint instead of leaving it to manicurists, masseurs, hairdressers and quacks. Much of this belongs to the dermatologist and internist, and for practitioners to treat the whole subject of "beauty doctoring" as beneath their dignity he regards as a great mistake for a number of reasons.

94. **Differential Diagnosis of Multiple Sclerosis and Compression of the Spinal Cord.**—Nonne gives the details of six cases to show that it is sometimes impossible to differentiate these conditions during life. One of his cases was remarkable in that the supposed tumor compressing the spinal cord was not found at the exploratory laminectomy which, however, was followed by subsidence of all the symptoms and during the five years since the young man, a gardener, has been in good health. The atypical forms of multiple sclerosis, and the atypical course of tumors compressing the cord explain the difficulties encountered.

104. **Gout in the Eyes.**—Krückmann states that he has encountered six cases in which attacks of gout occurred in the eyes. The acute pain came on suddenly during the night; the conjunctiva and eyelids became swollen, red and angry with extremely severe sharp pain, aggravated by the slightest touch or movement of the head. In some cases the disproportion was striking between the insignificant changes in the interior of the eye and the intensity of the external symptoms. Notwithstanding the stormy onset, the whole attack passes over, leaving scarcely a trace; even functional disturbances are rare afterward. Opacity of the vitreous body occurs and persists only when there are pre-existing

changes in the eye and the gout attack is particularly severe. In the first three of his cases the attack in a single eye was the first manifestation of the constitutional gout, and its true nature was not confirmed by other manifestations of the gout until several months later when a typical attack in the great toe cleared up the diagnosis. One such patient still has an occasional attack of gout but the eyes have never been affected since. The prompt improvement under colchicum is another argument in favor of the gouty nature of the attacks in all the cases. It is possible, he remarks, that many forms of headache are due to an attack of gout involving the dura mater just as the sclerotic was involved in his cases. In one of his patients the attack developed the third night after an operation for cataract and was exceptionally severe while complete restoration followed. This suggests an explanation for many postoperative eye disturbances, such as iridocyclitis, which subside without leaving a trace. In another case a traumatic iritis was evidently the seat of a typical attack of gout for which it provided a predisposition. In one case the gout seemed to be due to deposits of lime rather than of urates; the patient had ankylosis of the vertebrae and of some of the joints and radioscopy showed deposits of lime in one foot.

105. Crowding Out of Bromids by Chlorids in the Tissues.—The research reported seems to confirm the fact that the bromids are crowded out of the tissues by the chlorids. Retention of salt from insufficiency of the kidneys may affect the utilization of bromids, as also the changes from an intercurrent disease. In treatment it is important to know whether deficiency of salt or the specific action of the bromids is the main factor in the effect of treatment or in the intoxication.

106. Local Immunization of the Portals of Entry for Infections.—Lippmann's research seems to open further horizons for effectual immunization, the results indicating that it is possible to develop a local immunity in the mucosa lining of the alimentary canal so that it will be immune to infection by this route. This was realized in his experiments even when the animals were as susceptible as the controls to infection by other routes. The effect is like that observed with the colon bacillus; this causes no disturbances in the alimentary canal, but brought in contact with the bladder mucosa, it is liable to set up at once a lively cystitis. He experimented with 77 mice and with botulin toxin, introduced into the stomach of the mouse through a ureter catheter, the tip being first softened in the Bunsen flame to prevent injury as it was introduced through the cardia. In the few cases in which the mucosa was injured, the toxin acted as if given by the subcutaneous route, the mice all dying within 24 hours. The mice were immunized with 13 doses of the toxin, given at five-day intervals, the amounts ranging from 0.03 to 0.16 gm. After this the animals bore without injury ingestion of a dose of 0.5 gm. of the toxin while 0.000025 gm. by the subcutaneous route proved promptly fatal. The facts observed throw light on the experiences with immunization against typhoid, cholera and anthrax. Notwithstanding a general immunity realized from the immunization procedures, evidenced by the attenuation of the disease in the vaccinated, the intestinal mucosa seems to be as susceptible in them as in the non-immunized.

Among the 424 soldiers contracting typhoid in the African troops in 1905 were 100 who had been vaccinated against typhoid, but the disease ran an exceptionally mild course in them. On the other hand, Lippmann continues, an attack of typhoid modifies the intestinal mucosa in such a way that the individuals thereafter can ingest highly virulent typhoid germs without contracting the disease. When the cells have once learned to make antibodies, they react afterward to the slightest specific stimulus in this line, and even to the non-specific, with vigorous production of antibodies. A person immunized against typhoid, dysentery or cholera would probably react to either of these germs with antibody production which would render the germs harmless even if they lingered in the intestinal tract as in healthy bacillus-carriers. It may be possible, he adds, that this same principle of artificial local immunization might be applied to prevent further spread of an infectious process already installed.

Leber has succeeded in curing an experimental serpiginous ulcer by subconjunctival injection of pneumococci aggressins, while the process in the other, untreated eye showed no tendency to heal. There are also clinical experiences on record demonstrating a curative influence on furunculosis and impetigo contagiosa and colon inflammation of the bladder from local applications of the antigens.

113. Recurrence of Uterine Carcinoma After Five Years.—Semon insists that women who have been operated on for uterine cancer should be kept under supervision even longer than 5 years as he has observed recurrence later than this. In one case the woman of 53 returned for examination as ordered for 6 years after vaginal hysterectomy for carcinoma of the cervix. All was found in good order at these regular examinations but 4 years later there were pains in the pelvis and leucorrhœa, and finally a little blood escaped from the vagina. Examination two days later showed extensive hard infiltration around the vagina and a polypous growth in the depths of the vagina which proved carcinomatous. In another case the recurrence developed 5 years after total vaginal hysterectomy. The operation was done on account of a hemorrhagic myoma, but when the uterus was examined afterward a small carcinoma was found in the body of the organ, concealed entirely by the myoma close to it. He has found very few cases on record of recurrence of carcinoma of the body of the uterus; in his case the recurrence had the aspect of inoculation of the scar in the vagina, and yet the external os had been sutured together when the uterus was being removed. This case warns anew of the possibility of coincidence of carcinoma of the body of the uterus with submucous myoma; it may escape discovery even with careful palpation and microscopic examination of scrapings. If the operation consists merely of myomectomy, the interior of the uterus should be examined again carefully afterward for traces of cancer.

119. Present Status of Management of Placenta Prævia.—Gussakov concludes from a comparative study of the recent literature on this subject and his own experience with 25 cases of total, and 112 of partial placenta prævia, that everything tending to induce contraction of the uterus should be avoided if the membranes are still intact. He also believes that tamponing is not effectual in arresting hemorrhage while it invites infection. Puncturing the membranes frequently checks the hemorrhage with partial placenta prævia; if this does not succeed, he advises introducing the inflatable bag inside the membranes. This latter procedure is gentler and he believes that it guarantees better the birth of a living child than does the Braxton-Hicks version. With total placenta prævia, he advises boring through the placenta rather than attempting to separate it. Cure is necessary to prevent air embolism; no negative pressure must be permitted in the abdominal-pelvic vessels and the air in the birth canal must not be exposed to any increased pressure. In all such statistics he urges listing separately the cases of partial and total placenta prævia and the mortality separate with each. In his 137 cases, 6 per cent. of the women with total and 1.7 per cent. of those with the partial died, and 50 per cent. of these 8 deaths were due to air embolism, 12.5 per cent to

infection, while only 37.5 per cent. succumbed to anemia. The prognosis with presenting total placenta praevia is very grave and Cesarean section is justified, he says, in case the woman wishes a living child at any price.

122. **Treatment of Uterine Retroflexion.**—Adler relates that at Schauta's clinic in Vienna no attempt is made to correct retroflexion unless it causes disturbances, and he states that displacement alone is not able to cause menstrual irregularity. Even during the first months of pregnancy the displacement is corrected only if it is impossible to keep the woman under control and if it is causing much disturbance. If the woman complains of trouble ascribable to the displacement, gentle attempts are made to correct it, avoiding instrumental aids, except a pessary if this is able to hold the uterus in its normal position. Schauta disapproves of pessaries except as a transient means of relief; if operative measures are necessary he gives the Doléris technic the preference. In case of fixed retrodisplacement he has frequently found that conservative measures put an end to the disturbances, leaving the displacement uncorrected. The patients return once a year or so for a few weeks of massage which frees them again from all disturbances for another long period.

126. **Operative Mobilization of Ankylosed Joints.**—Payr gives an illustrated description of the methods that have given him satisfactory results in 9 out of 30 cases of ankylosis of various joints. The main factors for success are precision in diagnosis, and in determining the indications, with technic improving with experience both in the operations and in the after-care. Especially instructive is his study of the cases in which the outcome of his measures was unsatisfactory.

127. **Streptococcus Sepsis and its Relation to Acute Articular Rheumatism.**—Steinert reports eleven cases of acute or chronic streptococcus sepsis, beginning with an insidious course or with sudden embolism of an artery in the Sylvian fossa or slight diarrhea, or the syndrome may suggest an old valvular defect. In other cases pains in the joints were the first symptom; in one case pain in one hip was the only sign of trouble for months, until finally a slight occasional rise in temperature was noted. In other cases there was a long period of vague general disturbances. The syndrome at first did not seem at all grave but death was the invariable outcome, from cardiac insufficiency or embolism or from cachexia. Various strains of streptococcus are able to induce this syndrome; the sepsis assumes an acute form as a rule, but in those who have had acute articular rheumatism at any time the sepsis develops in a milder, more chronic form. This suggests that acute articular rheumatism is a streptococcus disease and modifies the reaction to later streptococcus invasion. It also explains Litten's "chronic, malignant, rheumatic, non-septic form of endocarditis" as a specific, chronic, malignant sepsis and endocarditis lenta occurring probably only in those who have had acute rheumatism in the past. Four of Steinert's patients were young women and the

streptococcus sepsis ran an acute fatal course. Another patient was a robust man. A recent endocarditis was the principal feature of the syndrome in all, with severe ulceration in the eight cases that came to necropsy. (Schottmüller's description of endocarditis lenta was summarized in these columns, May 14, 1910, page 1658.)

128. **Testing the Functioning of the Heart Vagus.**—Hering first describes the action of the vagus on the heart in checking the frequency of the heart beat and conduction and rendering the contractions weaker. Then he reviews the various tests for estimating the energy of its action in one or all of these directions, commenting on the acceleration of the heart beat during a deep inspiration and the retarded heart beat during apnea, the Cermak test by pressure on the vagus and Delio's atropin test, and the interpretation and clinical importance of their findings.

132. **Improved Technic for the Leukocyte Count.**—Dünker describes a simple technic for determination of the eosinophils. The blood is mixed in the pipette in the proportion of 10 to 1 with a mixture of 10 parts each of acetone and of a 1 per cent. aqueous solution of eosin with distilled water to 100 parts. This keeps well and shows up the eosinophils prominently.

133. **Causal Relation of Syphilis to Idiocy.**—Brückner found 16 among the 216 idiots in the institution in his charge who presented stigmata of syphilis or a positive Wassermann reaction, and he thinks that there is probably a causal connection with syphilis in a still larger proportion. On the least suspicion of idiocy the general practitioner should apply the Wassermann test to the child and its parents. Better still would it be, he adds, to make compulsory the Wassermann test of the blood from the umbilical cord at birth. This would reveal the taint in time and would enable successful prophylaxis of abnormal conditions leading to idiocy later.

134. **Course and Outcome of Chronic Strumitis.**—Riedel has encountered 3 cases of chronic strumitis among 1,064 cases of benign goiter in which he has operated. One of the patients has been under observation for 15 years. Silatschek not long ago added another to the 7 previously on record, and his patient spontaneously recovered. This possibility of spontaneous retrogression may explain the rarity of the condition, in case conditions progress to threaten suffocation, excision of a wedge-shaped piece out of the isthmus is the most rational treatment and is generally followed by spontaneous retrogression of the rest of the thyroid. A typical case is given in detail; a young man with a subacute swelling of the thyroid, which was of stony hardness, was threatened with suffocation, but there was no fever. After wedge excision the rest of the gland gradually subsided to normal size and there have been no further disturbances. The microscope showed an accumulation of young connective tissue between the normal elements of the gland, crowding the latter out, and there was a mild endarteritis as with many chronic inflammatory processes.

136. **Resuscitation by Artificial Ventilation of the Air Passages.**—Kuhn hails Meltzer's work in intratracheal insufflation as a great advance; it supplements admirably, he declares, his own work along the line of intubation for inhalation anesthesia, resuscitation, etc. Practical resuscitation should include the use of oxygen or a bellows or large rubber bulb to pump in air. A peroral intubation two-way tube or two single tubes and a longer tube like a catheter should also be on hand. The life-saver should clear the mouth from water, mucus, etc., and then introduce the thinnest tube deep into the larynx, and permit oxygen to flow through it continuously until the arrival of the physician, aiding the ventilation of the lungs by rhythmic compression of the chest as by the ordinary measures for artificial respiration. If the physician is on the spot or when he arrives, he should introduce the two-way tube and continue the inflow of oxygen through the finer catheter tube passed through the other. Whether and when the peroral tube is indicated it is for the physician to determine; the finer tube alone may answer all purposes. If there is no oxygen on hand, a large rubber bulb may be

used to pump common air into the trachea with this same technic through the tube. The patient is benefited by these simple measures and obtains more air than by the use of the oxygen tank with a mask. The mechanical measures for respiration must be kept up continuously according to the usual technic. Kuhn believes that his spiral peroral two-current tube has the advantage over a catheter tube that it does not interfere with the outflow of air as the patient rouses and commences to breathe. He declares that oxygen has no advantage over good fresh air for resuscitation purposes, but the oxygen tank gives a more even and controllable flow. Too little attention hitherto has been paid to the necessity for prompt evacuation of the carbon dioxide in resuscitation of the apparently drowned and others. A two-current tube with air or oxygen forced into the larynx from a tank or ordinary air blown in by a bellows or by a large rubber bulb answers both requirements of introduction of air and escape of waste products. All that the life-saver need have on hand therefore is the two-way tube, the fine catheter tube and the oxygen tank or bellows or bulb.

137. Impressions of a Psychiatrist on a Trip Around the World.—Lilienstein describes his impressions of a trip from one insane asylum to another around the world. At the Cairo asylum, alcoholism could be incriminated in the etiology of only 6 among the 425 Mohammedan inmates, but pellagra was responsible for the psychosis in 65 and hasheesh intoxication for 72 among 572 cases. The smoking of hemp, *Camabis indica* or hasheesh, is the vice of the lower classes throughout the Orient and helps to fill the insane asylums. In Ceylon the asylum was more in the nature of a prison, as also in some of the older of the five asylums in Australia. The distances that have to be traversed sometimes to bring the insane to the asylums in Australia are so great that the acute psychoses, curable under other conditions, become confirmed and incurable during the long trip to the asylum. He speaks with admiration of the asylum at Sydney, which is managed on the most enlightened principles and where all the discharged are kept under constant supervision; they or their family or guardian have to sign a contract to return for medical inspection every week or fortnight; if they fail they are promptly fined or otherwise punished or the former patients have to return to the institution. Lilienstein regards this as a most admirable provision. At Singapore he saw a peculiar form of psychosis. Epidemic convulsions and retrograde amnesia are its main features; it affects mostly middle-aged women from a certain district. Hysteria and psychic infection may be excluded. The separate attacks last from one to three days. In China neither the state nor the community takes any heed of the sick and least of all of the insane, outside the sphere of the work of the missions. In Japan, the asylums and clinics resemble eastern European models; alcoholism is rare, as also opium and hemp smokers' psychoses. The constant tea drinking in Japan does not seem to lead to nervous disturbances. Lilienstein comments on the resemblance of the coolies to each other; it was impossible even for a trained neurologist like himself to tell them apart. [A traveler in California recently said that the coolie workers there are paid "a certain wage and find themselves, but they are all so exactly alike that the hardest part of their work must be for each to find himself."] Lilienstein remarks that one would expect a very exalted grade of asylum in America after leaving the Japanese institutions, but one is disappointed in that respect. They have no special features. He refers to the Bicêtre hospital at Paris as the most interesting collection, Queen's Hospital for Paralyzed and Epileptics at London as the best neurologic clinic, that is, where the most careful diagnoses are made and treatment individualized, but nowhere, he says, were conditions all around so satisfactory as in Germany.

Therapie der Gegenwart, Berlin

September, LI, No. 9, pp. 385-432

- 138 Principles of Psychotherapy. P. Dubois.
139 *Insufflation of Air in Treatment of Pleurisy with Effusion. (Behandlung der serösen Pleuritis mit Lufteinblasung.) J. H. Gesellschaft.
140 *Digitalis in Treatment of Spontaneous Epistaxis. (Entstehung des spontanen Nasenblutens und seine Behandlung mit Digitalis.) C. E. Focke

142 *Idem. (Ueber die Ehrlichsche Syphilitisbehandlung.) W. Fischer.
143 *Hot Baths in Whooping-Cough. (Heisse Bäder bei Keuchhusten.) T. Schrohe.

139. Insufflation of Air in Pleurisy with Effusion.—According to the experiences at the Groningen medical clinic, air is as effectual as oxygen or nitrogen for therapeutic injection into the pleural cavity unless it is necessary to apply protracted compression to the lung; in this case the less absorbable nitrogen is preferable. In pleurisy with effusion the main points are to introduce the drain so as to empty the pleural cavity completely, and to allow the air to take the place of the effusion as it is drained away, thus preventing any sudden changes in the mechanical conditions in the thorax. The relief is immediate and great; the air being so much lighter than the effusion or other fluid in the pleural cavity, the diaphragm is not so weighted down. Some think that the air may prevent further effusion by the compression it exerts on the vessels in the pleura, but it is more likely that as the air is gradually absorbed the resulting negative pressure in the chest favors absorption rather than effusion of fluids. The only objection to this method of treatment is the possible liability to eclampsia of the pleura; this may be induced by the mere introduction of the cannula and is as liable to follow introduction of a drain or exploratory puncture. Extreme care is necessary on this account with all these measures.

140. Digitalis to Arrest Tendency to Spontaneous Epistaxis.—Focke has given digitalis for this purpose in 84 cases and it proved successful except in a hemophiliae and in a woman given to excessive coffee drinking and tight lacing. In 75 per cent. of the patients the tendency to nosebleed was promptly and permanently arrested within 24 hours after taking the digitalis, even in a few cases in which the bleeding was due to some anatomic anomaly, correction of which later permanently arrested the tendency to epistaxis. He adds that digitalis formerly was a common remedy for a tendency to hemorrhages but it was abandoned towards the close of the last century for theoretical reasons which have since been shown to be erroneous.

141. Ehrlich's "606" in Syphilis.—Meidner has treated 34 patients with the "606" and reports the details of some of the cases. He found the remedy effectual in curing syphilitic lesions on the skin and mucosa; with internal lesions it proved as effectual as a prolonged mercury and iodid course. Tabes and paralysis were not materially influenced, the only trace of effect being on disturbances in the ocular muscles and on the ataxia.

142. Idem.—Fischer reviews the entire list of publications on the subject; nearly all have been reviewed in these columns as they have appeared. The recurrences that have been observed show that a definite cure is not realized by the drug. Fischer states that his conclusions as to its efficacy are that it ranks just above calomel, one injection of the "606" accomplishing what it takes two injections of calomel to accomplish. Certain patients refractory to calomel seem to be favorably influenced by the "606." On the other hand, he says, syphilitic affections of the nervous system, on which calomel has a favorable action, respond well to the "606" in some cases, while in others it seems to have no influence or an unfavorable one. Frequently, papulous early syphilides seemed to respond more favorably to calomel than to the "606." On the whole, he states, one may count on obtaining with two or three injections of calomel equally good results, occasionally even better and sometimes not so good. To this he adds that calomel in small doses is much less harmful for the nervous system than the new drug. No syphilologist would think of such a thing as submitting all his syphilitic patients, responding normally to mercury, to a course of calomel. He would reserve the calomel, and this is what Fischer advises for the "606," for the rare cases of syphilis in which mercury and iodid fail. Only critical testing of its value for years to come will finally determine its rank in therapeutics. Already the tendency is noticeable, he says, to

increase the dosage; and this, as well as repeating the doses, exposes to dangers which impose the greatest caution. Fiseber is assistant in the skin diseases service at the Virchow hospital at Berlin.

143. **Hot Baths in Whooping Cough.**—Schrohe has always witnessed great relief follow a hot bath given toward evening. The water should be about 99 F. and the child should stay in the bath for from 10 to 15 minutes, the head being kept cool with a cold water compress. The children sleep well after it, and the number and severity of the paroxysms seem much diminished. He has noticed that the skin of children with pertussis is pale and cool, indicating contraction of the vessels in the skin; the hot bath counteracts this, and thus relieves the internal organs, promotes elimination of toxins and soothes the nervous system and the tendency to the paroxysms.

152. **Hemorrhoid Clamps.**—Schaack's clamp forms a semi-circle when closed around the base of the hemorrhoids; two clamps are used, thus forming a complete circle around the previously dilated anus. The projecting tops of the hemorrhoids are then cut or burnt off, and a few sutures taken through the base under the clamps. The anus is then packed with gauze around a large drain; the clamps are removed and there is nothing left of the hemorrhoids except a linear wound encircling the anus. Not a drop of blood is lost with this technic, while the hemorrhoids are radically removed and the rectum is drained without danger of infecting the wound. As the cicatrix is outside the sphincter and sonnd mucosa extends inward from it, there is no danger of stricture later. The curving clamp is illustrated.

154 Technic for Draining the Abdominal Cavity. (Bauchhöhlen-drainage.) J. Fabricius.

153. **Actinomycotic Parametritis.**—Bondy reports a case of parametritis in an unmarried woman of 28, a factory worker. The actinomycosis involved the ovaries and tubes on both sides and encroached on the connective tissue in the pelvis. As the health continued to decline under weeks of ordinary conservative treatment, the adnexa were removed. The fever subsided at once but the cachexia was too far advanced and the patient soon succumbed. On account of the possibility of radical cure under appropriate iodid treatment in time, the discovery of extensive, very tough parametritis, especially when there is a tendency to perforation toward the abdominal walls, should warn of the necessity for bacteriologic examination of the pus and histologic examination of the granulation tissue which can generally be readily obtained from the abdominal walls. The prognosis depends on this being done in time so that proper treatment can be instituted.

RECENT PROGRESS IN THE MICROSCOPIC ANATOMY AND DIFFERENTIATION OF CANCER*

F. B. MALLORY, M.D.

From the Pathological Laboratory of The Boston City Hospital
BOSTON

Cancer is a clinical term applied to malignant epithelial new growths. From the pathologist's point of view it may be defined as an epithelial tumor which infiltrates, and which may give rise to metastases. To understand the full significance of this definition it is necessary to study in groups by themselves all the tumors which arise from each variety of normal epithelial cells and which tend to differentiate like them. Each group has peculiarities of its own.

The tendency is steadily increasing to place together and study in a group by themselves all the tumors built up from the multiplication of single type-cells which tend to differentiate in a similar manner. As example of type-cells may be mentioned the fibroblast, the smooth muscle cell, the neuroglia cell. It must be borne in mind, however, that two or more varieties of the same type-cell often exist normally. For example we have the ordinary smooth muscle cell of mesenchymal origin and a second variety occurring only around the coil and mammary glands and ducts, and generally believed to be of epithelial origin. Both varieties of cells tend to differentiate in the same way. In like manner we have cardiac and striated (skeletal) muscle cells of different origins, in which a like differentiation of the cytoplasm takes place.

In the past, tumors arising from the same type-cell have been grouped and discussed separately because of differences in arrangement of cells, rate of growth, and tendency to invade tissues and to give rise to metastases, as though the tumors thus arbitrarily separated had little or no relation to each other. Thus adenomas have been put in one class and carcinomas in another; in like manner angiomas and endotheliomas have usually been separated and discussed as having little or no relation to each other.

The newer method of classification recognizes that every simple tumor is due to the proliferation of one of the type-cells and that the blood-vessels and stroma are furnished by the surrounding and included tissues and are not themselves tumor-cells. The type-cell out of which the tumor is built is the one important element and gives the name to the tumor. Rate of growth, arrangement of cells, invasion of surrounding tissues,

formation of metastases, and retrograde changes are all features of secondary importance.

This method of studying and classifying tumors demands exact knowledge of the morphologic and chemical differentiation of the normal cells, both in their fully developed state, as found in the adult, and in their early developmental stages as seen in the embryo, so that the information obtained may be applied to the study of tumor-cells; because long-continued observation has demonstrated that tumor-cells tend to differentiate as the cells from which they arise would do under normal conditions.

The epithelial tumors form the largest and most important group of the simple tumors, and are on this account often put in a division by themselves in contrast with all the other simple tumors. They should be studied together, not separated on a clinical basis into two groups, the benign and malignant epithelial tumors. Studying them together enables us to determine what features are common to all epithelial tumors. Inasmuch, however, as there are many varieties of epithelial cells of various origin, we must divide this large group into as many subgroups as there are normal varieties of epithelial cells in order to ascertain what are the peculiar characteristics of each subgroup of epithelial tumors. This subdivision is already recognized to some extent and has led to valuable results, but should be carried out completely and thoroughly. Thus the tumors derived from the epithelial cells of the enamel organ, of the chorionic villi, and of the adrenal cortex are usually grouped by themselves. This method leads to a careful study of all the epithelial tumors arising from an epithelial organ or tissue. It leads also to a separation of those tumors of which the cells differentiate like the cells of the organ involved from those arising from included epithelial cells of other origin; for example, adrenal tumors in the kidney and liver. It demands full knowledge of embryologic development and of embryologic possibilities in the way of cell remains and displacements from which tumors may arise.

In a brief presentation, such as this necessarily is, I am able to discuss and illustrate only a few of the various groups of epithelial tumors and to call attention to certain interesting points brought out by this method of studying them.

The different epithelial tumors are derived from a heterogeneous variety of epithelial cells most of which are not very sharply characterized. Epithelial cells produce no intercellular substances, unless possibly epithelial fibrils and the so-called intercellular bridges should be so regarded. We are limited, therefore, to the differentiation of nucleus and cytoplasm and to certain chemical products for our power, to recognize the different varieties of epithelial cells. Owing to this limited differentiation of the normal cells it is easy to go astray when

* Read in the Section on Pathology and Physiology of the American Medical Association, at the Sixty-first Annual Session, held at St. Louis, June, 1910.

* EDITOR'S NOTE:—This article is part of a Symposium on Progress in the Problems of Cancer. The other articles and the discussion appear in this issue of THE JOURNAL.

the tumors derived from them are studied, because the differentiation of the cells in them is usually less than that of the normal cells. And yet the careful study of the differentiation of the different types of epithelial cells is unquestionably the key to the full understanding of this large and important group of tumors.

The properties of the different groups of epithelial tumors vary greatly. Those derived from certain cells uniformly invade the surrounding tissues and give rise to metastases, while others derived from a different type of cell grow expansively only and cause disturbance solely by pressure. From still other cells both types of tumors frequently arise.

Of the different groups of epithelial tumors, two which have already been thoroughly studied and which are usually classified under distinct headings, will be mentioned. Little or nothing apparently remains to be

Figure 1

Figure 2

Figure 3

Figs. 1, 2 and 3.—Cells of rodent ulcer, characterized by their cubical, cylindrical and spindle shape, their small amount of cytoplasm and their intimate relation to each other, frequently producing long fine and coarse fibrils running in the long axis of the cells. These cells do not differentiate like the cells of the surface epithelium.

added to what is now known about them. I refer to the adamantinoma and to the chorionepithelioma. The cell differentiation peculiar to each and the embryologic origin of the tumors have been fully worked out and described.

ADAMANTINOMA

The adamantinoma arises from cells which differentiate like those of the enamel organ. The cells of this structure are of epiblastic origin, but do not undergo cornification. The cells of the outer layer are cuboidal in shape, those of the inner cylindrical. The cells between these two layers form the enamel pulp, and correspond to the prickle-cells of the epidermis; they become more or less separated from each other by vacuolization

but remain connected by cell processes so that they resemble to some extent mucous connective tissue cells. The nuclei in the cylindrical cells of the inner layer are situated away from the underlying connective tissue instead of close to it, as is usual in most other epithelium lining surfaces. It is these cylindrical cells which lead to the formation of enamel, and hence are known as adamantoblasts.

The cells of tumors which arise from adamantoblasts tend to differentiate like them: they produce cells like those in the enamel pulp but do not give rise to enamel so far as my experience goes. The tumor grows as branching masses of epithelial cells. There is a moderate amount of connective-tissue stroma in which bone derived from the jaw is occasionally present. Cysts often form in the epithelial masses owing to distention and coalescence of the vacuoles between the cells, corresponding to those in the enamel pulp; other cysts, which may be more numerous and larger, often occur in the connective tissue of the stroma as the result of focal collections of fluids. Rarely the cells corresponding to those in the enamel pulp assume a concentric arrangement and suggest epithelial pearls.

The adamantinoma grows expansively only, and produces no metastases. In sections it presents an alveolar arrangement with solid masses of cells or in consequence of edema a glandular or cystic appearance. Owing to its location and the size it sometimes reaches it may cause clinically much local disturbance.

CHORIONEPITHELIOMA

The chorionepithelioma arises from cells which tend to differentiate like those covering the chorionic villi. It contains, therefore, two varieties of cells which characterize it, epithelial-like cells, corresponding to the layer of Langhans, and multinucleated cells corresponding in structure to the syncytial layer. The syncytial cells originate either from the cells of the layer of Langhans or both arise from some one common cell.

The chorionepithelioma, a tumor of fetal origin, apparently always invades. It usually gives rise to metastases. Clinically it almost invariably is malignant and leads to death. In the tissue it invades it causes little or no reaction on the part of the connective tissue and hence no well-marked stroma is produced.

The pathology and origin of this tumor and its intimate relation to hydatidiform mole have been thoroughly investigated. Little or nothing seems to remain to be added to our knowledge of the subject.

ADRENAL-CELL TUMORS

A third group of epithelial tumors usually classed by themselves are those differentiating like the adrenal cells. The cortical cells of the adrenal are fairly characteristic, with their delicate vacuolated cytoplasm filled with fat droplets, the prominent cuticle, and the relatively small round nuclei, but other adrenal cells are not so well characterized. The adrenal tumors are therefore not always recognized with ease and certainty. One feature is noticeable; like the adrenal itself they contain little connective tissue stroma. Some of them grow expansively only, and are regarded as adenomas; others grow rapidly, invade readily, and give rise to metastases. Clinically these latter tumors may be rapidly fatal. The origin of these tumors in the kidneys and elsewhere from displaced adrenal cells has been generally taught and accepted. While much is known about these tumors it is doubtful if the subject can as yet be considered finished.

Other varieties of epithelial tumors can be best understood by studying in a group by themselves all those which originate from cells differentiating in the same way; for example, those derived from thyroid cells, liver cells, etc. In no other way is it possible to obtain a just appreciation of this large group of tumors and realize the nature and possibilities of the destructive tumors which may arise from each.

I wish to speak here a little more specifically about two or three groups of tumors bearing on this question.

EPITHELIAL BREAST TUMORS

The epithelial cells lining the glands and ducts of the breast are not particularly well characterized morphologically, but they possess in common with the cells lining the sweat-glands one distinguishing feature. Between them and the surrounding connective tissue is a layer of smooth muscle cells believed to be of epithelial origin.

In the breast arise a variety of epithelial tumors: some grow expansively, others infiltrate and frequently give rise to metastases. As will be shown, it is not possible to separate these tumors sharply into two groups and say definitely that clinically one group is benign and the other malignant. Certain tumors are on the border-line and may at any moment invade the surrounding tissues.

In the adrenal there is little connective tissue stroma; in the tumors of adrenal origin little stroma is produced. In the breast the epithelium rests on a layer of smooth muscle cells outside of which is a large amount of connective tissue. In tumors of the breast the muscle layer is produced in those which grow expansively or in papillary form within the ducts and glands, but disappears when the epithelium infiltrates outside the muscle layer. The connective tissue usually grows abundantly so as to form a well-marked stroma. It is so prominent in the ordinary type of adenoma that it is regarded by some pathologists as forming a part of the tumor which they look on as a simple type of mixed tumor, an adenofibroma. The epithelial cells of a cancer of mammary origin usually arouse the production of an abundant stroma wherever they are carried, for example, into lymph-nodes or bone-marrow, showing that they exert some specific influence on the proliferative activity of fibroblasts.

In chronic mastitis it is common to find small areas of proliferative activity on the part of the epithelial cells lining the ducts and glands. The cells often project in small papillary masses into the lumen. As these masses enlarge connective tissue and blood vessels grow into them. In this way a cellular, papillary growth may fill and dilate the ducts and glands. The epithelial cells in these areas may grow under the lining epithelium, between it and the smooth muscle layer, forming a mild type of invasion. Such a tumor may fill all the ducts and glands of the breast with epithelial cells and yet not pass beyond the smooth muscle layer. This type of tumor is rare but occurs. How is it to be classed? In the ordinary carcinoma the cells infiltrate the lymph-spaces, the lymph-vessels, and the blood-vessels.

It is this relation of the different types of epithelial tumors of the breast to each other and to proliferative processes occurring as the result of chronic mastitis, which requires more careful comparison and study.

The cells of the epidermis are characterized by the formation of numerous short fibrils, which bind the cells together and are known as intercellular bridges. Longer fibrils are sometimes present which are known as epithe-

lial fibrils. The exact relation of these two kinds of fibrils to each other and to the cell is not fully determined. They seem to be due, for the most part at least, to a differentiation of the cuticle of the cell, and not to be an intercellular substance. The cells of the epidermis are further characterized by retrograde changes involving the formation of eleidin and keratohyalin and ending in cornification. In tumors derived from epidermis the cells tend to undergo these same changes and the resulting cornified epithelial cells collecting in masses are termed epithelial pearls. The mitoses occur entirely in cells corresponding in development to the lowest layer, the rete Malpighii; but even in this layer the surface of the cells usually shows the characteristic surface fibrillation which becomes more prominent in the prickle cell layer.

RODENT ULCER

There is another tumor of the skin which deserves mention here. It is usually but not always the lesion which is known clinically to the dermatologists as rodent ulcer. It has been very unfortunately named and elaborately classified into numerous varieties by Krompecher on the theory that it is derived only from the rete Malpighii and that therefore the cells do not undergo the usual transformation into prickle-cells and cornified epithelium.

The tumor in question usually grows slowly; it may spread widely in the corium and form connection with the overlying epidermis at many points. It rarely in-

Fig. 4.—Showing that the cell differentiation in rodent ulcer is similar to that found in the adult and embryonal cells forming the hairs, having the oval to spindle-shaped nuclei, surrounded by little cytoplasm, forming no intercellular bridges, but giving rise to numerous delicate fibrils, indicating their origin from the hair matrix rather than from the rete of the epidermis.

vades the deeper tissues or gives rise to metastases. The cells may occur as large masses of spindle-shaped cells running in bundles so that seen by themselves they suggest a spindle-cell sarcoma. They also occur in broad and narrow connecting bands. The cells are characterized by their cubical, cylindrical, and spindle shape, their small amount of cytoplasm, and their intimate relation to each other. In addition they frequently produce numerous long fine and coarse fibrils (Figs. 1, 2 and 3) running in the direction of the long axis of the cells. Rarely there is a hint of the formation of intercellular bridges, and small epithelial pearls are occasionally formed. These cells do not differentiate like the cells of the surface epidermis.

If, however, the cells forming the hairs are studied in the adult and embryo, it will be found that the cell differentiation is much more like that in these tumors. The cells forming the hair shaft have oval to spindle-shaped nuclei surrounded by very little cytoplasm. The cells form no intercellular bridges but give rise instead to numerous delicate fibrils (Fig. 4) which later fuse to form a homogeneous mass which becomes the hair. The cells around the hair-shaft are cubical to cylindrical in shape, produce only short and delicate intercellular bridges, and undergo only a slight form of cornification.

The cell differentiation in this class of tumors strongly suggests, therefore, that they are derived from cells of a hair matrix and not from the rete Malpighii of the epidermis. They should be grouped and studied by themselves because they have pathologic and clinical characteristics of their own. They infiltrate, but rarely give rise to metastases. They are locally destructive but can hardly be considered clinically very malignant.

A third group of tumors which requires more careful study is that arising in and around the ovaries. The accidental finding of a small, infiltrating, ciliated, papillary adenocystoma in the broad ligament suggests that these tumors may arise from remains of the Wolffian tubes in the ligament. Similar ducts and glands lined with ciliated epithelium and surrounded by smooth muscle frequently occur in the uterine tube. It is the ciliated papillary adenocystomata which prove clinically to be especially malignant. It seems much more probable that they are derived from the ciliated remains of the Wolffian and perhaps Müllerian ducts than from displaced intestinal epithelium as suggested by Ribbert.

What is needed is the careful study of early cases before the ovaries are infiltrated and destroyed and all relations lost. The finding in ordinary routine examinations of small solid masses of squamous epithelium in the wall of two different normal uterine tubes and the occurrence of a thick layer of squamous epithelium lining one fold of the tubal mucosa while the rest was perfectly ciliated suggests the possible origin of epidermoid carcinomas in this region.

I have thrown a few sidelights on the subject of epithelial tumors and have called attention to the lines along which I believe our knowledge of their origin and development can be broadened from the morphologic side, namely, by a more thorough study of the embryologic origin of each kind of epithelial cell and of the histological differentiation which each type of cell undergoes. Each group of epithelial tumors of which the cells tend to differentiate alike should be studied in a group by themselves. To say which of them should be classed as adenomas or papillomas and which as carcinomas (the point about them in which the clinician is most interested) is not easy. From a pathologic point of view we may define cancer as an epithelial tumor which infiltrates and which may give rise to metastases. The infiltration may be only beneath the lining epithelium of a duct or a gland, but it is a beginning. Usually it is into lymph-spaces, lymph-nodes, and blood-vessels.

Harvard Medical School.

MECHANICAL ILEUS COMPLICATING PREGNANCY

PHILIP SCHUYLER DOANE, M.D.
CHICAGO

Mechanical obstruction, or ileus of the large or small intestine, is not infrequently encountered. Late diagnosis, together with imperfect technic, or late protracted operations, may be responsible for a high death-rate in all cases of this character. Refinement in diagnosis, with a perfected, rapid technic, will produce a marked reduction in this mortality. Nauwyn reports a recovery of 75 per cent. of all patients with ileus operated on the first or second day of the attack, but the mortality was very great in all patients operated on the third day or later. This is verified by an analysis of cases reported during the past year as listed in the index.

Very few cases are reported of ileus occurring during pregnancy. Williams reports two cases of intestinal obstruction complicating pregnancy. In one an intussusception occurred at the site of a tuberculous ulcer; the second was due to constriction by peritoneal adhesions in a case of tuberculous-peritonitis. Death occurred in both instances. He further states that ileus is a very rare complication of pregnancy.

Comparatively few text-books on obstetrics mention this subject in any way, and those doing so give the matter but meager consideration. Peterson recommends immediate Cesarean section if the complication occurs late in pregnancy.

Obstruction by bands and diverticula is given by Gibson as the second most frequent cause of intestinal obstruction. In his collection of reports of 1,000 cases, he classifies the ordinary form called ileus as an obstruction caused by bands and diverticula. The causes as given by him are:

Hernia 35 per cent.

Bands and diverticula 19 per cent.

Intussusception 19 per cent.

Volvulus 12 per cent.

Miscellaneous (fecal impaction, tumors, strictures, foreign bodies, gall-stones, worms, dynamic or adynamic conditions) 15 per cent.

He also states that 6 per cent. of all cases are due to Meckel's diverticulum.

The accompanying table of cases reported during the past two years shows the various causes of obstruction, the treatment of the incarcerated bowel, the time elapsing after initial symptoms and the result. From this report it is noted that death resulted in all but one case in which resection was done after the second day.

It will be seen that many patients were operated on before the bowel became gangrenous, so that resection was not necessary. This fact is most encouraging, for it shows an increasing ability on the part of the surgeon to make a diagnosis early. A study of cases previous to 1908 does not show this.

Abnormal openings in the omentum, mesentery or broad ligament may allow the bowel to become incarcerated.

A. E. Halstead had a case in which the ileum, with its long mesentery, became involved in an abnormal opening in the broad ligament with a resulting incarceration and strangulation.

The development of the pregnant uterus may cause a displacement of the abdominal viscera, and if the band or diverticulum preexists, it may be seen that strangulation could readily take place.

The delayed diagnosis and the subsequent severe shock and prostration in these cases occurring during pregnancy, has made the mortality very great. Accordingly, this may account for the few successful cases of this type being reported.

A well-advanced pregnancy may make the diagnosis more difficult, but the existence of the pregnancy should not deter the operator from relieving the strangulation at the earliest possible moment.

An ileus of the mechanical type may be relieved in its early stages by severing the bands which cause the strangulation. In many of these cases the progress is a slowly developing one; sometimes days elapse before the circulation is so shut off as to cause gangrene of the bowel. Once it has become gangrenous, there is no alternative but to resect and to make such anastomosis as the judgment of the operator may dictate. A lateral anastomosis is usually

selected because of its security, with less danger of subsequent stricture.

If resection is done, drainage must always be employed, but care must be exercised in the placing of this drainage in order that pressure necrosis may not follow. A gauze cigarette drain is used by most operators, the drain resting at one side and not on the anastomosed bowel.

The symptoms of intestinal obstruction should be familiar to the obstetrician as well as to the general surgeon.

Generally speaking, the symptoms may be summarized somewhat after the plan given by Van Zwalenburg, and are as follows:

1. Sudden onset of pain.
2. Vomiting, first of stomach contents, bile and mucus; the mucus with regurgitation of gas, and last, of mucus and

flammation seven years previous to the formation of the ileus; the inflammation at that time having been severe enough to produce adhesions which undoubtedly existed for a number of years:

REPORT OF CASE

History.—The patient, Mrs. M. B., housewife, aged 27, whose family history was negative, had had no eventful illness until the age of 21, when she had some abdominal inflammation which lasted a number of weeks and was evidently some form of peritonitis. Shortly after this abdominal disturbance, constipation was noted, increasing year by year. In the summer of 1906 constipation was very marked, and in August, 1907, a cystic tumor was found developing from the left ovary and bound down by adhesions into the cul-de-sac of Douglas, pressing upon the rectum, to which it was bound by dense adhesions. I removed it on August 27, 1907, at Michael Reese Hospital. Dense adhesions were encountered throughout the

regurgitation of gas with possible fecal matter, or a liquid substance resembling feces in odor and color.

3. Absence of fever the first four or five days.
4. Moderate diffuse tenderness, not always localized.
5. Obstipation, after bowel below obstruction has been emptied.
6. Marked and generally increasing prostration.
7. The visible peristalsis wave, falling as it reaches the point of obstruction.
8. Abdominal distention above point of ileus.
9. Borborygmus, or the sound made by flatus passing from one loop of intestine to another, as emphasized by John B. Murphy.
10. Leukocytosis in most advanced cases, but not dependable, especially in the early stages of any case.
11. Previous history of peritonitis or knowledge of existing adhesions.

The mechanical form of ileus is shown in the following report. There was a history of some intestinal in-

pelvis. The upper abdomen was not explored. Recovery was uneventful, with no symptoms of infection at any time during the two and a half weeks of convalescence. Constipation was relieved at once and the condition of the bowels remained normal up to the time of her pregnancy about one year later. In June, 1908, she was married, pregnancy following almost immediately. Nausea and abdominal distress were marked from the beginning. Constipation was again noted with continuous distention of the bowels by gas. Nov. 14, 1908, the patient was suddenly seized with abdominal pain which was located in the epigastric region, radiating to the right abdomen and back, a diagnosis of appendicitis being made by her then attending physician. Nausea was present within a few hours after the onset of pain. Vomiting also commenced within a few hours, vomitus being stomach contents with some bile. Pain was somewhat relieved by morphin given hypodermically, and the bowels were moved by an enema with good results. Symptoms then subsided for forty-eight hours, pain being present almost constantly but not as severe. There was

then a recurrence of the severe pain, vomiting and much gas from the stomach, which began to have a fecal odor. Cathartics were given but very promptly vomited. A slight action from the lower bowel was obtained by repeated enemata. Some distention of the upper abdomen was noted at this time, but all symptoms were again relieved by the use of morphin and did not recur with any great severity until the fourth day, when acute pain again became unbearable, the retching being pronounced. No gas passed by the bowel nor was any movement obtained by enemata or otherwise. The upper abdomen was markedly distended, with pulse growing rapid and weaker. Temperature first noted at this time 101. These symptoms were somewhat relieved by the administration of $\frac{1}{2}$ gr. of morphin, patient sleeping for several hours. The following morning the patient was sent to St. Joseph's Hospital still under the effects of morphin and feeling fairly comfortable.

Examination.—She then came under my care, and examination showed pulse 108, temperature 99. The patient was vomiting bile and mucus which had a fecal odor, but the vomitus at no time consisted of fecal matter. The abdomen was markedly distended; a five months' pregnant uterus partially filling the lower abdomen, while a distinct tumor mass could be palpated above the umbilicus, its outline being somewhat sausage-shaped. This mass extended from the lower border of the ninth and tenth ribs on either side, and from

Ileus delivered showing constricting band while pregnant uterus forces bowels upward.

the point a little below the ensiform cartilage to the umbilicus. The mass was markedly tympanitic and on pressure pain was elicited to the right and below the umbilicus, radiating apparently toward the cecum and to the back. The stomach was found distended. The patient claimed that the amount of fluid vomited was far in excess of that swallowed. Vaginal examination revealed some bulging at the en-de-sac. The five months' pregnancy was verified. Rectal examination revealed nothing but empty bowel. No marked peristalsis was visible at this time. Normal salt enema was given at a very low pressure but with negative result. The stomach was washed out. The pulse was rapid and thready and gradually growing weaker. Prostration of the patient became marked. A leukocyte count of 16,100 was noted the first hour after entrance into hospital, with one of 18,500 two hours later. The urinalysis made at the time of the second leukocyte count was negative, save for a high specific gravity and a distinct reaction for indican. A diagnosis was made of intestinal obstruction and immediate operation decided upon.

Operation.—After usual preparation the abdomen was entered through median line incision at upper part of old scar of previous operation. Omentum was found adherent to peritonium with much free fluid in abdomen. The pregnant uterus was filling the pelvis and the lower abdomen, causing the intestines to be pressed upward. The intestines first observed were found collapsed and empty. Approaching the tumor mass dense adhesions were encountered, several being of

the thick band type and evidently of long standing. The abdominal incision was enlarged upward about and above the umbilicus. The mass was then seen to be a black gangrenous loop of small intestine, forming a typical so-called ileus of the mechanical variety, a thick band passing from the free surface of the ileum at a point about 20 cm. from its junction with the cecum, then passing about a loop of the same intestine and apparently attached to the posterior wall of the abdominal cavity. The occluded bowel with its mesentery was enormously distended and gangrenous. The serosa of the intestine not occluded by the strangulating band was covered by a fibrinous exudate and was very dark in color. This part of the bowel also was somewhat distended. The band was severed at once. The gangrenous intestine with that portion of the mesentery which was in the same condition was clamped off and removed. It was 30 cm. in length. An end-to-end anastomosis was then made after bringing together the edges of mesentery where the V-shaped portion had been resected. A large cigarette drain was carried down to the bowel close to the anastomosis and the abdomen closed.

Postoperative History.—One pint of hot physiologic salt solution was given per rectum every two hours. The patient continued an uneventful course until the eleventh day, when she miscarried a five and one-half months' fetus. The shock following this was severe, but she rallied and her recovery was complete. It is now over a year since her operation and she remains in excellent health, with no more symptoms of the preexisting constipation.

It is possible that adhesions followed the operation of the year previous when the ovarian cyst was removed. The absence of any symptoms of infection, the quick and perfect convalescence with relief of constipation at that time, however, would refute this. Old and numerous adhesions were encountered at the first operation, differing in number and thickness from those usually associated with an ordinary ovarian cyst. The abdominal viscera were not molested in any way at that time, and from the accompanying drawing it is seen that the band was high up in the epigastric region. Had not pregnancy ensued this band might never have caused any trouble. The enlarging uterus gradually crowded the bowel upward until the band became taut about a loop of the incarcerated bowel, which became distended with gas and eventually completely strangulated.

It would seem that in this case the process was somewhat slow in developing. The administration of large doses of morphin, which usually tend to cloud symptoms, may have lessened intestinal peristalsis and delayed the process. Had it not been delayed, it is doubtful that an operation five days after the onset of symptoms would have been anything but fatal to the patient.

A diagnosis of appendicitis was first made by the physician in attendance. From the location of pain and the vomiting, together with the fact that the abdomen was distended by the existing pregnancy, the diagnosis was excusable. Very little credit can be claimed for making a diagnosis in the last stages of these cases. As has been shown here, the symptoms were typical, and it only remained to act quickly and decisively.

To relieve an ileus or intestinal obstruction by operation is usually an attempted life-saving measure of the last resort. The appalling death-rate of late operations proves most emphatically that grave mistakes have been made by procrastination. In no other abdominal work is speed of operation so necessary. Adjoining viscera, already devitalized by inflammatory processes, impaired circulation and restricted nerve-supply, should be handled as little as possible. Anatomic relations should be borne in mind, but not sought after.

If amputation is necessary, resection and anastomosis must be carried out with a rapid and simple technic. If

the serosa of the two ends of bowel adjoining the resection are healthy, a lateral anastomosis may be done quite as speedily as an end-to-end one. If, however, the bowel is covered with an exudate and is cyanotic, while the mucosa looks normal; or, if the mesentery has been resected and cannot be coaptated without folding under, as in a lateral anastomosis, then the end-to-end method must be employed. On the other hand, if the lumen of either distal or proximal end of the resected intestine differ greatly, a lateral anastomosis must be done.

Drainage is usually employed in cases of resection. Such drainage as will absorb exudate or leakage must be used and so placed as not to cause pressure on the sutured bowel.

After-treatment is important, but stress is laid only on the non-administration of such stimulants as those which favor peristalsis and increase blood pressure.

If pregnancy accompanies an ileus any attempt to relieve the patient of the pregnancy will jeopardize her life; that is, if the ileus is diagnosed late and a resection necessary.

Early diagnosis, followed by immediate and rapid operation with minimum anesthetic, means a lessened mortality in the treatment of intestinal obstruction by ileus.

COLON BACILLUS INFECTION OF OPERATION WOUND

REPORT OF INTERESTING CASE

EDMUND A. BABLER, M.D.

Visiting Surgeon City Hospital, Junior Surgeon Deaconess Hospital
ST. LOUIS

Escherich's classic description of the colon bacillus marked an epoch in medical literature and was quickly followed by an appreciation of the frequent presence of the organism in various parts of the body. Tavel was the first, however, to find the colon bacillus in the tissues of the body outside of the intestinal canal. He found this organism in the wound resulting from removal of a tumor of the thyroid gland.

Colon bacillus infection of a mild character of an operation wound is of not infrequent occurrence in abdominal surgery. I have a patient at the City Hospital who is now convalescent following gun-shot wound of the liver and colon, in which the abdominal incision became infected with the colon bacillus; the operative wound opened *in toto* on the sixth day, when Dr. Chamberlain removed the clips. Fortunately, however, the operative wound does not usually suffer very much from a colon bacillus infection, because the patient's body forces are able to combat the invasion successfully.

The following case of colon bacillus infection of the operation wound exemplifies the distressing result that occasionally follows such infection:

REPORT OF CASE

History.—J. McQ., a white man, a laborer, aged 45, was admitted to the medical department of the City Hospital, May 14, 1910. He had had frequent attacks of malaria; denied syphilis or any serious illness; was accustomed to drink and smoke moderately. Three days previous to admission, while tying his shoe, the patient was suddenly seized with a "stitch" in his right side. This had been more or less persistent since onset. The next day he had a chill, followed by fever. He now complained of severe pain in

region of the ninth right intercostal space in the anterior axillary line.

Physical Findings.—Inspection showed the patient's expression anxious; he was anemic and emaciated; respirations somewhat shallow and accelerated; he had a slight cough, which caused pain in the right side; the patient was nervous and excitable; had been drinking. Faint tremors of tongue and fingers were present. Auscultation in right axilla revealed harsh inspiratory and blowing expiratory sound. Numerous dry râles were heard throughout chest. Vocal and tactile fremitus were exaggerated over middle and lower lobes of right lung; relative dullness over left lower lobe; friction rub audible close to right costal margin, heard on both inspiration and expiration. On May 14 the chest was aspirated, but no fluid obtained.

Blood.—On May 16, the leukocyte count was 19,100. On May 30, it was 24,800. On June 5, it dropped to 10,700, while on June 11, it reached as low as 9,850. July 31, the blood showed 85 per cent. polymorphonuclears, 1 per cent. large lymphocytes, 13 per cent. small lymphocytes and 1 per cent. eosinophils. (This latter count was one month after operation.) Later the blood showed the presence of the colon bacillus.

The stools were devoid of amebas, and tubercle bacilli were absent from the sputum.

Necrotic operation wound, infected with colon bacillus.

On June 18, the patient came under the care of Dr. Luton, a member of the staff, and the diagnosis of subphrenic abscess was made. On June 23, I saw patient in consultation with Dr. Luton, and confirmed his diagnosis.

Operation.—On June 24, an incision, two inches in length, was made (under cocaine anesthesia) in the anterior axillary line over the most prominent portion of the bulging mass. About two quarts of fluid, resembling that of a liver abscess, were evacuated. Examination showed the abscess to be a subphrenic one, although the palpable liver surface was roughened. A double drainage-tube was inserted. Examination of the fluid evacuated showed liver cells absent, but a pure culture of colon bacilli.

Postoperative Course. The discharge from the wound was very profuse and the patient did not respond to treatment, although he was able to be up about two weeks after the operation. On July 18, the margins of the wound became very red and somewhat swollen. This process became more and more extensive. On July 23, the wound margins became necrotic and discharged a grumous substance. On July 24, a culture from this substance showed colon bacillus only. On August 10, six minims of a vaccine made from bacteria recovered from fluid from the pleural cavity of the patient, each cubic centimeter containing 100,000,000 dead bacilli, were injected. This injection was followed by a temperature

of 102 F., and seemed to make the patient worse. Injection was not repeated. Blood analysis showed the presence of colon bacilli.

The area of skin destruction became more and more extensive, until at the time of death, two months after the operation, the wound was necrotic to extent shown in the drawing made by Mr. Tom Jones. I am indebted to Drs. Kimzey and Burns, interns at the City Hospital, for valuable assistance rendered the artist.

Autopsy.—This was made by Dr. Gould. The principal findings were destruction of greater portion of the diaphragm between the base of the right lung and the liver. The abscess floor was formed by the liver, while the base of lung formed its roof.

COMMENTS

The true origin of the subphrenic abscess was not clearly determined. The fact that a large portion of the diaphragm was destroyed by the bacterial invasion is interesting. The main feature of the case centered in the action of the colon bacilli on the postoperative wound. I have not been able to find a similar report in the available literature. In my opinion the patient's lowered vitality, combined with the extensive distribution of the organisms, permitted but feeble opposition to the invasion into the skin and subcutaneous tissue.

THE TUBERCULOUS TONSIL *

ROBERT LEVY, M.D.
DENVER

In 1886 Trautman¹ made the statement that children of tuberculous parents suffering from hyperplasia of the pharyngeal tonsil showed marked local and general reactions following the injection of tuberculin, the continued use of which resulted in cure of the hyperplasia. From this he argued that such tonsillar affections were tuberculous. It was not, however, until 1895 that any serious attempt was made to prove by laboratory investigation the relationship between hypertrophy of the pharyngeal and faucial lymphoid tissue and tuberculosis. At this time intense interest was awakened by the experiments of Dieulafoy,² and, although it has since been shown that these experiments could not be considered conclusive, the interest awakened thereby resulted in the development of an enormous literature, much experimentation and more or less conclusive as well as confusing reports. To a clinician accustomed to using laboratory methods only for purposes of confirming diagnoses made from subjective and objective manifestations, the statement that tonsillar tuberculosis was found in twenty cases out of thirty-four of tuberculosis (Walsham³) came as a decided shock. Wood's⁴ table of seven observers gives 69 per cent., and it is generally conceded that a very much higher proportion of tonsillar tuberculosis exists than had previously been recognized. The reason for this changed belief may be ascribed to newer methods of investigation based principally on histologic findings and laboratory and animal experimentation. Clinically one finds evidences of tuberculosis of the pharynx with or without tonsillar involvement

among the rarer manifestations of tuberculosis. This being the case, I have frequently questioned whether the clinical diagnosis or the laboratory diagnosis should stand. For the purpose of comparing the frequency with which tuberculosis of the tonsils could be clinically diagnosed with the reports of laboratory findings by others I reviewed very thoroughly my private records. In a study of 450 cases of laryngeal tuberculosis I found the following:

Some portion of the pharynx was involved in 64 cases. The pharynx exclusive of the tonsils was involved in 32 cases; the pharynx and tonsils were involved in 24 cases; the faucial tonsils alone were involved in 8 cases.

In other words, of the 450 cases of laryngeal tuberculosis some portion of the pharynx was involved in 14.22 per cent., the pharynx alone in 7.11 per cent., the pharynx and tonsils in 5.31 per cent. and the faucial tonsils alone in 1.77 per cent.

Early stage of tuberculous tonsil.

It is generally conceded that laryngeal tuberculosis occurs in a very large proportion of pulmonary cases. The average frequency may be considered at 30 per cent. If this be accepted as a basis for estimating the frequency with which pharyngeal tuberculosis occurs in all pulmonary cases it may be stated that some portion of the pharynx is involved in 4.26 per cent., the pharynx alone in 2.13 per cent., the pharynx and tonsils in 1.59 per cent., and the faucial tonsils alone in 0.53 per cent.

It may seem difficult to make these figures coincide with those of other observers or even those of the authors⁵ published in 1896.

Confirmation of my previous report that pharyngeal tuberculosis occurs in 1.5 per cent. of all cases is found in the table compiled by Lockhard,⁶ which gives 1.47 per cent. as the estimate. Confirmation of my present report

* Read in the Section on Laryngology and Otology of the American Medical Association, at the Sixty-first Annual Session, held at St. Louis, June, 1910.

that tonsillar (faucial) tuberculosis is found in 1.77 per cent. of all laryngeal cases is found in Chiari's⁷ estimate of 1.88 per cent. (12 in 635 cases).

The great discrepancy between these figures and those reported from laboratory findings must be a source of much surprise. One explanation is in the present estimate of 30 per cent. instead of 15 per cent. as representing in 1896 the frequency of laryngeal tuberculosis. It also must be concluded that clinical tuberculosis of the tonsils and that determined by histologic examination present marked differences as to manifestations, and consequently as to significance. In order to reconcile this confusion the classification of latent tuberculosis has been made.

Clinical and latent tuberculosis are differentiated essentially by the absence of subjective and objective symptoms in the latter and definite subjective and objective manifestations in the former. Microscopically the differences are not so great, and still we do have distinguishing characteristics. In clinical tuberculosis of the tonsils one sees this structure but slightly if at all enlarged. If an enlargement exists it has no special bearing on the tuberculous process.

The characteristic appearance is a peculiar pallor with a slightly edematous or weeping surface covered with a tenacious, thin, somewhat milky secretion; localized areas of small pin-point or pin-head white or grayish deposits of greater or less extent are seen definitely situated beneath the surface of the mucous membrane. Somewhat later one sees the beginning of ulceration manifesting itself by a superficial excavation, irregular in outline and unattended by inflammatory surrounding redness. As the disease progresses these typical appearances become more pronounced, the ulcerations coalescing in irregular manner, giving a nibbled or mouse-eaten outline to the parts. With the excess of disturbance the edema becomes greater, presenting definitely outlined though not circumscribed swelling. The subjective symptoms are those of discomfort in the throat followed by pain which becomes excessive and is usually associated with more or less marked constitutional symptoms, such as fever, rapid pulse and loss of weight. It is true that these subjective symptoms when confined to the tonsils alone are rarely very marked, but involvement of surrounding pharyngeal tissues takes place so rapidly that the interval between the onset of the tonsillar manifestations and the development of constitutional symptoms is but short. The local appearances presented by this form of the disease are usually definite and characteristic. Occasionally one finds it difficult to distinguish a tuberculous ulceration of the tonsil from one due to syphilis, and this is especially true in instances in which the two diseases are associated. Such cases have at various times come under my observation. The case reported by Lack,⁸ in which tubercle bacilli were found but in which the administration of potassium iodid cured the patient, must be looked on as one of syphilis associated with tuberculosis. Here the histologic examination was suggestive though not conclusive of tuberculosis, but the result of treatment must be considered confirmatory of the diagnosis of syphilis.

The symptoms of latent tuberculosis, on the other hand, are extremely vague. Hurd,⁹ in describing the appearance of such a tonsil, says that it is "usually pale,

the crypts contain cheesy detritus, the edge of the anterior pillar may have a passive hyperemia and the associated lymphatic gland is usually much enlarged and hard." This description might be applied to the appearance of any number of tonsils seen daily.

Botey, quoted by Wright,¹⁰ states that it is impossible by simple inspection to distinguish hypertrophy of tuberculous character from the common hypertrophy of tonsils with which every one is familiar.

Baup,¹¹ in speaking of the symptomatology of larval tuberculosis, says that "this is still very vague" and that "locally the tuberculous tonsil is not distinguished from the hypertrophied tonsil."

Walsham,¹² in describing his twenty cases of tuberculosis found in thirty-four autopsies, states that all but two of these cases showed no tuberculous manifestations before death.

Histologic examination may also be subject to question and many of the findings attributed to tuberculous changes occur in other pathologic conditions.

Wyatt Wingrave,¹³ after examining a large number of so-called tuberculous cervical lymphatic glands, concludes that there are a large number of chronic non-suppurative glands included in the term "tuberculous" which are not due to tubercle at all, but which present all the histologic features minus the specific organism.

Wood¹⁴ states that giant cells and lesions resembling tubercles may result from irritation of foreign bodies and that certain acid-fast bacilli will sometimes give rise to changes scarcely distinguishable from true tubercles. One cannot but be impressed with the apparent difficulty of demonstrating the presence of tubercle bacilli in so-called histologic tuberculosis and authors are generally agreed that without the presence of these microorganisms the diagnosis must of necessity be still questionable. The elaborate and competent work of George B. Wood¹⁵ of Philadelphia forms an important part of the extensive research and literature devoted to this subject. In his experiments on guinea-pigs Pig 3 was the only one showing marked evidences of tuberculosis, and here tubercle bacilli were found in all of the glands. Wood quotes Ravenel's experiments in which after being fed tubercle bacilli by the mouth four hogs developed tuberculosis, three of the four showing ulcerative lesions of the tonsil, which is further evidence in favor of the contention that when these organs are truly tuberculous gross lesions, as shown by ulceration, are present. It may be possible that the ulcerative process is not of necessity a tuberculous manifestation and that, as Wood states, this lesion may be due to a mixed infection of a tuberculous structure whose ordinary resistance to bacterial invasion is lessened. Be this as it may, one must certainly feel better satisfied with a diagnosis based on definite physical signs than with one based on indefinite appearances.

"In undoubted tuberculosis the histologic findings are typical. In a case of unquestioned early tuberculous lesion of the right tonsil, of which a drawing is herewith presented, the histologic examination made by Professor Todd of the pathologic laboratory of the Denver and Gross College of Medicine showed the following:

7. Chiari: Die Krankheiten des Rachens, Franz Dentioke, Leipzig and Vienna, 1903, p. 151.

13. Wingrave: Jour. Laryngol. Rhinol. and Otol., January, 1905, p. 45.

14. Wood, G. B.: THE JOURNAL A. M. A., May 6, 1905, p. 1427.

15. Wood, G. B.: THE JOURNAL A. M. A., May 6, 1905, p. 1429.

The tissue consists of three rather soft whitish pieces which have been preserved in weak formaldehyd solution. The largest measures about 4 by 5 by 6 mm.

In general the histologic structure is that of tonsillar tissue. Scattered throughout all the sections are typical tubercles. They consist of a reticulum with numerous cells of the endothelial type and a very few lymphoid cells. Most of the tubercles contain one or more giant cells—in most cases typical tuberculous giant cells, having caseous centers and peripheral arrangement of nuclei. The tubercles themselves do not show caseation.

The covering of stratified squamous epithelium is intact over much of the free surface, but contains rather numerous wandering cells.

At certain points the tubercles reach the surface and coalesce so as to form a layer of rather diffuse endothelial hyperplasia with an occasional giant cell. Over these regions the epithelial covering is absent, and the most superficial portion is densely infiltrated with polynuclear leukocytes (ulceration).

A number of the sections were stained for tubercle bacilli. In an hour's search only one small group of bacilli were found lying among the endothelial cells at the periphery of a tubercle.

Here tubercle bacilli were found and, although Professor Todd would make a diagnosis of tuberculosis from such histologic appearances, nevertheless the tubercle bacilli must be considered essential factors. Any histologic report containing less than the above typical findings is open to question.

The significance of the latent form of tuberculosis of the tonsils is of particular importance in its relation to glandular involvement. It is known that many varieties of infection may pass through the tonsils and other portions of the pharyngeal lymphatic ring to the nearest glands, causing enlargement of these structures. It has also been shown that among the micro-organisms causing such disturbances tubercle bacilli have been demonstrated and that their passage through the tonsils has been followed by no change in these organs. Friedman,¹⁶ Strassmann,¹⁷ Krüeckman¹⁸ and others may be quoted in this particular. The significance of this phenomenon must be considered, as Grünwald¹⁹ puts it, dubious. Furthermore, it is not necessary to attribute all forms of cervical adenitis to tuberculosis, for, as Goodale²⁰ states, there are many instances of enlargement of the glands of a non-tuberculous nature which he is inclined to regard as of toxic origin. In a large number of children presenting various degrees of adenoid or tonsillar changes, enlarged cervical glands were almost invariably found. Tuberculin tests, such as the Moro or von Pirquet, were used in these patients, with the ultimate result that while many of them showed positive reactions the proportion in which negative results were obtained was sufficiently large to be considered as evidence of the non-tuberculous nature of the glandular enlargements.

The question of latent tuberculosis is of special importance in children. The frequency with which adenoids and hypertrophied tonsils are found in early life would make one incline to belief in the occurrence of this form of tuberculosis in children to the extent believed by some, but the infrequency with which clin-

ical, definite manifestations of this affection are found in children must be an argument against this belief.

A tonsil should not be considered tuberculous except under certain well-defined conditions, both clinical and histologic, as outlined above. Nevertheless these organs must be looked on as important gateways for infections of various kinds, tuberculosis included. At the same time one must not conclude that because many infective conditions have their initial lesions in the tonsils, tuberculosis, even though it be brought to the system through this channel, must also be attended with a tuberculous initial lesion here. The infrequency with which tuberculosis is localized in children is a matter of common observation, although it must be stated that exceptions have been reported. The cases of Plicque²¹ and Siegert²² are especially noteworthy.

The manner in which definite local signs of tuberculosis of the tonsils develop may be considered as due to a special reaction to the infection. The experiments of Cornet,²² in which an ulceration occurred at the point of inoculation almost invariably, are extremely suggestive. The cutaneous reactions described of recent years, in which pronounced local changes showed themselves in patients having tuberculous foci, suggest an explanation of the development of many of the lesions found and localized in the upper air passages. It is stated by Labbé and Levi-Surugue²³ that adults show lesions of the tonsils more commonly than children because of absence of expectoration in the latter, leaving the inference that tubercle-laden sputum is the source of direct infection.

Baldwin,²⁴ in his lecture on "Hypersusceptibility to Tuberculin in Tuberculosis, etc.," makes the statement that many symptoms and pathologic products in tuberculosis are probably due to this reactive function, and quotes Koch's experiments with dead tubercle bacilli, stating that a dose which is sufficient to kill the animal can produce an extensive necrosis of the skin in the region of the injected spot. May we not therefore consider the possibility at least of tuberculosis of the tonsils developing as a result of a local reaction?

PROGNOSIS

In discussing the prognosis of tuberculosis of the tonsils the form of the disease must be taken into consideration. That in which we as clinicians are especially interested is the clinical variety, because of the fact that the diagnosis is less obscure. This form of tuberculosis must be looked on as attended with most serious consequences, presenting evidences of the gravest form of tuberculous infection. Its curability is extremely doubtful. It is usually associated with involvement of other structures in the pharynx, larynx and elsewhere. When it occurs an unfavorable prognosis is justified.

The tuberculous tonsil as represented by the latent form less well recognized and less easily determined offers questions for prognosis also of great interest and importance. Among these questions that of the development of tuberculosis in adults from such infection during childhood has been considered at some length by Harbitz,²⁵ who concludes that this cannot at present be demonstrated, but that such infection must certainly be

considered of great significance. Campbell,²⁶ on the other hand, believes that if the tonsil and adenoids were more frequently removed infectious diseases, including tuberculosis, would be more infrequent. The supposed immunity from infection in childhood is also discussed by Harbitz, who states that for the time being this must be only a hypothesis.

TREATMENT

The infrequency with which manifest tonsillar tuberculosis is found, except as a complication of tuberculosis of other portions of the upper air-tract, makes the treatment by extirpation a method rarely if ever indicated. Of what value is the removal of tuberculous foci here in the presence of numerous foci adjacent or more remote? In these cases the only results that have been of value have been obtained by methods of treatment applicable to all the lesions found. These have been obtained by the use of local palliative measures, more or less vigorous application of the galvanic cautery, especially after the method of Grünwald²⁷ and by the use of tuberculin in well-selected cases in conjunction with judicious general, hygienic and climatic treatment.

The treatment of latent tuberculosis of the tonsils consists in their removal by the most complete method possible. The purpose of such an operation is not so much to remove a possible tonsillar involvement as it is to prevent further infection through structures known to favor such infection. The question as to whether all tonsils associated with enlarged cervical glands require operation depends on the view one takes as to the nature of the lymphatic involvement. The utter impossibility of determining this by inspection must be evident. The histologic diagnosis cannot be made until after the treatment has been carried out; therefore the judgment of the observer alone must be dependent on. Generally speaking, I believe that when there exists cervical adenitis of considerable degree and that whenever the patient's general condition indicates lowered resistance, such as is demonstrated by frequent colds and evidences of malnutrition, even though other well-recognized indications for tonsillectomy are absent, the best interests of the patient will be subserved by radical operation.

SUMMARY

Tuberculosis of the tonsils occurs more frequently than previously recognized, owing to newer methods of investigation.

Clinically, tuberculosis of the pharynx, with or without tonsillar involvement, must still be looked on as among the rarer manifestations of tuberculosis.

Clinical tuberculosis of the tonsils and that determined by histologic examination present marked differences. They are differentiated by the absence of symptoms in the latter and definite subjective and objective manifestations in the former.

Many of the histologic findings attributed to tuberculous changes occur in other pathologic conditions.

The diagnosis of true tuberculosis of the tonsils is more satisfactory when based on definite physical signs corroborated by typical histologic findings.

It is not necessary to attribute all forms of cervical adenitis to tuberculosis.

Tuberculosis of the tonsil may be considered the result of a local reaction.

The clinical form must be looked on as very grave, its curability being extremely doubtful.

Extirpation of the tonsils is rarely indicated in clinical tonsillar tuberculosis.

In the presence of cervical adenitis, lowered resistance and evidences of malnutrition the best interests of the patient will be subserved by radical tonsillectomy even though other well-recognized indications for the operation be absent.

CONDITIONS DEMANDING ENUCLEATION OF
THE FAUCIAL TONSILS *

JOSEPH C. BECK, M.D.

Clinical Professor of Oto-Laryngology of the College of Physicians and Surgeons (University of Illinois); Oto-Laryngologist to Cook County Hospital and to the North Chicago Hospital
CHICAGO

It is my belief that, with the rarest exception, whenever the tonsil requires surgical interference enucleation should be the procedure, and, consequently, whatever I may say of the pathologic conditions in the tonsil itself, in its immediate neighborhood and in the system in general, it will be understood that I consider radical removal of the tonsil required to improve these conditions. The subject of the pathology of the tonsil, with special reference to its causing not only local and regional disturbances, but also general manifestations, has been so thoroughly discussed in the past two or three years that I can add but little that is new and only confirm observations made by others.

In regard to the many general disturbances mentioned in this paper for which the diseased tonsils are held responsible, one may be led to believe that it is my intention to attribute too many diseases to this source of infection. Every one of the conditions to be mentioned, however, has the following three points to support this contention: First, many authenticated reports exist; second, attacks of tonsillitis, mild or severe, preceded the general manifestations, and, third, following the enucleation of the tonsils the general manifestations were either markedly improved or completely cured.

There are, however, two pathologic manifestations in connection with the tonsils on which I desire especially to dwell. These are the influence of the removal of the tonsils (1) in enlarged glands of the neck and (2) in the cardiac complications of the rheumatic affection.

CONDITIONS BENEFITED BY ENUCLEATION OF TONSIL

The following are some of the conditions which are distinctly and beneficially influenced by complete enucleation of the tonsils. They may be subdivided into three groups:

1. Local, or conditions affecting the tonsil itself.
2. Regional, or conditions in close proximity to the tonsil.
3. Systemic or general.

1. The local conditions demanding enucleation of the tonsils are the following:

1. Chronic lacunar tonsillitis in which there are repeated acute attacks.
2. Chronic lacunar tonsillitis in which there are repeated attacks of peritonsillar abscess.
3. Tuberculous tonsil.
4. Primary chancre of the tonsil.
5. Malignant disease of the tonsil.
6. Acute infections, such as diphtheria, scarlet fever, etc.

27. Grünwald: Die Therapie der Kehlkopf Tuberculosis, J. P. Lehmann, Munich, 1907.

* Read in the Section on Laryngology and Otology of the American Medical Association, at St. Louis, June, 1910.

2. The regional conditions demanding enucleation of the tonsils are as follows:

1. Chronic persistent pharyngitis, especially lateral.
2. Tubal catarrh, with associated middle-ear disease.
3. Enlarged glands of the neck.
4. Apical tuberculous infection.
5. Perpetuating bronchitis in children.

3. The general or systemic conditions are the following:

1. Rheumatism, with its complications and sequela, as, endocarditis and myocarditis, arteriosclerosis, arthritis, pericarditis, pleurisy, peritonitis, perineuritis, and myositis—so-called muscular rheumatism.
2. Blood changes, as chronic septicemia with secondary anemias.
3. Gastro-intestinal disturbances, such as gastro-enteritis, and duodenal catarrh, with a subsequent cholangitis.
4. Parenchymatous changes, such as parenchymatous nephritis, hepatitis and pancreatitis.
5. Changes in the special organs, as episcleritis and phlyctenular kerato-conjunctivitis.

RESULTS OF OPERATION

My cases exhibiting the above-named conditions have been carefully observed and recorded, so that definite conclusions can be drawn from them. It is unnecessary to tabulate all of them and a statement to the effect that either a cure or marked improvement was the result following complete enucleation of the tonsils is sufficient.

Comparative tests in which one tonsil was removed and the amelioration of the disease observed, while after the removal of the second tonsil a complete cure was obtained, were not at all rare. Some of the striking results were the following:

Tuberculous Tonsil.—Primary tuberculosis of the tonsil has occurred but once in my practice, and complete enucleation was followed by cure.

Primary Chancre of the Tonsil.—In one case of primary chancre of the tonsil, in which the operation of complete enucleation was performed, in 1907, the patient has remained free from any specific disease, negative Wassermann reaction was obtained three months ago.

Malignant Disease of the Tonsil.—In several cases of malignant disease, as sarcoma and carcinoma, in which complete enucleation was done, recurrence and death followed except in one case of sarcoma.

Acute Infections.—Acute infectious diseases, such as diphtheria, scarlet fever, etc., have been prevented by a complete enucleation of the tonsils; and when these diseases occurred, they have been of a very mild form. In the diphtheria hospital in Chicago, enucleation is performed on patients as soon as their cultures are negative.

Tubal Catarrh, with Associated Middle-Ear Disease.—In regard to the influence of complete enucleation of the tonsils in tubal catarrh and chronic adhesive middle-ear inflammation, I have observed distinct improvement in the symptoms of deafness and tinnitus, in five cases out of twenty-seven, and, in many of the remaining cases, which belong to the more progressed types, some improvement.

Enlarged Glands of the Neck.—That enlarged glands of the neck are caused by infections from the mouth and pharynx, is an established fact, and that Waldeyer's lymphatic ring, when infected, contributes the greatest source of infection to these glands, is equally well known. That the faucial tonsil, the largest of the

lymphoid bodies in this region, causes the greatest amount of infection is fairly well established in the surgeon's mind, and that the removal of this structure prevents reinfection of these glands is the contention of most observers. While the general surgeon who is dealing with the subject of enlarged glands of the neck, frequently spoken of as tuberculous glands, believes this statement, he has been accustomed to practice the radical removal of all the chains of lymphatic glands, with practically no attention to the atrium of infection, the tonsil.

I have heard one of the most prominent general surgeons of this country say, in connection with a case of enlarged glands of the neck: "This patient has now had three radical operations on the glands of the neck, the condition always recurring; and knowing that the tonsil, which in this case is diseased, is most probably the source of infection, we will direct our efforts to eradicating this source." I then saw him take a Matthews tonsillotome, ablate the protruding portion of the tonsil and, with a finger and a gauze sponge, curette the remaining portion. This is the usual attention given to this source of infection and, in many instances, even less is done; that is, the interior of the oral cavity is entirely ignored. Again, general surgeons have made statements that, notwithstanding the attention given to tonsils, adenoids, etc., recurrence in the glands of the neck have occurred, when, as a matter of fact, the greater portion of the tonsil was allowed to remain hidden in the supratonsillar fossa, or at the base.

In order to prove the efficacy of the enucleation of the tonsil in causing enlarged glands of the neck to disappear and preventing recurrence of the same, I have made the following tests: Taking a case of bilateral glandular enlargement, in which the tonsils appeared to be diseased, I performed a radical operation on the glands of one side, extending from the stylomastoid region to the region below the clavicle, in the anterior as well as in the posterior triangle, superficial and deep, amounting to forty-six enlarged glands. Some time after the recovery of the patient, an enucleation of the tonsil was performed on the opposite side where the glands of the neck had not been operated on. The patient was placed under the best hygienic, dietetic and climatic conditions and, after six months, returned for examination. I found the patient much improved. The glands on the side where the tonsil was enucleated had disappeared, whereas on the opposite side where the glands had been radically removed, but the tonsil left in place, four glands had become newly enlarged below the sternomastoid muscle. The conclusive evidence that the tonsil is the source of infection of these glands is given by its enucleation. When the glands do not disappear after a tonsil operation, one must assume either of the following conditions to be responsible for this: first, the tonsil was not radically enucleated; second, the infection is from some source other than the tonsil; or third, caseation or abscess formation has already taken place.

The thirty-nine cases of enlarged glands of the neck that I desire to place on record may be briefly analyzed as follows:

Analysis of Cases.—Of the patients, twenty-seven were males, and twelve were females, ranging in age from 3 to 46. Sixteen had radical removal of glands, some, as often as five times. Histologic examination of these glands showed twelve to be tuberculous, and four simple enlargement. Twenty-three patients never had had operation for enlarged glands. Ten had incomplete ton-

sil operations; thirty-six had evidences of tonsillar disease; eight showed distinct lung tuberculosis; five, joint tuberculosis; three, rectal fistulas; twenty-six, family history of tuberculosis; twenty-one positive tuberculin reaction.

Results of Treatment.—Twenty-seven of these thirty-nine patients who had complete enucleation of the tonsils, including the ten who had formerly been incompletely operated on, the stump being removed subsequently, never had any recurrence of enlargement of glands. Among the twelve remaining patients who also had complete enucleation of the tonsils, there was some recurrence of enlargement. These patients were treated along general lines, x-ray, hygienic, dietetic, climatic and medicinal with some improvement in that the glands did not break down. The histologic examination of the enucleated tonsils showed true tuberculosis with caseation in one case and, in four, slight evidences of tuberculous disease. The section revealed the characteristic picture of a chronic lacunar tonsillitis.

Apical Tuberculous Infection.—Patients suffering from lung tuberculosis and chronic lacunar tonsillitis improved markedly after complete enucleation. I do not, however, mean to imply that the patient was cured of his lung tuberculosis by the enucleation of the tonsils.

Chronic Bronchitis in Children.—A chronic bronchitis in children which does not yield to the ordinary expectant and medicinal treatment does yield invariably to the enucleation of the tonsils and removal of adenoids.

Rheumatism with its Complications and Sequela.—The group of so-called rheumatic affections mentioned in the classification above, which resisted all means of local and general treatment, were either cured or much improved when the tonsils were enucleated. The cardiac complications, to which I desire to call special attention were noticeably influenced for the better. For instance, a patient with loss of compensation with valvular disease which followed each attack of acute tonsillitis in a chronic lacunar infected tonsil, was markedly benefited by the enucleation of one tonsil, and cardiac compensation permanently restored after enucleation of the second tonsil. The analyses of these cases is most interesting and complete histories of them would, no doubt, be of additional value, but space does not permit me to give them. I wish, however, to place on record the cases, numbering twenty, all of which give a history of repeated attacks of tonsillitis, with rheumatism and cardiac complications, these cardiac complications consisting, as a rule, of loss of compensation, following each attack of tonsillitis. The patients vary in age from 8 to 50; fourteen were females and six were males. The last was operated on more than a year ago. All of the patients have remained in good condition since the operation. The primary bleeding was greater and the healing not as prompt in these cases as in cases in which cardiac complications did not exist. There was no deleterious effect noticed on the heart at the time of the operation.

Blood Changes.—In a large group of cases such conditions as chronic septicemia with secondary anemias, in which the symptoms of a low grade of vitality or malnutrition, slight rise of temperature in the afternoon and secondary anemias are present, cures are obtained by the enucleation of the tonsils.

Gastro-Intestinal Disturbances.—Patients suffering from attacks of gastro-enteritic disturbances, such as loss of appetite, constipation, diarrhea and flatulency, which usually are aggravated following the acute attacks of tonsillitis in the chronic inflamed tonsils, are cured

by the complete enucleation of the tonsils after other local and general measures have failed. Following acute attacks of tonsillitis in a chronic lacunar inflamed tonsil one not infrequently observes marked symptoms of gastro-duodenal inflammation such as jaundice, rise of temperature, loss of appetite, etc., which never recur after complete enucleation.

Parenchymatous Changes.—Nephritis, hepatitis and pancreatitis, which have resisted all other methods of treatment, have yielded beautifully to the complete enucleation of the tonsils and removal of adenoids.

Changes in Special Organs.—Phlyctenula, kerato-conjunctivitis, iritis, scleritis and episcleritis, when other methods fail, are permanently cured when the tonsils are enucleated and adenoids removed.

CONCLUSION

My views of the result of the tonsillar enucleation may appear excessively enthusiastic, and perhaps they are; at the same time I must insist that I have mentioned only facts based on actual cases in my practice, which have been observed long enough to justify these conclusions.

Before closing I should like to present a theory as to the raising of the opsonic index of the blood to all infections when the tonsils are enucleated. If, for instance, there exists some pathologic condition of the body, near to or distant from the tonsils, which refuses to yield to the treatment applied to the said condition, if there exists merely a lack of healing power, due, most probably, to the constant absorption of toxic matter from the diseased tonsils, and if this toxic absorption is done away with by the complete enucleation of the tonsils and the pathologic condition heals, is it not reasonable to assume that the drain on the system has thus been stopped and the blood given a chance to become powerful enough to cure the disease in question because of the enucleation of the tonsil? For example, operation is performed several times for osteoperiostitis of the zygoma, but the tissues refuse to heal in spite of all treatment, medical as well as surgical. The tonsils, which are diseased, are enucleated and the disease of the zygoma promptly heals, while every other evidence of marked improvement in the general health is presented. Again, we all recognize the increase in weight and improvement in the general health, especially in children, after the removal of the tonsils and adenoids.

This theory, moreover, applies not only to the tonsil, but to other structures as well; for instance, a man has tuberculosis of the kidney with an external fistula and a hip-joint tuberculosis; if the latter is arrested the patient gains in weight and strength and the fistula and tuberculous kidney promptly heal.

Such results as these are more than mere coincidences and, to my mind, can best be explained by the above-mentioned theory.

2551 North Clark Street.

Causes of Itching in Children.—In making a diagnosis of the cause of itching the age of the patient is an important factor. In children the most common causes are urticaria, scabies, pediculi, and ascariides. The presence of papules and wheals, the history of the lesions appearing "as if the child had been stung with a nettle," are diagnostic of urticaria, while the distribution of a scabies eruption, the presence of burrows on the hands and wrists, and the identification of the acarus leave no room for doubt. Thread-worms are a frequent cause of pruritus and in children, and when these have been got rid of the itching will be found to disappear.—J. L. Bunch, in *Merck's Archives*.

ENUCLEATION OF THE FAUCIAL TONSILS *

ITS DIFFICULTIES AND CONTRA-INDICATIONS

B. R. SHURLY, M.D.

Clinical Professor of Laryngology, Detroit College of Medicine;
Attending Rhinologist and Laryngologist, Harper Hospital;
Laryngologist and Otologist, Woman's Hospital
and Infants' Home; Attending Laryngologist,
Children's Free Hospital

DETROIT

It is indeed a sad commentary on surgical procedure that it should be necessary to discuss at the present day any problem connected with the removal of the faucial tonsil. The fact remains, however, that an investigation of this operation throughout the civilized laryngologic world reveals many widely diverging and conflicting ideas in physiology, pathology, therapeutics and surgery. It is particularly the function of this Section, acting as a higher judicial court, to weigh such problems, and to establish, between enthusiasm and experience, a just and definite scientific basis of practice.

HISTORY AND STATUS OF THE RADICAL OPERATION

A glance at the extensive bibliography of McKenzie shows that tonsillectomy was performed by the ancients, and that Celsus recognized the value of enucleation by the finger.

Writing in the year 10 A. D., Celsus¹ says: "Tonsils which remain indurated after inflammation, if covered by a thin membrane, should be loosened by working the finger round them and then torn out; but when this is not practicable, they should be seized with a hook and excised with a scalpel." Aetius in 480 A. D., takes a more conservative view and advises that one-half the gland or the projecting portion only should be removed.

Borelli, an Italian surgeon of Sardinia, fifty years ago, describes his revival of the method of Celsus as follows:

The index-finger is placed behind the summit of the gland and by working from above downward with the nail and making traction the tonsil is detached from its bed. A small piece which does not afford sufficient purchase to the finger in order to be torn away is generally left at the inferior part. This is seized with a forceps and separated by a slight movement of torsion.

The admirable historical abstract of the tonsil operation by McKenzie is exceedingly interesting and shows at once that the American furor for complete enucleation is little more than a revival. It is necessary, I believe, to define carefully the terms "tonsillectomy" and "tonsillotomy." Tonsillectomy should be applied to those procedures only which remove the gland with the capsule intact, while tonsillotomy should include all other operations in which some portion of the tonsil remains. Many surgeons who claim tonsillectomy as their favorite method advocate procedures that, in actual practice, leave a considerable remnant of tonsil undisturbed.

For many decades the teaching in the great medical centers of Europe has profoundly influenced American surgery. The waves of radicalism have originated in some foreign university city and swept quickly over our country. To-day the tide has turned, and the idea of radical enucleation of the tonsil is taken back to the home of its birth through American influence.

It has been the pleasure and privilege of many persons in this Section to observe tonsil work in the clinics of the Old World. If your personal experience agrees with mine, you have never seen a tonsillectomy performed in any of these great centers of teaching, except for malignant disease.

It has been my endeavor to obtain the recent views of some of the leading laryngologists of Europe in regard to this question. While in London this summer I asked Mr. Herbert Tilley, Dr. Dundas Grant, Mr. Davis, and others if they performed tonsillectomy. The reply was unanimously against this operation, as it was considered quite unnecessary in England.

It was my pleasure to demonstrate this operation before the postgraduate class of the West London Hospital, where, I am told, the complete enucleation had never been performed. The McKenzie tonsillotome is in general use there; and, usually, in expert hands it removes two-thirds of the gland. Occasionally, an entire tonsil will be removed by this method.

Dr. Logan Turner, of Edinburgh, Scotland, answered my questions as follows:

In the case of children we still as a rule do tonsillotomy. The exceptional cases are those in which the cervical glands are troublesome, and then enucleation is practiced. I find that hemorrhage during the operation under a general anesthetic is the difficulty. In adults we now usually practice enucleation; as a rule, under local anesthesia plus adrenalin injections. The indications are recurring peritonsillar abscess, tonsillitis, loaded crypts with fetid breath and enlarged glands. And occasionally we get cases of ill health, in which no other etiologic condition can be discovered. If the operation is made complete, we are not usually troubled with postoperative hemorrhage.

In France the punch or snare has come into prominence, and Luc describes his tonsillotomy as follows:

I have adopted for the last five or six years, the method of our colleague Vacher (of Orleans), consisting, first, in liberating the gland from its adhesions at the pillars, then in seizing and drawing it from its lodge by means of a Museux forceps previously passed through the loop of a cold snare, and finally closing the snare. For that operation I only have recourse to general anesthesia in young children, whereas in the case of adults I simply use local anesthesia by means of injections of a 1 per cent. solution of novocain under the mucous membrane.

Professor Killian says that, so far as he knows, the radical tonsil enucleation is not done in Germany. The operation is done usually without a general anesthetic. The greater part of the tonsil is removed with the tonsillotome or the cold snare. The radical operation is considered only under special indications and is the exception.

Professor Massei, of the University of Naples, a splendid observer, replies as follows:

In forty years of practice, I have never performed tonsillectomy, and so far as I know, it has never been performed in Italy, particularly by specialists, except for cases of malignant diseases. Personally I believe tonsillectomy (for simple hypertrophy of the tonsils) a fault, not only because I am convinced that the risks of a hemorrhage are more frequent than in tonsillotomy, but also because I think that it is more correct to leave something of the gland. In about three thousand tonsillotomies I have performed, I had only seven or eight severe hemorrhages (one arterial) all controlled by common measures.

If the Austrian methods can be demonstrated by the Viennese teaching in the clinics of Chiari, Hajek, and Koseher, tonsillectomy is rarely, if ever, performed.

* Read in the Section on Laryngology and Otology of the American Medical Association, at the Sixty-first Annual Session, held at St. Louis, June, 1910.

1. Celsus: De Medicina, Chap. 7, Sec. 12.

During my student days the Matthieu tonsillotome without anesthetic was the instrument of choice. The submerged tonsil was never operated on. It is evident, then, that the teaching in all countries except our own, and possibly Scotland, is opposed to the radical operation of enucleation. The two predominating factors that influence the question of conservative or radical tonsil enucleation seem to be, first, the latent doubt of a possible important function which the tonsil tissue may possess; second, the belief that a complete removal is unnecessary. Until these problems are definitely solved by forcible and convincing argument the radical methods cannot become universal.

Physiology has not completely and satisfactorily explained the function of the tonsil. If the normal tonsil has a constant outward current of lymph and secretion, it must have some function in eliminating pathogenic organisms or toxic material from the circulating fluids.

From Richard's admirable collective investigation on the present status of the tonsil operation, in which seventy-seven laryngologists gave their views as to the function of the tonsil, it is fair to assume that science has not definitely settled this question. It is permissible to believe with Bordley, therefore, that these glands in early infancy act as governors over the system of ductless glands and possess an internal secretion from the normal tissue which regulates various ratios of polymorphonuclear and mononuclear blood-cells. We have frequent clinical demonstrations of the relation and association of disturbed conditions simultaneously in the tonsils, the thymus, and the thyroid. We are all familiar with these conditions in the so-called status lymphaticus and sudden death. Numerous examples are on record of hypertrophy of the thyroid gland, together with the faucial tonsils, which hypertrophy subsided on the removal of the tonsils. Three of the prominent causes of exophthalmic goiter are tonsillitis, quinsy, and scarlet fever, all of which greatly disturb the normal function of the tonsil. It is my experience and belief, and that of others, that normal tonsils which produce no symptoms should be left severely alone. This is especially true in early infancy.

DANGERS AND CONTRA-INDICATIONS

As we peruse the literature of this subject, we are particularly struck by the fact that the literary laryngologist is not necessarily the practical surgeon. The dangers and contra-indications of the radical operation are dependent on the experience, judgment, surgical ability and personal equation of the individual operator. The men who persist in giving chloroform, who remove adenoids, and, then, immediately remove the tonsils, and who prefer a general anesthetic in the upright position, must remain in a class by themselves, until some great calamity brings home the fact that their methods of procedure are attended by additional dangers to the patient.

It is necessary to perform tonsillectomy in only one case of pernicious anemia or acute leukemia to impress the individual surgeon and those in his community with the value of a blood examination in all suspected anemias. One case of hemophilia is sufficient to establish the value of a routine examination to determine the coagulation point. One death from chloroform is a life-long lesson in the value of ether.

The dangers and contra-indications may vary from three distinct points of view: namely, observations from (1) the clinic or dispensary; (2) the hospital; and

(3) private practice. Again they may vary from the standpoint of the general practitioner and the specialist.

Tonsillectomy is an operation that requires an abundance of time and attention to the details of technic. It is attended by additional danger when performed in the dispensary under the hurry and pressure of work. The most alarming cases of hemorrhage that have come under my personal observation have occurred in patients who were operated on in the office or dispensary, and had returned home. There is less danger of hemorrhage from tonsillotomy with the tonsillotome or snare than from a bungling or imperfectly performed tonsillectomy. Since the complete enucleation has been recently advocated, a great number of general practitioners and specialists have attempted to change their methods and, in learning the new operation, the pillars have been hacked and torn and removed, with a resulting increase in cases of primary and secondary hemorrhage. If the general surgeon, the ophthalmologist, and the general practitioner must remove tonsils, they are respectfully advised to do a tonsillotomy until they may receive instructions, at least in the details of a complete enucleation.

According to my experience, it is impossible to perform more than a dozen tonsillectomies in an afternoon. In some dispensaries the operation is often hurried or neglected in the rush of work. Our most valuable deductions and lasting impressions come from our work on private patients of intelligence. I believe that in this class of tonsil enucleations we establish our best standards of work. The real criterion is determined by the methods we should choose for our own individual cases, and by the postoperative results five to fifteen years later.

We can agree, I am sure, that the average tonsillectomy is attended by a much greater amount of postoperative pain than tonsillotomy. The dangers of tonsillectomy, hemorrhage, shock, traumatism, and death from anesthesia, diminish greatly with a carefully perfected surgical technic and equipment. The disasters that have been reported occurred from the choice of the wrong anesthetic or a failure to loosen the tonsil completely from its bed before its removal was attempted. Ether is the only general anesthetic advisable, in my opinion, although it is contra-indicated in tuberculosis, abscess or other disease of the lung.

From more than 1,000 tonsil operations and from many observations of other operators, I have tried to select a method which insures safety, thoroughness and rapidity in execution. A general anesthetic is administered to children or those older individuals whose personal and peculiar characteristics of fear, nervousness, disposition, or idiosyncrasy to cocaine lead one to suspect that the operation with local anesthesia will be difficult or prolonged. In this class of cases an incision is made with Freer's knife, or some equally useful instrument between the anterior wall of the tonsil and the pillar and just below the inferior border of the velar lobe that will allow the finger (preferably) or some blunt dissector to pass outside the capsule. This incision I consider the key to the operation. If it is improperly made, the difficulties of the enucleation may be great indeed. The finger is then passed into the opening and upward, and the velar lobe released from its bed. Firm pressure downward frees the anterior border to the base. The attachments to the posterior pillar may not yield as readily. As gentleness is the rule, a blunt dissector may be of service to release some tougher bands. The

finger is usually successful, however, and the tonsil is absolutely free to the base. A good volsellum now holds the loosened tonsil well forward while a strong snare with heavy wire is slowly tightened along the slightly attached inferior portion of the capsule. If this latter part of the operation is unskillfully performed, the uvula or other muscle tissue may be removed; the pillars may be wounded and the contour and symmetry of the arch lost. This may result in impairment of the voice, or sloughing may ensue.

In many cases of tonsillectomy that have come under observation five to ten years after operation, the fact is evident that the successful result is in direct ratio to the more or less complete removal of the velar lobe.

While tonsillectomy may be indicated in incipient tuberculosis, it is contra-indicated in our climate in the more advanced stages. The dangers of shock, hemorrhage, and anesthetic outweigh the value of the complete operation. Septic arthritis and so-called rheumatism of tonsillar origin may certainly demand a complete destruction of tonsil tissue, yet we must carefully differentiate and classify these cases according to our known etiologic factors. Gout is a distinct disease that is often confused with rheumatism, and many of the phenomena classified as arthritis and rheumatism are the result of dietetic errors or faulty elimination from the gastro-enteric tract. This fact has been frequently and forcibly emphasized by Stucky.

I believe that it is a mistake to make an arbitrary rule that, because a patient has had tonsillitis twice in one year, the tonsils must come out. Many cases classified as recurrent tonsillitis are not such *per se*, but the patients are often the victims of prevailing infections of pneumococcus, influenza, or Klebs-Loeffler organisms that would infect remaining gland tissue in the throat on other occasions when the opsonic index is low. Many of these infected tonsilless individuals present themselves and mournfully proclaim their disappointment. Physicians are frequently called on to correct a mistaken idea that the removal of tonsils will prevent sore throat. The enthusiast and optimist must not claim more than results will justify, until Father Time shall have weighed the problem through a succession of years.

In quinsy the indications are established for complete and total removal as the procedure. When cervical adenitis is present it is necessary to differentiate between the simple and tuberculous forms. Many of these infections are of nasal and nasopharyngeal origin and respond promptly to local and systemic treatment. Those which are of persistent and aggravated type and in direct relation to the faucial tonsil require a complete removal of the cause by tonsillectomy.

When we have carefully weighed all argument in regard to tonsillectomy it is evident that the American laryngologist stands as the exponent of the ultraradical operation. He has revived the teaching of Celsus in every detail. He has led the surgical pediatricist, the ophthalmologist and the general surgeon a lightning pace. He has devised a dainty assortment of instruments, a series of dazzling lights and a line of technic that has left the abdominal surgeon thinking at the half mile house. It is good work and well done, but it is not always necessary. The tonsillotome has not outlived its usefulness. I believe that the general practitioner and the specialist, in selected cases, can use it with great relief and comfort to many patients. When the simple methods fail, tonsillectomy by the expert will destroy any offending tissue that may remain.

CONCLUSIONS

1. The normal tonsil should not be disturbed, particularly in early infancy.
 2. Simple hypertrophied tonsils may be removed satisfactorily with the tonsillotome.
 3. Pathologic tonsils, especially those of the submerged type that produce well-defined local or general symptoms, should be completely removed within the capsule.
 4. In children tonsillectomy requires a general anesthetic, preferably, ether. This should be a hospital operation when possible.
 5. Tonsillectomy is an operation that should be restricted to those who are specially qualified.
 6. The removal of the velar lobe and the complete separation of the pillars are the most important parts of the tonsil operation.
 7. Tonsillectomy is not indicated in all cases of so-called rheumatism.
 8. Complete enucleation is usually attended by more pain, a longer period of convalescence and greater danger of infection than tonsillotomy.
 9. When tonsillectomy is skilfully performed the hemorrhage is less than when the average tonsillotomy is done.
 10. Tonsils which have been involved in recent acute inflammation should not be operated on, until all evidence of the acute condition has subsided.
 11. Many tonsils seen by the general practitioner, with every appearance of serious pathologic condition, never develop local systemic symptoms.

ABSTRACT OF DISCUSSION

ON PAPERS OF DRS. LEVY, BECK AND SHURLY

DR. A. H. ANDREWS, Chicago: Dr. Shurly has given us some excellent indications and contraindications for tonsillar surgery, but my impression is that when the tonsil is sufficiently diseased to demand surgical interference on the part of the specialist, tonsillectomy is the only operation to perform. Many simply enlarged tonsils do not need to be removed, and are enlarged because of the presence within their crypts of cheesy material that is undergoing decomposition. If such a tonsil is simply cleaned out a few times the enlargement will subside; if it does not, then, in my opinion, the tonsil should be removed; and, when I say removed I mean enucleated. I agree with Dr. Levy that we never know the tuberculous tonsil until it is examined after operation. When the patient shows lowered vitality, or any trouble can be traced to the tonsil, the tonsil should be removed.

I have been interested in the change of attitude in the profession toward the relationship between rheumatism and tonsillitis, and it is a change which is not so complete as it will be, and in my opinion should be. I believe that rheumatism has absolutely nothing to do with the production of tonsillitis, but that tonsillitis frequently, though not always, is the cause of rheumatism. The attention of the practitioners and laity should be especially called to this fact.

Regarding other causes for cervical adenitis, we should not forget that the teeth may be responsible for this condition; disease of the sphenoid sinus will do the same, although usually the glands involved in this latter condition are the posterior cervical glands. Perhaps some members of the Section have had cases of inflammation about the wisdom teeth when these were coming through and have noticed the adenitis resulting. This shows that the glands of the neck may be involved and often are as a result of dental disease.

I think that there is no question regarding the raising of the opsonic index by the removal of tonsils; the same may be said of the appendix, disease of the antrum of Highmore, or any other condition in which there is absorption of toxins.

DR. W. E. SAUER, St. Louis: I am not sure that I understood Dr. Beck correctly as to the removal of tonsils in scarlet fever and diphtheria. A number of years ago it was

pointed out that in children in whom adenoids and tonsils had been removed diphtheria and scarlet fever ran a more severe course than in those in whom they had not been removed. At that time enucleation was not being done, of course, and the experience of Fraenkle must not be taken too seriously. However, it is a question to consider. We have not had enough experience to know just what influence the entire removal of the tonsils has in these cases. I agree that the tonsil that is simply somewhat enlarged should be let alone if normal in other respects. We have all seen striking results after removal of the tonsils in cases of rheumatism, but whether or not the removal of the tonsils is going to stop further attacks is questionable, because infection can take place through some other part of the lymphatic chain.

Technic is largely a matter of choice. Some men develop a certain technic along one line, and some along another. I agree with Dr. Shurly that the removal of a tonsil *in toto* is not an easy operation. It requires a great deal of experience and skill to do the operation properly. In many operations the pillars are damaged and the patients are worse off than before the operation. The question of bleeding has been touched on very lightly. In my experience, the bleeding from total enucleation of the tonsil has been decidedly less than from the old tonsil operation. At the time of operation we may run across a spurter but it can be tied.

DR. C. F. WELTY, San Francisco: I believe that tuberculosis of the tonsil is much more prevalent than Dr. Levy has shown by his conclusions. In the microscopic examination of tonsils from cases of so-called lung tuberculosis, I was able to demonstrate the tubercle bacilli in 6 different cases (in fact, in all the patients who were examined), and from this fact I believe that all patients with lung tuberculosis should have the tonsils removed when they are in physical condition to go through the operation. In 4 different cases, I was able to diagnose tuberculous lesions of the tonsils, verified by microscopic findings—all the patients had lung tuberculosis. In 3 cases, tubercle bacilli were found in patients who were supposed to be free from tuberculosis. These cases could not have been diagnosed as tuberculosis from the clinical appearance or history. Comparatively few microscopic examinations have been made at my suggestion, principally because I have not the facilities for carrying such work to an ultimate conclusion. So in summing up I am led to believe that tuberculosis of the tonsil is quite frequent.

In a case similar to the one that Dr. Beck reported, the patient had 4 different extensive gland dissections without removal of the tonsils. The glandular swelling was returning again and the tonsils were enucleated. The glands ceased to enlarge or disappeared entirely; tubercle bacilli were demonstrated in the tonsils as well as in the glands.

In an endemic of diphtheria among the nurses at the San Francisco City and County Hospital, 20 nurses contracted the disease; all had diseased tonsils. There were approximately 20 nurses who had the tonsils removed; none of them had diphtheria. It should be an accepted fact that diseased tonsils predispose individuals to diphtheria, as it is practically always the starting point for such infection. There is another condition to which I wish especially to call attention, and that is "underweight." It will be found that 90 or 95 per cent. of the patients have gained weight following tonsillar enucleation. This statement holds good in cases of "underweight" in which organic disease can be excluded and in fact is one of my own indications for the operation.

I wish to call attention to a series of 200 patients who were examined by the anesthetist prior to operation, showing that 20 per cent. had heart lesions.

I believe that adenoids, and tonsils especially, predispose to the whole group of infectious diseases and in fact everything that may enter by way of infection. No doubt whole chapters of internal medicine will be done over by the work we are engaged in to-day.

As to the difficulties encountered in doing the operation, there are many, when one does not understand the *modus*

operandi, which I would liken to a chain made up of links, every one of which must be perfect.

DR. J. E. LOGAN, Kansas City, Mo.: I concur in the main with each of the essayists, but I also desire to add a phase of this subject for consideration which to me is a necessary part of this discussion, viz., the radical extirpation of the pharyngeal tonsil. In my experience, whenever we find faucial tonsils in a state of inflammation or hypertrophy we will certainly find a pharyngeal tonsil in like condition. Whether this pharyngeal hyperplasia be much or little it is more important that it be removed than the faucial tonsils.

DR. O. T. FREER, Chicago: A pathologic condition of great importance in relation to tonsil surgery has not been mentioned in this discussion—I refer to chronic peritonsillitis. This condition is not found in simple hypertrophy of the tonsil, but is a common result of repeated or chronic inflammation of the tonsil, which spreads beyond it into the areolar and muscular structures forming its bed. These recurring inflammatory attacks finally leave a low grade of plastic inflammation which cicatricially unites the tonsil to the tonsillar fossa, firmly joining it to the glossopalatinus and pharyngopalatinus muscles and the fascia of the superior constrictor without. This condition makes enucleation by the finger, or even a blunt separator, an impossibility. Nevertheless, it is constantly being attempted with resulting injury from the violence employed. I have often seen evidences of such violence. A colleague called me in consternation because he had just torn the anterior pillar in two. In another instance both the pillars had been literally rent into shreds; this patient died of sepsis. In another, the posterior pillar had been torn from its bed far down into the pharynx. In many instances, the attempt to enucleate the tonsil bluntly resulted in excessive reaction, fever and prostration. Such results cannot be compared with the comfortable recovery from a clean knife excision of the tonsils such as I described in THE JOURNAL Feb. 13, 1909. While the knife accurately extirpates the diseased organ in a surgical manner, it leaves the surroundings of the tonsil intact, so that the delicate motions of the palate are not in danger of future interference from cicatrices resulting from damage to the pillars. After a long trial I recommend this method most heartily as the only technic required for the total removal of all tonsils whether of the large hypertrophied or cicatricial variety. I have never seen an instance of serious hemorrhage resulting from it, and long ago ceased to use the wire snare because of the rough work it performs in hard fibrous tonsils and the excessive reaction following its use.

DR. F. E. AUIEN, Belleville, Ill.: The tonsils and adenoids are the chief portals through which infection enters the system. The greatest prophylactic measure that has been brought out in recent years is the complete enucleation of these masses, and if it could be possible to enucleate Peyer's patches we would see a great reduction in enteric diseases. I have had seven years' experience in complete enucleation or tonsillectomy and I have never seen an individual who was not benefited and largely so by the operation. I believe that the best tonsil is the one that has been enucleated, just as the best Indian is a dead one. Two of the greatest internists of Berlin advise removal of the tonsils, even in acute muscular and joint rheumatism, to prevent further absorption of toxins into the system. We must remember that the intramuscular spaces and the synovial cavities are a part of the lymphatic system. One can reduce almost to a minimum the diseases of childhood by careful removal of these bodies. The trouble is that often we do not do clean, thorough work.

Two men in this country who deserve great credit for their work in this line are Drs. E. Pyncheon and O. Tydings, of Chicago. When Pyncheon said that it was not a question of large or small tonsils, but a question of their condition, he did a great deal for the advancement of this work. In 1901 I saw Dr. Tydings do what I think was the first tonsillar enucleation in capsule in America. I think the work of these men, and that of others in Chicago (and Chicago is the center from which this work has spread) have conferred a great favor on humanity. I am an enthusiast on the subject.

DR. M. A. GOLDSTEIN, St. Louis: Those who heard Dr. Mygind's reference to his first work on adenoids will recall his remark that it was ten years after the first scientific presentation of this progressive movement before American otolaryngologists took up this problem in an active way. This showed one extreme of conservatism of American otologists. On the other hand we have had in recent years the radical Killian operation on the frontal sinus and the radical work on the mastoid and it is interesting to follow the evolution of the otolaryngologist's mind on this problem. It has taken nearly a quarter of a century for us to become thoroughly familiar with the indications, the time, when and how, to do the radical or simple mastoid operation in each given case; it has taken nearly a decade for us to determine how infrequently we might operate by means of the radical Killian operation and still benefit our patients. It will also take a certain length of time before we are sure of the time and manner of operation on the faucial tonsils. We have perfected the technic of tonsillectomy, and the proper technic is familiar to every laryngologist, but the time to operate has not yet been so definitely determined. I believe in rational radicalism. I believe that there is a time for tonsillectomy and a time for tonsillotomy. The thymus and glandular tissue which develop in early infancy take care of themselves. The surgeon who operates on the thyroid to-day does not remove the entire gland; he leaves a small section. The faucial tonsil is also lymphoid tissue—it also has a function. With all due deference to Drs. Levy and Beck, I want to compliment Dr. Shurly on having produced a masterpiece of common-sense and good judgment, and I think we will all agree later that there is much food for reflection and much time for hesitation before attempting tonsil enucleation in every case.

DR. BRYAN D. SHEEDY, New York: I note by the literature that very few deaths have been reported in connection with tonsillectomy, yet I believe, judging from the large number of deaths, from 7 to 10, in New York City, an opportunity to record valuable information has been neglected. Last week in discussing a recent death with the coroner's physician and in going over his findings at autopsy, I learned that many of the deaths due directly or indirectly to tonsil removal were those of patients in apparently normal condition until the operation was performed, or at least up to the time that the local anesthetic was used. In London, chloroform is the anesthetic most in use; in America, ether and recently gas and ether are preferred. Lately, however, a great many nose and throat men have been using cocaine for local anesthesia combined with adrenalin chlorid. Local anesthesia for the removal of tonsils is very little used in the German-speaking countries, to-day, and it may be of interest for some to know that the operation of tonsillectomy is not being performed in these countries. In New York City all the recent deaths in connection with tonsillectomy have been in cases in which cocaine, with or without adrenalin, was employed. Of the recent deaths autopsies were held in but two of the cases.

DR. HENRY HORN, San Francisco: Following radical enucleation of the tonsils it is possible that some change takes place in the Eustachian tubes producing an exacerbation of an already existing catarrh. I have seen enough cases to be positive that after certain complete enucleation of the tonsils in which the pillars have been somewhat injured there has been some sort of change and a deafness has been increased thereby.

DR. JOSEPH C. BECK, Chicago: Dr. Horn mentioned the effect on the Eustachian tubes of enucleation of the tonsils. My results in 27 cases have been just the opposite of what he describes. That is one of the indications for the operation, tubal catarrh. Dr. Sheedy did not mention any post-mortem findings in the cases of death with the employment of cocaine, so we cannot speak of that. These reports are of hardly any value when we know how many patients receive injections without any harmful effects. Dr. Shurly has absolutely agreed with me as to the indications and I also said that with rare exception is tonsillotomy done. Many

general practitioners do it, but every specialist will prefer to do a tonsillectomy.

I did not mean to say that there are not other portals of infection for scarlet fever and diphtheria, but that when the children who had had the tonsils and adenoids removed had diphtheria and scarlet fever, it was milder in character. Dr. Freer mentioned peritonsillitis; that is known usually, I think, as lateral pharyngitis. That is one of the conditions in which the operation is indicated.

RECENT PROGRESS AND PRESENT STATUS OF EXPERIMENTAL RESEARCH IN CANCER*

LEO LOEB, M.D.
PHILADELPHIA

Not uncommonly the criticism is heard that no progress has been made in our knowledge of cancer. I do not believe this statement to be correct and I fear that it may have a paralyzing effect on those who devote all or part of their efforts to this branch of pathology. I attribute this and similar other criticisms, in part at least, to a lack of contact between the theoretical and practical worker in the field of medicine, and I believe it to be due to a lack of knowledge of what has been accomplished in this field, and also to an underestimation of purely theoretical work on the part of the practical worker in medicine. In medicine not less than in physics and chemistry the most far-reaching advances in diagnosis and treatment follow as a natural result, in a certain sense as a by-product, of new theoretical knowledge and conceptions. But apart from all practical considerations a purely theoretical study of pathologic phenomena is not only a justifiable but a necessary undertaking and can claim the same justification as the theoretical study of other branches of biology.

Cancer investigation has been and still is to great extent purely theoretical, although some of its results are beginning to be applied in the treatment and the diagnosis of cancer. The experimental study of cancer is a rather young branch of science; it is only in the last decade that very extended and continuous studies of an experimental character have been undertaken, although a few sporadic though brilliant attempts had been made previous to that period.¹ But the principal researches before the year 1900 were mainly concerned with the microscopic study of cancer; and although this was and still is a necessary and most valuable line of research, unaided by other means it is unable to give us an insight into the physiology of tumor growth, and the latter is especially needed. In all phenomena of growth the number of unknown and variable factors is exceedingly great and only by formulating new equations can we hope to eliminate some of the variable factors. The experiment alone can accomplish such a task. There are several points of attack on the problem of cancerous growth. Ultimately our complete knowledge of cancer will coincide with our knowledge of tissue growth in general. And

* Read in the Section on Pathology and Physiology of the American Medical Association, at the Sixty-first Annual Session, held at St. Louis, June, 1910.

¹ I refer here especially to the work of Hanau and Morau. Ten years ago the experimental researches were carried out on a large scale with several sarcomas of the thyroid of rats. In these investigations the tumors were carried through many more generations than in the case of Morau and Hanau, and here systematic studies in the biology of tumor-cells were inaugurated. This work was followed by that of Jensen, who used a carcinoma of a white mouse in his investigations.

from this point of view every contribution to the physiology of tissue growth is a step further in our knowledge of cancer growth, inasmuch as the latter is a special variety of tissue growth and new knowledge of cancer growth will also stimulate and enrich the general biology of growth phenomena.

It is furthermore fully acknowledged that morphologic phenomena of growth are invariably connected with chemical processes and are more or less the expression of underlying chemical and physical changes. Simultaneously with the experimental study, there developed, therefore, a chemical study of cancer, a study of its chemical structure and of its chemical activity, especially of its ferment actions. Furthermore we may include under the heading of experimental investigation of cancer, research in the distribution of cancer and in the factors that lead to the development of cancer among animals, the influence of heredity, environment and possibly of micro-organisms—studies which developed in close connection with the experimental investigation of cancer. Now all these lines of investigation, however young their history may be, have already led to the discovery of very interesting facts. Inasmuch as in the other papers in this symposium several of these special aspects of cancer investigations will receive a more detailed consideration, I shall limit myself here to a general survey.

Thanks to the experimental investigation of the last ten years we are beginning to obtain some definite knowledge concerning the physiology of the tumor cells and of the physiology of growth of the various normal mammalian tissues.

To enumerate a few of the facts which have been ascertained: Tumor cells in many cases can be propagated in other individuals of the same species and on the whole preserve their specific character as cancer cells. This fact at once disposes of various hypotheses concerning the etiology of tumors which have caused much discussion within a very recent period, inasmuch as it proves definitely that tumor cells are not merely regenerating tissue cells, and that they differ in their reactions from regenerating cells; and that the activities of cancer cells cannot be merely due to the peculiarities present in the individual organism in which the tumor originated. With this difference in the physiologic behavior of tumor cells agrees very well the discovery that the ferments of tumor cells differ quantitatively and probably also qualitatively from those of ordinary tissue cells.

On the basis of our present experimental data we have very strong reasons for believing that cancer cells may continue to proliferate indefinitely, so long as they obtain the adequate environmental conditions. And this in turn leads us to revise some of our fundamental biologic conceptions, according to which the germ cells are immortal, while the somatic cells are necessarily mortal. Through these investigations it has become very probable indeed that some at least of our somatic cells also possess the potentiality of an immortal life.

We are penetrating more deeply into those conditions which determine the energy of growth of tumor and of tissue cells. We now know that energy of growth of tumors (the rate of the propagation of their cells) is not a fixed character but is amenable to variations which can be produced experimentally. Experimentally it is possible to increase and decrease the rate of tumor growth. And these experimentally produced changes are transmitted to successions of generations of cancer

cells. We have furthermore learned that some experiences which surgeons have had in cancer patients are merely special instances of the more general laws which experimental tumor investigation has established and is continuing to establish.

New and unsuspected properties of cancer cells have been discovered. I might mention here especially their very great capability of recovering from external injurious influences, which may have exerted a markedly depressing effect in their vitality during a certain period of time. The tumor cells possess to an astonishing degree an elasticity which enables them to regain their old vigor, especially after transplantation into another individual.

By selecting for propagation, instead of average tumors, very well-growing tumor cells, it is possible to obtain more rapidly growing tumors, a method especially used by Ehrlich for the cultivation of virulent tumors. I confess, however, that in this case I am not yet certain to which factor the noticeable beneficial influence has to be attributed. These examples may suffice to indicate that we are obtaining outlooks into new fields which were possible only as the result of experimental investigation.

Experimental investigation permits us, however, not only to analyze the activities of the tumor cells but also the conditions in the host on which in part at least, the life of the tumor cells depends. Here also, on the basis of experimental work, very important facts have been found—facts which may appeal to the physician even more than that side of research which we have just spoken of. In this case also I shall avoid going into details and shall limit myself to a few general conclusions.

The transplantability of a tumor depends, first, on the character of the particular tumor and, secondly, on the character of the host. The majority of tumors, as far as we are able to judge at the present time, can be transplanted in the same individual in which the tumor originated; others can be transplanted into individuals nearly related, namely, individuals of the same family; while a certain number grow in a large number of individuals of the same species and a few grow even in different though nearly related species. These facts drew attention to somewhat similar conditions existing in the case of normal tissues—facts that had not received due attention in previous times. They indicate specific relationships, chemical adaptations existing between the body cells and the circulating fluids—adaptations which are of a variable degree of specificity in various cases.

Some individuals of the same species are usually found to be naturally immune to tumor growth; their body cells or body fluids react in such a way that the tumor does not find the suitable condition for growth. Other animals can be rendered artificially immune towards the growth of tumors, by inoculating them with cells of normal organs or with tumor material of the same or perhaps also of certain related species. A very potent immunity can be produced by inoculating living tumor material, the vitality of which has been lowered by previous heating. Such material gives rise to a large number of spontaneously retrogressing tumors after inoculation as I found very early in the course of my investigations. I therefore recommended seven years ago the use of such material for active immunization. Gaylord and Clowes and Sticker were the first to prove the existence of active immunity in animals in which a tumor had retrogressed spontaneously, es-

pecially after tumor material of experimentally decreased virulence had been inoculated. The mechanism of immunization is to be discussed by another essayist and I shall limit my remarks to the statement that, notwithstanding many attempts that have been made in this direction, no serum has been prepared so far which has a decided cytotoxic effect and which could be used for the purpose of passive immunization. Active immunization, on the other hand, appears to be much more promising for practical purposes. And attempts have been made to apply in the treatment of patients, some of the results of the experimental investigation in the tumor growth in animals.

We thus see that the first positive results have already been obtained in experimental immunization against tumor growth, a fact of great theoretical and practical significance. Our principal aim, however, which ultimately we wish to realize, is the perfect experimental control of all these conditions under which cancer develops. It might be argued that we are still far removed from being able to produce cancer experimentally; but even such a statement would no longer be absolutely correct. In a certain sense all those cancers which, as we know, arise in a definite proportion of cases in persons affected over a long period of time, by certain external injurious influences as soot, Roentgen rays and other physical and chemical agencies, may be regarded as experimentally produced cancers. And even in animals in a certain number of cases we have been able to create *de novo* malignant tumors, namely, sarcoma, and perhaps also adenocarcinoma by transplanting carcinoma, although in all these cases the presence of unknown variable factors complicates the observations as yet; but notwithstanding this limitation, we have here another instance in which discoveries, although their interpretation may in part still be obscure, promise us an outlook into new fields and a new point from which to attack the problems.

Stimulated by experimental cancer research and again stimulating the latter, of which indeed it forms an integral part, the experimental study of the physiology of tissue growth has led to some interesting results. Of these I shall mention only two achievements obtained within the last few years. Definite chemical substances, namely, amido derivatives of certain aromatic products have been found to be particularly potent in calling forth infiltrative growth of the epithelium into the underlying connective tissue; and infiltrative growth is one of the characteristic features of the cancerous proliferation. A further advance has been made in the analysis of formative stimuli: it has been found that a combination of an internal chemical and an external mechanical factor may exert a specific stimulus on the growth of certain selected tissues to an extraordinary degree; the chemical substance acting as a sensitizer of the tissues, preparing them for the action of the mechanical factor. We may conveniently designate such stimuli as "combination stimuli." In both of these instances we have not yet to deal with the production of true cancers, inasmuch as the growth is only of a transitory character; but in both cases means have been found of analyzing the two most characteristic attributes of cancerous growth, not only in a qualitative, but in part at least, also in a quantitative way.

In conclusion, I wish to draw attention to the fact that the experimental investigation of cancer has already exerted a stimulating effect on some other apparently unrelated fields of science. Thus the last-named in-

vestigation into the artificial production of deciduomas promises to clear up, to a great extent at least, the mechanism of the sexual cycle in the female mammalian organism, while certain studies in immunity against tumor growth appear to throw an unexpected light on the etiology of eclampsia.

In presenting this, an altogether incomplete and rather hasty review of some of the achievements of experimental investigation in cancer, it is fair to say that the investigators whose work is referred to are certainly far removed from any inclination to overestimate the results obtained or to underestimate the difficulties facing further progress in this field of science. But I am convinced that the facts elucidated within the last ten years deserve to be known well by the biologist and by the physician.

THE BIOCHEMICAL INVESTIGATION OF MALIGNANT TUMORS AND ITS DIAGNOSTIC APPLICATIONS*

RICHARD WEIL, M.D.
NEW YORK

It is not the object of the present paper to review the entire field of the biochemistry of tumors. Large and well tilled as is this field, it would be tempting but impossible to cover the ground in the brief critique assigned me. That aspect of the subject, in this symposium, therefore has been selected, which appears to be of especial interest and importance for the general understanding of cancer as a disease. The present paper will deal with those investigations which have attempted to elucidate the mutual relationship existing between the new growth and its host, the patient—the biochemical evidences regarding the cause of the cachexia and of the anemia induced by neoplasms, and on the other hand the biochemical aspects of the resistance or the relative immunity, which represents the protective mechanism of the host.

That such a protective mechanism exists in experimental animals is now no longer open to doubt, and there are many facts which seem to demonstrate the occurrence in human beings of a tendency which is similar in kind, even though markedly less in degree. At all events it is possible to place this interpretation on the notable resistance which is shown by some patients to the disease, as manifested by the prolonged well-being and absence of cachexia in spite of considerable tumors, and also by the local conservative processes which in some cases hem in the otherwise relentless progress of the cancer.

The two phases of this subject, as above outlined, which have especially occupied investigation are generally known in the literature as the hemolytic reaction and the antiferment reaction.

THE HEMOLYTIC REACTION

It was long ago suggested by Marchand that the overgrowth of other tissues by malignant new growths was probably due to the presence of some toxic substance in the latter which overwhelms the healthy tissues and impairs their resistance. This same hypothetical substance has been supposed by many writers to pass into the gen-

* From the Department of Experimental Therapeutics, Cornell University Medical School, New York City.

* Read in the Section on Pathology and Physiology of the American Medical Association, at the Sixty-first Annual Session, held at St. Louis, June, 1910.

eral circulation, where it presumably exercises a similar destructive influence on the general tissues, thus inducing the anemia and cachexia so characteristic of the disease. Recently, indeed, metabolic studies have cast some doubt on this belief, but they have, apparently, not shaken its hold on the minds either of the clinician or the pathologist. Biochemical research has been active in the attempt to isolate and identify this hypothetical toxic substance, and the results, even though not entirely satisfying, are at least of much interest. Two agents have been identified in tumors which might be accused of this toxic influence on the somatic cells, namely, a hemolytic substance and a proteolytic ferment. The hemolytic substance has been studied in some detail by Italian investigators, and by members both of Ehrlich's staff and of the Pasteur Institute. In general, these observers are agreed that tumors contain a hemolytic substance which is coctostable and soluble in alcohol, and belong, therefore, in the group of the simple hemolysins. I have succeeded, further, in isolating another type of hemolysin from tumors, which is thermolabile, and requires activation by a substance corresponding to the "endo-complement" which Lyes and Sachs extracted from red blood-cells, and used to complement cobra-venom. The simple hemolysins are chiefly present in necrotic, and the complex hemolysins in non-necrotic tumors.

The questions arise whether these substances pass into the circulation, and whether they are to be regarded as the active agents of the tissue destruction which accompanies malignant growths. On this point it is at present difficult to reach a final conclusion, although there is ample evidence that such a process does with great probability actually occur. In the first place, it has been possible to identify hemolysins in the circulating blood of individuals affected with cancer. It is true that such hemolysins have also been detected in a variety of other conditions, notably tuberculosis, and even that they have been found in apparently perfectly normal individuals. The inference is natural that the artificial conditions under which hemolytic experiments are performed may contribute materially to the resulting destruction of red blood-cells, whereas it is perfectly conceivable that the vital conditions which they seek to imitate may be entirely free from any such results. A test-tube is not a blood-vessel, nor is two hours in an incubator followed by sixteen hours in an ice-chest the natural habitat of a red blood-cell. I have attempted to meet this objection by incubating a mixture of hemolytic dog serum and of alien dog's cells in the ligated vein of another dog, and have found that hemolysis occurred in the same manner as it did under ordinary experimental conditions. There is, however, a far more potent reason for concluding that these hemolysins are under certain conditions active agents of destruction during the life-time of the individual. This is to be found in the character of the red blood-cells of the cancer patient whose own blood is hemolytic. It was first pointed out, I believe, by Chanel,¹ in 1880, that the red cells under certain conditions of disease become altered in their resistance to certain destructive agents, namely salts in solution. Since that time, a succession of careful investigators, such as Lang,² have shown that especially in advanced cancerous conditions there is a very marked increase in the resistance of the red cells to anisotonic solutions of common salt. During the past

year, Kraus³ and his co-workers in Vienna determined that the red cells of rats affected with carcinoma became extremely resistant, as compared to the normal, against the hemolytic action of cobra-venom. They also found a similar change in the corpuscles of a large proportion of human subjects of cancer. This is an observation which I am able fully to corroborate from a large series of tests. In other words, the corpuscles of cancerous individuals manifest a marked resistance to such widely varying hemolysins as cobra-venom and anisotonic salt solutions. What is the significance of this change? It was pointed out for the first time by Morawitz and Pratt⁴ last year that the injection of phenylhydrazin, a markedly hemolytic substance, into rabbits, produces a severe anemia but that in addition to this, a very remarkable phenomenon supervenes. The red cells of the animals treated in this fashion become excessively resistant, one might almost say immune, to a large variety of hemolysins, including distilled water, saponin, snake-venom, etc. I have found that the same phenomenon could be produced in a much more specific manner by the continued injection into rabbits of graduated doses of saponin, which also results in the marked anemia, and in the production of a race of cells specifically resistant to saponin, but to no other hemolysin.⁵ The same characteristic specific resistance may also be produced by the injection of eel serum (Kossel⁶). It was suggested by Pratt and Morawitz that this result was due solely to the direct action of the dissolved hemoglobin of the disintegrated red cells on the stroma of the remaining cells. This explanation, however, does not seem sufficient, for the reason that this sort of resistance is never found in simple primary anemias, even the severest types of pernicious anemia, and practically in none of the secondary anemias except those of cancerous origin. On the other hand a very instructive analogy may be found in the experiments made by Ehrlich⁷ with trypanosomes. He discovered that by the continuous injection of a trypanocidal substance into the host he was able to produce a race of organisms specifically immune to the poison injected, but still susceptible to the destructive action of other agents. Thus he produced "fuchsin-feste" strains of trypanosomes. The explanation is probably to be sought in a modification of the race by the survival of the fittest—in this specific instance of those individuals resistant to fuchsin, or, as Ehrlich puts it, "deprived of their receptors for fuchsin." In the same way, it is probable that the hemolysin above described destroy the more vulnerable erythrocytes, leaving a non-resistant type, and that this result tends to be perpetuated by a similar action on the generative cells in the bone-marrow.

Whatever be the explanation, the fact remains that anemia of marked grade, with normoblasts in circulation, and the development of a race of resistant erythrocytes can be induced experimentally only by the repeated injection of hemolytic substances. In human pathology, the only anemia which corresponds identically to these criteria is the anemia of cancer; it is, therefore, fair to assume that some hemolytic substance is the agent in its production. If now, the fact be recalled that a hemolysin can be extracted from cancerous material, and that in a considerable proportion of cancer cases a hemolysin

is found in the circulating blood,⁸ the chain of evidence seems fairly to establish the belief that the anemia of the disease is caused by this hemolysin, and that the resistance of the corpuscles is traceable to its action.

What, if any, are the diagnostic applications of this apparently characteristic biochemical feature of the growth of cancer? I showed,⁹ some years ago, that in dogs experimentally inoculated with lymphosarcoma, the interaction between the hemolysin within the blood and the blood cells themselves resulted in a very characteristic condition. The serum of dogs with tumors was found to be hemolytic for the red blood-cells of normal dogs but not for the red cells of other dogs with tumors; in other words, the latter had become immune to the hemolysin. Thus, in dogs a specific diagnostic criterion was established for the presence of tumors, depending essentially on the resistance of the red cells to the circulating hemolysin. To avoid a confusion which has vitiated a large proportion of the literature on this subject, it should be realized that this method differs essentially from the simple determination of the presence of iso-hemolysins in the serum, as practiced by Maragliano, Ascoli, and others. Very shortly after the publication of this fact, Crile applied the method to the analysis of human serums and reached the conclusion that it afforded practically an absolute diagnostic criterion for human cancer, in exactly the same manner as had been described for dogs. I have not been able to confirm these findings. In my study of human serums, I found that 26 per cent. of the non-cancer cases gave the type of reaction found to be characteristic of tumor in dogs, while on the other hand only 56 per cent. of the cancer cases gave this reaction. Obviously, such a result cannot be considered a specific, or even a diagnostic reaction. This view has received the support of a large number of careful investigators—Richardt,¹¹ Whittemore,¹² Janeway,¹³ Smithies,¹⁴ Blumgarten,¹⁵ Epstein and Ottenberg.¹⁶ Nor has it fared better with the so-called "reversed hemolytic reaction," which Crile described as differentiating the serums of tuberculous from those of cancerous individuals. I believe, therefore, that it may now be considered as settled that in human beings the "hemolytic reaction" as a test for the presence of carcinoma is not diagnostic. A positive reaction does, however, occur in cancer cases with more frequency than in non-cancer cases, and may, therefore, be cautiously considered in connection with other symptoms as an auxiliary to the diagnosis.

THE ANTITRYPTIC REACTION

The antitryptic reaction is another illustration of interaction between the tumor and its host. It was first

shown by Salkowski that the various tissues contain proteolytic ferments, and in 1902, Petry found that such a ferment could be demonstrated in carcinomas. The demonstration of this fact is very simple, depending on the digestion of a proteid such as milk, egg-white, or gelatin, by the tissue extract, and has been thoroughly carried out by Buxton and Shaffer. The function of these ferments is still somewhat doubtful, but it seems eminently probable that they play an important rôle in the metabolism of the tissues. In cancers, these ferments occur in relatively large amounts, which is, perhaps, in accordance with the view of Vernon, that the quantity of ferment contained by a tissue is in direct ratio to its vital activity. Until very recently it was a matter of grave doubt whether these intracellular ferments of the tissues could exercise any direct influence on the general organism. Opie¹⁷ has succeeded in showing, however, that in certain pathologic conditions there is clear evidence that ferments may pass into the circulation, as shown by the fact that there is then a reactive formation of appropriate antibodies, or antiferments. In cancer, the conditions are extremely favorable to the liberation of the intracellular ferments, since there is generally a certain amount of necrosis and cellular destruction. It is not surprising, therefore, that search should have been made in the blood serum for evidence of an antiferment to the ferments liberated by this cellular disintegration in cancers. The difficulty of this problem has lain in the fact that all normal serums contain an antiferment, or "antitrypsin," as it usually is called, so that any reaction due to cancer could, apparently, make itself manifest only as a quantitative variation in the amount of antitrypsin normal present. The quantitative estimation of antitrypsin, however, even in very crude form, has only very recently become possible, largely owing to certain modifications of technic introduced by Brieger and Trebing,¹⁸ and by Bergmann and Meyer.¹⁹ As a result of this work, Brieger and Trebing were able to announce in 1908, that they had discovered evidence of an increase of this antiferment, or "antitrypsin," in the blood of cancer patients; that it occurred in a very high proportion, even as high as 95 per cent., of the cases of cancer, and that it rarely occurred in any other condition. The method of which they made use was to test the inhibitory power of graduated quantities of the blood serum on the digestive action of definite solutions of commercial trypsin. All serums, as had long been known, exercise an inhibiting action, but they found that it was characteristically and markedly increased in cases of cancer. Very soon, however, it appeared that they had overstated their case. An increased inhibitory action of the serum—or, technically, an increased "antitryptic index"—was found to occur not only in cancer, but in many of the infectious diseases, such as typhoid and tuberculosis, and in certain other conditions, such as the anemias and Graves' disease. It has, therefore, come to be understood that the antitryptic reaction may accompany a number of widely differing pathologic conditions; on the other hand, it is also true that its occurrence in cancer is so general as to make it a striking symptom of this disease.

A great obstacle to the general application of the method and to the further analysis of the phenomenon has been the inherent difficulty of obtaining even moderately accurate results; and this holds true both of the

8. Moss (Bull. Johns Hopkins Hosp., 1910, xxi, 63) has recently asserted that he can determine no difference in the hemolytic power of cancerous, as compared with non-cancerous individuals. This finding is not in accord with that of other sera. But even were it true that the hemolysis could never be found in the serums of cancer patients, the characteristic alterations in the resistance of the red cells would still strongly suggest the notion of such a substance, and its disappearance from the serum would be attributable to its absorption by the red cells, just as most toxic substances injected into the blood disappear from the serum and unite with the tissues for which they possess the strongest specific affinity.

rum plate and of the casein methods. (Trebing²⁰). This difficulty has been obviated by an alteration in method, which I introduced in collaboration with Dr. J. Feldstein, whereby it becomes a simple matter to make extremely delicate and accurate estimations of the antitryptic content of serum. (Weil and Feldstein²¹). This alteration consists in determining the degree of digestion by an instrument which measures the change induced by digestion in the viscosity of gelatin. Furthermore, the viscosimeter has made it possible to penetrate very much further into the character of the antitryptic reaction. It has already been stated that the inhibitory power of the serum has always been tested against commercial trypsin. This, it may be said, is generally derived from the pancreas of the pig. We have prepared proteolytic or "tryptic" enzymes from a variety of human organs, such as liver and kidney, and also from carcinomas, and have tested the inhibitory activity of the serums not only against commercial pig's trypsin, but also against these various human trypsins. The result is very striking. It appears that each serum has a definite, and distinct, inhibitory value for each of these "trypsins." These values may arrange for the same serum from 5 per cent. of inhibition for one "trypsin" to 95 per cent. for another, while a second serum may reverse this relationship. It is, therefore, evident that the conditions are very much more complex than had hitherto been suspected, and that it is entirely inadequate to speak of the "antitryptic" value of a serum. Indeed, it seems impossible to avoid the conclusions that there are differences between these various proteoclastic enzymes, or "trypsins," as has already been suggested by Vernon and by Aberbalden, and that for each of them the serum may contain distinct antibodies. In general, these studies show that the inhibitory values of human serums for ferments derived from human liver and kidney vary but slightly, while the values for commercial trypsin, and for human pancreas, and cancer extract show very pronounced and decided differences. The measurements by the viscosimeter have amply confirmed the belief that serum from cases of cancer show an increased inhibitory value against commercial (pig's) trypsin. This increased index is, however, by no means universally present. In the group of cancer cases, it does not hold for new growths of ectodermal origin, including those of the larynx and esophagus, no matter how far advanced the resulting cachexia. Nor does it hold without exception for all glandular cancers. A very striking feature of almost all of the cancer cases hitherto tested by us has been the enormous reduction of inhibition for the ferment extracted from human cancers, which falls far below that found in most of the control cases, and contrasts strongly with the increased inhibition for trypsin. The biologic significance of these facts is at present obscure, and it seems wiser not to speculate on them.

The diagnostic application of the antitryptic reaction has received a great deal of attention in Germany and England. The general consensus of opinion maintains that it furnishes a very valuable aid in the diagnosis of cancer, especially if certain complicating factors, such as tuberculosis, can be excluded. As has been shown, the fact that an increased antitryptic index may occur in certain other conditions deprives the reaction of its specific character; but although this diminishes, it does not destroy the value of the test as a clinical adjunct.

The use of the viscosimeter will, I believe, very materially further not only an understanding of the reaction, but its practical applicability and value. Moreover, the use of cancer ferment has added a further criterion, which much more sharply and characteristically defines the serums of cancerous individuals. It is, therefore, certainly not too optimistic to express the hope that still further refinements of technic may develop a reaction of specific value.

The scope of this paper does not permit an exhaustive discussion of the numerous so-called diagnostic reactions for cancer which have developed on the analogy of the well-known specific reactions of immunology. Among these are included a precipitin reaction, a complement deflection test, and an anaphylactic method; none of them has been proved to be of value. Finally, Ascoli has recently suggested a reaction based on the diminution of surface tension when antigen and antiserum are brought together, the "meiostagmin" reaction, but although the early reports are encouraging, it is still too soon to decide as to its merits.

163 West Eighty-sixth Street.

THE RELATION OF HEREDITY TO CANCER*

E. E. TYZZER, M.D.
BOSTON

That the development of malignant tumors—commonly grouped together under the name of "cancer"—are the manifestations of inherited peculiarities is a conception probably less generally held than formerly. For a time the subject of heated controversy, the question of heredity with reference to tumors has received little attention in recent years. It seems quite possible that the dictum of the statistician has been too readily accepted, and it is not improbable that something may be learned by a further inquiry and a utilization of certain recently established laws of inheritance.

In inheritance we have to deal with the transmission of certain characteristics, which may be visible, as in the case of coat pigmentation in animals, or invisible, such as those exemplified in physiologic peculiarities, temperament, wildness, etc. Tumors belonging to the group to which the term "cancer" is applied occur most frequently late in life so that, strictly speaking, it is the question of the inheritance of a predisposition to cancer with which we have to deal rather than the inheritance of cancer itself. Most of the characteristics which have been dealt with in the study of heredity appear in the course of development of animals under ordinary conditions of environment. Only the intrinsic factors affecting development are thus considered in the study of heredity.

In the etiology of cancer, however, it is necessary to consider also extrinsic factors, for the frequency with which malignant tumors occur as the result of chronic processes, such as are produced by repeated exposure to the *x*-ray, to heat, to certain chemical irritants, and to mechanical injuries, has been definitely established. With definite knowledge of the influence of external conditions in the development of certain types of tumor, should we therefore ignore the intrinsic factors in the development of all tumors?

20. Trebing: *Berl. klin. Wchnschr.*, 1909, xvi, 2296.

21. Weil and Feldstein: *Proc. Soc. Exper. Biol. and Med.*, 1910, vii.

* Read in the Section on Pathology and Physiology of the American Medical Association, at the Sixty-first Annual Session, held at St. Louis, June, 1910.

The occurrence of several cases of cancer in a single family often leads the physician to conclude that the condition is based on an inherited peculiarity or "taint." Whether or not the conclusion is correct, it is impossible to establish the fact on isolated observations in the experience of the physician. Cancer not infrequently occurs in several closely related individuals, and even the same organ may be affected. Thus Cullen has reported an instance of uterine cancer in three sisters. It is difficult to believe that such instances are of the nature of coincidences.

Most of the systematic investigation of the question has been of a statistical nature. Statistical inquiry has in practically every instance been undertaken with the object of determining whether the incidence of cancer is greater in the families of cancer patients than in the families of non-cancerous patients. This method of investigation has furnished results that are often diametrically opposed.

Paget, an ardent advocate of the importance of heredity in cancer, maintained that cancer occurred much more frequently in the antecedents of cancer patients than in the antecedents of the non-cancerous. Employing the statistical method, certain investigators obtained results similar to those of Paget while others failed to find a greater incidence of cancer in the families of cancer patients.

The results of the more recent statistical investigations are opposed to the importance of heredity in cancer. Pearson, working with data furnished by Hillier of the Middlesex Hospital, found in the antecedents of 2,368 women with cancer, 359 with a history of cancer, and in the antecedents of 753 non-cancerous women, 102 with a history of cancer. With a probable error of 0.04, the coefficient of 0.0335 for the cancer heredity is opposed to the inheritance of this condition. Pearson states that although these results are not final, they tend to show that there is no marked inheritance.

Bashford found in the data obtained from 669 cases of cancer that there was cancer in the father in 58 cases and in the mother in 114 cases. These proportions of 1 to 11.5 in the fathers and 1 to 6 in the mothers are almost identical with those obtaining for the general population dying from all causes. Guillot has obtained similar results. He found a history of cancer in 10 per cent. of the antecedents of non-cancerous and in 17.4 per cent. of the antecedents of the cancerous hospital patients. He found that a greater proportion of the parents of the non-cancerous were still alive and, revising his figures on this basis, he estimated the incidence of cancer in the antecedents of the non-cancerous as 16 per cent., against 17.1 in the antecedents of the cancerous. His statistics obtained from city records showed cancer in 18 per cent. of the non-cancer antecedents and in 16.6 per cent. of the cancer antecedents. Most of the recent statistical inquiry has, therefore, tended to disprove the heredity of cancer.

Another mode of inquiry has to do with the frequency of cancer in certain families—a phenomenon which is quite generally recognized. For example the famous "family of Madam Z" reported by Broca, in which there were fifteen deaths from cancer in twenty-six offspring who attained the cancer age. Of seven males, one had cancer while in nineteen females there were fourteen cases. The subsequent history of this family is at the present time being followed up by Ledoux-Lebarde. Statisticians, however, point out the great rarity of such families and, from a consideration of the general dis-

tribution of cancer in the population at large, regard their occurrence as falling within the law of probability. A more comprehensive historical review of the investigations of the subject of heredity with reference to cancer will be found in a communication by Ledoux-Lebarde.¹

In statistical inquiries of this sort there are so many contributing factors that the results obtained are of slight value. It is in the first place a most difficult matter to obtain facts concerning the occurrence of cancer in antecedents. Not only are the histories unreliable, but the interpretation of the statements may be a matter of dispute. As Lebarde has pointed out, the cancer and non-cancer series should correspond with regard to age, sex, country, etc. Taking the age factor as an example, cancer would be expected to occur more frequently in long-lived than in short-lived individuals. On the whole, the statistical inquiry of the subject under discussion has proved rather unsatisfactory. This method has furnished results which, though far from conclusive, indicate that heredity is of no great importance in the incidence of cancer. I believe however, that this form of investigation is open to criticism from the failure to recognize that under the term "cancer" are included a greater number of non-related conditions. It would mean much more if the incidence of each type of tumor was taken up separately. Thus, the occurrence of a number of tumors of a single type in a given family would mean much more than an equal number of tumors of various types and organs.

With certain types of tumors, the importance of the heredity factor appears to be definitely established. Thus it is well known that melanosa, known to occur in horses of other color, is much more frequent in gray horses. It has been noted that nearly all the offspring of certain gray stallions have developed melanosa.

The condition known as xeroderma pigmentosum is often found in several members of the same family and in this condition light apparently has an injurious effect on the tissues. As the process continues the epidermis becomes greatly modified and cancer frequently develops. It is evident that for this condition an inherited peculiarity is necessary as well as the light-rays. It frequently occurs in brothers or sisters, but as the individuals either die before maturity or are terribly disfigured the condition is not ordinarily transmitted from generation to generation.

In a third condition, known as von Recklinghausen's disease, heredity is evidently an important factor. About one-fourth of the patients give a history of the occurrence of the condition in the other members of the same family. Harbitz reports this condition in five consecutive generations of a single family, nine individuals in all. The condition is characterized by multiple fibromas situated along the peripheral nerves, and in the skin, associated with anomalies of pigmentation. There are also frequently other anomalies and mental defects. In addition to the typical cases, there are often other patients in the same families who present certain of the features just enumerated, but in whom the condition is not well defined. The fibromas often recur when excised, but are usually cured by repeated excision.

In certain cases the tumors take on more rapid growth, acquiring a sarcomatous nature. These individuals also frequently present tumors of other types—carcinomas, leiomyomas, etc. There is little doubt that in this dis-

1. Ledoux Lebarde: Bull. de l'Assn. franc. p. l'étude du cancer, 1908, xcll.

case we have a distinctly inherited condition in which the individual not only develops multiple fibromas, but is also prone to more malignant tumors.

The experimental aspects of the study of heredity with reference to cancer have been for the most part neglected. In a former communication I called attention to the frequency of tumors of the lung in certain families of mice, and suggested further lines of work in the experimental breeding of short-lived animals. Bashford has recently taken up this problem along similar lines. In the offspring obtained by the inbreeding of mice with mammary tumors, he has as yet failed to find evidence of any increase in the incidence of these tumors, although the investigation is not yet complete.

Whether epidemics of cancer in mice such as have been reported by Borrel, Michaelis, Gaylord, and others are to be attributed to heredity is a question which yet remains to be solved. Borrel states in substance that actual experience is wholly opposed to the notion of a cancer heredity in mice. In a recent article I have shown the great frequency of tumors in a given family, the offspring of a single female with a tumor of the lung. In this family sixty-five mice attained the age of six months and of these twenty, or 32 per cent, presented tumors. In seventeen, the tumors were of the same type as the tumor in the parent (homologous inheritance). On dividing the offspring into two groups, one composed of those neither of whose parents had a tumor, the other composed of those of whose parents had a tumor, it was found that tumors were more frequent (39 per cent.) in mice with a tumor parent than in mice with parents without any tumor (13 per cent.) It is my opinion that results obtained from the experimental breeding of short-lived animals will throw more light on the question of heredity in cancer than is possible by the use of the statistical method with human beings. Even with animals the problem is a difficult one, but here it is possible to obtain facts instead of depending on the statements of patients for data.

Differences in the susceptibility of various races of mice to the inoculable tumors have been noted by various observers. Environment is believed to account for these differences in certain cases. Whether heredity accounts for racial differences in other cases has been left undetermined.

I have found that such racial differences are inherited and persist in mice kept in the same environment. On cross-breeding a mouse of a susceptible with one of an insusceptible race, I have found the hybrids as susceptible as the susceptible parent. Furthermore, the growth of the tumor is more rapid in these hybrids. On breeding the hybrids together their offspring in all subsequent generations are found to be invariably insusceptible. By cross-breeding, therefore, a character apparently accentuated in the first filial generation fails to appear in subsequent ones. Inasmuch as the growth of the inoculated tumor depends on a transplantation of tumor cells, inherited differences in susceptibility to the inoculated tumor will have no bearing on tendencies to develop tumors spontaneously. Thus mice which have been found insusceptible to inoculate tumors may later on develop in certain instances spontaneous tumors.

Cuénot found that there was no correlation between inherited characters such as pigmentation, waltzing, etc., and susceptibility to the inoculable tumors. I have found that this is also true of the spontaneous tumors in mice.

CONCLUSIONS

In conclusion it may be said that heredity plays a rôle in the general incidence of cancer with regard to species as is indicated by the frequency of mammary tumors in mice while they are rare in cattle which, however, frequently develop primary tumors of the liver and adrenal (Bashford).

The question whether tumors are inherited as such is not raised by modern investigators. Statistical inquiries concerning the inheritance of a predisposition to cancer lack accuracy, and are surrounded by almost insurmountable difficulties. The results of these investigations fail in most instances to indicate the inheritance of such a disposition.

The occurrence in rare instances of families in which cancer is notably frequent appears to be well established. The occurrence of these families is regarded by many as not remarkable, but as wholly consistent with the law of chance in the distribution of cancer throughout the population. Others point out that if the occurrence of cancer families is established, the question of heredity will not be solved for peculiarities of environment are not eliminated. In melanosis in gray horses, and in both xeroderma pigmentosum and von Recklinghausen's disease heredity appears to be an important factor.

Although much of the evidence collected tends to indicate that heredity is not an important factor in the development of cancer, it would appear that this question cannot be definitely settled without the use of more accurate methods than have heretofore been employed. For this work the importance of the experimental breeding of animals cannot be overestimated, for here it is possible not only to obtain accurate data, but to shape the course of the experiment.

21 Fairmount Avenue, Wakefield.

RECENT PROGRESS IN SURGICAL TREATMENT OF MALIGNANT GROWTHS*

JOSEPH C. BLOODGOOD, M.D.
BALTIMORE

The problem assigned to me is strictly a practical one, and if there has been any recent progress in the surgical treatment of malignant growths, it has been due to the fact that a number of surgeons have been critically investigating the accumulated evidence of years of experience in the results of their interventions to eradicate malignant disease.

The best results have been obtained only in those cases in which there has been a painstaking study of the pathologic picture, an exact record of the extent of the operation, or other methods of treatment, and of the ultimate results.

In my opinion the recent progress has led to a better conception, not only of the pathologic varieties of the different neoplasms, but also of their local growth and tendency to metastasis.

Surgeons are beginning to learn that in some instances the extent of the local operation must be increased, while in other cases the patient is assured of a permanent cure with a more restricted operation, which, when

* Read in the Section on Pathology and Physiology of the American Medical Association, at the Sixty-first Annual Session, held at St. Louis, June, 1910.

the neoplasm is situated in some regions, accomplishes this cure with less mutilation.

It is also my view that there has been recent progress in the fact that surgeons recognize that in many instances malignant disease may have its onset in lesions, which may be present a varying length of time, and during that time be comparatively benign.

BENIGN TUMORS

A large number of benign tumors, the existence of which is known to the host for months or years, in the past have been left alone until they have shown signs of growth, or even until they have assumed the definite clinical picture of malignancy. There is no question that the best time to intervene is during the benign stage. On this fact both the public and the profession need education. Here we need publicity.

I have in the discussion at the symposium on cancer of the skin before the Section on Dermatology brought out the fact that up to the present time there is, to my knowledge, neither among my personally studied cases, nor recorded in the literature, an undoubted permanently cured example of the malignant pigmented mole. To prevent this malignant tumor it is necessary for the public to know that apparently innocent moles may at any time, especially after 30 years of age, show local growth, and this local growth is so quickly followed by dissemination of the cells, that up to the present time no operation yet performed has eradicated the disease. Physicians constantly see these moles in the routine examination of patients for other conditions, but it is only recently that they have begun to advise their removal. In my experience the majority of the profession at this time do not consider seriously this view of the benign mole.

In my paper before the Section on Dermatology, I have presented evidence to urge the immediate removal of certain epidermal and dermal tumors which have a varying period of innocence and which may be either of congenital or later origin. In this stage it is sufficient to remove the tumor with a small zone of uninvolved tissue. These tumors are, with rare exceptions, circumscribed, and there should never be any difficulty in removing them without leaving residues behind. There is sufficient evidence also to make it very clear that it is better to leave such a benign tumor alone than to excise it partially.

In the same paper I have ventured to make the statement that excision with the knife is the best method. There are, however, many advocates of other means of getting rid of the dermal tumor—the x-ray, radium carbon-dioxid snow, caustics, the Paquelin cautery, the electric needle, etc. There is no doubt that these methods, when properly employed, do eradicate the disease. From my experience, however, I cannot but conclude that as compared with excision with the knife, these methods have elements of danger in certain cases. I am willing to admit that incomplete excision with the knife is more dangerous than the treatment with any of the above other methods, but there is no necessity for an incomplete removal with the knife if the operation is to be performed at all. There are some cases of benign dermal lesions, which, on account of their situation on the ala of the nose, eyelid, and the ear, when subjected to excision would leave a somewhat greater deformity than when treated by one of these other methods.

The accumulated evidence of years has shown that it is dangerous to trifle with some of these apparently

innocent dermal and epidermal tumors. Space forbids a detailed account of the questions in this problem, but I am anxious to record here that before undertaking the treatment of an apparently innocent epidermal or dermal tumor the operator should know what the tumor is.

If it is agreed to enlighten the public on the fact that all apparently innocent tumors, wherever they may be situated, should be investigated by one having sufficient knowledge to properly treat them, then we should resolve as quickly as possible on the best method of treatment. There is absolutely no objection to excision with the knife, except the resultant scar when the lesion is situated in certain localities, and it has been my experience that in the hands of a properly trained surgeon the scar here is no more of a defect than when the lesion is removed by other methods. It is well to mention that in some instances, on account of the position of the tumor, the surgeon feels that the scar will be less if the margin of healthy tissue is kept within narrower limits. Here the knife should be replaced by, or combined with, the cautery. This is true of the basal epithelioma of the face when situated near the nose, eye or ear.

I trust that in emphasizing the importance of the removal of tumors in their innocent state, I have placed in equal prominence the fact that the lesion must be properly removed.

Apparently there are other lesions which hold the same relation to malignant tumors as the benign tumors.

TRAUMA AND SARCOMA

From the beginning of the literature on sarcoma, investigators of the clinical type have been impressed with the frequency with which sarcoma follows trauma. Trauma, with its local effect—the wound, and the wound always associated with the inflammatory process, which gives rise, first, to granulation tissue, and then to scar tissue—is an every-day occurrence. Both physician and patient concern themselves with trauma and wounds only when the immediate local conditions demand attention. The various open wounds give rise to the problems of preventing and treating infection and the question whether the wound should be closed or not. Fractures and dislocations always force immediate attention. But the contused wound with unbroken skin and without fracture or dislocation, or injury to a great vessel or nerve, or without extensive rupture of muscles or tendons, receives only the attention that the patients demand on account of discomfort or loss of function. With the rarest exceptions it is after a wound of this character (contusion) that sarcoma develops.

After the injury there may be only slight swelling and discomfort, or not even that; then later, after weeks or months, a swelling develops, which finally assumes the picture of a sarcoma. In other cases there is considerable swelling, due to a hematoma or a more diffuse extravasation of blood. In a few cases this swelling may never completely disappear, but later the signs of sarcoma develop. In other cases it does disappear, and there is a free interval between this and the development of the secondary symptoms due to the sarcoma.

The sarcomas which develop after trauma are usually situated within muscle or bone, either periosteal or medullary. There are also benign lesions, which may be secondary to trauma—the organized hematoma, the different forms of myositis, especially the ossifying

myositis, and the interesting desmoid tumor of the abdominal wall following trauma to the rectus muscle during labor. In the bone there is a distinct ossifying periostitis of traumatic origin. Both tuberculous and pyogenic osteomyelitis may be secondary to trauma. Trauma often localizes the syphilitic gumma or ossifying periostitis.

The point that I wish to emphasize is that the physician should constantly bear in mind the late effects of trauma. The immediate effects of trauma as a rule speak for themselves. The now routine x-ray examination discovers the latent fracture, but rarely if ever are physicians and surgeons keen in searching for the late effects of trauma. In the experience of the surgical clinics throughout the world the first appearance of a sarcoma weeks or months after trauma is rarely appreciated until the patients themselves demand investigation.

It is not necessary to frighten the laity with too cold-blooded statements or too plain speaking in regard to the danger of sarcoma after trauma, because it is relatively rare. But if members of the profession will caution their patients to return to them for examination if the symptoms of the contusion do not quickly subside, or if there is any recurrence of pain and swelling, or any appearance of limp, loss of function or weakness, there will be an opportunity by careful palpation and x-rays to decide whether exploration is justifiable.

I would therefore look on the recognition of trauma as an etiologic factor in sarcoma of the soft parts, and of the bone, and the attempt to get such cases at an earlier period, as definite evidence of progress in the surgical treatment of malignant growths.

PRECANCEROUS LESIONS

The relation of a single trauma to cancer is less distinct and more remote than it is to sarcoma. But the more we investigate the previous condition of the skin and mucous membrane at the site of the carcinoma before the definite picture of carcinoma began, the more often do we find that this epithelial area has been the seat of some form of chronic irritation. Attention has been called to this so frequently in the literature for a number of years, that it is unnecessary to give any references. In the chairman's address before the Section on Surgery, at this meeting, Dr. Charles H. Mayo chose for his subject: "Prophylaxis of Cancer," and he took the opportunity to bring out the various precancerous lesions, and to advocate that when possible surgery should attack the lesion in that stage.

In my paper before the Section on Dermatology, I called attention to the fact that it has been my own experience, and in the publications of the accessible literature every author emphasizes the fact, that carcinoma of the skin of neck, body and extremities rarely begins except in a pre-existing tumor, ulcer, scar tissue, or some local form of chronic inflammation, for example senile, x-ray, and solar dermatitis, or the keratosis of lead and arsenic, psoriasis, syphilitic and tuberculous granuloma, etc. Surgery, therefore, has better and better opportunities to attack and cure the precancerous lesions, and I should look on this as recent progress in the surgical treatment.

DIAGNOSIS

Whether in the precancerous, or in the early or late malignant stage, proper treatment is absolutely impossible until a correct diagnosis has been made. Different pathologic processes can be cured by local operations

of different magnitude. The same pathologic process requires operations of different magnitude, according to its situation in various tissues, organs or regions.

As surgical diagnosis must indicate that operation or treatment which will give the patient the best assurance of a permanent cure with the least mutilation, it is in this sense broader in its application than a pathologic diagnosis pure and simple. Surgeons have opportunities to study the clinical picture and to follow the ultimate results, and, for this reason, are in a better position than the pathologist to apply the pathologic diagnosis to prognosis and to methods of treatment. It appears to me very emphatically that surgical diagnosis, in this broader sense, should be the aim of the physician who operates for malignant disease.

My own studies of tumors, benign and malignant, have shown that the same tumor in various localizations may be eradicated by somewhat different procedures; while in one locality a carcinoma of a certain type may, from its onset, be hopeless on account of its position, in another the tumor is relatively benign, and surgery has accomplished cures by complete excision. For example, in the adenocarcinoma of the colloid type in the upper jaw, as with all the carcinomas involving the antrum, whether primary here or springing from the nose, the most complete eradication, in my own experience and in the literature, has up to the present time failed to accomplish a cure, while in the breast the same adenocarcinoma of the colloid type has been permanently cured with but few exceptions. The surgical diagnosis must therefore recognize the pathologic type of the lesion, and the individual who makes this diagnosis must be familiar with the proper operation for this pathologic lesion in this special locality.

CLINICAL DIAGNOSIS

When the correct interpretation of the pathology of the lesion can be made with sufficient certainty, without an exploratory incision, or without the aid of a frozen section, the term "clinical diagnosis" applies. This, of course, should be looked on as the highest art in surgery, and it should be the aim of all surgeons to educate themselves to become more and more proficient in clinical diagnosis. At the present time, however, a sufficiently positive diagnosis to justify a radical operation without the aid of the gross appearance or a frozen section is impossible in many instances. As a matter of fact, to-day we see more patients in whom a clinical diagnosis of a malignant tumor is impossible or uncertain, than we did ten years ago, and this is due to the fact that such lesions come to surgery at an earlier period.

It is true of malignant disease that, with but few exceptions, no matter where it is situated, clinical diagnosis becomes more difficult the earlier after the onset the lesion is first seen. It is also true of malignant disease, that the easier and more positive the clinical diagnosis, the worse the prognosis. Therefore, the stage at which the best results can be obtained is the one in which the clinical diagnosis is most difficult. Undoubtedly, a larger experience with tumors in this stage will educate surgeons in the ability to make even here a positive clinical diagnosis, but nevertheless it is a fact that to-day surgeons with the largest experience find themselves very frequently unable to make a sufficiently positive clinical diagnosis to allow them to proceed either with the restricted operation for the benign lesion, on the one hand, or the radical operation for the mal-

ignant lesion, on the other. They are of the opinion that justice is not done the patient, unless there is a positive diagnosis before the operation is completed. These exploratory incisions have been made for a period long enough to demonstrate that in such cases the results of treatment are much better than the results of the same treatment for the same disease at a later period in which exploratory incision is unnecessary for diagnosis.

OPERATIVE DIAGNOSIS

I employ this term for the diagnosis made at the operation, either from the gross appearance of the tissue exposed by the knife, or from a rapid frozen section. The method by which the surgeon gets at an exact interpretation of the pathologic process is immaterial in its relation to proper treatment, provided that method is one which will allow the diagnosis to be made at once and with sufficient accuracy for immediate action. Some surgeons have trained themselves to have confidence in their ability to make an exact diagnosis from the fresh appearance; others in addition wish to see a frozen section; some prefer to have a pathologist associated with the clinic to make the cellular diagnosis for them. Apparently it is the consensus of opinion that to cut into the tumor, excise a piece, or even to excise the whole tumor locally, then to close the wound, and wait a few days for a microscopic diagnosis based on a more careful technic of fixing and staining, does not offer the patient as good an assurance of a permanent cure as the method first described.

The ability to make a diagnosis clinically or at the operation, with or without frozen sections, is by no means to be considered sufficient. The surgeon must have kept himself abreast of the times by the careful study of his own cases and their ultimate results and by a study of the literature, so that he may be familiar with the extent of the operation which will give the patient the best assurance of a permanent cure with the least mutilation for the diagnosed pathologic lesion in its special situation.

I shall attempt to bring out practically this broad question of surgical diagnosis by considering lesions of special tissues, glands, organs, and regions.

BONE LESIONS

In the December numbers of *Progressive Medicine*, beginning with 1899 and continuing up to date, I have presented each year the literature and my own experience illustrating the points in treatment as based on correct surgical diagnosis, and have shown that the accumulated experience among surgical clinics which have carefully investigated their material, demonstrates, it seems to me, without question the correctness of the statements made in the introduction to this paper.

In both periosteal and medullary lesions it is frequently impossible to make a correct clinical diagnosis even with the aid of the *x*-ray. As amputation and even resection are operations which produce mutilation and disability, it is imperative for the surgeon, before proceeding with the performance of them, to establish an accurate diagnosis, and to perform these operations only for those lesions in which a permanent cure can be accomplished by these means alone.

At the recent meeting of the American Surgical Association in Washington, I presented a paper on "Bone Cysts, Giant-Cell Sarcoma and Bone Aneurisms." Rather than take space here, I would refer to that paper.

Table 1 gives the relative frequency of the benign and malignant bone tumors of which I have notes in the Surgical Pathological Laboratory. The majority of these patients were treated in the surgical clinic of Professor Halsted in the Johns Hopkins Hospital.

In the first place, it should be noted that among the 154 cases 60 were distinctly benign. With few exceptions the 34 cases of exostosis could be diagnosed clinically from the *x*-ray. Operative diagnosis was unnecessary and operation not indicated, except because of the size or discomfort of the growing exostosis. In small exostoses it may be difficult to differentiate the growth, even in the *x*-ray, from an ossifying periosteal sarcoma. Here exploratory incision should settle the question.

Now and then an exostosis is associated with the bursa, which may become the seat of inflammation and produce a rapidly growing tumor on account of the distention of the bursa with fluid (exostosis bursata). I have had one such observation in which everything in the clinical picture suggested a rapidly growing sarcoma situated in the muscles of the buttocks. The patient was an adult aged 30, and following a trauma there had been a rapidly growing tumor in this region. The veins and the skin over the tumor were dilated, the deeper tissues infiltrated; the tumor had somewhat the feeling of a cellular sarcoma covered with muscle. The *x*-ray showed no bone changes. (The exostosis did not show in the *x*-ray on account of its position; only an antero-posterior view was taken.) The exostosis grew posteriorly from the shaft opposite the great trochanter, and a lateral view to demonstrate its presence would have been a difficult task. The patient was sent to me prepared for hip-joint amputation, and, on account of the intense pain, loss of weight, and emaciation, it seemed justifiable to make such an attempt to give the patient some comfort for the few months he had to live. But following the rule that no such operation should be performed until a positive diagnosis was made, an exploratory incision was made into the tumor. Before reaching the tumor proper the edematous condition of the tissue suggested a sarcoma, but there was quickly exposed a definite capsule which consisted of a membrane 5 mm. in thickness. When this was divided blood-stained fluid escaped. The exploring finger found the exostosis, and the character of the lining membrane excluded a malignant growth. The operation consisted of chiseling the exostosis and the partial removal of the membrane. A complete removal would have been impossible without excising the sciatic nerve. A permanent cure has followed.

The bone cyst is a medullary lesion distinctly benign. Those who have had the largest experience are of the opinion that it cannot be differentiated in the *x*-ray or clinically from the giant-cell sarcoma or the bone aneurism. Such tumors should be explored. As the bone cyst contains a blood-stained fluid, it must be differentiated from the bone aneurism, because simple incision is sufficient for the bone cyst, while for the aneurism resection, or even amputation should be attempted to accomplish a cure. A bone aneurism is a term employed in the literature to describe a rare medullary tumor; there is a bone shell, a very narrow zone of tumor tissue of the round-and-spindle-cell type, and a central hematoma, due to hemorrhage into the originally solid tumor.

The periosteal and medullary giant-cell sarcoma is a very important bone lesion to recognize. This tumor grows rapidly and may break through its bone shell and involve muscle. Yet there have been cures by

local resection, even in this late stage. Many cases of medullary giant-cell sarcoma have been permanently eradicated by curetting. I have reported such a case in which the tumor involved at least one-third of the upper portion of the tibia. All of these cases are considered in the paper just referred to. The giant-cell sarcoma practically can be recognized only at the operation. If one is not familiar with the naked-eye appearance, its peculiar cellular structure can be easily appreciated in the frozen section. If this giant-cell tumor is a sarcoma, it is one in which recurrence after an attempt at a cure by curetting adds no risk to the patient. A number of cases are on record in which a permanent cure has been obtained after two or more operations. I have a patient who had been subjected to three unsuccessful operations for a giant-cell sarcoma of the lower end of the radius; he is now perfectly well, after the fourth conservative operation, and the hand has sufficient good function to allow him to work as a mechanic.

Among the less malignant bone tumors there is one of great interest—the periosteal osteosarcoma. This must be differentiated from the traumatic and syphilitic ossifying periostitis, and from the ossifying myositis. As a rule the diagnosis seems not difficult from the *x*-ray. But in a recent case, which I demonstrated before the American Orthopedic Association, during its visit to Baltimore in May, 1910, the difficulties and dangers of depending on the *x*-ray were well shown. An experienced Roentgenologist was of the opinion that it was an osteomyelitis with periosteal bone formation. A distinguished orthopedic surgeon was quite as positive that it was a syphilitic ossifying periostitis. The operation revealed a periosteal sarcoma surrounding the entire tibia, with periosteal bone formation.

Until very recent years the majority of American and English surgeons had been of the opinion that amputation should be performed as the routine operation for bone sarcoma, and in the past many limbs have been sacrificed for bone tumors, which were strictly benign (bone cysts), or which could have been cured by curetting or resection (giant-cell sarcoma), or for which resection was sufficient (periosteal osteosarcoma, myxochondrosarcoma, and fibrosarcoma). Apparently surgeons had been impressed with the great malignancy of bone tumors, and when now and then a cure was accomplished, even by amputation, they were surprised. If these cases had been studied pathologically it would have been seen that these cured patients suffered from tumors, which had been cured by other surgeons without amputation.

Now, as a matter of fact, the more malignant spindle-and-round-cell periosteal and medullary sarcoma kills by metastasis and rarely by local recurrence. If one is fortunate enough to get such a tumor when it can be removed by local resection, the probabilities of a permanent cure are just as good from this operation as from amputation. Theoretically, they should do better after resection, because such a tumor can be resected only in its early stage, and, as a matter of fact, in the literature, in spite of the small number of cases subjected to resection, this small group has at least an equal percentage of cures.

The experience, therefore, of to-day reverses the old rule: amputation is not indicated and should not be done for sarcoma of bone, unless the resection of the malignant disease would leave a limb without function. Now, if this malignant disease is a spindle or round-cell, peri-

osteal or medullary sarcoma, grown to such dimensions as to require amputation, one cannot expect a permanent cure from an amputation at so late a stage; metastasis has most certainly taken place. These patients should not be subjected to the mutilation of an amputation for the few months they have to live, unless the tumor is giving so much pain or discomfort as to demand operation. On the other hand, if the tumor belongs to the less malignant type, amputation should be performed, because, in the majority of cases it will accomplish a cure. It was von Mikulicz who first took this position against amputation, and he came to this conclusion somewhat indirectly. He found that patients who suffered with bone tumors in their early stage, from which they had but little discomfort or loss of function, refused the amputation advised, but would consent to resection. Von Mikulicz and others then found that some of the most malignant bone tumors which were resected in their very early stage were permanently cured.

It was Koenig who first called attention to the comparative benignity of the giant-cell tumor, and since then the literature on this subject has gradually accumulated. And, as our experience grows, our faith in the conservative principle increases. It should not require courage to perform these conservative operations, but knowledge, which will allow an accurate diagnosis. As a matter of importance, it would be better to err on the side of conservatism. In the past, surgeons, in the majority of cases, have amputated when in doubt.

My own investigation of bone tumors has impressed on me the belief that diagnosis becomes most accurate when the surgeon has before him all the evidence—the clinical picture, the *x*-ray, and the fresh appearance of the tissue exposed at operation and the frozen section. I look on these, as stated before, as the elements of the surgical diagnosis. With this evidence the trained surgeon can act with assurance.

LESIONS OF THE FEMALE BREAST²

If 40 per cent. represents the usual proportion of cases of cancers of the breast, in which the patients remain well after a period of five years, and 80 per cent. the prognosis for the smaller group, in which the operation has been instituted relatively earlier, it seems fair to conclude that the prognosis will be better when laity and profession look on a mass in the breast as an acute disease, and subject it to examination by a properly trained surgeon within a few days of its discovery. When a breast lesion is malignant there should be no compromise in the operative removal. The mutilation by the most extensive dissection and the function of the arm are no worse than after a less radical procedure. The evidence at my disposal proves that, with the rarest exceptions, the prognosis for a relatively *incomplete* operation in an early case of cancer of the breast, when the diagnosis cannot be made from the clinical picture, is worse than after a *complete* operation at a later period.

In the study of the ultimate results after operations performed by Dr. Halsted and his associates, where the tendency, on the whole, is to perform a most radical operation, I have been surprised to find among the relatively few local recurrences, that the majority of them were observed after operations for the most favorable

2. In Kelly-Noble's *Gynecology and Abdominal Surgery*, 1908, ii, 180. I have contributed Chapter XXXI, based on a clinical and pathologic study of 1,048 cases.

type of tumor, and that the notes made at the operation recorded that the area of skin removed was less than usual and that the wound in some cases had been closed without skin-grafting. These facts illustrate that a favorable malignant tumor tends to influence even the most radical surgeon to a conservative position. This conscious or subconscious influence works with a subtlety most difficult to overcome. Especially for carcinoma in those regions where the experience of the surgical world has demonstrated that the best results are only obtained by the most radical, careful and painstaking dissection, it requires eternal vigilance, great enthusiasm and mental and physical strength of a high order to keep one's self at the tedious task. It is so easy to cut corners. There is a great temptation to save time. It is difficult to keep out of the mind the complete closure of the wound.

The time elapsing between the operation and the result in carcinoma has been in the past, and, I am sure, will continue to act in the future, as a negative force. Only those surgeons who keep the most thorough records of the relation between their operations and the results will find sufficient stimulus to still maintain enthusiastic advocacy of the most radical operation for carcinoma in certain localizations. Halsted's operation for cancer of the breast is an example of the method, and its author an example of this type of surgeon.

In the operation for cancer of the breast the skin incision and the subcutaneous dissection should be planned only to give the carcinoma the widest possible berth necessary. It should not for one moment consider the closure of the wound. Only after the operation for the malignant disease has been completed should this become the subject of the surgeon's concern, and there is no danger in such an attitude.

Fortunately for women, not all breast tumors are malignant, nor is the differential diagnosis at the exploratory incision a great obstacle. If the operator is trained to differentiate he will find that a large number of cystic and solid tumors can be recognized, differentiated from the malignant, completely removed, and the patients saved the mutilation of removal of the breast.

As is true elsewhere, so with regard to the breast, this education of the public will bring breast lesions earlier and earlier to surgeons for diagnosis at the operation. It will also be true that the surgeon's ability to diagnose cancer clinically at an earlier period will improve, and that exploratory incision will be required less and less frequently. It seems to be the consensus of opinion that the removal of only the tumor, to be followed a few days later by the complete operation if it prove to be cancer, does not give the patient the same chance for permanent cure as when the same radical procedure immediately follows the exploratory incision.

The benign lesion of the breast most difficult to differentiate at the exploratory incision and from frozen sections is the benign cyst, in the formation of which the breast is the seat of a peculiar epithelial activity most common at the menopause. This has received various names: abnormal involution, senile parenchymatous hypertrophy, chronic cystic mastitis, etc. As I have discussed this disease elsewhere,² it seems unnecessary to take space to do so here. But the ability to recognize this lesion, which is the most frequent benign tumor in the female breast during the cancer age, is of great importance. I would advise, however, that if there is any doubt in the operator's mind, the operation for cancer should be performed.

SYMPTOMS OF ONSET

In this paper on the recent progress in the surgical treatment of malignant growths, I cannot miss the opportunity to devote a few lines to the attitude towards symptoms of onset less frequent in breast lesions than tumor. Apparently the attitude towards tumor has been settled.

An ulcer of the nipple which appears spontaneously in a woman not nursing a child should to-day be looked on as sufficiently positive evidence of cancer (Paget's disease), to justify the radical operation. I have evidence to confirm this statement.

A discharge of blood from the nipple is not a sign of malignancy. If there is no palpable tumor in the breast, there is no danger from non-interference; if there is a tumor, it should be treated like any other breast tumor. The operator may be certain that he will find a cyst with a papilloma, and it will be his duty to distinguish the benign from the malignant.

Retraction of the nipple, or dimpling of the skin, is seldom observed, except when a cancerous nodule can be palpated. If, however, one comes across such a symptom before any tumor can be palpated, it should be looked upon as a sign of cancer.

The relation of *lactation hypertrophy and mastitis* to malignant disease is an important one. Studies of my own have shown that during the enlargement of the breast in a pregnant woman all lesions are very unusual. On account of this fact a mass which appears at this period should immediately be explored, because carcinoma infiltrates so rapidly. The prognosis after removal is distinctly worse than for the same tumor growing in the gland at rest. Now and then the benign fibro-epithelial tumor, which has not shown itself before pregnancy, appears after it. This is due to the fact that the tumor tissue takes on the same lactation hypertrophy as the normal breast tissue. Tuberculous mastitis may have its onset in the breast during pregnancy. I have observed carcinoma during pregnancy as often as the benign tumor or the tuberculous focus, and it is for this reason that I urge exploration for a positive diagnosis immediately after the first appearance of the mass. There is no mutilation and no injury to function after the removal of the fibroepithelial tumor, and it is also best to get at the tuberculous focus early. The breast may be saved, as the lesion is usually single. Of course, if a carcinoma is exposed the most radical procedure should follow. Apparently there is a prevailing impression among the profession that a lump in the breast during pregnancy is some form of mastitis, and for this reason such patients have been observed until the tuberculous mastitis ruptured or cancer becomes evident on account of infiltration of skin or retraction of the nipple.

After the birth of the child the most common lesion of the lactating breast is pyogenic mastitis. The portals of entrance are traumatic lesions of the nipple, caused by the nursing infant. Preventive measures of cleanliness, well understood by trained obstetricians and nurses, usually protect the woman from mastitis. This mastitis is rare after the fourth month. The evidence at my disposal teaches that a cake in the breast up to the fourth month of lactation can be considered, *a priori*, to be mastitis, but this mass should very quickly exhibit the signs of abscess and be treated by incision, or disappear. If this does not happen the suspicion that it is malignant should at once lead to exploration. I have observed

carcinoma as frequently as chronic lactation mastitis. In all of the cases of which I have a record, the lesion unfortunately has been treated as mastitis until the growth of the cancer has become manifest clinically. In this stage the prognosis from operation is practically hopeless. Fortunately obstetricians have found out that massage is bad for mastitis; it is distinctly worse—perhaps fatal—for cancer. A caked breast should receive only one treatment—Bier's hyperemia; in other respects there should be non-interference until the signs just mentioned indicate exploration.

Pain localized in a breast is not a sign of cancer if there is no tumor; it is not an indication for operation. When associated with tumor, it is more often suggestive of benignity than of malignancy. But, as the indication for the exploration of the tumor is distinct, whether pain be present or not, this symptom cannot be looked on as any aid in the clinical diagnosis. If it appears late after the tumor it is suggestive of carcinoma.

The chief reason for the removal of any *single tumor* of the breast immediately after it is first observed is to extirpate cancer at the earliest possible period. But there is another reason: it may be looked on as a preventive measure, locally and completely, to remove a benign tumor. Therefore, if a woman presents herself for the first time with a perfectly circumscribed and freely movable tumor of the breast, which has been present and quiescent for years, this clinical fact practically excludes malignancy. But such a tumor may at any time become malignant, and for this reason it should be removed. If the patient has multiple tumors in one or both breasts it is apparently wiser to remove at least one for a positive diagnosis. In the young woman the tumors are of the fibroepithelial type, usually the so-called intracanalicular myxoma, rarely the fibroadenoma. It is not necessary to remove the breast in order to eradicate the disease. There is no objection, however, to removing those tumors which are growing or causing pain, or to removing all of them if they are few in number, and if this can be accomplished without too much destruction of breast tissue. In a few instances the multiple tumor in the breast may be metastatic from the concealed sarcoma. The removal of one simply establishes early the fact of a hopeless disease.

In older women the multiple tumors are cysts associated with the epithelial disease, which I have mentioned. It has been my experience that cancer has so rarely been observed in such breasts that operation as a preventive measure need not be considered. In fact, my clinical and pathologic study of over one hundred such lesions gives rise to the conclusion that this disease produces immunity from cancer, and for this reason I am of the opinion that in the past we have been unnecessarily radical in our treatment of single or multiple simple cysts. The cysts can and should be removed. The parenchymatous lesion which has caused their formation has a strong tendency to spontaneous resolution.

The frequency with which large intracanalicular myxomas of the breast degenerate into sarcoma establishes a definite operative procedure for them which should never be omitted. When such a tumor has reached such a size that its removal practically amounts to the removal of the entire breast, it should be attacked as if it were sarcoma. That is, the tumor should be removed with the breast, the overlying skin and the underlying pectoralis fascia and muscle. In the first few cases which I studied in which the tumor was re-

moved by enucleation as it seemed encapsulated, local recurrence in the pectoral muscle followed and proved fatal. In a larger number of cases observed since then, in which the rule established on the early experience was followed, there have been no recurrences.

Space forbids the consideration of the recent progress of the surgical treatment of malignant tumors in other regions. In these two papers I have covered considerable ground, more, I think, than sufficient to exemplify the principles of the broad question of surgical diagnosis which must always be the basis for surgical action.

In conclusion I would draw attention to the remark of Koehler in his most recent publication in which he diseusses his twenty-five years' experience with cancer of the stomach. In the critical study of his cases he asked himself the question: What have those cases of cancer of the stomach in common in which the patients have remained well after gastrectomy? He found that all of them were freely movable tumors of the stomach wall, and with few exceptions situated at the pylorus; all of them were adenocarcinoma and many of these of the colloid type; there was but one scirrhus.

When the abdomen is opened and the surgeon palpates in the wall of the stomach a tumor, which is freely movable, gastrectomy should be performed. As a matter of fact this is the best treatment for ulcer and the only hope for cancer. If the mass, however, is adherent, and the surgeon is unable to decide whether it is cancer, resection is contraindicated, because posterior gastroenterostomy will give relief if it is ulcer, while adherent cancer will be practically hopeless. If the lesion is distinctly cancer, resection should, if possible, be attempted, because the patient, if he survives the operation, may be given months, or even a few years of comfort; in doubtful cases resection should not be employed, because an ulcer-patient ought not to be subjected to so great a risk.

CONCLUSIONS

Until we have found some other method of treatment for malignant growths, future progress must proceed along the lines which have developed up to the present time. There must be a correlation between the clinical, gross and microscopic pictures of the lesion in the same locality, and although the time which elapses between the operation and the result is remote, we must bring together ultimate result and operative procedure for lesions of the same kind and in the same locality. In every instance there must be a microscopic study. In this way surgeons will be able to make accurate surgical diagnosis, and, with the knowledge of the local growth and pathology of the lesion, they will be better fitted to plan and perform that procedure which will give the patient the best assurance of a permanent cure with the least mutilation. The surgeon will also understand how to give the greatest comfort to those unfortunates whose malignant disease has passed the period in which there is any hope of a permanent cure. In some the greatest comfort will come from non-interference, in others from palliative interventions.

These pitiable individuals with inoperable and incurable malignant tumors should not be left to the mercies of the quack with his various cancer cures. There is no doubt that the surgeon is able to do more for them and give them greater comfort than is any untrained individual, and there is the hope that, while the former is performing this eminently merciful duty, more opportunities will be offered for that research work

which may in time lead to the discovery of a cure other than operative removal alone.

We have by no means reached the limits of the early recognition and treatment of what might be called the pre-cancerous lesions, nor in the early diagnosis of the malignant lesion itself. There is every evidence that surgery, which in the past has accomplished permanent cures of both cancer and sarcoma, can, along definite lines, increase very greatly the number of cures.

904 North Charles Street.

ABSTRACT OF DISCUSSION

ON PAPERS OF DRs. LOEE, TYZZER, WEIL, MALLORY * AND BLOODGOOD, CONSTITUTING A SYMPOSIUM ON CANCER †

DR. LOUIS B. WILSON, Rochester, Minn.: Dr. Bloodgood has called attention to the importance of the surgeon's ability to diagnose cancers from their gross appearance at the operating table. Dr. Mallory has shown us beautiful pictures, illustrating the diagnosis of cancer by the microscopic examination of fixed tissues. There is between these two view-points an important connecting link, namely, the immediate microscopic examination of stained frozen sections of fresh tissue. Tumors in the stage for most successful operation are frequently of microscopic size and no amount of knowledge of gross pathology will help us in their diagnosis. Yet unless the diagnosis is accurately made microscopically while the initial operation is in progress, the patient is either needlessly mutilated, or, more frequently, suffers an incomplete removal of affected tissues with a resulting extension of the cancer. Some pathologists fail to get satisfactory results from sections of fresh tissues because the tissues are not really fresh; others use microtomes so crude that a good section is an accident; and yet others use single-tone stains which do not differentiate tissues; but most failures are from lack of experience with tissues properly prepared. In the scientific exhibit we have a number of autochrome photomicrographs of sections of fresh tissue stained with polychrome methylene blue, which no competent pathologist would hesitate to diagnose. In St. Mary's Hospital we have given a diagnosis from the microscopic examination of fresh frozen sections in 364 cases of doubtful mammary tumors alone. Subsequent examinations have revealed but one apparent error in this series. This accuracy has been due in part to the fact that in small doubtful mammary tumors the surgeons have invariably submitted to the pathologist the entire tumor with some surrounding tissue, but the diagnosis has invariably rested on the microscopic appearance. Frozen sections by no means give sufficient data for all diagnoses, but, if the data are within the tissues, properly stained, thin sections of really fresh material enable one to determine carcinoma as accurately as may be done from sections of the most elaborately prepared tissue.

DR. F. B. MALLORY, Boston: I would call Dr. Wilson's attention to the fact that in the Massachusetts General Hospital, diagnoses are and have for years been made from frozen sections. The same thing has been done in the Boston City Hospital for thirteen years. It is a common procedure everywhere, so far as I know.

DR. H. GIBSON WELLS, Chicago: Within the last few months I have made some observations regarding the enzymes of cancer, which I wish to place on record at this time. One of the characteristic features of malignant tumors is the persistency of the histologic structure; so if a tumor is primary in one structure and secondary in other organs, it maintains the same histologic structure in all. Few attempts have been made to ascertain whether in their chemical constitution and biologic behavior these tumors also maintain a consistent condition, and fail to partake of the nature of the second organ in which they have formed metastases. It is possible that a primary tumor might retain its original structure

as a secondary tumor, but might acquire chemical or biologic characteristics from that second tissue. I have, consequently, attempted to learn whether we can determine whether the enzymes are different in primary and in secondary tumors. As the best way to learn this with some degree of accuracy, I have selected secondary tumors in the liver, because in that organ we have an enzyme that will oxidize xanthin into uric acid, and this enzyme is not present in any other tissue in the body. A number of experiments have shown that when primary tumors occur in various parts of the body and produce secondary growths in the liver, the secondary growths do not acquire this power of converting xanthin into uric acid.

DR. LOUIS B. WILSON, Rochester, Minn.: I do not wish to claim priority for the frozen-section method, though I published four years ago what has proved to be a useful modification of the technic. But I do wish to urge the importance of the routine examination of contrast-stained, thin sections of perfectly fresh material, as a means of increasing our skill in the rapid microscopic diagnosis of tumors to guide the surgeon during the progress of a patient's first operation. Many pathologists have abandoned the procedure from lack of material, bad technic or insufficient experience, but it too frequently has a vital relationship to the patient's welfare to excuse our failure to perfect ourselves in its use.

CARDIOSPASM WITH DILATATION OF THE ESOPHAGUS *

REPORT OF TEN CASES

JESSE S. MYER, AB., M.D.

Lecturer on Clinical Diagnosis, Medical Department of Washington University
ST. LOUIS

Although the symptom-complex of cardiospasm has been known to the medical world under a variety of names for several decades, but few authentic cases found their way into the literature prior to the last decade. As early as 1821, in fact, the condition had been observed by Purton, and trauma considered by him as a causative factor. Esophagus spasm, however, had been known to medicine even long before this, and it is not at all unlikely that some of the early reports, which go back to 1740, even as far back as Hippocrates, were certain stages of the condition known to-day as cardiospasm.

In 1878 Zenker and Von Ziemssen had collected reports of seventeen cases under the title of "simple ectasia," and stated that in these cases there was enormous ectasia of the tube without any underlying stenosis. The reports of cases collected by them were those of Purton (1821), Hannay (1833), Rokitansky (1840), Delle Chiage (1840), Abercrombie (1843), Oppolzer, Spengler (1853), Wilkes (1859), Giese (1860), Ogler (1866), Luschka (1868), Klebs, Davy (1875), Stern (1876), Dave (1877).

Hamburger in 1871 presented a very lucid description of spastic stenosis of the esophagus with mention of two cases in which, however, there was nothing said of an accompanying dilatation. He described the condition as "stenosis spastica fixa" in contradistinction to "stenosis spastica migrans or intermittens." He understood by the former "the cramp-like contraction of the circular fibers of a small area of the esophagus, which never varies from this position, not occurring paroxysmally, but which remains at one and the same place for weeks and months." According to the present acceptance of

* Dr. Mallory's article is the leading one in this issue.

† Another symposium on cancer will be printed next week, the one presented in the Section on Dermatology at the St. Louis Session.

* Read before the American Gastro-Enterological Association, St. Louis, Mo., June 6-10, 1910.

the subject this would seem to answer a description of cardiospasm in which dilatation had not yet occurred, or was unrecognized.

Since the reports of these earlier cases isolated examples had been recorded up to 1900 by such observers as Strümpel, Mikulicz, Meltzer, Leichtenstern, Maybaum, Reitzenstein, Russell, Rosenheim, Westphalen, Fleiner, Boas, Netter, Strauss and others. At this time Newman was able to find but 10 cases reported in the literature, and even as late as 1904 Mikulicz estimated that reports of a hundred cases could be collected. In the last decade, but more especially in the last five years, the cases have rapidly multiplied, doubtless to twice this number. In this country Erdman, Sippy, Einhorn, Plummer and others have made valuable contributions to the literature. Plummer alone reported forty cases, all of which had come under his own observation, and three-fourths of them in the last four years.

In my own experience nine of ten cases have come under my observation in the last three years. It is quite probable, however, that because of a lack of intimate knowledge of the symptom-complex prior to this time, such cases may have escaped unrecognized. In 1905, for instance, Ibrahim made a most exhaustive study of congenital pylorospasm, reporting 113 cases; of this number no more than ten or twelve were found in American literature. In the past five years this phenomenon in infants has become so frequently recognized as no longer to call for the recording of isolated cases. The same must apply to the condition here under discussion, and the probabilities are that with the wider dissemination of knowledge of this affection it will be much more frequently encountered.

It has been variously described heretofore under the titles "simple ectasia," "spindle-shaped dilatation of the esophagus without anatomic stenosis," "congenital dilatation of the esophagus," "idiopathic dilatation of the esophagus," "spasmogenic diffuse esophagus dilatation," "paralytic dilatation of the esophagus," "cardiospasm with secondary dilatation," etc. While there is still slight confusion as to the name to be applied, the general tendency is to accept the last term to cover all of the cases heretofore described under these various titles.

There has been throughout a remarkable unanimity of opinion as to symptomatology and treatment of the condition, but a vast amount of discussion as to the pathogenesis, and the question of priority of the spasm and the dilatation. Though Strümpel and Mikulicz as early as 1881 had recognized the etiologic significance of spasm in diffuse dilatation of the esophagus, to Meltzer belongs the credit of recognizing its true importance in this connection. He was the first to look on dilatation in these cases as a stagnation ectasia, due to the abnormally contracted cardia, which he attributed to a disturbance in the nervous mechanism controlling the cardia. He based this belief on theories that he had evolved and observation that he had previously made on the physiology of the esophagus. Rosenheim took exception to this theory, maintaining that the dilatation was primary and the cardiospasm secondary, pointing to the fact that in anatomic stenosis of the esophagus as, for instance, in carcinoma, or benign scar formation, sacculation rarely develops. He has been a firm adherer to this belief and still maintains that there is an idiopathic dilatation of the esophagus. Strauss believed that the spasm and dilatation occurred simultaneously, and were due to the same cause, namely, vagus paralysis. In this way he explained

the simultaneous occurrence of the two conditions. Fleiner explained the dilatation on a congenital basis, believing that it existed from birth, and even went so far as to maintain that a congenital dilatation might remain latent for years. Acceptation of this belief has resulted in the reports of cases of so-called congenital dilatation of the esophagus in which the first symptoms occurred even late in life.

My experience in a series of ten cases leads me to the belief that there is a congenital basis for the development of the sacculation, but not according to Fleiner's acceptation of the subject. Though this experience has been limited—too limited perhaps, to justify definite conclusions—I have been greatly impressed in my cases with the relationship existing between this phenomenon and the enteroptotic type of individual. Glénard, Stiller and their followers have shown beyond a doubt that there exists a type of individual, presenting certain well-defined outward evidences, which indicate a congenital tendency to a general asthenic state—asthenia universalis congenita. They are characterized by a slender gracile build, long, flat thorax, acute costal angle, floating tenth ribs, pulsating aorta, splanchnoptosis, etc. In these individuals not only are the viscera in a state of ptosis, but the hollow viscera especially are atonic, manifesting at the same time, paradoxical though it may seem, a tendency to spasticity as well. This is shown in the *corde colique transverse* of Glénard and the spastic cecum and sigmoid so often encountered in these cases.

That cardiospasm is of nervous origin seems to be the general consensus of opinion. How or why it develops in certain persons has, however, never been satisfactorily explained in spite of the splendid work on the physiology and pathology of the esophagus by such distinguished investigators as Sinnhueber, Meltzer, Mikulicz, Rumpel, etc. Many etiologic factors have been considered in previous case reports, but in none, with the possible exception of trauma, has any direct connection been determined. For the development of cardiospasm, as for certain other conditions dependent on nervous causes, there are probably necessary two factors, a predisposition and an irritant. Assuming, therefore, cardiospasm to be a disturbance of innervation, we may expect it most often in individuals with neuropathic tendencies. With the onset of the spasm at the cardia, dilatation of the esophagus could readily be explained, if the congenital tendency to atony which is known to exist in the hollow viscera of the abdomen also is present in the esophagus.

It would not be justifiable for me to assume, simply because of my observation in a limited number of cases, that a majority of cases of cardiospasm with dilatation occur in persons with universal congenital asthenia. The relationship was so striking in my experience, however, that I felt constrained to look on cardiospasm as the expression of an exciting cause, be it trauma or what you will, in that type of individual in whom almost every shock to the nervous system gains expression in some local or general manifestation.

The symptomatology is brought out in the case reports which are appended and will need no repetition here. The same is true of the final results of the treatment in each case. It will be seen that while the ultimate results have not been so uniformly satisfactory as those described by others, on the whole the results have been good. If these cases are carefully followed after stretching of the cardia, I question very much if any of the patients in whom sacculation had occurred will be found

to be entirely free from symptoms at any time. My experience has been that they will always have to exert more or less care in the amount and character of food taken and the manner of ingesting it. In other words, I doubt if complete relief is possible after sacculatation of the esophagus exists.

Therefore, the earlier a case can be recognized the more complete will be the cure, for when sac formation has occurred irreparable damage has been done. While the patient's life may be practically saved and the individual made reasonably comfortable, he can never be restored to a perfectly normal state. These patients are, however, so grateful for the relief given that they always report in optimistic terms, and are apt, therefore, to mislead even the physician. This in all probability is responsible for some of the assertions that absolute cure has been obtained.

The dilator which I have used in the stretching of the cardia is practically the same as heretofore described by Russell, Strauss, Plummer and others, consisting of the double rubber bag with a silk bag inserted between, attached to the ordinary stomach-tube, having no opening in the end. Having had considerable difficulty with the rubber bags obtained from the manufacturer, I have found it expedient to make my own dilators through the employment of what is known to surgeons as the Penrose drainage tubing. This is made of rubber dam and can be obtained in yard lengths of varying diameters, so that the dilator may be varied in size according to the caliber of the rubber dam tubing and the silk bag. This tubing has the advantage of being very durable and at the same time very inexpensive. The outer bag is removed after each operation and discarded. The introduction of the dilator is facilitated by the use of a steel spiral as a mandarin. This can be easily removed after the dilator is in position. The location of the spasm is carefully determined through the use of a sound and a mark made at such a point on the dilator tube as to indicate when the stricture is at about the middle point of the dilating bag. I have not found the thread method of Plummer necessary, nor would it have aided me especially, except in one case. I have rarely failed in the introduction of the dilator when it was preceded by the use of the esophageal bongsies varying from 24 to 36 F. In dilating the stricture a large glass syringe is used, such as is employed in the irrigation of the bladder. With this the exact amount of fluid can be carefully measured and pressure exerted gradually. I have not found a manometer necessary or helpful, because after all, one must depend on pain and the patient's ability to endure it, as an indicator. This is the best indicator of the degree of pressure to be used, and after the first two or three divulsions one can determine very readily the degree of pressure to be used in the individual case. This will vary greatly; therefore a manometer reading would not be especially significant. Having previously noted the amount of water that it will require to dilate the bag to its fullest extent, one can tell pretty exactly to what extent the bag is inflated by the reading on the piston of the syringe. It has been my plan to stretch the cardia biweekly during the first two or three weeks, then each week until the symptoms of spasm have been entirely relieved.

For determining the capacity of the sacculated esophagus, a small rubber dam bag, sealed to the end of a stomach-tube, was introduced and gradually filled with water under pressure, until the patient complained

of a marked sense of pressure. The quantity of water required gives the approximate capacity of the sac.

Often when using the soft tube in these cases to obtain stomach contents, one will be in doubt as to whether the tube has passed through the stenosis into the stomach, or is, perhaps, rolled up in the sac. This can be readily determined by having the patient take a deep breath while holding the distal end of the tube in a glass of water. There being a negative pressure in the esophagus on deep inspiration, water will be drawn into the tube if the other end is in the esophagus pouch, while the opposite will be the case if the tube has entered the stomach. This test also aids in the diagnosis of sacculatation, for if such be present more water will be drawn up into the tube than in the normal esophagus. In the cases here reported there were seven males and three females, averaging 37 years of age, eight whites and two negroes. Two gave histories of injuries, one (Case 7) shortly before the development of the cardiospasm and one (Case 1) thirteen years before; one (Case 2) occurred shortly after childbirth; in one (Case 5) there was an indefinite history of hies, but not until after the development of epigastric symptoms; in one (Case 8) a history of pneumonia with pleurisy fifteen years before. In five there was nothing in the history which could have been considered of the slightest etiologic import. Superacidity of the gastric contents which has been mentioned as an etiologic factor, was present in but one of my cases; a marked subacidity existed in three cases; and the rest were within normal limits. Nine of these persons were definitely enteroptotic, exhibiting the various stigmata.

Four patients declined the necessary treatments for relief. Two of these (Cases 1 and 6) have since died of inanition; the other two (Cases 2 and 3) it is hoped will submit to the stretching of the cardia later. In four of the six patients who have submitted to treatment (Cases 4, 8, 9 and 10) the results have been highly satisfactory. Comparatively speaking, they are well, but strictly speaking there remains evidence of the sacculatation many months after the treatments have been discontinued. They must eat slowly, chew their food thoroughly, avoid drinking cold water, and two patients (Cases 4 and 5) must, through a slight regurgitant effort, empty the pouch of the fluid collecting there occasionally. It is questionable whether the dilated sac is ever entirely empty, for the negative pressure in the sac is probably always sufficient to retain a small column of fluid there, whether it be saliva swallowed, mucus secreted or fluid ingested.

Two patients have been only partially relieved. In one of these (Case 7) the spasm was entirely overcome and deglutition made possible, but an ulcer at the cardia causes most intense pain with every act of deglutition. The ulcer evidently existed prior to the stretching of the cardia, but was unquestionably rendered worse thereby. This patient has recently returned to the hospital with a very small irregular mass on the anterior wall of the stomach near the cardia, either of an inflammatory nature, or an early malignancy. Patient 5 has been greatly benefited, but the treatment has had to be continued from time to time during the past year on account of relapses, in spite of the fact that each time the procedure has been carried to what we consider the rational limit, viz., 4.5 cm. Mikulicz hesitated to employ this method, because he was unwilling to carry out a procedure that he could not control by vision. Though developments have shown that he was not justified in this position, it behooves the operator to use the utmost care.

It is interesting to note that cough was a persistent symptom in Case 4, and was greatly aggravated in the recumbent posture, evidently owing to vagus irritation, as in a case reported by Westphalen. In Cases 4 and 5 water would flow into the mouth during the night if the patient assumed certain positions and would often cause strangulation. The patient often awoke to find his pillow saturated with the fluid that had gravitated into the mouth from the sac.

It was striking to note the regularity with which the patient reported that inability to swallow cold water was one of the earliest symptoms, and we may add, one of the most persistent ones, the cold directly or indirectly stimulating the contraction of the circular fibers at the cardia.

In the various tests to which the esophageal contents has been subjected to differentiate it from the gastric contents, I have seen no mention of sugar. In the former sugar is present in much larger amounts than in the latter, owing to the fact that in sacculations of the esophagus the conditions are ideal for sugar production, namely, stagnation, warmth, the salivary ferment and carbohydrates. For similar reasons (*viz.*, stagnation, sugar, warmth and bacterial flora) lactic acid is present in considerable amount. Case 10 is reported here as presenting a possible congenital dilatation of the esophagus and cardiospasm, because of similar reports which have been handed down in the literature under this name. Certainly if the term "congenital" is ever justifiable in connection with dilatation of the esophagus it would be here. My impression, however, is that we have here to deal with a case of congenital, partial stenosis or atresia of the cardia, with secondary dilatation of the esophagus, in a child with the enteroptotic habitus, rather than cardiospasm.

Judging by a review of the literature there seems to me insufficient justification for ever considering dilatation of the esophagus congenital and primary. It is more likely that in all of these cases there were congenital obstructions, following which dilatation developed. In some of the cases that have been reported in the literature as congenital dilatation there were no symptoms manifested until the patient had attained an advanced age. This seems most illogical.

Case 11, while not strictly belonging to the class of cases here under discussion, may be included in such a report with perfect propriety. This was considered a case of cardiospasm with dilatation of the esophagus, the patient was so treated, and only after an effort to relieve the condition through laparotomy was the true nature of the obstruction revealed. There was found to exist an infiltrating scirrhus carcinoma, involving the entire fundus of the stomach, which had contracted down to the size of a hen's egg. The symptoms in this case had existed for several years. Though it is possible for a growth of this type to have existed for this length of time, it nevertheless seems possible that malignancy developed following or as a result of cardiospasm. I wish to make no definite claim, however, and report the case chiefly to show how one may fall into error in the matter of diagnosis.

REPORTS OF CASES

CASE 1.—*Patient*.—S. R., a man aged 50, with negative family history, thirteen years before seen, January, 1907, had fallen from a wagon, injuring his neck. This accident was followed by partial paralysis of the right side of body, which gradually cleared up. The right leg would tire easily and "went to sleep" often. The present trouble began about the

middle of 1905 with difficulty in swallowing, and stabbing pains in the region of the liver during deglutition, under the lower part of the sternum. In the beginning the patient was unable to swallow meat, which often lodged and was eructated; he could drink fluids more easily, but found coffee and other fluids harder to swallow than water. At this time he was observed at the Jewish Dispensary, but no obstruction could be made out by the physician in charge. The gastric secretions and motility were normal. A few months later he was observed by another physician, who also found that large sounds and tubes entered the stomach without difficulty. In January, 1907, a small bougie met obstruction at the cardia, and at this time he came under my observation.

Examination.—Since the beginning of trouble patient had lost 15 pounds. The esophagoscope was introduced and the obstruction could be easily detected, there having developed as yet no marked degree of dilation of the esophagus. There was at the cardia an annular stenosis, rather white and glistening, showing no irregularities and not bleeding on manipulation.

Course of Disease.—The patient was under observation only a short time, during which I was unable to introduce the cardiodylator, though succeeding with the larger sounds. Unfortunately he passed from observation before we had succeeded in dilating the obstruction. He died about a year later, of inanition.

CASE 2.—*Patient*.—Mrs. B., aged 31, was observed March, 1907. Her present trouble had begun shortly after the birth of her child seven years previously with sharp pains in pit of stomach, belching and sour eructations. The pains disappeared, but there persisted a fulness, as if a "lump lay there"; the food seemed to lodge above the stomach and could be forced down only by taking a few swallows of water. The patient at the time of observation eructated gas after eating and could "spit up food at any time." She tried to eat little and often; otherwise the food would not pass down. She experienced shortness of breath after eating.

Examination.—The patient was a small, emaciated woman of typical enteroptotic type, with acute costal angle, 30 degrees, floating tenth ribs, marked degree of gastropnoia, the lesser curvature being on a level with the umbilicus, and long slender thorax. On the introduction of the stomach-tube into the esophagus 4 to 8 ounces of liquid containing large particles of meat, bread and undigested food were obtained, slightly acid in reaction, containing lactic acid decidedly positive, sugar in considerable quantity, much viscid saliva and no free hydrochloric acid. At the cardia an obstruction was met but was easily overcome, and from the stomach 2½ ounces of well-digested contents were obtained; free hydrochloric acid 12, total acidity 33. If fluids of different color such as carmin and methylene blue were introduced, one into the stomach and the other into the dilated esophagus, after an hour's time the two solutions could be obtained separately. An x-ray plate of the thorax following the ingestion of a quantity of bismuth pap showed the presence of a very large spindle-shaped dilatation, involving more than one-third of the lower esophagus.

Course of Disease.—The patient passed from observation for a time, returning in February, 1908. In the meantime a cardiodylator of the Russell type had been obtained and was employed but once. The patient objected to the distress caused by use of the dilator and passed from my observation.

CASE 3.—*Patient*.—H. W., aged 44, seen April, 1907, had had migraine since childhood; there was no venereal taint, no history of trauma. Six years before he had had pneumonia with pleurisy. When 24 years old, while eating a sandwich consisting of bread and sardines the patient had a sudden severe attack of pain lasting for several hours, just at the end of the sternum. He had the impression at the time that a small bone had lodged there. Ever since had had difficulty in swallowing on account of an obstruction in lower part of esophagus; he was compelled to eat very slowly, chew food thoroughly and at frequent intervals during the meal to wash it down with a glass of water. He would eat enough solid food "to fill up the esophagus" and then drink enough water to force it through into the stomach. For many years he had taken but two meals a day, "because it was too much

trouble to eat." He had not enjoyed a meal in twenty years and "ate only to live." At certain times solid food would pass through better than at others; at other times even water passed through with considerable difficulty. In the beginning the patient often eructated his food, but after he learned how to eat, this rarely occurred. Through a thorough understanding of his case the patient succeeded in keeping himself in a very excellent state of nutrition.

Examination.—The physical examination was practically negative; the patient was not of the enteroptotic type. The soft tube met an obstruction at the cardia, which was easily overcome with bougies of varying sizes. The sac contained at all times a small quantity of fluid, but no macroscopic food particles. The stomach contents showed marked reduction in acidity: free hydrochloric acid 10 to 12; total acidity, 20 to 24.

The patient manages his case so well that he has thus far declined stretching of the cardia.

CASE 4.—Patient.—E. G., aged 46, seen October, 1908, denied lues; had suffered no trauma. Present trouble dated back three years, to a time when the patient began suffering from occasional burning pains in the epigastrium after eating. These would be relieved by taking a drink of water. There was pain occasionally when the stomach was empty and more or less indigestion, characterized by belching, for a year. During the past six months the patient had had difficulty in swallowing and at times had to leave the table to bring up food which would not pass down. He had a cough at night, which would continue for several hours, until he had brought up several ounces of liquid. This would not occur again during the remainder of the night and never during the day. When he lay on right side his pillow would be wet in the morning as if the saliva had been drooling all night. If he took a glass of cold water during a meal he was unable to get anything else down after that and would have to leave the table to vomit. He had been treated for various forms of stomach trouble, but rapidly lost weight, became weak and incapacitated for work and was now compelled to spend most of time reclining.

Examination.—The patient was 6 feet 2 inches tall, with long slender thorax, moderately acute costal angle, floating tenth ribs, relaxed abdomen and pulsating epigastric aorta. The introduction of the tube into the esophagus removed a quantity of undigested food, five hours after eating, slightly acid in reaction, lactic acid positive, no free mineral acid, rich in sugar. The respiratory test was decidedly positive. The stomach-tube encountered an obstruction 49 cm. from the teeth, which could easily be overcome. The tube could then be passed into the stomach and normal stomach contents removed. The free hydrochloric acid was 56 to 70; total acidity 87 to 92 in repeated examinations. The sac easily contained from 3 to 5 ounces. If a methylene blue solution were poured into the stomach, the tube then withdrawn into the esophagus and carmin solution poured into the sac, a half hour later these two solutions could be obtained separately. The *x*-ray, after the ingestion of a bismuth pap, showed marked dilatation of the lower third of the esophagus.

Course of Disease.—From October 2 to 18 the cardioidilator was used every day or two. Amount removed from the esophagus at the beginning of each examination diminished from 5 to 2 ounces, at first containing food remnants of all kinds with lactic acid, etc., and later consisting of nothing but watery fluid, with no food remnants at all and no lactic acid. The patient gained in weight from 138 to 148 pounds. His difficulty in swallowing is relieved and he returned to work.

May 28, 1910: Treatment was discontinued year and half ago, since which time the patient has been at work without the loss of a day. Toward latter part of meal he still feels a sensation of pressure under end of sternum, which is relieved by several swallows of water. He empties the sac every night by leaning over with his head low and forcing the fluid out; there are rarely any food particles, unless it be something like cracker, which floats on water. If the sac is not emptied before retiring he is apt to awake with a slight cough due to the fluid trickling into larynx and is then

compelled to empty the sac. His weight is 160. He finds that cold water is practically the only substance which does not go down freely. He has no difficulty with other fluids. He regurgitates no food and has no pain.

CASE 5.—Patient.—C. D., aged 30, seen February, 1909, had a doubtful primary lesion six months before coming under observation; no history of injury. Present trouble began about two years before observation when the patient noticed that "food seemed to stop above the stomach and gradually pass down." He was compelled to masticate his food well and eat slowly. Cold water met the same obstruction, but hot water always passed without difficulty. The condition grew worse, so that most of the food "clogged up" just above the stomach, and would have to come up. By getting up from the table and moving about the patient could often make the food pass into the stomach, and he then would have relief. He became accustomed to getting up three and four times during every meal. After a time even this failed to give relief, and most of his food had to be regurgitated. He would often have pain in his chest, severe, cramp-like in character, but not lasting long; had often brought up food taken twelve hours before. Sometimes at night while asleep he awoke coughing and almost strangling from the esophageal contents gravitating into his throat. He learned that soft food taken warm would pass with least difficulty. He then gained some weight and strength, but any change from this rigid diet caused trouble.

Examination.—The patient was poorly nourished, of medium height and enteroptotic habitus. He had acne vulgaris, acute costal angle, floating tenth ribs and succussion over stomach. Introduction of the stomach-tube into the esophagus removed a quantity of undigested food, slightly acid, rich in lactic acid and sugar and much viscid saliva. At the cardia an obstruction was met which at first could only be passed with the smallest bougie. After gradual dilatation with bougies the cardioidilator could be introduced and inflated. The respiratory test was positive. The esophagoscope revealed a dilated pouch just above the cardia with food remnants and mucus clinging to the mucosa, which was thrown into vertical folds. The point of constriction itself could not be seen, because of the thick, tenacious saliva which collected at the bottom of the sac, and could not be removed completely.

Course of Disease.—The stenosis was stretched at intervals of three to four days. Patient was instructed to empty the sac after each meal and at night, so that no stagnant food should remain.

May 27, 1910: The patient has now been under observation for over a year and the cardia-dilatation carried out at intervals of a month or more since. The difficulty which he now experiences is such as one might expect from a sac without tone. He cannot take solids easily and cold water will not pass through. Semisolids and mushy foods pass readily, while the more solid foods require water, soup, or some other liquid to carry them down. The patient does not spit up his food at all and whatever he eats finds its way eventually into the stomach, but with considerable distress. He has gained weight and in general is greatly relieved.

CASE 6.—Patient.—Mrs. H. C., aged 40, was seen April, 1909; her father died of apoplexy; she had three children, and two years before the time of observation had rheumatism. The first symptoms of the present disturbance began about five years before the time of observation with pain in the epigastrium, occurring chiefly at night, once or twice a week. It was usually promptly relieved by swallowing water. Occasionally pains occurred soon after eating. There was no vomiting at any time. Shortly after the inception of the pain the patient began to have difficulty in swallowing, "the food simply refusing to go down." A drink of water would sometimes help. This difficulty persisted more or less ever afterward. The patient was able to get small amounts of food down through great persistence. She was treated at the Washington University Clinic for several years by means of bougies, and thus kept alive. There was a slight obstruction at the cardia, but a moment's pause without much manipulation would remove the difficulty and the tube

would enter the stomach easily, without pain or marked discomfort.

Examination.—The patient was greatly emaciated and her lips were slightly cyanotic. Aside from a slow heart-beat, examination of chest was practically negative. The abdominal wall was very thin; there was slight separation of the recti, movable right kidney, palpable, pulsating aorta, vertical stomach, gastroptosis. The gastric analysis showed free hydrochloric acid, no lactic acid. I am indebted to Dr. Fischel for the opportunity of observing this case, and of stretching the cardia on a single occasion.

The patient did not submit to further treatments, and has, I have learned since, died purely of inanition.

CASE 7.—Patient.—D. E., aged 47, seen June, 1909, denied luetic infection. Past history was unimportant with exception of an accident in December, 1906, when the patient was knocked down by the tongue of a wagon, one wheel passing across his chest. He was confined to bed for three weeks. The present trouble made its appearance shortly after this, at first in an inability to swallow solids easily. This condition gradually grew worse and the patient was compelled to take one or two glasses of water to wash the food down. He finally regurgitated both solids and fluids, being able at times to retain warm liquids only; did not vomit or belch, but "spat up food." He consulted a number of physicians and submitted to various forms of treatment without benefit. Two weeks prior to my first observation he began having burning pains in the epigastrium when bougies were passed, and even when he ate or drank. The pains were behind the lower part of the sternum, were greatly aggravated by efforts to swallow and often awakened him at night. In the beginning they were relieved somewhat by the application of hot packs, rest, alkalies, etc., but at the time he was seen by me nothing gave relief.

Examination.—This revealed a weak, emaciated individual, whose facial expression gave evidences of great suffering. The bougie met a resistance at the cardia, which was only momentary, the sound slipping into the stomach. The passage of the bougies caused the patient to complain bitterly of pain, which persisted even after the removal of the sound. The diagnosis was cardiospasm with dilatation of the esophagus and peptic ulcer, either the cause of the spasm, or the result of constant manipulation.

Course of Disease.—It was thought wise to use the cardiodylator to relieve stenosis as well as the irritation, as in dilatation of the sphincter ani to relieve fissures of the anus. The large dilator was inflated to its utmost, namely 3 cm. diameter causing intense pains and returning streaked with blood. Several dilatations were carried out from which the patient obtained great relief, so far as the obstruction was concerned, but the pain was only increased thereby. He gained weight and improved in a general way through the increased nutrition. The pains could be temporarily relieved with orthoform.

June 1, 1910: No obstruction to the passage of food, but the pain still persists. A small, irregular, flat mass is palpable on the anterior wall of the stomach on deep inspiration, and is evidently near the cardia. It is impossible to say at this time whether this is an inflammatory mass extending from the cardia, or whether it is a beginning malignancy.

CASE 8.—Patient.—Mrs. A. M., aged 43, seen November, 1908, fifteen years previously had pulmonary disturbance which was interpreted by her physician as gangrene of the right lower lobe; was confined to her bed for thirteen weeks with fever, expectoration, etc. The pain in the right side continued to exist for many months. There was no history of either lues or trauma. Two years before the time of observation the patient began having difficulty in swallowing and distress under the sternum after eating. Food would apparently "stop halfway" and cause great discomfort until it passed into the stomach. Shortly after this the patient was unable to take cold water, which would be immediately regurgitated. She lost weight and strength rapidly, and was under treatment for a year without benefit. Periods of from one to three days would pass during which she was unable to get a single morsel through the cardia. This condition was

finally relieved by the passage of sounds by her physicians. After this if food did not pass through the cardia promptly she would invariably have to bring it up. The stricture would seem to be spontaneously relieved, when the swallowing was better for a time. It had gradually become worse until November, 1908, when the patient was taking nothing but small quantities of mushy foods and warm fluids.

Examination.—There was slight, harsh, vesicular breathing at the apex of the left lung; otherwise normal thoracic conditions. There were no abnormal physical signs over the region of the right lower lobe. The patient was still fairly well nourished, though 20 pounds below her usual weight. The stomach-tube, passed readily to a point 39 cm. from the teeth, met a slight obstruction which was easily overcome. The same was true of the large bougies. There flowed from the esophagus sac 3 or 4 ounces of fluid containing food particles. The stomach contents showed free hydrochloric acid 43; total acidity 66. The esophagoscope was introduced without difficulty to a point 10 inches from the teeth where the esophagus seemed to bend slightly to the right and backward so that the lumen could not be seen ahead. The lumen of the esophagus at this point, however, was not especially encroached on; the esophagus seemed rather to be pulled to one side by an old periesophageal inflammation. Beyond this point was a dilated sac extending down to the cardia. The cardiodylator was introduced with some difficulty.

Course of Disease.—The dilatations were carried out first twice a week, then once a week, finally once every two or three weeks for a period of about six months, the large dilator, 3 cm. in diameter, being used.

May 31, 1910: Almost a year has elapsed since the treatment of this patient was discontinued. She reports that she has been able to eat a general diet with comparative satisfaction. From time to time she has a little discomfort and must at all times exert great care in the manner of eating. She can never take anything very cold without its being regurgitated; otherwise she never regurgitates her food. There are times even now when the food seems to lodge for a moment and then pass through. Her weight has remained fairly constant. She eats heartily, but has learned to devote twice as much time to her meals as she did formerly. She finds that she should not drink anything while eating, but takes fluid after meals. The sac now holds 180 c.c. of fluid.

CASE 9.—Patient.—C., seen June 7, 1909, had had no injury and denied lues. Present trouble commenced a year previously with disturbance in swallowing and pain in the right half of the chest. In the beginning he could eat solid foods better than fluids, which were usually regurgitated. Ice-water he was unable to drink at all, warm fluids passing down with less difficulty. For a period of two or three weeks at a time the obstruction and pain would entirely disappear, only to return in a more severe form. He was finally unable to swallow any food without taking a few mouthfuls of water to wash it down. Often when the pain was severe, warm water would give relief. Finally the patient was compelled to "fill his gullet with food" and then force it through by drinking hot water. If he did not take water the food would be regurgitated. Often he would leave the table to regurgitate his food and then return and eat again.

Examination.—The patient was tall, slender, emaciated, fairly well developed, with a moderate enteroptotic habitus, costal angle 50 degrees, floating tenth ribs and a mild degree of gastroptosis. The obstruction at the cardia on the introduction of soft tubes was easily overcome.

The cardiodylator was used with almost immediate relief of the spasm. Following two or three introductions the patient was able to eat what he wished, and could even take cold water, which he had not been able to do for months. The esophagoscope was employed a number of times and could easily be introduced into the dilated sac showing corrugated, collapsed walls with mucus and food clinging to them and an injected state of the mucosa. The patient rapidly regained his weight and was able to do hard physical labor.

May 27, 1910: After a year the patient states that he experiences little or no difficulty, if he takes moderate care, in his eating. He must chew his food thoroughly, take plenty

of time to his meals, and finds that he has less difficulty if he takes no cold water with his meals. He must eat nothing that floats on water, otherwise it is apt to come up. He can often evacuate two or three ounces of mucus and saliva through a slight regurgitant effort. The sac is still present and will contain as much as 160 c.c. of water without much discomfort to the patient. This was determined through the employment of a rubber bag in the esophagus gradually filled with fluid until the patient complained of discomfort. Large tubes pass into the stomach without the slightest difficulty. Though the spasm has been practically entirely overcome the dilated sac still remains after one year and continues to produce mild symptoms. It has been possible to remove food remnants when the patient was not aware of their presence.¹

CASE 10.—Patient.—O. F., aged 8, seen October, 1909, was an eight months' child. There was no evidence of lues in him or his parents. He had never been well or strong. He began vomiting within a month after his birth, when he was put on artificial food because of insufficient mother's milk. Up to six months he developed fairly well, but was always under normal weight. Throughout life he had spat up more or less of his food immediately after taking it, with no retching or straining. He was always constipated and passed little urine. He began teething at 1 year and walking at 2 years of age. When solid food was begun, vomiting became even more marked. The patient developed very slowly physically, but was always alert mentally. During the last two or three years he had occasionally had a week of freedom from vomiting, but this was seldom. He was frequently compelled to get up from the table to vomit, and would return to eat more. He complained at the time of observation that the food "lodged under the breast-bone," seldom accompanied by pain. He lives practically on fluids, because of the distress caused by solids. He had been treated for all forms of stomach trouble, though a stomach tube had never been inserted prior to my first examination.

Examination.—The patient was a small, frail, emaciated, anemic child, weighing 36 pounds and appearing to be about 5 years old. He had lobulated tonsils and adenoids, a number of small, palpable cervical glands. The junctions of the second, third, and fourth ribs with the costal cartilage were prominent. There was a floating tenth rib, costal angle of 50 degrees, movable right kidney, etc. A small, soft rubber, nasal tube, 22 F., encountered an obstruction 26 cm. from the teeth, making it impossible to pass the tube into the stomach, even with a mandarin. Paraffin-covered bougies varying from 22 to 26 F. were carefully forced through the constriction with considerable discomfort to the child, the operator gaining the impression that the bougies suddenly passed through a hard, annular, circumscribed stricture. When given half a glass of water the patient was very uncomfortable until permitted to eructate it, which he did without the slightest effort. On swallowing there was no second murmur to be heard anteriorly or posteriorly over the region of the cardia. When large bougies were passed a very small quantity of blood-tinged mucus would follow. The sacculenation of the esophagus would contain about three ounces of fluid. The examination of the stomach contents showed a normal motility and a slight superacidity; free hydrochloric acid 56, total acidity 80.

Course of Disease.—After the introduction of the larger bougies, up to size 34 F., the patient was able to swallow solid foods with little difficulty, so that forcible stretching with the bag was not resorted to until it was found that the cardia would again contract. Stretching was then resorted to on three or four occasions. The patient now partakes of every kind of food, liquids and solids alike, without any difficulty. On June 1, 1910, the patient had been under observation for about six months and had gained 10 pounds, about one-quarter of his entire body weight.

CASE 11.—Patient.—I. G., aged 58, seen August, 1908, for two years had complained of "a clutching pain" under the sternum, at times extending into the right arm, especially

after exertion and after eating. If he would lie down after meals the pain would not occur. Six months after this trouble he began to have pain when swallowing. The food would pass into the stomach without difficulty, but cause "burning" pain as it passed down. The appetite was good and the bowels regular. There was slight dyspnea on exertion. The patient had lost 25 pounds in the last two years; had had much to worry about.

Examination.—There was a mild degree of arteriosclerosis, a slight accentuation of the second aortic sound, blood-pressure 125. Further examination was entirely negative. The case was considered one of mild arteriosclerosis, with angina and accompanying nervous dyspepsia. About eight months later the patient returned complaining of considerable difficulty in swallowing and pains during deglutition. Food seemed to lodge at end of sternum, and he was often compelled "to spit it up." There was great distress after meals until the food had been forced into the stomach. The stomach-tube and bougies encountered an obstruction at the cardia, which it was possible to overcome. On the introduction of the stomach-tube into the esophagus 2 to 4 ounces of viscid fluid could always be removed containing food remnants, a trace of lactic acid, and always more or less sugar. The test breakfast removed from stomach showed free hydrochloric acid, 44, total acidity, 60, with normal motility.

Course of Disease.—The patient obtained considerable relief through the use of dilator and stretchings, which were carried out once and twice a week for a period of three months. There was at no time any bleeding on the introduction of either the sounds or the dilator. Frequent palpation of the abdomen failed to reveal the slightest evidence of any tumefaction in the epigastric region. There was no cachexia or high degree of anemia. Though able to eat much better the patient did not regain weight. It soon became impossible to introduce large bougies through the stenosis and a very small shot on the end of a thread did not find its way into the stomach. Frequent efforts were made with all sorts of devices to get through the cardia, but this was seldom successful. Even if the dilator was successfully used the patient obtained no relief. In view of the rapid emaciation it was deemed advisable to dilate the stricture from below. There was still no cachexia, no tumefaction and no blood in the feces or stomach contents. The dilatation of the esophagus was very evident from the amount of fluid that it would contain and was also revealed by the x-ray. The gradual development of the trouble through a period of two years with the dilation of the esophagus seemed to justify a diagnosis of cardiospasm. A laparotomy revealed an infiltrating carcinoma, scirrhus type, involving the entire cardiac portion of the stomach with the fundus contracted down to the size of a large hen's egg under the left lobe of liver and margin of ribs, the pars pylorica being entirely free. An attempt was made to feed the patient through a gastrostomy, but he died within four or five days.

3894 Washington Boulevard.

STRANGULATED CONGENITAL UMBILICAL HERNIA

I. R. MAERCKLEIN, M.D.
OAKES, N. D.

As strangulated congenital umbilical hernia is rare, I report the following case:

History.—July 7, 1910, I was called to attend Mrs. A. in confinement, but arrived twenty minutes too late, the call being nine miles in the country. I found that the baby had a congenital irreducible hernia. Having answered the call hurriedly I had forgotten my pocket case, so after ten minutes futile taxis, I instructed the parents to keep cloths wrung out of hot water on the hernia during the night and told them that I would return in the morning to operate on the child.

Operation.—The next morning, after again trying taxis and failing to reduce the contents of the sac, I operated,

1. This patient has since died, having developed acute tuberculosis. The autopsy findings confirmed the diagnosis of dilatation of the esophagus, without anatomic stenosis.

opening the sac, which contained about one foot of cecum and ascending colon and eighteen inches of ileum. Being unable to reduce the contained intestine *en masse*, due to adhesions of bowel coils and constriction at the umbilical opening, I broke up the adhesions and incised the constricting bands of the umbilical opening upward and to the left. The bowel loops being considerably inflamed, hot salt solution was applied on sterile towels and the intestines then returned to the abdominal cavity. The sac was then tied and cut off at the umbilical aperture and its stump returned intra-abdominally; with a catgut suture the peritoneum was reunited. Three silkworm-gut sutures were then "purse-stringed" around the remaining opening and tied. I next applied antiseptic dressing of iodoform gauze. The wound healed very nicely.

Subsequent History.—On the fifth day following operation, a hydrocele of the cord developed, which two days later burst spontaneously, discharging about two ounces of pus. The small opening in the scrotum was enlarged and antiseptically dressed, after which the babe made an uneventful recovery.

Remarks.—During the entire operation, from 10 to 12 drops of chloroform were given to quiet the child's movements, the baby (then only 12 hours old) taking the anesthetic fairly well.

A UVULA FORCEPS AND A COMBINED TONSIL SCISSORS AND SEPARATOR

HENRY R. BOETTCHER, M.D., CHICAGO

The fewer instruments one has to deal with in the tonsil operation, the more quickly and successfully can the tonsil be removed. The scissors illustrated here have a keen knife edge, extending completely around the outer margin, making them when closed a double-edged curved separator. This places at once in the hands of the operator in a single instrument a pair of scissors and a double-curved separator to be used in the usual way.

Fig. 1.—The tonsil scissors with knife edge around outer margin, making a combination of scissors and separator.

Fig. 2.—The uvula forceps, to hold the uvula out of the way during operations on the tonsil.

In the tonsil operation there is always more or less danger of the uvula being injured, and especially is this true where the snare is used, a piece or all of the uvula being looped up and snared off. To overcome this point I have been using the forceps here shown by which the uvula is grasped and held out of the way by an assistant.

I find also that applying the uvula forceps as the first step in the tonsil operation assists to uncover the head of the tonsil, and by outlining the pillars makes it easier to grasp the submerged tonsil, and also to separate the pillars from the tonsil. The spring in the forceps is sufficiently strong to hold the uvula for all purposes, but does not mutilate it.

34 Washington Street.

A NOTE ON THE TREATMENT OF TYPHOID

LOUIS M. WARFIELD, M.D.

WAUWATOSA, WIS.

A recent epidemic of typhoid afforded opportunity for observing over one hundred consecutive cases from the laboring class. Many patients had been ill from two to seven weeks and were even desperately ill on admission. A procedure which has seemed to have been life-saving and which, so far as I know, is not mentioned in any books or articles (except in the treatment of bowel hemorrhage), is the following:

The beds of all seriously affected patients are elevated on blocks placed beneath the feet of the beds. The elevation is from 9 to 12 inches.

The position is not at all uncomfortable. We have kept patients in this inclined position for two to three weeks continuously. This position, we believe, tends to keep the blood near the vital centers and causes less work on the part of the heart. When the pulse has been very rapid, the blood-pressure very low, and the patient seemingly *in extremis*, we have applied the method of Crile in the experimental recovery from profound shock. That is, we have bandaged the legs tightly from the toes to the thighs, and have drawn a binder as snugly as possible around the abdomen. The foot of the bed is also elevated. To bandage the legs we use first raw cotton, torn in strips about eight inches wide, wrapped around the legs. A six-inch muslin bandage is then wound around the cotton, an assistant holding the leg well elevated. The pressure is made firm and evenly distributed. These bandages are left on for two hours, removed for an hour or two and replaced for two hours, as often as occasion demands.

Observations made with the Janeway sphygmomanometer have not been conclusive in demonstrating an increased pressure in the brachial artery. Further observations will be reported later, with full records of results for the past year.

The impression gained by us is that we have saved some of our desperately ill patients. For instance, one patient, now well, had for three days a temperature which ranged from 105 F. to 106.4 F.; she had involuntary bowel movements and urination, and was covered over the chest and abdomen with furuncles, many of which necessitated opening and daily dressing. I feel that our results from the employment of this simple, yet rational means of treatment have been so uniformly excellent that I offer it to the profession with the hope that it may aid in further reducing the mortality, which in such a hospital as this is close to 10 per cent.

MEDICINE-DROPPER CLIP

PERCY R. WOOD, M.D., MARSHALLTOWN, IA.

Ordinary droppers are constantly being broken, lost or inadvertently exchanged for others previously impregnated with medicaments. When combined with the stopper they corrode and disintegrate, and for various reasons become useless. The result is that one seldom has on hand a perfectly reliable sterile and serviceable instrument. To overcome this difficulty I have had made, as here illustrated, a blued steel clip, which springs securely over the sides of the bottle and at the same time holds firmly a common rubber pipette, which, after using, is readily returned, to be at hand when wanted, and which, being cheap, is easily replaced.

THE HOME OF THE ASSOCIATION

A BRIEF HISTORY OF MATERIAL PROGRESS AND OF THE GROWTH OF THE ASSOCIATION BUILDING

CHAPTER II. THE ERECTION OF THE NEW BUILDING

As stated last week, in spite of twice enlarging the original plant, once by adding a fourth story to the building and extending it in the rear, and a second time by occupying

Fig 4—Wrecking the old buildings.

one of the adjoining houses, more room became a necessity, even though there should be no further development in the various enterprises carried on by the Association, and no further increase in the circulation of THE JOURNAL.

After due deliberation, the Board of Trustees decided that the next step must be the erection of a first-class building on the main corner of the Association's property. The board, therefore, instructed the architects, Holabird and Roche, to prepare provisional plans for a new building.

This was accordingly done, and the proposal to erect a new building, with these provisional plans from the architects, and an estimate of the cost, were submitted by the Board of Trustees to the House of Delegates at the Atlantic City Session in 1909.

Fig 5—View looking toward the old building, showing the work of excavation still going on and the pile-driver with its power-plant being placed

THE NEED FOR WORKING SPACE

The report of the Board of Trustees in presenting this question is interesting:

"The Board of Trustees is called on to meet and handle many problems, but there is one question that continues to rise before it again and again. This is the question of working space in our building. When the present building was erected it was thought ample for our needs for a considerable time to come, but no one then dreamed of the work expanding so rapidly as it has. Three years ago the building was extended to the full depth of the lot and raised an additional story, which is all the walls will stand. The additional room thus acquired was soon fully occupied, and last year it became necessary again to enlarge our space by extending to the limits under the sidewalk and utilizing the space in one of our buildings next door. The relief, however, was relatively slight, and now we are once more confronted by the same problem, but in a more serious way. Additional space is urgently needed in practically every department. Since the councils and standing committees have become active working bodies and since the permanent working forces of these bodies have wisely been centralized in our own building, our entire clerical force has been augmented materially and is at present unavoidably crowded and badly quartered. We need more space for linotype machines and for our stereotyping department. We are working our

Fig. 6.—Another view of the excavation with the pile-driver at the left and some of the 50-foot piles. Holes in the ground show where piles have already been driven.

men in two shifts of eight hours each and on rush days they are worked overtime in two shifts of ten hours, thus keeping our mechanical departments in operation for twenty hours out of the twenty-four.

"Your Trustees have given this matter careful consideration for some time, and after thoroughly discussing the matter with our architects and with our general manager we are unanimously of the opinion that the only solution of the question is the erection of a new building large enough not only to accommodate us now, but to allow for our growth for many years to come. We already own the ground adjoining our present building and the available funds and securities will permit the construction and equipment of the building as proposed. In view of the urgent need of more room we believe the work should be undertaken at once. The matter is therefore submitted for your consideration. Owing to the great urgency, however, the board has gone ahead and secured, provisionally, architects' plans and construction bids, believing that its action would meet with the approval of this body. The estimated cost of the new building, for which the plans

will be submitted to the House of Delegates, including architects' fees, is approximately \$200,000."

The Board of Trustees which made this report consisted of Drs. William H. Welch, Miles F. Porter, M. L. Harris, W. W. Grant, Philip Marvel, W. R. Townsend, Philip Mills Jones, and W. T. Sarles. Dr. T. J. Happel was also a member, and was present at the board meeting when the matter was discussed, but died May 24, and his name is not attached.

The reference committee of the House of Delegates to whom this question was referred, made the following report:

"This committee is advised that with regard to the project of erecting a new building the conditions are as follows:

"The money is on hand for the enterprise in the shape of bonds, certificates of deposit in banks drawing interest, and cash on hand. The building can be erected without incurring indebtedness and without curtailing the present work of the Association or its committees. The old building can be let for manufacturing purposes, returning a good interest on the money invested.

"The building will enable the Association to conduct its business more economically than at present on account of the present necessity of "overtime" work with double pay, due to the lack of sufficient room. It will provide sufficient space in which to install the working head-

Fig. 7.—View of the excavation with the pile-driver in action.

quarters of the various councils and standing committees, which is essentially the accomplishment of results. The Association already owns the land on which the building is to be erected.

"It is therefore recommended that the Trustees be given full authority to proceed in the matter of erecting the proposed building.

"DONALD CAMPBELL, J. W. PETTIT, D. S. FAIRCHILD,
"E. DENEGRE MARTIN, ALEXANDER R. CRAIG, Chairman."

BUILDING AUTHORIZED

This report was adopted by the House of Delegates, and thus the Board of Trustees was authorized to go ahead with the erection of a new building according to final plans to be approved by them.

The instructions to the architects specified two general principles to be kept in mind: first, that the new building should be a strong one, sufficiently so to bear any reasonable weight on any floor, and second, that it should be absolutely and positively fireproof. The plans and specifications prepared

by the architects provided for a fireproof structure six stories in height with a high basement, covering the whole lot, 60 by 120 feet in size, with provision for future enlargement by the construction of additional stories.

THE EXCAVATION FOR THE FOUNDATION

The design and specifications submitted by the architects having been accepted, the contract was let to the firm of McCarty Brothers, and in March, 1910, workmen began to raze the old building which covered the site (Fig. 4). This work proceeded rapidly, the old material being carted away as fast as torn down, and soon the workmen began widening and

Fig. 8.—General view of the excavation and the old building, with the pile-driver in place.

deepening the excavation. It took about six weeks to complete this work.

The first essential of a strong building is that it shall have a solid foundation. In order to make a solid foundation for this building, piles were first driven into the solid earth (Figs. 5, 6, 7 and 8). Three hundred and seventy-seven piles, or in other words, 377 cypress trees, 50 feet long and 14 inches in diameter at the butt, were used in forming the basis for the foundation.

The driving of a large number of piles in an excavation near the walls of another building has the effect of first raising and later lower-

Fig. 9.—Wall of the old building, showing the method of preventing collapse or damage to the building by the driving of the piles.

ering the latter to such an extent as to make it liable to collapse. To prevent this bricks were taken out of the wall, as shown in the illustration, and jack-screws inserted the whole length of the building to support the wall, and any variations were adjusted by lowering or raising the jacks. These jacks were allowed to remain in the wall until the wall had adapted itself to the new conditions (Fig. 9).

In a later issue we shall describe and illustrate the further progress of the work.

CULTIVATION OF SARCOMA OUTSIDE OF THE BODY

A SECOND NOTE *

ALEXIS CARREL, M.D., AND
MONTROSE T. BURROWS, M.D.

NEW YORK

We have succeeded in cultivating a very malignant sarcoma outside of the body. The purpose of the experiments was to develop a general method which would permit a study of the evolution of tumor tissue under known conditions and to observe living cancer cells at every instant of their growth.

We used a fowl sarcoma that Dr. Rous has propagated from generation to generation for more than a year. Through the kindness of Dr. Rous, two chickens with actively growing tumors were placed at our disposal. Four series of cultures were made with fragments of the tumor extirpated from the animals in four different operations. The cultures started to grow after a very short latent period. While normal tissues of adult dogs and of young kittens began to develop respectively about forty-eight hours and twelve hours after inoculation of the plasmatic medium, sarcomatous tissue of the chicken showed, in some cases, evidence of activity after two and one-half hours. Fusiform cells appeared on the edge of the tissue and after five or six hours, many elongated cells and chains of cells could be seen radiating out into the culture medium. This rate of growth approximates that observed by Burrows in sixty-hour-old chick embryos. After a very short time, the cultures reached their period of full vegetation. The growth of the tissue was extremely rapid. In a culture of the fourth set of experiments we saw, after the tenth hour, a large area of new cells surrounding the fragment of tissue. The surface area of this new growth was greater than the area of the original fragment. At the end of the first twenty-four hours the surface of the new tissue in one of the cultures was fourteen times that of the original fragment. After forty-eight hours this area might reach twenty-two times the size of the original fragment. Associated with this wide extent of new tissue was a slight decrease in the size of the old fragment. It showed that the new growth was partly built of cells wandering from the original fragment into the plasmatic medium. This wandering of cells is a phenomenon frequently noticed in the cultivation of normal tissue. But the new tissue was also composed of new cells. In a culture fixed and stained after twenty-four hours, we observed many karyokinesis figures. The new cells are morphologically different from the chick embryonal cells. They are round, fusiform or polygonal, filled completely or partially with large refractive granules. They grow in many layers in

the medium and are apparently little influenced by the architecture of the fibrin net.

The nature of the plasma has a marked influence on the growth of the tumor. In seven cultures, the plasma of a normal animal was used. Only two positive results were observed. In six test cultures we employed the plasma of the animal from which the tumor had been extirpated. Six positive results were obtained. We have endeavored to cultivate sarcomatous cells in series in order to obtain a pure culture of the more virulent elements. The second generation grew very easily. The original tissue and the adjacent new cells of a culture were extirpated, and the free space left by their removal in the old culture medium was filled with new plasma. The surface of the old medium was also covered with new plasma. In every case the sarcomatous cells entered immediately the new medium. In twenty-four hours long chains of fusiform cells spreading out from the area covered by the sarcoma cells could be seen invading the new medium. On the fifth day of the culture the cells were still in full activity. Up to the present, perfect second generation has been obtained.

These results show that sarcomatous tissue grows luxuriantly outside of the organism, that a second generation can be produced by the cells grown in a first culture and that the whole process can be observed with ease at every instant of its evolution. It is probable that the malignant tumors of the human organism can, in a similar manner, be caused to grow outside of the body. The method, therefore, will be a valuable addition to our means of studying the problem of cancer.

Therapeutics

PROSTATITIS AND SEMINAL VESICULITIS

During the last decade or more great advance has been made in our knowledge of the etiology and treatment of disease of the prostate gland. It is proposed at this time to discuss only its acute inflammation and not its chronic hypertrophy. The most frequent, and the only frequent cause of inflammation of this gland and of the seminal vesicles is gonorrhoea. Without regard to the importance of acute inflammation of these parts the chronic and persistent harboring of the gonococcus by these organs, making the carrier of these germs a menace to himself and others, makes the subject of vast importance. It is hardly necessary to state that most gynecologic inflammations are due to the gonococci, and most frequently the infection is received innocently and is due to a latent gonorrhoea, or a chronic prostatitis or vesiculitis due to an uncured gonorrhoea. Chronic gonorrhoeal infection of the prostate and seminal vesicles is of frequent occurrence. The symptomatic evidences may be slight. There often is an increased frequency of urination; there may be a feeling of fullness or uncomfortableness in the perineal region; there may be a slight sticky, or mucopurulent exudate and the urethral drop, and the urine may be cloudy. On the other hand, the urine is not always cloudy with this subacute or chronic prostatitis.

While it is probably rare to find gonococci in prostatic exudate a year after the original infection, it does occur, and before a year the gonococci may be frequently found when there are no apparent evidences of the previous gonorrhoeal infection. When from massage of the prostate and stripping of the seminal vesicles the exam-

* From the laboratories of the Rockefeller Institute for Medical Research, New York

ination of the slide from the drops of secretion exuded from the urethra show gonococci, of course the diagnosis is positive. If such an examination shows no gonococci in a suspected individual, it has been suggested that from 1 to 2 c.c. (5 to 10 minims) of a 1 per cent. solution of nitrate of silver be injected into the posterior urethra with the Ultzman syringe. The stimulation from this injection will cause, the next day, an increased discharge, which should cause gonococci to be found on microscopical examination, if they are still present.

Besides the local symptoms above described of chronic prostatitis, patients who are suffering from this condition often have symptoms of neurasthenia and hypochondriasis. Men otherwise well, with no apparent cause for symptoms of nerve tire, should be carefully questioned as to previous gonorrhoeal infection, and the prostate and any secretion that can be expressed from it should be carefully examined, even if the local symptoms are negative.

Therefore, too great importance can not be ascribed to, and too great care can not be taken in, determining that a patient who has had gonorrhoea is free from gonococci and is cured of chronic inflammation before he is dismissed from treatment. This means not only frequent examinations by the microscope of slides prepared from actual urethral discharge, but also any discharge that may be expressed from the prostate and seminal vessels, and until such examinations are negative the patient should never be discharged, and lest he stop treatment before he is cured, he should be thoroughly cautioned in the beginning of his treatment of the persistency of this particular germ and the absolute necessity for a complete cure for his own and his family's future.

Acute gonorrhoeal inflammation of the posterior urethra is, of course, readily diagnosed by the cloudiness of the urine. A later involvement of the prostate or seminal vesicles is diagnosed by the finger passed well up the rectum and noting the enlargement and tenderness of the prostate, and, if the seminal vesicles are involved, by noting their fullness and tenderness. Normal seminal vesicles are hardly palpable.

Acute inflammation of the prostate and vesicles should be treated with rest, a diet of milk and simple cereals, plenty of water should be taken, and hot sitz baths once or twice a day. The urine should at first be rendered alkaline with potassium citrate during the acute irritation, and later hexamethylenamin or salol (phenyl salicylate) should be administered. There should generally be no urethral injections and no manipulation of the prostate, and certainly no passing of instruments into the urethra. If the prostatitis becomes localized and causes an abscess, of course the treatment is surgical interference.

In subacute prostatitis the prostate should be gently massaged, and some of the exuded fluid which is received on a glass slide should be examined under the microscope for pus and gonococci. Generally, there will also be found living spermatozoa and often dead spermatozoa, with prostate epithelial cells, and perhaps crystals of spermin. The tenderness of the prostate determines the frequency and the amount of massage that it should receive: perhaps every second day for a short time, and then twice a week. At each massage the seminal vesicles should be thoroughly stripped. During this subacute inflammation all violent exercise must be prohibited; alcohol should certainly not be allowed, and the patient is usually better without tobacco than with it. Tea and coffee, if allowed at all, should be in small

amount. Constipation should never be allowed in any prostatitis. It is always best to wear suspensory bandage during acute gonorrhoea, and during acute and subacute inflammation of the prostate.

The prognosis is good if the patient will give himself the proper rest in the acute condition, if he will take care of himself in the subacute condition, and will persist long enough in his treatment of the chronic condition.

If gonococci are present in this secretion in subacute or chronic inflammation, vesical injections of weak silver solutions, such as from 1 to 500 to 1 to 1,000 of one of the albuminate silver preparations, should be given daily or every other day, and at least every other day or generally every day the prostate should be massaged while the solution is in the bladder. The patient then urinates and thus washes out the bladder. These bladder washings should soon be less frequently repeated, and as soon as the gonococci are found absent from the prostatic secretion, the bladder injections are given only infrequently. A microscopic test should be made once a week for three or four times, and then again in a month. The gonococci remaining absent, the patient may be considered cured of the infection. The old assertion that when the gonococci had infected the prostate vesicles the patient could never be cured, but harbored them for the rest of his life, is probably not now true if the affected individual will allow himself to be properly treated before the germs have found a more permanent harbor deeper within in the glandular tissue.

In chronic prostatitis without gonococci, or after the gonococci have disappeared, besides massage of the prostate once or twice a week, local applications can be made by high injection of from 1 or 2 c.c. (5 or 10 minims) of various silver solutions, the strength of which should vary from 1 to 3 per cent. Instillations should not be used more frequently than once in 5 days. Ichthyol solutions have also been used for this purpose. The cold sound is occasionally of as much advantage in the posterior urethra as it is in gleet conditions of the anterior urethra. Not infrequently the double closed catheter, which allows the circulation of cold water, is one of the best tonic treatments of the posterior urethra and prostate. Such treatment is indicated only in the chronic form of the inflammation when the prostate has not returned to its normal size, normal tone and normal feel.

Like any other inflammation that has become chronic, a patient who has become neurasthenic and mentally disturbed, and perhaps below par physically, should receive tonic treatment and such a vacation as he may be able to take, and the local inflammation will often rapidly improve when it has not improved under more active medication. It should be urged that after the gonococci have disappeared, too long use of instruments should be discouraged.

THYROID

Reid Hunt, in recent experiments on the effect of foods on the activity of the thyroid, has proved, by the tolerance of animals for certain poisons, which tolerance varies with the activity of the thyroid (*Bulletin No. 69, Hygienic Laboratory, Public Health and Marine-Hospital Service*), that dextrose, oatmeal, liver and kidney stimulate the thyroid gland to greater activity.

It was already known clinically that patients with exophthalmic goiter, or, more definitely, with hypersecretion of the thyroid, did better not only without foods rich

in pürins, such as liver and kidney, but also without meat of any kind. It was not known, however, that dextrose and oatmeal stimulated the thyroid. Theoretically, then, oatmeal should not be allowed a patient with exophthalmic goiter.

It of course has been known that the administration of thyroid stimulated the thyroid gland, but Hunt shows that other glands, especially the prostate, ovaries and testicles, are stimulant to the thyroid, while thymus, parathyroid and suprarenals seem to have the opposite or depressant effect on the thyroid.

Eggs, milk, cheese and various fats were apparently shown in these experiments to decrease the activity of the thyroid gland.

These experiments are of great therapeutic value when we apply the knowledge thus gained to the treatment of hypersecretion and hyposecretion of the thyroid, and a very tangible part of the practice of medicine is concerned with the correction of the disturbances in the secretion of the thyroid gland.

DIPHThERIA

Diphtheria is a local infection, and if immediately or soon eradicated, general infection will not occur. The toxin produced by this germ is a circulatory and nerve depressant, and it is this action of the germ that causes it to be so dangerous to life. A large part of the symptoms of throat and nasal diphtheria is due to septic poisoning: in other words, secondary infection from the putridity occurring in the throat. This secondary infection generally represents neglect, medical or lay.

It is well recognized that it is often impossible to make a diagnosis of diphtheria on the first examination of a patient who has a suspicious throat. Generally spots or membrane on the tonsils, whitish in color, rather readily removed by means of a swab, with temperature above 102 F., headache, lumbago and other muscle pains, with a pulse of good tension, show that it is a streptococcal infection and may be termed follicular tonsillitis. In true diphtheria, *i. e.*, infection with the Klebs-Loeffler bacillus, the patient is often found on the first visit with low temperature, soft pulse, no great muscle pains, a throat that is not badly swollen or painful, suspicious dark red patches in the throat; such exudate as is present generally in membrane may, however, be small in amount and of a grayish color, not readily removed with a swab. As just stated, these diagnostic signs are not positive, and should not be positively relied on. If the cervical glands are enlarged, it points rather more strongly toward diphtheria. On the other hand, a diagnosis should generally be made before the glands of the neck have become enlarged from diphtheria. Tender and enlarged glands, however, readily occur from any throat infection. While a probable and many times positive diagnosis can be made from these clinical signs, often only a bacteriologic examination (from a culture made from a sterile swab brushed over a suspected tonsil or pharynx) can make the diagnosis positive.

Successful treatment of this disease means that: (1) infection of others does not occur; (2) any odor coming from the throat or nose is not present after the first twenty-four hours of treatment; (3) the nutrition is kept up; (4) great cardiac weakness does not occur; (5) no subsequent paralysis occurs; (6) the patient has thoroughly recovered his muscular and heart strength before he is considered fit to return to his occupation, school, or strenuous plays. This means that his convalescence should be carefully supervised.

TREATMENT BEFORE A DIAGNOSIS HAS BEEN MADE

1. *Isolation.*—Every suspicious throat should be isolated. This requires no discussion; it has been proved not only from the personal experience of every physician of the contagiousness of even ordinary colds, but from the bacteriologic discoveries that have shown the different kinds of germs that cause different kinds of colds and sore throats, and that many of these particular germs occur in other persons closely associated with the one first infected. When there are spots or membrane in the throat, isolation must be insisted on. In fact, while the results are not so serious from so-called follicular tonsillitis and pharyngitis and streptococcus infection, the contagion is more rapid and infection more easily acquired from these than from true diphtheria. Therefore, always isolate. This means keeping the infected patient in one room, with some one person to care for him; a proper care of drinking and eating utensils; the use of cheesecloth or pieces of old cotton cloth or old handkerchiefs for the secretions from the nose, throat and mouth, to be placed in a paper bag after use and the bag and its contents burned. The gargling should be into antiseptic solutions, and care should be exercised that there are no splatterings during the gargling on anything that cannot be thoroughly cleansed. A newspaper spread over the bed or on a chair on which is placed the gargling basin is the best method for cleanliness; the paper can then each time be burned. If the nurse, or the patient himself, if he is an adult, thoroughly washes the face and hands after gargling, and exercises the simple care suggested, infection of others cannot occur.

2. *Hygiene.*—The most suitably situated, sun-lighted, and well-ventilated room should be selected for the patient, and if possible it should have ready access to a bathroom. As is so well understood with all contagious diseases, as soon as the diagnosis of diphtheria is positive, unnecessary draperies, rugs, and upholstered furniture should be removed from the room. The patient should receive hot sponge baths daily.

3. *Diet.*—A simple diet suited to the amount of rise in temperature the patient may have is correct during the first day or two of the illness, or throughout the illness if it proves to be follicular tonsillitis and not diphtheria.

4. *Bowels.*—As in all fevers and all infections, it is necessary to administer a purgative first, which will clean the alimentary canal, reduce the temperature, and prevent the absorption of toxins from constipation, which almost always occurs in the first stage of a fever, and especially of an infection. Perhaps the best cathartic is calomel. The dose need not be large, and is best administered in one single dose and not in divided doses. An ordinary aloin, belladonna and strychnin tablet given with one or two grains of calomel, administered with a little milk, generally produces splendid catharsis without griping. Of course a more quickly acting purgative may be administered if desired. It has been claimed that calomel in divided doses has a specific action on the throat, causing an increased secretion of mucus and aiding in the loosening of the membrane; consequently, many physicians advise that a 1-10 grain tablet of calomel be administered every hour until ten or more have been taken, or until the bowels begin to move. With this method of administration, salivation may be caused, and, in fact, it is only by this increased flow of saliva and mucus that the calomel can have much specific action in the throat. Many years ago

calomel was used in good-sized doses for this purpose, but such use is inexcusable. After the action of the purgative, on the following day or on the second day, the bowels should be moved with any gentle laxative if they do not move of themselves, and after this time the bowels must move daily. It cannot be too much emphasized that the more perfect the normal activity of the intestines, the fewer toxins accumulate in the blood, the less the liver is disturbed by resorbing old bile and products of indigestion, the better it is able to act as a Pasteur filter to the blood, and the better the blood is able to form its antitoxins and fight the infection. For this same reason there never should be over-feeding or mistaken feeding in diphtheria or any other infection. A good laxative in diphtheria and of advantage in most infections is yeast. From 1/8 to 1/6 of an ordinary moist, compressed yeast cake, dissolved in a glass of water (less quantity for a child) makes a sour drink that is both a laxative and a preventive of bowel fermentation. It also stimulates, on account of its nuclein, the production of white blood-cells which are needed to fight infection. Yeast may also be of value as a gargle in membranous throats.

5. *Local Treatment.*—This is of primary importance in follicular tonsillitis, and is secondary in importance only to antitoxin in diphtheria. It is absolutely inexcusable to administer antitoxin to a patient with diphtheria and expect the throat to care for itself. There is no medical or surgical condition so responsive to continual and repeated care as is diphtheria of the throat and nose. There is no excuse for a disagreeable odor emanating from the mouth or nose in diphtheria after the patient has been under treatment for twenty-four hours; and there is probably but little opportunity for the spread of infection after the patient has been under treatment for twenty-four hours. It must be again urged that this disease is at first local, and is not a general disease, and the more completely the throat is cared for, the less absorption of the toxins of the specific germ and the less absorption of toxins from the pus germs and the germs of putrefaction.

The local treatment, then, consists of gargles, sprays, and insufflations. The best gargle is solution of hydrogen peroxid. It should be diluted with from 1 to 3 or 4 parts of warm water, and this should be gargled thoroughly every three hours during the day and every four hours during the night. About two or three minutes after the peroxid gargle the patient should wash out the mouth and throat with either a Seiler's tablet solution (a tablet dissolved in 1/3 of a glass of warm water), a saline solution (1/4 of a teaspoonful of salt to a half a glass of warm water); or the liquor antisepticus alkalinus (N. F.) diluted with equal parts of warm water. This is to remove the irritant caused by the chemical action of the peroxid, and it also soothes the mucous membrane. Also every three hours, alternating with the peroxid solution, the patient should gargle with either a 4 per cent. solution of boric acid or a 5 per cent. solution of potassium chlorate, or the liquor antisepticus diluted with 1 or 2 parts of warm water. The gargling should therefore be done every hour and a half during the day, at one time the peroxid solution and the alkali, at the other time the boric acid or other solution. The intervals at night may be double those of the day. As the patient often tires of gargling, swishing is just as efficient, and with each solution several mouthfuls should be taken.

If the patient is a child too young to gargle, spraying must be done with an atomizer. The same solutions may be used, only more diluted. As spraying is much

less efficient than gargling, it is advisable with children, and often with adults, to insufflate pure boric acid directly on the membrane or spots of follicular exudate. The boric acid stimulates the flow of the mucus and causes the secretion to loosen the membrane, and it comes off more rapidly than by any other treatment. In the meantime it acts as a gentle, non-poisonous antiseptic. With these local treatments septic infection cannot occur, and the patient will not die of secondary infection.

If there is much congestion and swelling of the throat, weak suprarenal solutions may be sprayed into the throat, or a suprarenal tablet or a little suprarenal powder may be occasionally dissolved in the mouth. It must be remembered, however, that suprarenal solution should not be used too often, as it is absorbed from the mouth, throat and nasal membranes, and may do harm. If the nose and nasopharynx become involved, warm sprays must be carefully directed into the nostrils, or if the patient is older, gentle nasal douches must be used. The solutions must be much weaker than above described. Boric acid diluted with some non-irritant powder, possibly subgallate of bismuth, occasionally may be blown into the nostrils, and should be blown into the nasopharynx.

6. *Internal Medication.*—In the early stages of follicular tonsillitis, rarely in the early stage of diphtheria, headache, muscle aches and high temperature may call for special medication. The following powder is efficient:

R	Gm.	
Acetphenetidini	1	50
Phenylis salicylatis	1	50
M. et fac chartulas 5.		

or ññ gr. xxv

Sig.: A powder every three hours.

Or:

R	Gm. or c.c.	
Acetanilidi	1	25
Sodii bicarbonatis	1	or
M. et fac chartulas 5.		

gr. v
gr. xv

Sig.: A powder every 2 hours.

More than five doses of any antipyretic will not be needed, and even the whole five may not be necessary, depending on the symptoms. In follicular tonsillitis little other internal medication is needed, except perhaps a tonic to hasten convalescence and complete recovery, such as:

R	Gm. or c.c.	
Strychninae sulphatis	2	02
Quinine sulphatis	2	or
Ferri reducti	1	
M. et fac capsulas siccas 20.		

gr. 1/3
3ss
gr. xv

Sig.: A capsule three times a day after meals.

7. At the first visit, or as soon as possible thereafter, when a throat looks suspiciously like diphtheria, a properly prepared swab should be taken or sent to a bacteriologic laboratory for an examination of the culture.

(To be continued)

Duties of Physicians.—We should not only be torch-bearers for the enlightenment of the people, regarding their bodily and mental welfare, but should also be the guardians of the public health. Although at all times recognizing the rights and liberties of the people, it is our duty to enforce the laws of sanitation and to protect the people from their own ignorance and from the dangers of designing quacks and unscrupulous pretenders.—M. B. Heyman, in *Long Island Medical Journal*.

SATURDAY, OCTOBER 29, 1910

DATE OF NEXT SESSION

The Board of Trustees, at its meeting last week, appointed June 27, 1911, as the date for the opening of the next session of the American Medical Association, at Los Angeles. This refers to the scientific session; the House of Delegates will meet on June 26. This date was chosen after considerable study, and is in accordance with the wishes of the great majority of those who replied to the letter of the Chairman of the Board of Trustees, published in *THE JOURNAL*, September 17. The date will not interfere with those who are connected with medical colleges, and will be more generally convenient for those who desire to take advantage of this occasion for a vacation. At that time of the year the weather is pleasant in Los Angeles; and the season will be ideal, especially for those who wish to go or return by the northern route, taking in Oregon, Washington and Yellowstone Park.

URINARY CHANGES IN CANCER

Scattered items of information concerning metabolism in cancer indicate that we may find eventually that the presence of malignant tissue, even in small amounts, may have a greater influence on the entire organism than was formerly suspected. Repeated attempts to extract from cancers some poison which shows enough activity to account for cancer cachexia have all failed, when properly controlled. Some observers have sought an explanation of this in the production by cancers of enzymes which cause abnormal cleavage of food and tissue elements, thus introducing into the blood unusual and toxic metabolites. Although the direct evidence for this hypothesis is anything but satisfactory, some support for it may be found in the results obtained by Salkowski and by Salomon and Saxe through their studies of the urine of patients with cancer.

About five years ago Salkowski¹ reported that in certain diseases, and especially in cancer, the urine contained relatively large amounts of nitrogen in compounds of colloidal nature, which could be precipitated with alcohol for quantitative estimation. Recently Salomon

and Saxe² have been studying the occurrence in the urine of one of these colloidal nitrogenous substances, the so-called oxy-proteic acid, and have found that an increase in the excretion of this substance is characteristic of cancer, even in the early stages. Normally about 1.5 per cent. of the total urinary nitrogen is present in this form, the maximum figure not exceeding 2 per cent. Of thirty-eight carcinoma cases, however, in thirty-one the oxy-proteic nitrogen amounted to from 2.5 to 3.5 per cent., and in only three was less than 2 per cent. found. Apparently the size, location and degree of cachexia are not of particular moment in determining the degree of oxy-proteic acid elimination. It is presumable that this oxy-proteic nitrogen and colloid nitrogen indicate an abnormality of cellular metabolism caused by the cancer, in support of which assumption is the fact that similarly high colloidal nitrogen figures are obtained in the urine of advanced pregnancy and in certain liver diseases, both being conditions in which metabolism is notoriously altered.

To the pathologist, these observations are of much significance as adding to our knowledge of the biology of malignancy, but to the clinician they hold forth hope of another point of support in the diagnosis of cancer. The investigators quoted believe that the practical application of their experimental studies will prove to be of much value, especially since the urinary change seems to be present early in malignancy, and to occur in few other conditions likely to cause confusion. Not until the methods of determining these factors—total colloidal nitrogen and oxy-proteic acid nitrogen—have been developed to a degree of simplicity and reliability suitable for routine application in the clinical laboratory, can we hope to secure that great volume of evidence on which alone final judgment can rest; but the needs for help in cancer diagnosis are so pressing that there is no doubt that this clue will be followed to its end with all possible expedition.

ATTEMPTING TO CRIPPLE THE PURE FOOD LAW

Under the powers given it by the Food and Drugs Act, the federal government has done good work in putting out of business those unconscionable scoundrels who defraud sufferers from cancer by selling alleged cures for this disease. The section of the act under which these people are prosecuted is that which declares a drug misbranded "the package or label of which shall bear any statement . . . regarding such article . . . which shall be false or misleading in any particular." From the simplicity of the wording of the law and from the fact that the intent of its framers was to protect the public, one would imagine that there could be little question as to its interpretation. Such does not seem to be the case, however.

1. Berl. klin. Wehnschr., 1910, xlvii, 533

2. Beitr. z. Carcinomforsch., 1910, II, 2.

O. A. Johnson, a quack of the "cancer-cure" variety who plies his trade at Kansas City, Missouri, is legally entitled to practice medicine—to the shame of the state be it said. Not long since, he was prosecuted under the Food and Drugs Act on the charge of shipping misbranded drugs, the government contending that, since Johnson implied on the labels of his nostrums that they would "cure cancer" and since such an implication is an unwarranted falsehood, the stuff was misbranded. Such a contention to the man in the street seems conservative enough, and plain enough. But Johnson's trade has been a profitable one—to him—and one that was not to be given up without a struggle. When, therefore, the United States grand jury indicted this "cancer-curer," his attorneys filed a motion to quash the indictment on the ground that the Food and Drugs Act applies merely to the composition or ingredients of the medications and not to their therapeutic effects. In other words, the defense is that, so long as an exploiter does not falsify on the label regarding the composition of his nostrum, he may lie to his heart's desire concerning its effects. And, strange to say, Johnson's position was sustained by a federal district judge! Fortunately the Supreme Court of the United States will have a chance to reverse this astonishing ruling.

Should it finally be decided that the ruling as it now stands represents the Supreme Court's interpretation of the Food and Drugs Act, the sooner the act is amended the better. Under the decision of the district judge it would be possible for an enterprising scoundrel, fortified by immunity from prosecution, to sell common salt "Guaranteed under the Food and Drugs Act" as a sure and positive cure for cancer, consumption, Asiatic cholera, or for any other deadly scourge that an imagination untrammelled by conscience might suggest.

To all thinking men, to all men who believe that the Food and Drugs Act was intended to protect the public rather than to afford avenues of escape for conscienceless quacks, to all whose mental horizon is not bounded by hair-splitting legal technicalities—to all, in a word, who feel that it is an outrageous shame that those who are suffering or incurably ill can be defrauded and impoverished under protection of the law—to all such the present ruling on the scope and intent of the Food and Drugs Act must seem deplorable.

the requirement is simply a high-school education. The peculiar situation is thus presented of laboratory instructors endeavoring to expound the intricate problems of medicine to classes made up in part of college-trained men and in part of those with only a secondary school training. It is inconceivable how a condition of this kind could exist in a state university which has long held so prominent a place among educational institutions as has the University of Michigan.

This difference of entrance standards is eminently unfair to the students. If they lack the proper preliminary training they will fail to grasp the instruction given, or if they enter with the higher qualifications they will be retarded by the more elementary methods required to teach the students admitted on the lower requirement. This diversity of standards is also unfair to the teacher. Furthermore, indications are that this state of affairs is to go on indefinitely. In an apparent effort to forestall the adoption of more equalizing regulations, the members of the homeopathic faculty are reported to have secured the adoption by the regents of a resolution that in the year 1912 the entrance requirements for homeopathic students be increased to one year of collegiate work or its equivalent. This is still one year less of college work than is now required of all other medical students, and no mention is made in the resolution of any requirement of the preliminary sciences.

Equally astonishing is the clause in the resolution which makes this "one year of college work or its equivalent" subject to the approval of the homeopathic faculty! It may be fairly asked: Why such discriminations in the admission of medical students? Why should two such widely varying standards be permitted? And why should special provision be made for the certification of entrance credentials of homeopathic students, when the credentials of all other students who do not hold collegiate degrees are subject to the approval of the dean of the liberal arts department? This disparity of standards of admission would seem to indicate that to master homeopathic medicine requires less preliminary training than is required for other medical courses.

One would suppose that the homeopaths would be the first to demand an immediate correction of this reflection on themselves.

ENTRANCE STANDARDS AT THE UNIVERSITY OF MICHIGAN

Last year the entrance requirements of the medical department of the University of Michigan were increased to two years of collegiate work, to include a reading knowledge of German or French and at least a year's college work in each of three sciences, namely, physics, chemistry and biology. An exemption is made, however, for those who enter with the expectation of taking their clinical work under homeopathic instructors; for these,

Current Comment

A HEALTH EXHIBIT ON WHEELS

Our local and state health authorities are showing an increasing disposition to use up-to-date methods in educating the public on hygiene and sanitation. In Louisiana the State Board of Health is preparing a "health car," which is to be sent all over the state as an exhibit and as an object-lesson. As it is impossible to bring all of the people to a health exhibit, the board proposes to take the exhibit to the people. A special car has been

donated by Mr. D. D. Curran and Mr. H. B. Hearn, president and superintendent of the Queen and Crescent Route. The car will make its first appearance at the Louisiana State Fair at Shreveport, after which it will start on its journey through the state, crossing on the Vicksburg, Shreveport and Pacific road, thence diagonally across the state again over the line of the Louisiana Railway & Navigation Company, next through the state over the New Orleans and Northeastern, after which it will be transferred from one road to another until the people in every railroad station in the state have had an opportunity to visit it. The car will contain a large collection of normal anatomic specimens in contrast to specimens showing pathologic conditions due to tuberculosis. This exhibit is contributed by the Souchon Museum of Tulane University. Several lecturers will accompany the car and will deliver instructive addresses at every stop. A laboratory has been installed for the examination of milk, water, sputum, etc. At each stop sanitary inspection will be made of the markets, slaughter-houses, schools, churches and other public buildings. Literature on health matters will be distributed. A moving-picture machine will show, at each stop, "The Gymnastic Fly," "The Pesky Fly," "The Man Who Learned" and other story-telling series of pictures, whose educational value is well-nigh unlimited. Lantern-slides showing insanitary conditions existing in various parts of the state will also be used to illustrate lectures. A mere statement of the work to be done by this Louisiana health car is in itself a sermon on the possibilities of public education. The people of Louisiana are fortunate in having a board capable of exhibiting such enterprise, energy and solicitude for the health of the people. A similar exhibit prepared by the State Board of Health of California has done much good and has demonstrated the feasibility of such a plan. If this example could be followed in all of the states and if each state board of health could start such a moving center of instruction, the problems of public education and popular support for sanitary measures would soon be solved.

LET THE ADVERTISEMENT TELL THE TRUTH

According to the press reports government officials recently discussed the plan of extending the power delegated through the Food and Drugs Act to the government to insist on truthfulness in drug advertising, to cover newspaper advertisements. That this position is the only logical one must be admitted. As at present administered, the Food and Drugs Act makes lying on the label illegal but takes no cognizance of the misstatements in advertisements. Under the present limitations of the act, therefore, the nostrum manufacturer who has to restrain his mendacity in writing the labels for his stuff is still able to falsify to the limit of his capacity in his newspaper advertisements. As the majority of nostrum users get most of their information—or misinformation—from the pages of the press it is easy to see that the Food and Drugs Act only indifferently protects the public against this evil. That a large proportion of the newspapers of the country would fight to the last ditch against any such extension of the law as that sug-

gested is doubtless true; yet the number of papers which are taking a high stand in the matter of nostrum advertising is increasing yearly. In Chicago, when the news report regarding the matter appeared, two of the most influential newspapers of the city commented favorably on the suggestion. If the same proportion of newspapers all over the country would take this attitude, one of the greatest movements in the interests of the public health would soon be inaugurated.

WATER-SUPPLY AND SEWAGE-DISPOSAL SYSTEMS AND HEALTH AUTHORITIES

The intelligent cooperation of municipal and health authorities in the provision for water-supply and sewage-disposal systems is the only correct principle to follow. Too often the subject is treated only as an engineering and business problem; and the most important feature—the sanitary—is not sufficiently regarded. Water-supply and sewage-disposal systems are constructed, and their effect on the health of the community is figured out by the health authorities after the systems are in operation and conditions arise which show that the public health is being jeopardized from some cause. An instance of law embodying the correct principle is the law of the province of Saskatchewan requiring the approval of the commissioner of public health before a water-works or sewage-disposal system can be constructed. Any debentures issued for the payment of the cost of such improvements, if not approved by the commissioner, would not be legal, and therefore could not be negotiated. This operates as an effective check on careless methods of providing water-supplies and prevents the adoption of defective sewage-disposal systems, both of which are of the most vital importance in connection with the health of any community.

INFLUENZAL MENINGITIS

There occurs, mostly in very young children, an acute and fatal form of meningitis, caused by the influenza bacillus, or by influenza-like bacilli, which might easily be confused with other forms of meningitis unless carefully studied by bacteriologic methods. Influenzal meningitis appears to be a rare disease, as only about forty cases are recorded, but the fact that Davis¹ ran across seven typical cases in Chicago in little over one year may be an indication that the disease is not so rare as it appears to be. It is a highly and, usually, rapidly fatal disease, the mortality rate being about 90 per cent., and it affects especially young children, the ages in Davis' cases running from five days to thirteen months. These cases occurred at a time when there was no epidemic of influenza. There does not seem to be anything unusual or peculiar about the symptoms in this form of meningeal infection. The cerebrospinal fluid is turbid and contains many polymorphonuclear leukocytes as well as the characteristic bacilli, which are easily overlooked in specimens stained in the ordinary ways, because of being so small. It is well to use dilutions of carbol-fuchsin for

1. Trans. Chicago Path. Soc., 1910, viii, 39.

staining; cultivation is successful only on media containing blood or hemoglobin. After death there is usually a rich, purulent exudate at the base of the brain. It is believed that the infection takes place by way of the nose.

—
KISSING THE BABY AS A CAUSE OF DIVORCE

One can readily conceive that the conveyance of certain germs might be as legitimate a cause for divorce as many that are now accepted. According to the newspaper reports, however, a California court has gone a little farther than a good many people can follow it, in granting a decree of divorce to a woman whose plea is alleged to have been that her husband insisted on entering her germ-proof nursery and administering kisses to their aseptic baby when "he was fairly reeking with germs collected on the streets" that he frequented in common with the unsterilized public. Kissing has been so long in fashion and its medically demonstrable effects have been so comparatively innocuous in most cases that the advanced ground taken by the California court seems rather extreme. It is true that too much kissing of babies has been medically condemned, but this is the first instance that we have seen of the legal dissolution of marriage for this reason. One would naturally think that milder antiseptic methods than divorce could have been employed.

Medical News

—
ALABAMA

Vital Statistics.—Dr. William H. Sanders, Montgomery, chief of the department of health, has commenced his second tour of the state in the propaganda to secure more complete vital statistics.

Personal.—Dr. Robert Nelson has been appointed health officer of Birmingham, vice Dr. Robert B. Harkness.—Dr. William H. Oates, Mobile, has been appointed inspector of jails, cotton mills, and almshouses.—Dr. William G. Somerville, Tuscaloosa, has recently returned from Europe and will practice in Memphis, Tenn.—Dr. William W. Dinsmore, Decatur, has been appointed local member of the hookworm commission.—Dr. Albert M. Reid has been elected health officer of Florence.—Dr. Oliver P. Board, Birmingham, has been elected assistant health officer of Jefferson county.—Dr. Abner Farned, Frankfort, is reported to be critically ill.

ARKANSAS

Sanatorium Opened.—The Arkansas Tuberculosis Sanatorium, three miles south of Boonesville, was opened September 1. The buildings are modern, and there is a good system of water supply and an excellent sewerage system.

Personal.—Dr. James W. John, Pine Bluff, has been elected state grand medical examiner of the A. O. U. W.—A health league was organized at Fayetteville recently. Dr. William B. Welch was appointed a member of the committee on program, and Drs. Thomas W. Blackburn, William N. Yates, and Charles F. Adams, were appointed a committee on organization.

CALIFORNIA

Personal.—Dr. Martin Regensburger, San Francisco, has been reelected president of the State Board of Health.—Dr. W. LeMoyne Wills, Los Angeles, has been elected vice-president, and Dr. William F. Snow, Stanford University, secretary of the State Board of Health.—Dr. Thomas B. Roche has resigned as a member of the San Francisco Board of Health.—Dr. Samuel N. Cross, Stockton, has withdrawn from active practice and retired to his ranch at Mantika.

Court Convictions.—Dr. Orra C. Hyde, Oakland, is said to have been fined \$100 recently for selling prescriptions containing opium to drug habitues. The fine imposed is the maximum allowed by the state law.—In the case of J. L. Bohannon, Oakland, an advertising cancer specialist, who was fined \$300 several months ago for practicing medicine without a license, and who appealed the case, Judge Brown, on October 4, is said to have denied the appeal and affirmed the judgment of the lower court.

Hospital Notes.—The new hospital opened recently in Visalia has been named the Visalia General Hospital.—St. Caroline's Hospital and Sanitarium, Redding, was formally opened September 26.—The Los Angeles Federation of Parent-Teachers' Associations, at its quarterly meeting, decided that the chief effort of the federation for the coming year should be the building of a charity hospital for children to be known as the Parent-Teachers Association Hospital.—The San Joaquin Hospital is practically completed and will, it is expected, be ready to receive patients this month.—The supervisors of Yuba county have made arrangements for building a ward for tuberculosis patients at the County Hospital.

ILLINOIS

Chicago

Tag Day for Children.—As a result of Tag Day, October 17, for the benefit of institutions caring for sick, crippled, and defective children, a sum of more than \$60,000 was realized.

Gynecologists Hold Annual Meeting.—At the annual meeting of the Chicago Gynecological Society, held October 21, the following officers were elected: president, Dr. Gustav Kolischer; vice-presidents, Drs. Charles E. Paddock and Rudolph W. Holmes; secretary, Dr. Robert T. Gillmore; treasurer, Dr. Charles B. Reed, and editor, Dr. H. Bond Stowe.

Historical Society Incorporated.—The Society of Medical History of Chicago was incorporated October 21 by Drs. George H. Weaver, Nathan S. Davis, and Henry T. Byford, with the object of preserving data, curios, writings, and specimens pertaining to medical progress in the middle west. Dr. Isaac N. Danforth is president.

Personal.—Dr. Jacob Frank has been appointed consulting surgeon to Michael Reese Hospital.—Dr. Thomas J. Sullivan is reported to be seriously ill in the Post-Graduate Hospital.—Dr. Carl H. Von Klein, who has been ill for some time as the result of a cerebral hemorrhage, has almost entirely recovered.—Dr. L. Blake Baldwin, city physician, has sailed for Europe. The work of his office will be undertaken by Dr. Frank J. Griffin during Dr. Baldwin's absence.

Bequests.—By the will of the late Hon. Lambert Tree, provision is made that, after the death of the son and grandson of the deceased, one-half of the residue of the estate shall go to St. Luke's Hospital for the building of an addition to be known as the "Lambert and Anna J. Tree Addition."—By the will of the late Mrs. Mary Hunt Loomis, \$25,000 is devised to St. Luke's Hospital, \$10,000 to the Children's Memorial Hospital, and \$10,000 to the Home for Destitute Crippled Children.—By the will of the late Ezra J. Warner, \$5,000 is bequeathed to the Presbyterian Hospital of Chicago.

INDIANA

Negro Professions Meet.—The third annual session of the Indiana Association of Negro Physicians, Dentists and Pharmacists met in Indianapolis, September 27. A clinic was held at the City Hospital by Dr. Daniel H. Williams of Chicago, and addresses were delivered by Drs. Samuel E. Earp, Clarence Lucas and Calvin R. Atkins, Indianapolis; Dr. William J. Woodlin, Columbus, Ohio, and Miss Josephine Holmes, head of the Normal Department of Wylie University, Marshall, Texas. The following officers were elected: president, Dr. Henry L. Hummons, Indianapolis; vice-president, D. A. Berthea, Terra Haute; secretary-treasurer, Dr. Calvin R. Atkins, Indianapolis, and executive committee, Dr. William E. Brown, and William W. Stuart, and Ward Wilson, all of Indianapolis. Indianapolis was selected as the next meeting place.

Report of Tuberculosis Clinic.—The report of the tuberculosis clinic of the City Hospital, Indianapolis, from Jan. 1 to Sept. 1, 1910, shows the following results: Patients treated, 331; apparently cured, 4 per cent.; arrested, 5 per cent.; improved, 18 per cent.; unimproved, 16 per cent.; died, 11 per cent.; whereabouts unknown, 18 per cent.; non-tuberculous, 28 per cent. The "apparently cured" patients were those who had tuberculosis in its earliest stages, with few exceptions, and who adhered strictly to the advice and treat-

ment. Not a single patient of this kind grew worse. Of the patients, 14 per cent. were colored; 61 per cent. were married, and 13 per cent. were under 15 years old. Attention was called to the fact that 12 per cent. of all deaths in Indianapolis for the same period were from tuberculosis. Of the patients living in the Tuberculosis Colony on the City Hospital Grounds, 1 patient recovered, 33 improved, 9 did not improve, 1 died and 5 remained.

IOWA

District Medical Society Meeting.—The Second District Medical Society of Iowa held its sixth annual meeting in Davenport, October 11, and elected the following officers: president, Dr. David N. Loose, Maquoketa; vice-presidents, Drs. George E. Decker, Davenport, and George Hofstetter, Lyons, and secretary-treasurer, Dr. John V. Littig, Davenport.

MARYLAND

Personal.—Dr. Timothy Griffith has been appointed first vice-president, and Dr. Abbott R. Walker a member of the executive committee of the Board of Trade of Frostburg.—Dr. John M. B. Rogers, Ellicott City, is reported to be ill with typhoid fever at Govanstown.

Hospital Report.—The annual report of the Springfield Hospital for the Insane, Sykesville, shows a net increase of 30 males and 45 females during the year; that 43 males and 23 females died; that 37 males and 20 females were discharged recovered; 24 males and 15 females were discharged improved, and 14 males and 7 females were discharged unimproved. The total expense was \$274,093. During the year 60 per cent. of the males and 40 per cent. of the females had employment. The superintendent asks for an appropriation to build an amusement hall.

Baltimore

Personal.—Dr. Robert T. Wilson has been reelected president of the Hospital Relief Association of Maryland.—Dr. Charles W. Mitchell has returned after a summer abroad.—Dr. Adolph Meyer, who is superintending the erection of the Phipps Psychiatric Clinic connected with Johns Hopkins Hospital, has settled in Baltimore.

NEW JERSEY

Isolation Hospital Offered.—Dr. John W. Wade, president of the Millville Board of Health, has offered property in West Millville to be used by the town as an isolation hospital.

Tuberculosis Items.—An open-air school has been opened in Montclair with an initial attendance of 21.—The day camp conducted by the Antituberculosis Association at Newark is to be closed November 1 on account of lack of funds.

Personal.—Dr. Ralph R. Charlesworth, Millville, was taken to the Jefferson Hospital in Philadelphia, October 2, with appendicitis.—Dr. Alice H. Ward, Newark, has been appointed a factory inspector.—Dr. Edward S. Sharpe has been appointed a member of the staff of attending physicians of the Atlantic City Hospital, vice Dr. William F. Ridgway, deceased.—Drs. Harvey Lloyd and Edward T. Craney have resigned from the staff of Mercer Hospital, Trenton.

NEW YORK

Chiari Addresses Society.—At the semi-annual meeting of the Medical Society of the County of Albany, held in October, Prof. Hans Chiari, professor of pathologic anatomy in the University of Strassburg, delivered an address on "The Portals of Entry of the Infection of Tuberculosis in Human Beings from an Anatomic Standpoint." At the close of the lecture a reception was given Prof. Chiari at the University Club.

Sanatorium Notes.—The Medical Society of Dutchess county, at its annual session in Poughkeepsie, October 12, urged the immediate building of a tuberculosis hospital on the Pendall farm.—The Welch farm, adjoining the county farm, near Syracuse, will not be approved as a site for a tuberculosis sanatorium in Onondaga county, as the State Health Commissioner is opposed to locating a tuberculosis sanatorium near the county farm.

Personal.—Dr. Montgomery E. Leary, Rochester, has been elected superintendent of the Iola Sanatorium for the Treatment of Tuberculosis, the Monroe county institution, and Dr. John E. W. Whitbeck, president of the board.—Dr. William Kemble, Kingston, broke two ribs in an automobile accident at Dashville Falls, October 7.—Drs. Thomas Curran, Edward S. Yess, John J. Butler, and Roy C. Kestler

Schenectady, have been appointed district city physicians.—Dr. Emmott Howd has been appointed a member of the obstetric staff; Dr. Frank J. Noonan, a member of the medical staff, and Dr. Ovila Mallet, a member of the surgical staff of St. Joseph's Maternity Hospital, Troy.—Dr. George W. Mills has been promoted to second assistant physician at the Central Islip Hospital.

Changes in Faculty.—The following changes in the faculty of the College of Medicine of Syracuse University are announced: Prof. W. H. Stiles, Tulane University, New Orleans, professor of anatomy; Dr. E. H. Haskell, University of Michigan, assistant professor of anatomy; Dr. William A. Curtin, department of internal medicine, and St. Joseph's Hospital; Dr. Henry B. Doust, department of materia medica; Dr. Albert S. Hotaling, obstetrics for juniors; Dr. Eugene W. Belknap, obstetrics for seniors; Dr. Joseph R. Wiseman, department of medicine; Dr. Joseph C. Palmer, department of operative surgery; Dr. William A. Groat, laboratory work at St. Joseph's Hospital; Dean John L. Heffron, superintendent of clinical clerks and laboratory examinations, Hospital of the Good Shepherd; Dr. I. Harris Levy, assistant superintendent of clinical clerks and laboratory examinations; Dr. Frank L. Harter, sectional work for juniors; Dr. Herman G. Weiskotten, department of pathology and bacteriology, and postmortem examinations; Dr. Charles D. Post, department of medicine, and Dr. Harold G. Kline, department of laryngology to assist Dr. Thomas H. Halsted.

New York City

Infirmery Opened.—The Bayside Infirmery, Bayside, Long Island, was recently opened to receive patients, and within a week after the opening, half of the available beds were reported occupied.

Sajous in New York.—At the meeting of the Manhattan Medical Society, held October 28, Dr. C. E. de M. Sajous, Philadelphia, was the guest of the society at a reception, and later Dr. Sajous read a paper entitled "The Adrenals in General Pathogenesis."

Election.—The New York Medico-Surgical Society, at its annual meeting October 16, elected Dr. John A. Irwin, president; Dr. Daniel S. Dougherty, vice-president; Dr. Samuel McCullagh, secretary; Dr. J. Arthur Booth, treasurer, and Dr. John A. Bodine, member of the executive committee.

Dean Recommends Large Hospital.—Dr. Samuel W. Lambert, dean of the College of Physicians and Surgeons, in his annual report, suggests that a hospital building, to be used as the College of Medicine Hospital, be erected on the Morningside Heights Campus at a total cost of from six to eight million dollars.

City to Pasteurize Milk.—At a recent hearing of the budget committee on the estimate on the Department of Health it was explained that this department contemplates establishing pasteurization stations. Borough President McAneny states that the plan is approved, and that, if Mr. Straus should decide to discontinue his work, the city will take it up. They ask \$50,000 additional for this purpose.

College Opens.—The Cornell University Medical College opened September 28 with a total enrollment of 127, distributed as follows: first year, 28; second year, 20; third year, 11, and fourth year, 56, and special students, 12. The decline in numbers from the fourth to the third year, marks the falling off since the A.B. degree with the full year's work in physics, chemistry, and biology is required for admission.

Would Increase Research Laboratories.—Dr. Hermann M. Biggs, general medical officer in the Department of Health, is making a vigorous fight for money for the extension of the work of the city's research laboratories. He asks for \$60,000, but says that the benefit to be derived from this investment will be incalculable to the poor of the city. He wishes to establish a division of specific therapy and preventive medicine.

The Straus Milk Stations.—A mass meeting was held at Cooper Union, October 8, when resolutions commending the work done by Mr. Straus were passed and a continuation of the work was urged. Among the speakers were Dr. Abraham Jacobi and Dr. William A. Evans of Chicago. The aldermen have passed a resolution urging Nathan Straus "to continue his splendid efforts in behalf of the poor and needy in the supply of pure milk."

Anniversary Meeting at the Academy of Medicine.—At this meeting to be held on Nov. 17, the topic for consideration will be "Animal Experimentation in Medicine." Dr. William H. Welch, president of the American Medical Association will

read a paper on "Objections to Proposals of Further Legislation to Regulate Animal Experimentation," and Dr. Walter B. Cannon, Harvard Medical School, one on "The Character of Antivivisection Literature."

Personal.—Dr. Belle J. Macdonald has returned from abroad.—Dr. Isaac S. Hirsch has been appointed roentgenologist to Bellevue Hospital.—Dr. Raymond Kelly, ambulance surgeon of Kings County Hospital, was injured by being caught between the ambulance and a trolley car, October 9.—Dr. Herbert E. Baright has been made associate physician at the Saratoga Springs Sanatorium.—Major Frederick F. Russell, Medical Corps, U. S. Army, delivered the Carpenter lecture on "The Control of Typhoid Fever in the Army by Means of Vaccination," October 20.

Tuberculosis Wards Overcrowded.—At the recent meeting of the State Board of Charities, the overcrowded condition of the tuberculosis wards at the Metropolitan Hospital on Blackwell's Island was under discussion. The charities commissioners have decided that it is necessary for the city to take immediate steps to add to the accommodations on Blackwell's Island and to complete the Sea View Hospital on Staten Island. The report presented states that of 148 rooms examined two-thirds had less than 800 cubic feet of air space per patient and only one had an air space of 1,200 feet. At night the alcoves and hallways are filled with cots and conditions are positively inhuman. The two new infirmary buildings which are soon to be opened on Blackwell's Island for tuberculosis patients can at best but temporarily relieve the congestion. It was also stated that there were hundreds of new cases awaiting attention.

The Question of Venereal Disease.—At a meeting of between forty and fifty women representing as many different organizations, held October 14, at 110 Second Avenue under the auspices of the Women's Prison Association, the following resolutions were passed, after a discussion of the cause of the Page Commission Bill dealing with the medical examination of prostitutes:

WHEREAS, The germs causing the venereal diseases are no longer matters of uncertainty, but have been perfectly and conclusively demonstrated by medical science, and

WHEREAS, The favorable breeding conditions and modes of transmission of these germs are also thoroughly understood by the medical profession, and

WHEREAS, The method of attempting to check the spread of venereal diseases by systematically hunting down certain classes of women only has survived from a period when the germs of these diseases were yet undiscovered and their modes of transmission therefore not certainly demonstrable, and

WHEREAS, A legislative mandate to continue so crude and barbarous a method of attacking any infectious or contagious disease is an offence against scientific truth and an indignity to the medical profession, an insult on women and a slur on the intelligence of the public, therefore be it

Resolved, That health boards should place the venereal diseases on the same status as all other contagious, infectious or communicable diseases; should take the same measures against them, irrespective of class or sex, as are applied in the prevention of all other contagious, infectious or communicable diseases, and should conduct in respect to them the same policy of instruction of the public as to the preventability of these diseases as is now conducted in respect to others; and be it further

Resolved, That public authorities should make ample provision for the full and sufficient free, voluntary treatment of patients suffering from venereal disease.

OHIO

Medical Women Elect. Dr. Olive Johnston was elected president; Dr. Mary D. Crane, vice-president, and Dr. Olive Littlejohn, secretary-treasurer of the Columbus Women's Medical Club, at the annual business meeting, October 11.

Licenses Revoked.—On a rehearing ordered by the governor and attorney general, October 5, the state medical board is said to have sustained the revocation of the licenses of Drs. James M. Luburg, Dayton; Paul DeWitt Hlale, Dayton, and Joseph H. Leatherman, Columbus.

Assistant Physicians' Association.—The sixteenth annual meeting of the Association of Assistant Physicians of the Ohio State Hospitals was held in Cleveland, October 5 and 6. Dr. John C. George, Dayton, was elected president; Dr. Arthur G. Hyde, Cleveland, vice-president; Dr. Dorr, Athens, secretary, and Dr. Mary K. Isham, Columbus, treasurer.

Gift to Western Reserve.—It is announced that Mr. John D. Rockefeller has recently offered to give to Western Reserve University for further endowment of its Medical Department the sum of \$250,000 provided \$750,000 additional is raised. Toward this \$1,000,000 fund, as was announced in May last, Mr. H. M. Hanna of Cleveland has given \$250,000. The trustees are planning to secure the \$500,000 needed to complete the fund.

Personal.—Dr. R. Harvey Cook has succeeded his father, the late Dr. George F. Cook, as medical superintendent of Oxford Retreat, Oxford.—Dr. George W. O'Grady, Lancaster, has been appointed associate physician at the Jackson Health Resort, Danville, N. Y.—Dr. Arthur W. Bartel, Dayton, has been appointed first assistant surgeon in the Home Hospital, Hampton Roads, Va.—Dr. Edward E. Campbell, health officer of Logan, who has been seriously ill with diphtheria, is reported to be convalescent.—Dr. Frederick S. Baron, Zanesville, has returned from Europe.—Dr. James G. Shier has succeeded Dr. William H. Knuss as health officer of Newark.—Dr. August Schumacher, Hamilton, is recovering from a serious illness.—Dr. James B. Ray has been elected city physician of Portsmouth, and Dr. Samuel P. Fetter, president of the board of health.—Dr. Clarence E. Exline, Canton, was seriously injured, October 6, in an automobile accident near his home.—Dr. Clarke D. Sackett, Ashland, sustained a fracture of the right clavicle from the recoil of a gun while hunting, October 1.—Dr. Albert J. Moorman has succeeded Dr. Pearl L. Gunkel as physician of the Dayton Workhouse.—Dr. George S. Weger, Delphos, announces his retirement from the practice of medicine.

Cincinnati

Personal.—Dr. Charles A. L. Reed has returned after a visit to the clinics of Europe.—Dr. Paul G. Wooley, professor of pathology in the Ohio-Miami Medical College, has been appointed dean of the department.—Dr. Leon G. Tedesche, bacteriologist of the Cincinnati water-works has resigned to accept a similar position with the Milk Commission of the Cincinnati Academy of Medicine.

PENNSYLVANIA

Bequest.—The will of the late Mary S. Bean, contains a bequest of \$10,000, to build in or near Norristown a hospital for children suffering from contagious diseases, to be a memorial to her daughter, Emily S. Bean.

Nuns' Sanatorium Opened.—The sanatorium founded at Hyde Park, near Reading, by Rev. George Bornemann, rector of St. Paul's Catholic church was opened October 21. The sanatorium is for nuns of various orders of the church, who are afflicted with tuberculosis.

Physician Convicted.—Dr. Henry C. Lawton, Camp Hill, who has been tried on several counts, charged with a criminal operation on Mrs. Mattie Hamilton, which resulted in her death, is said to have been convicted October 6. The defendant was indicted on eight specific charges, on the seventh of which he was found guilty, namely that of performing a criminal operation by means unknown.

State Secretaries' Conference.—The fifth annual meeting of the Conference of Secretaries of Component County Societies of the Medical Society of the State of Pennsylvania was held in Pittsburg, October 4. The president, Dr. William Rowland Davies, Scranton, delivered an address on "The Year's Work," and each member was called on to give briefly a feature of the work in his particular society. Dr. John J. Coffman, Scotland, was elected chairman, and Dr. Charles E. Shaw, Williamsport, secretary-treasurer. The next meeting will be held at Harrisburg at the time of the meeting of the state society.

To Study Milk Problem. Mayor Reyburn, at the suggestion of Dr. Joseph S. Neff, has decided to appoint a commission of five medical and technical experts to study the milk problem of the city—that is, to examine: 1. Sources of the city's milk supply, within and outside the state. 2. Condition of cattle, dairies, methods of handling milk at dairy farms and creameries, and in transit to the city. 3. Conditions prevailing in the wholesale and retail distribution within the city. 4. Scope and methods of milk inspection as now carried on by the Bureau of Health. 5. The problem of tuberculosis among cattle in the districts from which the city's milk is drawn. 6. Methods of tracing to their sources typhoid fever and other infectious diseases commonly carried by milk. Dr. Joseph S. Neff and Dr. Alexander C. Abbott spoke on this problem at a special meeting of the City Club, October 15. The subject was freely discussed and the motto established was "Cleanliness, Proper Temperature and Expeditious Transportation."

Philadelphia

Pathologic Society to Visit New York.—The members of the Pathologic Society of Philadelphia will be the guests of the New York Pathological Society at the latter's regular meeting, November 9, at the Academy of Medicine, 17 West Forty-Third Street.

New Hospital Building for University's Foreign School.—Authorization of a new hospital building to cost \$16,000 was cabled by the Christian Association of the University of Pennsylvania on October 13, to Dr. J. C. McCracken, of the University Medical School in Canton, China.

New Site for Children's Hospital.—Deeds have been recorded conveying to the Children's Hospital of Philadelphia, the lot at the northeast corner of Eighteenth and Fitzwater Streets, purchased about two years ago by Eckley B. Cox and presented to the hospital as a site for new buildings. Plans have already been prepared but there is no intention to begin immediately the erection of the building contemplated, as the funds necessary to carry out the project have not as yet been subscribed.

Children's Country Week Report.—At the semi-annual meeting of the directors of the Children's Country Week Association, held October 10, a report of the summer's work showed that 5,589 babies and their mothers have been given trips to the mountains and seashore. The total amount of money expended by the association was \$16,727.21. In addition to giving outings and excursions under their direct supervision, the association distributed 18,500 tickets for the Bristol boat excursions to mothers and children who were unable to go to the country.

Changes in University Faculty.—The following changes in the University of Pennsylvania Medical Department are announced: Dr. David L. Edsall has succeeded Dr. James Tyson as professor of medicine; Dr. Edsall has been succeeded, as professor of pharmacology, by Dr. A. N. Richards; Dr. Alonzo E. Taylor of the University of California has been assigned to the new chair of physiologic chemistry; Dr. Richard M. Pearce, New York City, to the new chair of medical research; Dr. Milton B. Hartzell, to the chair of dermatology, vice Dr. Louis A. Duhring, resigned; Dr. Allen J. Smith, dean of the Medical department, has been assigned to the section on tropical medicine.

Councils Approve Health Budget.—Councils' committee has reviewed the budget of the department of health and charities for 1911. Dr. Neff outlined the improvements for which he asked \$6,000,000. The improvements include \$5,000,000 for the erection of hospital buildings for the insane; \$500,000 for the hospital for contagious diseases; \$100,000 for the alteration of the building and maintenance of a home for the indigent; \$45,000 for a cold storage and ice plant; \$15,000 for a tuberculosis sanatorium at Byberry and numerous smaller items. The committee gave its approval, leaving the question of financing the department to the financing committee.

Personal.—Dr. Ivan Clark of the receiving ward of the University Hospital, was removed to the Municipal Hospital October 15, suffering from diphtheria.—Dr. Thomas Stotesbury Githens has been given a fellowship in the pharmacologic department of the Rockefeller Institute for Medical Research.—Dr. Benjamin A. Thomas has been elected professor of genito-urinary surgery in the Philadelphia Polyclinic and College for Graduates in Medicine.—Dr. Allen J. Smith, dean of the medical department of the University of Pennsylvania, was given the degree of doctor of science by Pennsylvania College, Gettysburg, October 20.—Dr. Paul J. Pontius and Dr. John Jones have been appointed to the ophthalmologic department of St. Joseph's Hospital.

Veteran Physicians Honored.—Twenty-nine physicians from various parts of the state, who have been practicing for half a century or more were the guests at a reception given by the Medical Club of Philadelphia in the ball room of the Bellevue-Stratford Hotel on October 21. The following were the guests:

Stephen D. C. Brodhn, '55, U. of P., East Orange, N. J.
John B. Chapin, '59, Jefferson Medical College, Philadelphia.
James E. Clawson, '55, University of Maryland, Philadelphia.
Jacob Solls-Cohen, '60, U. of P., Philadelphia.
Robert S. Dana, '57, Jefferson Medical College, Morrisville, Pa.
James Darrach, '51, U. of P., Germantown.
Emanuel K. Deemy, '60, New York University, Mechanicsburg, Pa.
Robert N. Downs, '56, U. of P., Germantown.
Edward L. Duer, '60, U. of P., Philadelphia.
William B. Erdmann, '50, U. of P., Macungie, Pa.
Jonathan L. Forwood, '57, U. of P., Chester, Pa.
William M. Gullford, '52, U. of P., Lebanon, Pa.
Charles W. Houghton, '60, Pennsylvania Med. Coll., Philadelphia.
Theodore Jacobs, '60, U. of P., Norristown.
William S. Janney, '54, Pennsylvania Med. Coll., Philadelphia.
William F. Knox, '54, U. of P., McKeesport, Pa.
Benjamin Lee, '56, College of P. and S., of Cincinnati, Harrisburg.
John B. Laddy, '56, Western Reserve University, CLEVELAND, Pa.
S. Weir Mitchell, '50, Jefferson Medical College, Philadelphia.
Matthew J. McKinnon, '53, University of Maryland, York, Pa.

Henry C. Paist, '54, Pennsylvania Medical College, Philadelphia.
Jonathan B. Pottinger, '54, Jefferson Medical College, Hamburg.
Peter J. Roebuck, '60, U. of P., Lititz, Pa.
Abraham Stout, '55, U. of P., Bethlehem, Pa.
Samuel R. Shillern, '54, U. of P., Philadelphia.
H. Genet Taylor, '60, U. of P., Camden, N. J.
Benjamin W. Wilson, '57, U. of P., Philadelphia.
Daniel Yoder, '58, Pennsylvania Medical College, Catasauqua, Pa.
William R. Longshore, '60, Pennsylvania Med. Coll., Hazleton, Pa.

TENNESSEE

Medical School Opens.—Vanderbilt University Medical Department opened September 22, with an address by Chancellor Kirkland.

Guilty of Mislabeled.—Dr. Samuel H. Harris, Nashville, charged with selling misbranded drugs, is said to have been found guilty as charged in the indictment. Sentence was postponed pending a motion for a new trial.

Personal.—Dr. Margaret Gilleland, Knoxville, has returned after two years abroad.—Dr. Alfred B. DeLoach, Memphis, has been elected a member of the State Board of Medical Examiners, vice Dr. Frank S. Raymond, deceased.—Dr. William G. Somerville, Memphis, has returned after fifteen months abroad.—Dr. José M. Selden, Sewanee, has located in Chattanooga.—Dr. Cary A. Snoddy has been elected superintendent of the Knoxville General Hospital.

Eastern Tennessee Physicians Meet.—The eighteenth annual meeting of the East Tennessee Medical Society was held in Bristol, September 29 and 30. The following officers were elected: president, Dr. Leon L. Shedd, Knoxville; vice-presidents, Drs. Nathaniel F. Dulaney, Bristol, John W. Cox, Johnson City, and Henry M. Cass, Morristown; and secretary-treasurer, Dr. William M. Copenhaven, Bristol. Morristown was selected as the next place of meeting.

GENERAL NEWS

Military Surgeons to Meet in Richmond.—The Association of Military Surgeons of the United States, whose membership is made up of medical officers of the Army, Navy, Public Health and Marine-Hospital Service, and organized militia, will hold its annual meeting in Richmond, Va., November 1-4, under the presidency of Col. Joseph K. Weaver, N. G., Pa.

Death of Professor Bombarda of Lisbon.—Professor Miguel A. Bombarda, the leading psychiatrist of Portugal and the president of the International Medical Congress at Lisbon in 1906, was shot in his office by Lieut. Grinée, who had entered apparently to consult him, as at one time Grinée had been a patient in his charge. The horror at the murder is said to have been the spark that lighted the flame of the revolution which has resulted in the proclamation of the republic in Portugal.

Southern Association to Meet.—The annual meeting of the Southern Medical Association will be held in Nashville, November 8-10. Headquarters will be at the Hermitage Hotel. General sessions will be held in the auditorium of the Y. W. C. A., the section on medicine will meet in this auditorium, the section of surgery will hold its sessions in the assembly hall of the Hermitage Hotel, and the section of ophthalmology will have its meeting place on the same floor. On November 9, there will be an excursion to the Hermitage, where Dr. John A. Witherspoon will deliver an address on "The Life and Character of Andrew Jackson." In the evening a general reception will be given at the hotel.

Health of the Army.—According to the annual report of the surgeon-general of the army, the general health has shown steady improvement for several years. The constant non-effective rate of 41.48 per 1,000 during the last fiscal year, which compares favorably with the rates for the previous years, were 42.66 in 1908, 46.17 in 1907, and 49.79 in 1906. The total number of deaths from all causes was 370, of which 228 were due to disease. The admission rate for disease was 865.92 per 1,000 of mean strength; a steady improvement since 1899 when the rate was 2,125.74 per 1,000. More tuberculosis was noted than in previous years, but there was a marked decrease in the prevalence of malarial infection. The health of the troops in the Philippines is reported to improve year by year, and the records now show that insanity is no more prevalent in troops in the Islands than in troops in the United States. During the fiscal year 11,338 persons in the army were vaccinated against typhoid, and among these only three cases have occurred, with no deaths. The surgeon-general therefore advocates typhoid fever vaccination as a routine procedure throughout the army.

The Alvarenga Prize.—The College of Physicians and Surgeons of Philadelphia, announces that the Alvarenga Prize for 1910 has been awarded to Dr. M. Katzenstein of Berlin, Germany, for his essay entitled "The Formation of an Arterial Collateral Circulation in the Kidney." The next award of the prize, being the income for one year of the bequest of the late Señor Alvarenga, amounting to about \$180, will be made on July 14, 1911, provided that an essay deemed by the committee of award to be worthy of the prize shall have been presented. Competitive essays may be on any subject in medicine, must not have been published, must be typewritten, must be received by the secretary of the college on or before May 11, 1911; must be sent without signature but must be plainly marked with a motto and be accompanied by a sealed envelope having on the outside the motto of the paper and within the name and address of the author.

Health of the Philippine Islands.—The report of Dr. Victor G. Heiser, director of health of the Philippine Islands, calls attention to the inadequacy of the filter capacity of the water supply of Manila; announces the demonstration of the presence of hydrophobia for the first time in the history of the Islands; notes the confirmation of the theory that beriberi is caused by the continued consumption of polished rice as a staple article of diet; and reports that during early April cholera made its appearance in Pangasinan with a considerable spread in this and adjoining provinces, and the infection of Manila. An effort has been made recently by the medical officers of the Philippine Medical School and Bureau of Health to furnish better obstetric service to the indigent poor. An out-patient obstetric department has been established, to which are attached a sufficient number of physicians and two nurses. During May the average daily number of cases was 37, and the total numbered 1,147 for the month. Many rats were sent to the laboratory and bacteriologically examined, but no plague rats were found. After many delays one sanitary barrio is nearly completed on the San Lazaro estate and another is under construction, so that shortly there will be facilities for transferring from two to three thousand persons living in insanitary surroundings to properly drained land, where every house will face on a street or alley, so that sanitary carts may enter and keep the premises clean.

Meetings of Railway Surgeons.—The American Association of Railway Surgeons, at its seventh annual meeting, held in Chicago, October 19-21, elected the following officers: president, Dr. Albert R. Mitchell, Lincoln, Neb.; vice-presidents, Drs. George W. Cole, Jr., St. Louis, Oliver B. Quinn, McComb, Miss., and Ira K. Gardner, Newhampton, Iowa; secretary, Dr. Louis J. Mitchell, Chicago (reelected); and treasurer, Dr. Henry B. Jennings, Council Bluffs, Iowa.—At the meeting of the Railway Surgeons Association of the Pennsylvania Lines east of Pittsburg with that of the Pennsylvania Lines west of Pittsburg, held in Pittsburg, October 3 and 4, the following officers were elected: president, Dr. Spencer M. Free, Dubois, Pa.; vice-presidents, Drs. Hanson T. A. Lemon, Washington, D. C., and Ellwood Patrick, Westchester, Pa.; secretary, Dr. Amos W. Colcord, Clairton, Pa.; treasurer, Dr. Eugene H. James, Harrisburg, Pa.; and member of the executive committee, Dr. Joseph M. Wells, Trenton, N. J.—The ninth annual meeting of the Association of Seaboard Air-Line Railway Surgeons was held in Birmingham, Ala., October 11 and 12. The following officers were elected: president, Dr. Jarvis G. Dean, Dawson, Ga.; vice-presidents, Drs. Hampden A. Burke, Petersburg, Va., Milton L. Wood, Montgomery, Ala., and Bartlett J. Witherspoon, Charlotte, N. C.; secretary-treasurer, Dr. Jarrett W. Palmer, Ailey, Ga.; and member of the executive committee, Dr. Robert L. Harris, Jacksonville, Fla. Washington, D. C. was selected as the place of meeting for 1911.

Cholera.—The health officer of New York, on October 22, decided that beyond a doubt the case of illness and death on the steamer *Tuormina*, which arrived October 21 from Genoa and Naples, was due to cholera, and the steamer has been held at quarantine for inspection.—The International Bureau of Public Hygiene, on October 21, recommended the calling of an international sanitary conference to combat the cholera epidemic.—On October 19, 37 new cases of cholera were reported in Italy, 13 of which were in Naples and 19 in Caserta. On October 21, 21 cases were reported with 11 deaths.—The surgeon-general of the Public Health and Marine-Hospital Service considers that cholera is not so threatening as in 1893. Between June 25 and October 7, there were 332,881 cases and 153,581 deaths in Russia, and the disease is believed to be increasing. Careful investigation is made at the German frontier by the government and in addition all emigrants are being held five days at the point of embarkation, and the same course

is being pursued in cases of emigrants passing through England. As an additional precautionary measure, every emigrant from Russia and Italy will be followed to his destination by a report from the health officer of the port of entry to the board of health of the community to which he goes.—The North German Lloyd steamship *Breslau* was detained at Quarantine until October 15, in order to permit of the thorough examination of the steerage passengers and their baggage. Three suspects are under observation at present.—Cholera, which had almost ceased in St. Petersburg, is said to have broken out afresh in the Municipal Psychopathic Hospital, from which 33 employees have been sent to the pesthouse, and there are still suspected cases.

CANADA

New Building for Foundling Hospital.—The Montreal Foundling and Baby Hospital will erect a new building to cost \$100,000. The capacity of the present building is inadequate, as 350 babies were refused admission during the last year.

Changes in Insane Hospital Staff.—Dr. William C. Herri-man, assistant superintendent at the Toronto Hospital for the Insane, is to be chief medical superintendent of the hospital at Orillia, vice Dr. Alexander H. Beaton, resigned; Dr. George A. MacCallum of the Penetang Institution, has retired from the service and is succeeded by Dr. William T. Wilson of the Coburg Hospital for the Insane. Dr. Thomas J. Moher, superintendent of the Brockville Institution, replaces Dr. Wilson at Coburg. Dr. James M. Forster, assistant at London, becomes superintendent at Brockville, Dr. Harvey Clare, Mimico, becomes assistant superintendent at Toronto, and Dr. James Rollins, Orillia, is transferred to Mimico.

Personal.—Dr. Murray Maclaren, St. John, N. B., has gone to Germany.—Dr. Bert Wiley, Fredericton, N. B., has returned from Europe.—Dr. Charles Sheard, retiring medical health officer of Toronto, was presented with a gold watch by the staff of the City Health Department, October 4.—Dr. John O. Todd, retiring president of the Winnipeg Medical Association, gave a reception at his home in honor of Dr. Samuel W. Prowse, the new president of the association, October 11.—Dr. Helen MacAlmurchy, one of the newly-appointed medical inspectors of the schools of Toronto, is said to have been asked to resign on account of differences with the chief inspector of schools.—Mr. George G. Nasmith, assistant in the laboratory of the Ontario Board of Health, has been appointed chief of the bacteriologic laboratory of Toronto.

Public Health Campaign.—The formation of the Canadian Public Health Association was completed at a meeting held in Ottawa, October 13. Dr. Peter H. Bryce presided, and the following officers were elected: honorary president, Sir James Grant, Ottawa; president, Dr. T. A. Starkey, Montreal; secretary, Major Lorne Drum, Ottawa, and treasurer, Dr. George D. Porter, Toronto. The Dominion government will be asked to grant increased aid to the work of the prevention of tuberculosis, and steps will be taken to secure crown lands in favorable localities for colonies for persons suffering from tuberculosis, and for their families. Efforts will also be made to establish a permanent national council of health and public health laboratories to manufacture vaccines and antitoxins and to supervise the manufacture, and sale in, and importation of these products into Canada. The proposed central council is to be composed of Dominion health officers attached to the several departments of government at Ottawa and the chief officers of the provincial departments and is to be under the supervision of the Conservation Commission.

MANILA LETTER

(From Our Regular Correspondent)

MANILA, SEPT. 9, 1910.

The Chinese Red Cross Society

The Chinese Red Cross Society, which was organized during the late war in Manchuria, has at last received the official recognition of the Chinese government. The Board of Rites in Peking has prepared an official seal of the society which has been transmitted to Shanghai and formally "opened." The Chinese Red Cross Society was organized by their excellencies Sheng Hsuan-huai (Sheng Kung-poi) and Lu Hsi-huan and other Chinese officials and merchants in accordance with the rules of the Red Cross Society adopted by the Geneva Convention and the Hague Peace Conference, but for some reason it seems that the society did not receive imperial

recognition until last February, when an imperial rescript was issued through the grand council appointing H. E. Sheng president of the society and ordering the Board of Rites to prepare an official seal. The seal, which is cast in Chinese characters throughout, signifies in English: "Official Seal of the Red Cross Society of the Ta-ching Empire." A complete change in the rules has been made since the organization of the society and the institution is now put on a permanent basis. It is reported that the governments of the various powers have been informed of the formal "opening" of the official seal of the society.

Health Standards of the Philippines

An important step in maintaining the present health standard in the Philippines, and particularly in raising the standard as the Americans are striving to do, was the adoption by the Far Eastern Association of Tropical Medicine of resolutions concerning epidemic diseases, particularly those sections relating to publicity and quarantine. The islands now seem to be entirely free from plague, cholera is on the decline in Manila and in the provinces, and the lepers are being collected into a leper colony and segregated on Culion island. Added to these also is the relative scarcity of typhoid and, for a tropical country, the occurrence of very little malaria of any type. Now if the delegates present at the first annual meeting held in Manila in March and the Association as a whole can procure the support of the governments represented the outlook for excellent health conditions in the Philippine Islands will be particularly good. While greatly interested in the unity and advancement of medicine in the Orient promised by these measures, the Philippines are particularly interested in the notification (of epidemic diseases) aspects of the resolutions; for there is not a tropical country in the Orient in which at least one of these serious epidemic diseases is not more prevalent than in the Philippine Islands. Among the resolutions of the greatest local interest are the following:

Resolved, That the Far Eastern Association of Tropical Medicine, appreciating the benefit which would accrue from concerted sanitary action on the part of the eastern governments, be empowered to approach the following governments, namely: Philippine Islands, Japan, Hongkong, French Indo-China, Siam, Netherlands-India, Straits Settlements, and Ceylon, with the view, if possible, of obtaining their official support on the following lines:

To have a common standard for the term "epidemic," when making reports to or imposing quarantine against each other. The following definition is suggested for consideration: Plague, cholera, small-pox or yellow fever shall be considered to be epidemic, when, after the first telegraphic report of its occurrence, any weekly report thereafter shall show the occurrence of an average daily number of three cases.

To agree to notify each other's territories as infected only when the infectious diseases shall have assumed epidemic proportions as defined above, and automatically to withdraw such notification when the average number of cases for three successive weeks has fallen below the status epidemicus as defined above.

To circulate weekly returns of plague, cholera, smallpox and yellow fever among each other, and also a telegraphic report on the first occurrence of any of these diseases, in a clean port or territory.

To insist on a bill of health being carried by all ships leaving a country declared to be infected, which intend to proceed to the port of another signatory; such bills of health to include a return of infectious diseases for the previous 48 hours.

To report by telegram to the country concerned the departure of an infected or suspected ship (as defined by the Paris convention) which may intend to proceed to any port in the territories of another signatory; and to endorse the bill of health of the said infected or suspected ship with a full account of the measures taken to disinfect or otherwise deal with the said vessel.

With regard to plague and leprosy the following is urged:

In our opinion the only practical measure concerning plague that we can recommend is the advisability of each country represented agreeing to notify other countries of the occurrence of cases of plague within its borders, the first case by telegram and afterward by weekly returns. Leprosy is to be regarded as a dangerous communicable disease. Compulsory notification of all cases of leprosy to the authorities is essential. Compulsory segregation of all cases of leprosy is necessary, and preferably in special colonies constructed for that purpose. The entrance of all aliens afflicted with leprosy into a country must be prohibited.

The Tuberculosis Campaign

The antituberculosis movement has spread to the Orient and the Far Eastern Society of Tropical Medicine has pledged itself to "use its influence to cause the formation of a national antituberculosis society in each political entity represented in the Far Eastern Association of Tropical Medicine; these societies to be formed along the lines of existing antituberculosis societies in other parts of the world, yet revised to facilitate work under local conditions." Yet it is doubtful if such societies in most of the Oriental countries will be able to wage an effective campaign. The ignorance of the vast majority of Orientals of any form of modern medical methods, the widespread lack of absolutely any sanitary precautions,

the great density of the population in most of the countries in question and the great poverty of the inhabitants would seem almost to make any campaign against tuberculosis futile.

The Library of the Bureau of Science

One of the most pleasant surprises that a medical or scientific man experiences in coming to the Philippine Islands is the finding of so complete and well-selected a library in both the medical and the general sciences. In the reorganization of the libraries of the Philippines, the scientific library of the Bureau of Science becomes a part of the general library scheme of the Philippine government. All scientific books and journals are collected together into a common scientific library, located in the Bureau of Science. Since its organization the Bureau of Science has been and still remains the center of scientific activity and research in the Philippines and naturally demands the largest scientific library. Investigation of the many local medical problems has from the first been a part of the program of the American administration in the islands. This is particularly true of the Bureau of Health and the Bureau of Science. The problem of making the country a healthful one, not only for the Filipinos, but also for Americans, has been a big one and a great deal of research along medical lines has been and is still necessary. Of course, in this work, not only are scientific men and good laboratories necessary, but also good library facilities. In this line, as well as along other scientific lines and in the field of industrial investigation, the government has shown itself liberal. To make the library funds go as far as possible, there is practically no duplication in the different branches of the general library and the various government bureaus are permitted to borrow books freely from each other.

The current scientific journals form a very important part of the library. The shelves are well supplied with a majority of the better scientific journals in all languages, from English and German to Chinese and Russian. Back numbers and sets of many of the more important journals are to be found. Every branch of medicine is represented, not only by the standard text-books, but also by the current journals. On Jan. 1, 1910, aside from the current journals, the medical section of the scientific library was represented by 5,832 bound volumes, 471 unbound volumes and 818 parts. Many additions have been made since that date and the recent library budget of the Philippine Medical School will bring up the total considerably. Works and journals on tropical medicine naturally form an important part.

LONDON LETTER

(From Our Regular Correspondent)

LONDON, Oct. 15, 1910.

Town-Planning

An important conference on town-planning, organized by the Institution of Architects, has been held at the Guildhall. Mr. John Burns, president of the Local Government Board, who represented the government and who has framed an excellent act for the regulation of town building, insisted on the necessity of providing better houses and streets for the workers. The object of his act was to promote comfort in the home, dignity in the streets, space in the roads, with less of the smoke, noise, advertisements, and nuisances that accompanied a city without a plan, because its rulers were without ideas and its citizens without imagination. A picture of the ideal town of the future was sketched by Sir William Richmond. He hoped that all town-planning schemes would make gardens an important element and said that places should be arranged for fountains and bandstands. To render the air as pure and immune from smoke as possible, all grates should consume as much smoke as possible, and every encouragement should be given to the manufacturers of smokeless coal. Indeed it might be the part of the town-planning enterprise to devise, especially for the dwellings of the poor, central heating stations from which the necessary warmth might radiate. Cooking stations and cheap restaurants should also be erected for the poor and encouragement given for them to club together, a system which would promote economy and healthy food. With the smoke evil cured, gardens on the house tops might be possible, even in our climate. At present the dirt produced by London smoke made this impossible. When the necessity for the change from dirt to cleanliness was recognized a whole row of houses of the poorer classes might possess a large area of flat roof which would be a healthy playground for children. The architect, who should

be the prime director of all town-planning, should consult the sculptor and the painter. When the smoke of towns was abated mural painting would probably come into general use.

Outbreak of Food Poisoning Due to a Bacillus-Carrier

An outbreak of food poisoning due to eating pork pies has occurred at Wrexham and resulted in the serious illness of over one hundred persons and the deaths of five. From two samples of the pies, which were all made at one factory, an organism was cultivated which was undoubtedly either the paratyphoid B bacillus or the *Bacillus enteritidis* of Gaertner. The indications generally were in favor of the former organism, which in certain circumstances is of great virulence. The several ingredients which entered into the pies were examined, but the flour, lard and gelatin did not yield the organism. No opportunity was afforded of examining the meat as originally delivered to the baker, but it was ascertained that the meat formed part of a common batch, a portion of which was made into pies by other bakers, which were largely sold and from which no ill effects could be traced. The feces of an employee in the shop in which the pies were made showed numerous colonies of an organism which by its cultural and agglutination characters was found to be identical with the organism in the pies. Professor Smith therefore concluded that the outbreak was due to this bacillus-carrier.

Plague in London

A native member of the crew of the S. S. *Oceana*, which recently arrived in London from Bombay, complaining of illness was landed at the Port Isolation Hospital at Denton for observation and found to be suffering from plague. He is isolated and the ship has been thoroughly disinfected.

Medical Education

When distributing the prizes at the Leeds Medical School Mr. Howard Marsh, professor of surgery at the University of Cambridge, dealt with the increasingly difficult problem of medical education. Medicine had now become a department of biology. It rested on chemistry, anatomy, physiology and pathology. The student had difficulty in keeping pace with his subjects and for the average man this had from the first been hopeless. He was not a sensitive photographic plate on which a short exposure would secure a clear and abiding picture. He had been outpaced. The problem was how to arrange the work so that the curriculum of the student would lead to satisfactory results. The difficulty was one of the oldest in the field of education. It was a question of selection. They had to consider the result of the present system not merely in reference to what the student had learned and would retain in a serviceable form but what kind of mental training he had been passing through, and what effect his work had on his mental evolution. Mere information was but raw material and of little value to the student unless he could manufacture it for his own use. But how could he do that when he was constantly being overfired with material which he could not assimilate? Professor Marsh found that intelligent and serious students showed an altogether deficient acquaintance with, for instance, the essentials of surgical anatomy. The rejections in anatomy and physiology at the conjoint examinations of the Colleges of Physicians and Surgeons in the last five years had been between 39 and 47 per cent. This high rate was in some degree due to the fact that the students were struggling under the incubus of an overloaded curriculum. He suggested that a medical education conference might be held. The meeting of the different teachers would emphasize the fact that the object was not the training of specialists in the individual sciences concerned but the education of students of medicine. As medicine had now become a department of biology they should appeal to specialists in other subjects for assistance. Each teacher should be absolutely independent and in every sense unfettered. Each should be able to make his teaching thorough and turn out students who had acquired not merely an evanescent smattering, but a sound and permanent grip of principles. Demonstrators of anatomy should have constant opportunities for going beyond mere tedious anatomic facts to their meaning as to function and their bearing on medicine and surgery. In the hospital wards the teaching could with advantage be remodeled. Every ward teemed with material for clinical teaching but the surgeon could not give his time to systematic teaching. For this purpose ward teachers should be appointed, as had already been done in some hospitals.

The Relation of Religion to the Falling Birth-Rate

At the Church Congress which has just been held at Cambridge the subjects discussed were not entirely theological; papers attracted considerable attention on sociologic topics, such as heredity, social responsibility, etc., which had important medical bearings. In a paper on parentage the Bishop of Ripon deplored the lessening of the fit and the strong, and the increase of the unfit and the weak, which had been brought about by modern conditions. The shortage of children in the last twenty years was over a million. The decline was not confined to the mother country. In twenty-two years the birth-rate of New Zealand had fallen from 36 to 29 and in thirty years that of Australia from 41 to 27. The problem that had to be faced was an arrest of the birth-force in the English-speaking races and, unfortunately, this decline was greatest in the best classes of the population. An important paper on this subject was also read by Mr. C. Whetham, F.R.S., who said that all previous conclusions in sociology needed re-examination in the light of the voluntary restriction of the birth-rate which began about 1875. Since that year, the average number of children produced by a fertile union had halved in the best families of all classes of the nation. The discrepancy had become so great that no amount of care of children could compensate for the diminished number of births. That this restriction was voluntary was shown by the fact that Jews and devout Roman Catholics in all ranks of life were not affected by it, while the Protestant clergy had been much less affected than the laity. At this period of our evolution, for religion to have its biologic survival value it must have a definite message on the subject. It must teach people that for the sake of the future welfare of humanity, possibly for the ultimate welfare of eternity, large families were to be encouraged among the sound and able stocks, of high moral and intellectual worth, but that where definite hereditary unsoundness existed selfish and irresponsible procreation meant future misery for themselves and a lowering of the average quality of humanity, which was the temporary home of souls of eternal spiritual significance. The new revelation of the power of a conscious selective birth-rate to modify the average character of a nation must be acted on in fearless faith. While those nations who ignored it would suffer deterioration and decay, the race that was taught by its faith to accept and act on the new knowledge would improve, multiply and replenish the earth. It would carry its ideals through nations and its religion to the ends of the world.

PARIS LETTER

(From Our Regular Correspondent)

PARIS, Oct. 7, 1910.

Formation of an International Association of School Physicians

At the time of the International Congress of Educational Hygiene, held recently in Paris (*THE JOURNAL*, Aug. 20, 1910, p. 707), the school physicians of various countries met to consider the organization of an international association. The assembly entrusted the organization of the new association to a provisory bureau, the honorary presidents of which are Sir Lauder Brunton of London, Sir James Grant of Ottawa and Professor Chantemesse and Dr. Albert Mathieu of Paris.

The Public Emergency Service in 1909

During 1909, the first-aid stations established in Paris on the borders of the Seine and the canals have received 357 submerged persons (269 men, 88 women), of whom 9 had been too long in the water to revive; 154 had thrown themselves into the water intentionally. The stations in the suburbs received 15 submerged persons, 2 of whom died. As for first-aid to the sick and wounded, 273 persons (255 wounded and 18 sick) received attentions in the first-aid stations of Paris. The litters of the various posts were utilized 517 times—for confinement, illness, sudden death, natural death and accidents. It is interesting to observe that the ambulances installed at the time of the ceremonies and public celebrations received only 285 persons altogether. Carnival Day furnished 40 sick and 23 wounded, and the national holiday 38 sick and 23 wounded—very modest figures compared with statistics of the American Fourth of July accidents.

Injurious Results to the Eye from Tared Roads

At the last session of the Académie des sciences, Dr. True, professor of clinical ophthalmology at the Montpellier college of medicine, and Dr. Fleig, read a paper on the effect of the

dust from tarred roads on the eye. It seems that while tarring roads markedly diminishes the dust raised by the passing of automobiles, the dust from roads so treated has an exceedingly harmful effect on the eyes. More than other dust, tarry dust inflames the conjunctiva and provokes the ophthalmia. Incrusted on the cornea, the particles of tar produce leukomas, which sometimes persist for a long time and sometimes are permanent. Cases of blepharitis and corneal ulcer from this cause are not rare.

Second Conference for the Study of Cancer

The first Conference for the Study of Cancer, convoked by the central German committee for the study of cancer, met at Heidelberg and Frankfurt in September, 1906. A committee, consisting of delegates from thirteen different countries, was authorized by the first conference to arrange for the organization of an International Association for the Study of Cancer, to meet triennially. The opening session of the second conference was held in Paris on October 1. M. Doumergue, the minister of public instruction, presided and made the opening address. On the platform were the official delegates of the twenty-three foreign governments represented at the conference, namely, Great Britain, Germany, Austria, Belgium, Bolivia, Brazil, Bulgaria, Chili, China, Denmark, United States, Greece, Italy, Japan, Hungary, Luxemburg, Mexico, Peru, Persia, Argentina, Russia, Sweden and Turkey.

Professor Czerny, who spoke after M. Doumergue, says that according to the statistics of the last ten years, cancer is increasing and that in civilized countries especially it already holds second place among the causes of mortality among adults. The study of neighborhoods, houses and families seems to be most promising for ascertaining etiology. The work of the French committee, therefore, deserves particular commendation since it is in direct communication with practitioners. By statistics from one country of frequent cases of cancer in a single organ, for example, the stomach, the esophagus or the bladder, and by an exhaustive study of the surroundings and the circumstances in which the patients live, it may be possible to make more rapid progress than by general and universal statistics. The endemic increase of cases of cancer in certain localities and in certain houses, which was reported first in France, then in Germany and in England, speaks in favor of a parasitical cause of many cancers, although the efforts of innumerable investigators to discover this cause have so far remained unsuccessful. New experimental data lend support to the theory of irritation.

Professor Pierre Delbet of Paris closed the series of official speeches by defining the character and spirit of the meeting. "We have," he said, "called it a conference to emphasize the fact that it is a limited association. In an open congress the special aims of the meeting might perhaps have been missed among communications from which neither science nor the patients would draw much benefit." In this conference, only members of associations belonging to the International Association, invited guests and official delegates of foreign governments can participate. The conference has 150 members.

The program was intentionally limited to general questions. Unfortunately, as frequently happens, many papers came too late, so that the printed papers could not be distributed before the conference. It is also unfortunate that the papers in German were published in that language without being abstracted in French, and that the reading of these papers was not followed by such abstracts.

On motion of Professor von Hansemann of Berlin a committee composed of all the foreign delegates was appointed to devise an international nomenclature of cancer before the next meeting of the conference, three years hence. Professor Pierre Delbet spoke of the inconvenience arising from the fact that in various countries the same lesions received different names and the same words were employed in different senses. Therefore, he, with Drs. Ménétrier and Herrenschmidt had drawn up a scheme of nomenclature, which without pretending to be complete, constituted a terminologic framework. Professor Delbet's nomenclature was endorsed as a temporary scheme.

It is probable that the next international conference on cancer will be held at Brussels in 1913, although no decision has been taken as yet.

The Benefit of Surgery in the Army

The new physical requirements for military service have had, among other good effects, that of surgically relieving many young men of more or less troublesome infirmities, such as varicocele, hemorrhoids, hernia, etc., besides improving their general physical condition during their periods of service.

The number of radical cures of hernia (the most frequent surgical infirmity in the army) obtained in the course of military service, has continued to increase since 1903. In 1903, 1,886 radical cures were effected; in 1904, 2,533; in 1905, 2,868; in 1906, 2,896; in 1907, the last year for which statistics have been published, the number of these operations was 3,731. This is explained by the fact that since 1902 hernia has been only exceptionally a cause for exemption, while in 1903 the eliminations for hernia by the Council of Revision reached the enormous number of 3,116; in 1907 there were only 751.

Death of Mme. Pasteur

Mme. Pasteur died suddenly at Arbois, Jura, near where her illustrious husband was born. Her funeral, which was held on September 28, was very numerously attended. The body lay in state at the Pasteur Institute at the entry of the crypt where the mortal remains of her husband already repose. The ceremonies were conducted by the members of the council of administration of the Pasteur Institute, headed by Dr. Roux, director of the institute, and M. Metchnikoff. After the religious ceremony at the church, the body was brought to the Pasteur Institute to the crypt where it will be buried, Mme. Pasteur having expressed the desire to rest near her husband. Dr. Roux pronounced a moving discourse, in which he rendered homage to the character of the admirable woman who was the devoted companion of Pasteur.

BERLIN LETTER

(From Our Regular Correspondent)

BERLIN, Oct. 7, 1910.

Inexpensive Hospitals for Mild and Chronic Cases

This title was the subject of a report made by Professor Grober of Essen at the recent meeting of the German Public Health Association. Grober is director of the hospital there and he urged the erection of such hospitals first for the relief of the large and to a certain extent necessarily expensive general hospitals, in which the stay of the convalescents and those who are recognized as chronic invalids can be materially shortened, and secondly because the development of medicine demands institutional care for classes of cases which formerly were treated without it. For these patients the expensive apparatus of the large hospital is not necessary. Under the auspices of the Prussian department of education, Grober visited a large number of hospitals in Germany, Holland, Switzerland, without having so far found a type which could be regarded as a model. This is due partly to the fact that the requirements for such a hospital in various places must differ because of the varied character of the conditions. The demand is quite general that in the building and equipment, all expense not distinctly necessary must be avoided. In particular the provisions for the purely medical part can be much simpler than in institutions intended for major surgery and severe internal diseases. But it must not be forgotten that the institution must be thoroughly hygienic. In hospitals of this kind in foreign countries this is seldom the case. Medical oversight is necessary and the physician should have the deciding word in the arrangement of the institution. Whether such a hospital should be a branch of an already existing institution or separate from it depends on the special needs and the local conditions. If the house is to be especially for mild cases, it should be more like a private home. For chronic cases the public institution type is preferable. It is quite permissible to erect buildings of several stories on the corridor system. For chronic tuberculous patients suitable arrangements against infection must be provided. It would be very desirable that all the patients received should have been for a time in a general hospital and that the medical direction of both should be in one person's hands. If possible, the management should also be connected for the sake of economy. For this purpose also the patients may be employed in the work of the house. In general a bed can be provided for from \$750 to \$1,000 (3,000 to 4,000 marks), and the maintenance is much cheaper than in complete hospitals. The number of beds should not exceed 1,500.

Education of Girls and Race Hygiene

A short time ago the above title was the subject of a lecture by the renowned Munich hygienist, Professor von Gruber, delivered before a woman's club. This lecture has excited great interest on account of the position he takes in opposition to the modern woman's higher education movement. There is some reason to think that part of the ad-

dress delivered by the Kaiser at Königsberg, which dealt with the woman question, was based on Gruber's address. Professor Gruber is strongly opposed to the attempts of the leaders of women to train every girl to be self-supporting, and to secure the complete economic and political independence of women. In his opinion this effort will result in a destruction of the family and in sterility and will therefore affect most injuriously the strength of the nation. The passionate insistence of women on economic independence, for a trade and a career, is in Gruber's opinion, disastrous, because as a rule (with rare individual exceptions) the physical and mental power of women is insufficient for industrial and professional labor, in addition to the severe burden of bearing, nursing and bringing up their children. The condition is especially serious in the higher intellectual occupations. The conflict between the business career and the position of the woman as wife and mother, leads to prevention or the frequent miscarriage of pregnancy, to weakness and illness of the new-born infants and inability to nurse them, to neglect of the training of children, and avoidance of marriage. As evidence for his claims he cites the report on morbidity and mortality in the Leipzig local Krankenkassen, recently published, as showing the small number of confinements among saleswomen and the like, amounting annually to only 6 or 7 per thousand of the women of child-bearing age (as opposed to the average, 43) and the strikingly large number of premature births among them (28 per cent. of all deliveries as opposed to the average of 17) and for which artificial interference is undoubtedly responsible. Not only is reproduction hindered or limited by the employment of the woman, but also in consequence of economic competition, marriage and the founding of a family are distinctly impeded and in this way the increase of the population is lessened. The birth-rate in our large cities, is rapidly diminishing. The work done by women is not valuable enough, he said, to compensate for the harm which comes from the employment of women. Comparison of the accomplishments of women in science, art, technique and government with the corresponding work of men shows that there is no hope that woman will be able to equal man. The natural task of woman is to become a wife and mother, and her physical and mental nature is fitted for this task. There is no such excess of women in Germany as some claim, Gruber added, for there were in Germany Dec. 1, 1900, about 8.5 million women between 20 and 40, and 8.7 million men between 25 and 50, that is 0.2 million more men of the marriageable age than women. Woman is to be helped, he continued, not by the economic elevation of woman at the expense of man, but by the economic and social elevation of man himself. Gruber admits that for such girls as must refrain from marriage and for women who cannot marry as well as for widows, some provision must be made, but professions should be chosen which are not commonly occupied by men and which correspond to the chief employment of women, namely, motherhood, such as the care of lying-in women, infants, orphans, the sick and the poor. The profession should not close to woman the road to marriage but it should, as far as possible, furnish capability and knowledge which will be of value in the married state. The chief function of the training of girls should still be to make the girls fit for mothers of families and to that belongs, above all, the preservation and improvement of their health. This will be secured by protecting the woman's strength, especially in the years of development, by simple nutritious food, by abstinence, by activity in the house and outdoor physical exercise without overexertion, by much sleep and not much intellectual work. That the leaders of the woman movement do not agree with von Gruber's views goes without saying. Already the president of the woman's club in which the lecture was delivered, Madame Heyl, a well deserving person in many respects and the publisher of a cook book which is very extensively used in Germany, has protested against Gruber's demands. In her opinion a thorough education of woman so as to secure later capability of action, intellectual clearness, strong character and thorough ability assures the better bringing up of the next generation. The existing social conditions require the cooperation of women. In addition to the occupation as mother, which takes only twenty years of the life of a woman, there remains still a long period for a self-supporting career which every girl should strive for. Similar protests from other women will not be lacking.

Ernst von Leyden

Professor von Leyden died October 5, at the age of 78. For many years his mental and physical strength has been diminishing and it was therefore for the good of the first medical

clinic which he conducted when he regretfully decided to resign. Still, with his physical elasticity he would have passed many years in the midst of medical Berlin had he not over two years ago suffered an accident which proved the beginning of a somewhat rapidly progressing illness. The great importance of Leyden as an investigator and teacher is so well known that a few lines will suffice here to show the general character of his achievements. He wrote a pioneer work on diseases of the spinal cord. In various departments of internal medicine he has done very valuable work, especially on diseases of the kidneys and still more particularly, on nephritis in pregnancy. He proved that endocarditis could be produced by the gonococcus, found Charcot's crystals in asthma, wrote an illuminating work on pyopneumothorax, etc. His efforts for the establishment of tuberculosis sanatoriums, which he may be said to have inaugurated in Germany and Austria, are well known. In this his most striking characteristics appear in their best light. He had an indefatigable capacity for work, an inexhaustible fertility in ideas, a remarkable talent for organization, and great shrewdness and energy in overcoming the difficulties which stood in his way; and he was filled with an unconquerable optimism which gave him firm faith in the realization of his plans and the greatest perseverance in pursuing his fixed purpose. To reach his goal he tried all means, for to him success justified everything. He was an opportunist in both a good and a bad sense. This peculiarity appeared even in his scientific work. It was not simply accident that at his clinic alleged discoveries were made, not only by his pupils but by himself, which soon were found to be erroneous; indeed, it must be admitted that the readiness of some of his pupils to fly off at a tangent was merely the natural result of his opportunism. The confident announcement by his assistant Scheurlen of the discovery of the cancer bacillus, which was soon identified as a potato bacillus, will be recalled; and of late years the investigations of P. Jakob on the cure of tuberculosis ended in the complete discrediting of this assistant. The alleged discovery of a cancer parasite by Leyden himself may be attributed to the advanced age at which he undertook the investigation; but the tenacity with which he held to his view in spite of all adverse criticism is characteristic of his optimism. Leyden, on account of his brilliant personal qualities, played a great rôle from the beginning, not only in the medical affairs of Berlin, but also in those of Germany and in the general society of Berlin. The recognition which was accorded him gave him great pleasure; this peculiarity indeed amounted sometimes to weakness. Nevertheless he knew how to win over, by his lovable disposition and shrewdness, those who disapproved of his fondness for distinction, which amounted sometimes to childishness. So up to the time of his resignation he enjoyed an undisputed leadership in many societies, particularly in those founded by himself, like the Verein für innere Medizin and the Kongress für innere Medizin. Wherever he appeared he always was the central point of interest and as such was able to unite about himself opposing interests. Leyden's striking personality will live not only in the history of medicine but in that of many organizations.

VIENNA LETTER

(From Our Regular Correspondent)

VIENNA, Oct. 6, 1910.

Death of Professor Chrobak

One of the best-known gynecologic surgeons of Vienna, or in fact of Europe, Rudolph Chrobak, has died recently, after a prolonged illness, and his death will be a grief to many eminent surgeons all over the world. He was born in 1870, became a physician in 1887, and succeeded Breisky in 1889. Chrobak took up the study of diseases of women at a time when there was no place to learn it, and therefore he regarded it as most important, in building smaller hospitals, to provide special beds for gynecologic purposes, claiming them from the "all-round surgeons" for the gynecologist proper. He became the director of the first gynecologic and obstetric clinic in Vienna, but resigned his post two years ago. His best known pupils were Rosthorn (his immediate successor) and Wertheim (the second successor), of cancer fame.

Chrobak had also a prominent part in the organization of the curriculum of medical students, where he emphasized the necessity of adequate instruction in diseases of women, as well as the thorough teaching of midwives. One of his tasks was the work connected with the new clinics for gynecology, which he supervised very earnestly. He knew he would not

be master there himself, but he did the work for his successor and favorite pupil.

Chrobak was well known as the originator of the method of hysterectomy named after him. His sympathy for his patients was best illustrated by his motto, "primum non nocere." This he had inscribed in all his wards and operating theaters, and it was really one of his proudest boasts that all patients knew, when they came to his service, that they could rely on getting the best of all possible help. He was recognized by the British as one of the ablest surgeons of his time.

Chrobak's books deal mostly with the histology and pathology of gynecologic conditions, while the immense amount of obstetric work done in his clinic (6,000 cases per year) gave him an enormous experience on that subject too, so that his private practice was extraordinarily successful. He was an able teacher, beloved as an examiner and an excellent consultant.

The Work of the Rettungsgesellschaft in 1910

The "first-aid" corps of Vienna, a private institution for all cases requiring instant help, has just published its report for the last month. It had 2,977 casualties attended by its officers, of which 1,039 had to be brought to hospital. The nature of the work is evident by the following figures: 850 sudden attacks of illness, 1,096 injuries and accidents, 69 suicides, attempted and successful, 9 cases of acute mania, 28 persons found dead. Since the existence of the institution, 241,996 cases were attended to (29 years). The institution is a private one, being supported by voluntary contributions and gifts, but the funds are already large enough to give it a material independence. This was evinced some time ago, when a yearly subvention was offered by the municipality, on the condition that the administrative board would admit members of the town council. Political reasons were clear in that offer; the Rettungsgesellschaft promptly declined the grant, saying that "charitable institutions cannot bear to be meddled with by politicians." This act has greatly increased the sympathies of the population for the institution.

The Eighth International Congress of Physiologists in Vienna

September 27-30, there was held in Vienna the eighth International Congress on Physiology, which was frequented by scientists from all parts of the world. The proceedings were very interesting, many papers being read in German, English, French and Italian. As usual social festivities, banquets and receptions interfered somewhat with earnest work. It was much remarked that so many men are working on the electrocardiogram, showing that this modern method of examination is still full of puzzles and problems. Electricity played altogether a great rôle in the proceedings. Thus electric thermopenetration in the treatment of rheumatoid disease was discussed by Docent Ulman. The phenomena of electric discharges of the fish known as the *Torpedo marmorata* were made the subject of a paper by Professors Kreidl of Vienna and Kinoshito of Japan. The electric organ of the fish is exhausted in 30 minutes by involuntary discharges, if the animal is placed in common river-water or well-water. The process is interrupted at once by cocaine or chloral hydrate, while, if the fish gets a dose of strychnin, the organ is discharged rapidly also in sea-water, the usual habitat. The electric condition within the cells and the electric irritability of the various organs of the human and other bodies were also discussed. An important part of the proceedings was taken up by the papers dealing with glycosuria. Bornittau of Berlin, Reich of Vienna and many other scientists gave the result of their experiments with the pancreas and heart muscles of the mammalia. Anaphylaxis was the subject of papers by Kraus, Biedl, Paltani, while Professor Starling of London also contributed a valuable paper in that section. The papers on chemistry of colloids (Bayliss), of imbibition (Hoffmann), of peristalsis (Pal), were very interesting. Trendelenburg reported his experiments on temporary exclusion of parts of the brain or other sections of the nervous system by lowering its temperature to nearly freezing point. Dr. Dubois of Paris discussed the problem of sleep. He asserts that the anterior brain does not possess the function with which it is credited in this respect. A demonstration of artificially made rats by Steinach of Prague was much commented on. Steinach had removed the sexual organs from young female rats and had implanted testicles of rats into their anterior abdominal walls, thus changing the sex of the animals permanently. The rats grew to become normal masculine individuals, proving the effect and influence of the inner secretion of the sexual glands. Naturally the ultramicroscope of Siedentopf, in combination with kinetographic plans of living bacteria,

was much discussed. Physiologic blood conditions of birds were examined by Stübel of Jena, who has found that the pulse-rate and blood-pressure of birds are much higher than in mammals of the same weight. Metabolism in high altitudes was shown by Wendt of Helsingfors, who concludes that, medium heights favor the increase of hemoglobin and erythrocytes; higher levels, however, also cause an increase of muscles. The plankton cells of the ocean, which form the food of the vast majority of the inhabitants of the seas, were examined by Hensen, who asserts that the laws of Darwin do not hold good for these simple organisms. The opening and the closing address, by Riebet of Paris and Ebner of Vienna, were, as is the rule now, of a general nature, except that Ebner took the opportunity to celebrate the centenary of the birth of Schwann, the discoverer of the cellular nature of the higher organisms.

The next congress will take place in two years in Groningen, Holland. Many members of the congress were present at the unveiling of a monument in honor of Gregor Mendel, the priest who discovered the laws of heredity named after him, in Brunn, a city three hours from Vienna, where he was born and died. The occasion was celebrated by the municipality, and numerous official representatives of various countries and corporations took part in the proceedings.

Professional Services to Medical Men

The question of fees among professional brethren has been discussed recently by several medical councils in this country. The Moravian Medical Council, representing about 1,500 practitioners in the northern districts of Austria, has passed a resolution that it shall not be considered unethical for a practitioner to accept a fee for medical services to the family of a brother practitioner, or even to the doctor himself. The doctor is, of course, free to grant his confrère patient a reduction of 50 to 75 per cent. of the ordinary fee. The grounds for the resolution are that very often the physician and his family are worse off in case of illness than any other patient, for since the physician sent for will not accept a fee, the patient does not want to accept an unnecessary favor. Therefore cases of disease in a practitioner's family often lack the adequate and early attention which they would have received had an outside physician been called in. On the other hand, it is only just that the services of specialists, called or consulted by physicians with whom they have no other connection, should be paid for. Physicians who are on friendly terms with each other may, however, recognize services rendered by useful presents. A suggestion by another medical council, that the fee paid by one medical man to another should be devoted to a fund, a providential or other charitable institution, does not meet the requirement that the work should receive its own reward. It has been observed that, while the older generation of doctors was against the acceptance of such fees by a physician, the younger generation favors it. It is intended to settle the question by obtaining the opinion of the profession on the point within a short time.

A Convention of Deaf-Mutes

A convention of deaf-mutes was recently held in this city under the auspices of the ministry of education. As the chief points of the discussion centered around economic and social complaints, medical interest in the proceedings was limited to the fact that deaf-mutes could successfully adopt this method of communication. The proceedings were remarkable for the absence of voice, as nearly all speakers used a combination of the French (finger) method with the German (oral) method. It must be remembered that the oral method has been in use here only for about fifteen years, and that the persons educated after this method are perhaps not yet grown up enough to take part in a congress. At any rate about 300 deaf-mutes, representing all sorts and conditions of men—business men, engineers, clerks, laborers, painters and house-keepers—had gathered, proving that although severely hampered in their progress, they still could become useful members of the community. An attempt was made to obtain reliable data in regard to the cause and duration of the condition among those present, but the exact results are not yet obtainable. One outcome of the convention was the adoption of a resolution that, if possible, both methods of conversation should be taught with due preference to the oral method. An aerobic entertainment, at which all performances were given by deaf-mutes, was also interesting, as it proved that in spite of severe pathologic changes in the cochlea (most likely also in the vestibulum) equilibrium need not be interfered with.

Marrriages

MARCUS E. WILSON, M.D., to Miss Agnes Schneider, both of Cincinnati, October 11.

ALFRED KARSTED, M.D., to Miss Annie O'Donnell, both of Butte, Mont., October 7.

GARLAND DIX SCOTT, M.D., Chicago, to Miss Hester Crowder of Sullivan, Ind., September 13.

PIERRE NORBERT BERGERON, M.D., to Miss Margaret O'Brien, both of Philadelphia, October 18.

PAUL F. COLE, M.D., Steffenville, Mo., to Miss Nora M. Yancey of LaBelle, Mo., October 12.

GREGORY JOSEPH EGAN, M.D., to Miss Freda Kathryn Michel, both of LaCrosse, Wis., October 12.

JOHN RUTHERFORD HERRICK, M.D., New York City, to Mrs. Constance Braine French, October 12.

JOHN BEVERLY POLLARD, M.D., U. S. Navy, to Miss Alice May Albaugh, at Baltimore, October 14.

HUGH A. BEAM, M.D., Afton, Iowa, to Miss Mayme Jones of Rolfe, Iowa, at Des Moines, October 10.

JAMES F. CHURCHILL, M.D., Chicago, to Miss Virginia Busey of Urbana, Ill., at Champaign, October 8.

BEDFORD F. COOP, M.D., Greenville, Ill., to Miss Ethel Reed of Highland, Ill., at East St. Louis, October 4.

SAMUEL WILLIAM HAMMOND, M.D., Norfolk, Va., to Mrs. Elizabeth M. Crockett, at Baltimore, October 10.

RUSSELL ANDREW ROBERTS, M.D., and ANNA KREMER MASTERSON, M.D., both of Kansas City, Kan., October 5.

LEE COLLINS HARLAN, M.D., Madison, Ill., to Miss Margaret Groves of Bunker Hill, Ill., in St. Louis, October 12.

CHARLES AUGUSTUS KATHERMAN, M.D., Sioux City, Iowa, to Miss Helen Louise MacKern of Chicago, October 12.

BRICKERTON L. PHILLIPS, M.D., Frederick's Hall, Va., to Miss Vera Mildred Harris of Louisa county, Va., October 13.

BENJAMIN H. B. HUBBARD, M.D., White Stone, Va., to Miss Lloyd Estelle Betts Smith, at Heathsville, Va., October 11.

CHARLES O. BAKER, M.D., Fort Madison, Iowa, to Mrs. Henrietta Emick of Cedar Rapids, Iowa, at St. Joseph, Mich., October 5.

Deaths

Carl Svantè Nicanor Hallberg, one of the leaders of American pharmacy, pharmaceutical publicist, editor, and teacher, died at his home in Chicago, October 22, after a long illness, aged 54.

Professor Hallberg was born in Helsingborg, Sweden, and graduated from the Philadelphia College of Pharmacy in 1876; he was a member of the Committee on the Revision of the National Formulary in 1886, 1895, and 1906; and a member of the National Committee on the revision of the United States Pharmacopoeia from 1890 to 1910. He was professor of pharmacy in the Chicago College of Pharmacy from 1890 to 1910, and professor of pharmacology in the Illinois Medical College from 1894 to 1896. From 1883 to 1903, he was editor of the *Western Druggist*, and since 1906 has been editor of the *Bulletin of the American Pharmaceutical Association*. He was given the degree of M.D. *honoris causa* by Harvey Medical College, Chicago, in 1903, and that of doctor of pharmacy by the Medical-Chirurgical College of Philadelphia in 1909. He was a member of the American Medical Association and secretary of the Section on Pharmacology and Therapeutics from 1901 to 1909. In great measure to Professor Hallberg's exertions was due the founding of the Council on Pharmacy and Chemistry, of which he was a member from the time of its organization in 1905, and its secretary for one year thereafter.

Charles H. Fisher, M.D., University of Nashville, Tenn., 1864; a member of the Medical Society of the State of Pennsylvania, and a charter and honorary member of the Lackawanna County Medical Society; a medical cadet, acting assistant surgeon, U. S. Army, and surgeon Ninety-Sixth Regiment, United States colored troops, during the Civil War; one of the founders of the Lackawanna Hospital, Scranton, and first surgeon to the institution; a member of the staff of the West Side Hospital, Scranton; died at his home in that city, October 17, from heart disease, aged 73.

Levi Ives Shoemaker, M.D., University of Pennsylvania, Philadelphia, 1886; a member of the American Medical Association,

and American Academy of Medicine; a member of the attending staff of the Wilkes-Barre Hospital, and the consulting staff of Mercy Hospital, Wilkes-Barre; physician to the home for Friendless Children and the Humane Society; local surgeon for the Pennsylvania Railroad and Central Railroad of New Jersey; died in Germany, Sept. 27, 1909, from heart disease, aged 50.

Paul Louis Brick, M.D., College of Physicians and Surgeons, Chicago, 1890; for thirty-five years a practitioner of LeMars, Iowa; a member of the American Medical Association; local surgeon for the Illinois Central Railroad; president of the local board of pension examining surgeons; a member of the State Commission on Insanity; died in St. Joseph's Hospital, Sioux City, October 14, from heart disease, aged 64.

Joseph Lucius Gray, M.D., Northwestern University Medical School, Chicago, 1885; a member of the American Medical Association; formerly of Chicago, and assistant physician of Cook County; for several years health officer of LaPorte, Ind., and coroner and physician of LaPorte County; died in the Holy Family Hospital, LaPorte, October 21, from meningitis following otitis media, aged 50.

William Duffield Bell, M.D., Bellevue Hospital Medical College, New York City, 1888; major and surgeon of the Seventy-First New York Infantry, U. S. V., during the Spanish-American War with service in Cuba; died in the J. Hood Wright Memorial Hospital, New York City, September 28, from acute gastritis, aged 47.

Herbert O. Smith, M.D., Hahnemann Medical College, Chicago, 1881; formerly a member of the American Medical Association; United States pension examiner at Shakopee, Minn.; for several years health officer and a member of the board of education; died at his home, October 4, from cerebral hemorrhage, aged 52.

Frank W. Simmons (license, Texas, years of practice, 1907); for more than 40 years a practitioner of Hackberry, Texas; a charter member of Karnes County Medical Society; for one term a representative to the legislature, and mayor of Yoakum; died recently at the home of his daughter, near Runge, aged 80.

Richard B. Potter, M.D., Medical College of Ohio, Cincinnati, 1866; a member of the American Medical Association; local surgeon at West Palm Beach, Fla., for the East Coast Railway; sanitary inspector of the port of Palm Beach, and local agent of the State Board of Health; died in July, 1909, aged 65.

John Alexander Farnsworth, M.D., University of Colorado, Boulder, 1897; a member of the American Medical Association; at one time president of the Colorado State Medical Society, and twice mayor of Littleton; died at his home in Fort Morgan, October 12, from organic heart disease, aged 40.

John L. Neagle, a surgeon in the Confederate service during the Civil War; comptroller of South Carolina from 1868 to 1872, and thereafter for several years an employee of the Pension Bureau, Washington, D. C.; died at his home in Seattle, Wash., October 19, 1909, from heart disease, aged 72.

David R. Greenlee, M.D., University of Pennsylvania, Philadelphia, 1867; a veteran of the Civil War; for several years surgeon at the Minnesota Soldiers' Home, Minneapolis, and a member of the local pension examining board; died suddenly in that city, October 10, from heart disease, aged 78.

Homer Alvin Smith, M.D., New York University, New York City, 1877; of Bondsville, Mass.; hospital steward in the Navy during the Civil War; formerly a member of the school board of Palmer, Mass.; died at the home of his brother in Stafford Springs, Conn., October 10, from uremia, aged 65.

August Berg, M.D., University of Berlin, Germany; for many years a practitioner of St. Louis; died at the home of his daughter in Collinsville, Ill., September 18, from the effects of a gunshot wound of the head, believed to have been self-inflicted with suicidal intent, aged 74.

William Frederick Holthausen, M.D., College of Physicians and Surgeons, New York City, 1904; a member of the Medical Society of the State of New York; of Brooklyn; was instantly killed in a collision between interurban trains near Tipton, Ind., September 24, aged 29.

Benjamin Franklin Whiteside, M.D., University of Maryland, Baltimore, 1877; of Hickory, N. C.; a member of the American Medical Association; died in the Whitehead-Stokes Sanitarium, Salisbury, N. C., October 2, from septicemia due to a carbuncle of the neck, aged 58.

Louis Auerbach, M.D., University Medical College of Kansas City, Mo., 1882; a member of the Colorado State Medical

Society, and since 1878 a practitioner of Denver; died in St. Luke's Hospital in that city, October 14, two days after an operation for nephritis, aged 58.

George F. Wilson, M.D. University of Alabama, Mobile, 1889; formerly a member of the American Medical Association; a member of the Louisiana State Medical Society; of Bienville; died at the Shunpert Sanitarium, Shreveport, after a surgical operation, October 4.

Richard N. Beauchamp, M.D. New York University, New York City, 1850; a member of the Kentucky legislature in 1890 and 1891; first president of the Logan County Medical Association; died at his home near Russellville, October 10, from senile debility, aged 87.

Isaac Wood, M.D., Queen's University, Kingston, Ont., 1892; successively lecturer on chemistry, assistant professor of obstetrics and gynecology, and professor of pediatrics in his alma mater; died at his home in Kingston, September 1, from cerebral hemorrhage, aged 57.

Luis Abella y Ocampo, M.D. University of St. Tomas, Manila, P. I., 1892; an efficient member of the staff of the Bureau of Health of Manila since the establishment of the United States Government in the Philippine Islands in 1898; died July 12, from heart disease.

Leon Ray Pheasant, M.D. State University of Iowa, Iowa City, 1902; a member of the American Medical Association; was instantly killed in an automobile accident, while making a professional call six miles from his home in Pierce, Neb., October 4, aged 31.

Samuel William Fletcher, M.D. Harvard Medical School, 1858; a member of the Massachusetts Medical Society; surgeon of the Thirty-second Massachusetts Volunteer Infantry throughout the Civil War; died at his home in Pepperell, April 13, aged 77.

Edna D. Timms, M.D. University of Oregon, Portland, 1899; a member of the American Medical Association; of Portland, Ore.; aged 41; while making an emergency call, October 14, was instantly killed in a collision between her automobile and a street car.

Howard Warden Taylor, M.D. Hahnemann Medical College, Philadelphia, 1899; of Pittsburgh; anesthetist to the Homeopathic Hospital; died in that institution October 12, from gunshot wounds, self-inflicted, it is believed with suicidal intent, aged 38.

William H. Riley, M.D. Tulane University, New Orleans, 1861; surgeon in the Confederate service during the Civil War; a member of the first board of fire commissioners, of Algiers, New Orleans; died at his home in that place September 30, aged 72.

Andrew Strang, M.D. College of Physicians and Surgeons, Baltimore, 1880; formerly of Wilkes-Barre and Scranton, Pa.; died in Largs, Scotland, September 10, from epithelioma of the tongue for which operation had been performed a year before, aged 64.

George Edward Miller, M.D. College of Physicians and Surgeons, Chicago, 1905; a member of the American Medical Association; health officer of Sanborn, Iowa; was instantly killed, October 17, in an automobile collision near Struble, aged 37.

George Howard Jones, M.D. Harvard Medical School, 1864; of Brookline, Mass.; assistant surgeon of the Fifth Massachusetts Volunteer Infantry during the Civil War; died in Harrison, Maine, September 15, from valvular heart disease, aged 67.

James H. Donovan, M.D. Louisville Medical College, 1891; a member of the Kansas Medical Society; United States pension examiner at Medicine Lodge; died in Lakeside Hospital, Chicago, August 29, after a surgical operation, aged 46.

Henrik S. Schanche, M.D. University of Christiania, Norway, 1903; a member of the North Dakota State Medical Association; formerly of Park River, N. D.; died at his home in Minot, N. D., June 1, from spinal meningitis, aged 34.

Elera John Abbott, M.D. Chicago Homeopathic Medical College, 1887; of Chicago; a specialist on diseases of the eye, ear, nose and throat; died in Hahnemann Hospital, October 16, from peritonitis, following a surgical operation, aged 51.

Clarence Morfit, formerly a practitioner of Baltimore; an officer in the Confederate service during the Civil War; and later an employee of the Philadelphia mint; died at his home in New York City, May 22, from senile debility, aged 82.

Cyrus Barklay White, M.D. Eclectic Medical Institute, Cincinnati, 1878; a member of the Medical Association of Geor-

gia; a director of the First National Bank of Fitzgerald; died at his home in Fitzgerald, September 29, aged 71.

Chauncey Ely Billington, M.D. Bellevue Hospital Medical College, 1875; for one term coroner of Onondaga county, N. Y.; and a well-known physician of Syracuse; died at his home, October 3, from typhoid fever, aged 62.

Clarence F. Tillman, M.D. College of Physicians and Surgeons, San Francisco, 1903; formerly of Goldfield, Nev., but recently of San Francisco; died at St. Luke's Hospital in that city, September 25, from appendicitis, aged 32.

Frederick J. Bauer, M.D. University of Wooster, Cleveland, Ohio, 1880; of Mogadore; a member of the Ohio State Medical Association; died suddenly, October 5, at the home of a neighbor, from arteriosclerosis, aged 56.

Mary Augusta Stackercoll, M.D. Sioux City (Iowa) College of Medicine, 1905; a member of the Iowa State Medical Society; died at her home in Sioux City, from acute nephritis, and was buried September 23, aged 42.

Orris Kingsbury Griffith, M.D. Eclectic Medical Institute, Cincinnati, 1861; a pioneer practitioner of Huntley, Ill.; president of the village board, and school and township trustee; died at his home September 24, aged 74.

David A. Robertson, M.D. College of Physicians and Surgeons, Keokuk, Iowa, 1882; a pioneer practitioner of Williams, Iowa; a veteran of the Civil War; died at his home, September 29, from chronic cystitis, aged 70.

William E. King (examination, Texas, 1907); for twenty-five years a practitioner of Collin County, Texas; died at his home in Oak Cliff, Dallas, September 14, from septicemia, due to a carbuncle on the neck, aged 56.

John Puckett Wolfe, M.D. Ohio Medical University, Columbus, 1899; died at his home in Johnstown, Ohio, October 11, from the effects of cannabis indica, self-administered, it is believed, with suicidal intent, aged 36.

Charles Fletcher Bush, M.D. Vanderbilt University, Nashville, 1902; state inspector of cotton mills, jails and almshouses of Alabama; died at his home in Montgomery, September 24, from tuberculosis, aged 32.

John Turner Mullin, M.D. Victoria College, Coburg, Ont., 1857; for many years medical health officer, and councilor, and for one term mayor of Brampton, Ont.; died at his home in that place, August 14, aged 78.

Louis Plette Walley, M.D. Hahnemann Medical College, Philadelphia, 1883; a member of the Medical Society of the State of Pennsylvania; died at his home in Millintown, in April, from tuberculosis, aged 49.

Andrew E. Thompson, M.D. Michigan College of Medicine and Surgery, Detroit, 1905; a member of the Saginaw Valley Medical Society; died at his home in Elkton, Mich., October 9, from pneumonia, aged 31.

Joseph Fletcher, M.D. Washington University, St. Louis, 1867; formerly a member of the American Medical Association; died at his home near Mendon, Ill., September 26, from paralysis agitans, aged 76.

James Henry Heavrin, M.D. Kentucky School of Medicine, Louisville, 1885; chairman of the board of health of Hancock County, Ky.; died at his home in Hawesville, October 1, from chronic gastritis, aged 48.

George Marshall, M.D. Medical College of Ohio, Cincinnati, 1878; formerly a member of the American Medical Association; died at his home in Columbus, Ohio, September 14, from paralysis, aged 64.

Peter L. Opsvig, M.D. University of California, San Francisco, 1900; of Everett, Wash.; a member of the American Medical Association; died in San Diego, Cal., March 11, from tuberculosis, aged 42.

Henry Levi Bevans, M.D. Washington University, Baltimore, 1869; a member of Garrett County Medical Society; died at his home in Grantsville, Md., September 27, from paralysis, aged 66.

George Steurnagel, M.D. Michigan College of Medicine, Detroit, 1883; formerly a member of the American Medical Association; died at his home in Chicago, October 9, from paresis, aged 57.

Harlan Page Reynolds, M.D. New York University, New York City, 1869; a member of the Canadian Medical Association; was burned to death at his home in Lepreux, N. B., October 8, aged 70.

Frederick W. Smith, M.D. New York Homeopathic Medical College, New York City, 1877; of New London, Conn.; died

at the home of his sister in Niantic, Conn., September 24, aged 69.

Jesse Franklin Jones, M.D. University of Nashville, Tenn., 1874; a member of the Medical Association of Georgia; mayor of Hogsansville; died at his home, October 3, from pneumonia, aged 55.

James Anderson, M.D. Miami Medical College, Cincinnati, 1869; a member of the Indiana State Medical Association; died at his home in Versailles, June 11, from acute gastritis, aged 62.

Ellis A. Merkle, M.D. McGill University, Montreal, 1897; a member of the American Medical Association; died at his home in Gouverneur, N. Y., October 2, from anemia, aged 49.

Rufus Elisha Belding, M.D. Homeopathic Medical College of Pennsylvania, Philadelphia, 1866; formerly of Troy, N. Y.; died at his home in Keuka Park, N. Y., September 21, aged 69.

W. D. Snoddy, M.D. Physio-Medical College, Cincinnati, 1850; of Warrensburg, Mo.; died at the home of his son in that city, September 30, from angina pectoris, aged 88.

James B. Wolford, M.D. Kentucky School of Medicine, Louisville 1889; a member of the Kentucky State Medical Association; died at his home in Montpelier, June 23, aged 53.

William Henry Pollard, M.D. Washington University, St. Louis, 1856; a member of the Pike County Medical Society; died at his home in Eolia, Mo., September 14, aged 76.

William A. Empey, M.D. Queen's University, Kingston, 1891; of Vars, Ont.; was shot and killed by a patient, August 18, while making a professional call in that village.

Isaac J. Hawkes, for more than forty years a practitioner of Henrico County, Va.; died at his home in East Richmond, September 8, from pneumonia, aged 79.

John M. Evans, M.D. Tulane University, New Orleans, 1889; of Corpus Christi; a member of the State Medical Association of Texas; died in Denver, October 5, aged 34.

Allen Perry Poaps, M.D. McGill University, Montreal, 1879; formerly of San Francisco; was found dead near his office in Oakland, May 14, from apoplexy, aged 50.

Cornelius Henrichs (license, Neb.); for many years a practitioner of Henderson; died at his home in that place, August 3, from cerebral hemorrhage, aged 70.

Edward S. Coburn, M.D. New York Homeopathic Medical College, New York City, 1864; died at his home in Troy, N. Y., October 4, from diabetes, aged 69.

Benjamin Franklin Dismant, M.D. University of Pennsylvania, Philadelphia, 1867; died at his home in Limerick, Pa., October 10, from paralysis, aged 65.

Peter Schwind (license, Iowa, 1889); for 46 years a practitioner of medicine; died at his home in La Mars, October 2, from diabetic gangrene, aged 72.

Marcus F. Rodgers (license, Mississippi); a Confederate veteran; died at his home in New Albany, Dec. 17, 1909, from hemoglobinurie fever, aged 58.

Jacob T. Miles, M.D. Cincinnati College of Medicine and Surgery, 1874; died at his home in Bryant, Ind., July 23, 1909, from dropsy, aged 64.

Frank Ferrell, M.D. New Orleans School of Medicine, 1859; during the Civil War; died at his home in Ashland, Miss., September 13, aged 79.

John Albert Jones, M.D. Tulane University, New Orleans, 1873; of Springfield, Ill.; died recently from mental disease, at New Orleans, aged 62.

D. Thomas Robertson, M.D. McGill University, Montreal, 1857; died at his home in Lennoxville, P. Q., September 7, from uremia, aged 74.

William W. Sanders, M.D. University of Maryland, Baltimore, 1861; died at his home in La Plata, Md., October 6, from cancer, aged 74.

John Hewetson, M.D. McGill University, Montreal, 1891; of Riverside, Cal.; died in Victoria, B. C., September 26, from tuberculosis, aged 43.

Frederick Emerson Chandler, M.D. Tufts College Medical School, Boston, 1896; died at his home in Everett, Mass., June 23, aged 51.

Andrew Jackson O'Bannon, M.D. Eclectic Medical Institute, Cincinnati, 1876; died recently at his home in Elizaville, Ky., aged 69.

Carlos C. Sherman, M.D. Hahnemann Medical College, Chicago, 1884; died at his home in Colton, Cal., October 7, aged 64.

Samuel K. Poling, M.D. Eclectic Medical Institute, Cincinnati, 1876; died at his home in Bryant, Ind., July 12, 1909, aged 68.

Alfred J. Lopez, M.D. Howard University, Washington, D. C., 1894; of New Orleans; died in that city, January 11.

Philip B. Rooks, M.D. Nashville; died at his home in Troup, Texas, Dec. 21, 1909, from typhoid fever, aged 78.

List of Drugs for State Board Examinations

To the Editor:—We have noted with interest and pleasure the publication (*THE JOURNAL*, Oct. 8, 1910, p. 1302) of the list of drugs recommended for state board examinations. While we consider this list a good one, and hope to see it adopted by the various state boards, we wish to submit to you a list that might be interesting for various reasons. In the first place, it is of interest because of priority both in its conception and in its adoption. It was devised by the Committee on Pharmacology of the Chicago Medical Society in the winter of 1908, and has since been adopted by the Illinois State Board of Health to serve as a guide in the elaboration of its examination questions in materia medica and therapeutics. Secondly, it is of interest because of the similarity of the two lists, compiled originally by two entirely different bodies. These lists have later been compared and certain minor changes have been made in both in consequence. Thirdly, the therapeutic classification shows the reason for the choice of the agents included in the list, the aim having been to choose at least one typical member of each therapeutic group. Certain useful agents, such as syrup and glycerin, have been omitted because a fair knowledge of their nature is common to all intelligent persons, and because they are not likely to form subjects of examination questions.

We believe that the publication of this list not only will not antagonize the success of the list previously published, but will actually reinforce it by showing how generally has been felt the need for it, and that at least one state board of health has seen fit to adopt such a list.

The list of drugs as presented to the Council of the Chicago Medical Society is given below.

WALTER S. HAINES
BERNARD FANTUS, Chicago.

LIST OF DRUGS

Circulatory Stimulant: Digitalis.
Preparations: Infusion, tincture, extract.
Circulatory Depressants: Aconite.
Preparations: Tincture, aconitin.
Cerebral Stimulant: Caffein.
Cerebral Depressant: Alcohol.
Cord Stimulant: Nuxvombea.
Preparations: Tincture, extract, strychnin sulphate.
Cord Depressant: Bromids of potassium and sodium, and dilute hydrobromic acid.
Vasoconstrictor: Epinephrin.
Vasodilators: Amyl nitrite and nitroglycerin.
Alteratives: Mercury.
Preparations: Gray powder, blue mass, ointment, both chlorids, both iodids, yellow oxid, white precipitate.
Iodin.
Preparations: Tincture, comp. solution, potassium iodid, dilute hydriodic acid, iodoform.
Arsenic.
Preparations: All the official preparations.
Antiperiodic: Cinchona.
Preparations: Comp. tincture, quinin sulphate and hydrochlorid.
Anesthetic (general): Ether.
Anesthetic (local): Cocain hydrochlorid.
Antispasmodic: Camphor.
Preparations: Spirit, liniment.
Narcotic: Opium.
Preparations: Powdered, extract, Dover's powder, tincture, paregoric, morphin sulphate, codein sulphate, apomorphin hydrochlorid.
Hypnotic: Chloral.
Analgesic: Acetphenetidin.
Oxytoic: Ergot.
Preparations: Fluidextract and extract.
Anthelmintic: Aspidium, sautonin, thymol.
Germicide: Phenol.
Emetic: Ipecac.
Preparations: Syrup, fluidextract.
Laxative: Rhamnus purshiana.
Preparations: Extract, fluidextract, aromatic fluidextract.

Simple Purgative: Aloes.
Preparations: Aloin, purified aloes.
Drastic Cathartic: Croton oil.
Hydragogue Cathartic: Magnesium sulphate.
Cholagogue: Resin of podophyllum.
Expectorant: Ammonium chlorid.
Diuretic: Potassium acetate.
Diaphoretic: Pilocarpin hydrochlorid.
Mydriatic: Belladonna.
Preparations: Extract, fluidextract, tincture, atropin sulphate.
Miotic: Physostigmin sulphate.
Astringents, Mineral: Zinc sulphate and oxid.
Astringent, Vegetable: Tannic acid.
Rufefacient: Turpentine.
Vesicant: Cantharides.
Escharotic: Silver nitrate.
Hematinic: Iron.
Preparations: Reduced, mass and pill of carbonate, tincture of the chlorid, Basham's mixture, pyrophosphate, syrup of iodid, ferric hydroxid with magnesia.
Antirheumatic: Salicylic acid, sodium salicylate, phenol salicylate (salol), oil of wintergreen, salicin.
Antiseptic, Urinary: Hexamethylenamin.
Antiseptic, Intestinal: Bismuth subnitrate and subcarbonate.
Antiparasitic: Sulphur.
Disinfectant: Formaldehyd.
Antacid: Sodium bicarbonate.
Acid: Hydrochloric acid.
Miscellaneous: Colchicum.
Preparations: Fluidextract, extract, colchicin.
Diphtheria antitoxin.
Vaccine virus.
Thyroid.
Of toxicologic importance: Hydrocyanic acid, phosphorus, lead, carbon monoxid.

Iodids in Goiter

To the Editor:—I read with some interest your answer to the question of the correspondent regarding "Simple Goiter and Its Treatment," published in THE JOURNAL, October 8, p. 1306.

I was somewhat surprised that your answer contained a recommendation for the use of iodids in the treatment of simple goiter. Many years ago, I followed out this treatment to some extent without seeing any benefit from it, but I have seen several cases, in both my own and outside practice, in which I believe the iodids converted the simple goiter into exophthalmic goiter. One of these cases, which I saw two years ago, gave such positive evidence of this, that the attending physician who had administered iodids to the patient was convinced of this influence. Strange as it may seem, in the same issue of THE JOURNAL, p. 1329, in an abstract from the *Archiv für klinische Chirurgie*, Kocher is reported as believing that extensive iodid treatment is responsible for the development of exophthalmic goiter in more cases than is generally recognized, stating that this iodin-Basedow, as he calls it, is a frequent form of exophthalmic goiter. He describes a case in which the thyroid was over 160 grams in weight and contained a small part of a gram of iodid. The patient had a simple goiter for nearly seven years and applied local innunction of a mixture containing iodid. In four weeks she lost 16 pounds; then typical exophthalmic syndromes developed.

For the past eight or ten years I have refrained from the use of iodid or thyroid extract in all cases of simple goiter, fearing the influence toward the more serious disease. Under the use of many different kinds of treatment other than iodid in simple goiter I have known of favorable results, but only a few, and also without any treatment at all. The gland will sometimes decrease in size, and again increase independently of any treatment.

W. O. BRIDGES, M.D., Omaha.

[COMMENT: Our correspondent's caution as to the use of the iodids, even in undoubted simple goiter, is pertinent and valuable. It should be carefully determined whether a condition of hypothyroidism or hyperthyroidism exists before iodids or thyroid are administered. But a reading of the question and answer referred to above will show that we did

not "recommend" iodids, our statement being: "It seems to be the opinion of many authors that iodids are the best agents for the condition," etc. We simply attempted to give an enumeration of different approved agents and methods used, without recommending any. We fear our correspondent did not carefully read the article by Kocher to which he refers, as it is said therein that all goiters should be removed which do not yield in a few weeks to careful treatment with iodid in small doses. It will thus be seen that Kocher himself suggests the use of iodids. It is no doubt true, however, that the continued use of the iodids in considerable dosage in any form of goiter would not be advisable, as seems to be proved by the experience of Dr. Bridges and others.—Ed.]

Embryologic Specimens Desired

To the Editor:—I wish again to request through THE JOURNAL that physicians send me embryologic specimens which are constantly falling into their hands. The collection of such specimens at the Johns Hopkins is now one of the best in existence, has been studied carefully by the staff, and is being used constantly by anatomists at home and abroad. About 100 published studies on human embryology are based on this collection, including the "Manual of Human Embryology," in two volumes, published recently by the J. B. Lippincott Co.

Much more material than is now at hand is needed by investigators to further the science of human embryology, as well as to study with greater care the diseases of the ovum and the cause of abortion. To be of most value, the material should be preserved immediately after the abortion in a 10 per cent. dilution of liquor formaldehydi, or by more refined methods, if they are at hand. Small specimens should not be dissected, but preserved entire in formaldehyd solution. Of very great value are good histories of the cases, for through them we may discover the cause of abortions, and ultimately their cure. Studies of this kind enable embryologists to be of use to physicians in active practice. Specimens should be packed in bottles filled *completely* with the preserving fluid, and not wrapped in cotton. If there are no air spaces in the bottle, no amount of shaking will injure the most delicate embryo. Small specimens may be sent by mail, while larger ones should be sent by express, charges collect, addressed to me.

F. P. MALL, Johns Hopkins Medical School, Baltimore.

The Scientific Name of the Spotted-Fever Tick

To the Editor:—In many of the publications on the spotted or Rocky Mountain fever, the tick is referred to as *Dermacentor occidentalis*. This, I believe, is due to an identification of Dr. Stiles, following Neumann, who included it under that species. It is not *Dermacentor occidentalis*. Dr. Stiles, in a paper on this disease in 1905, mentions in two places the name *Dermacentor andersoni*; he furnishes no figure and not a word of description, so that the name cannot, according to the rules of zoologic nomenclature, hold from that date. On June 6, 1908, a revision of the classification of the ticks of the United States was published by me in a bulletin of the Department of Agriculture. In this I described the spotted fever tick as *Dermacentor venustus* n. sp. On July 3, 1908, Dr. Stiles, in a report of the Public Health and Marine-Hospital Service, gave some notes on this species, using the name *D. andersoni*, and mentioning some points in which it differed from other ticks.

According to the rules of zoologic nomenclature, the first name given (provided it is described or figured) is the proper name to use for an animal. The name *Dermacentor venustus*, Banks, antedates the name *D. andersoni* by a month. Dr. Stiles, in a recent bulletin (No. 62) of the Public Health and Marine-Hospital Service, has tried to resurrect his name *D. andersoni* by giving to the first (1905) mention of the name the value of a published description, contrary to the custom of the zoologists. Moreover, he has misapplied my species, *D. venustus*, which was a manuscript name of the late Dr. George Marx, by attaching it to a form that I did not study, although

the type of my *D. venustus* was easily accessible to him (or to anyone) at any time had he chosen to see it.

The recent article of Dr. Stiles will doubtless be seen by many medical men; therefore, I deem it best to call attention in a medical journal to this gross violation of the rules of nomenclature through which he calls the spotted-fever tick *D. andersoni*. The scientific name of this tick is *Dermacentor venustus*, Banks; *D. andersoni*, Stiles, is a pure synonym of it.

NATHAN BANKS.

Washington, D. C.

Interstate Reciprocity in Licensing Physicians

To the Editor:—The letter by Dr. Dunlop in THE JOURNAL, October 15, p. 1397, is of interest to every old practitioner. The ideals for which state boards were created were made by the physicians themselves, but it seems that the moment people create an ideal and secure a law to fulfil that ideal, some state board official will invariably try to interpret it as if he were the law itself. Recent experience with one state board seems to indicate that it is trying to make it just as hard as it can for the older practitioner and just as easy as it can for the new graduate. Reasonable educational standards and ten years of reputable practice ought to entitle any one to receive a reciprocal license in any state.

DANIEL S. HAGER, M.D., Chicago.

Queries and Minor Notes

ANONYMOUS COMMUNICATIONS will not be noticed. Every letter must contain the writer's name and address, but these will be omitted, on request.

LIABILITY FOR ATTENDANCE ON A RELATIVE

To the Editor:—Some time ago I was called by the patient's sister to a case of typhoid fever. The patient, who was delirious and in no condition to judge for himself, had been brought by his sister to her home. The course of the disease was severe, with relapse; the patient was delirious for several weeks, and this sister suggested that I should call in counsel from a neighboring town, which I did. Can this other doctor and I hold the sister legally liable for the bills for attendance on the patient, medicine, etc.? The patient's father paid the nurse's bill.

S. P.

ANSWER:—It is generally understood that to call a physician for one who needs attendance merely evinces a desire to prevent suffering, and does not necessarily imply liability to pay, unless the relationship is such that this liability naturally follows. For example (we quote from 22 American and English Encyclopedia of Law, 790): "To entitle a physician to maintain an action against a person to recover for professional services rendered a third person, he must show a promise by the defendant, either expressed or implied, to pay therefor When a person requests a physician to perform services for a patient, the law does not raise an implied promise to pay the reasonable value of the services so rendered, unless the relation of the person making the request to the patient is such as raises the legal obligation on his part to call in a physician and pay for his services. Whether or not the implied liability is created must depend largely on the circumstances of the particular case."

The courts have gone even further than this in denying the liability; for example, in the case of *Holmes vs. McKim* (syllabus), 109 Iowa 245, we read: "One is not under any implied obligation to pay for the services of a physician called to attend a minor living with his family and supported by him, but not otherwise related to him, though he acquiesced in the attendance and had on a former occasion paid the same doctor for attending the same minor, the physician knowing, however, the true relation of defendant and said child."

TYPHOID AND THE WATER SUPPLY OF MONTREAL

To the Editor:—1. What is the source of the drinking water supply of Montreal?

2. To what is the typhoid in that city attributed?

3. What is being done to better conditions there and with what success?

T. W. CURRY, Streaton, Ill.

ANSWER.—1. The water supply of Montreal is derived from the St. Lawrence River and receives practically no storage before it goes to the consumer.

2. During the fall and winter of 1909-1910 an unusually severe outbreak of typhoid fever was attributed to the water supply by an investigating committee composed of Drs. Adami, Armstrong, Ruttan, Strakey, Bernier, Guerin, Hervieux and Lachapelle, representing the medical faculties of McGill and Laval universities. The committee found overwhelming evidence that "the chief cause of the disease is the water supply of the city and its suburbs." The report also contains the following statements: "The exhaustive investigations into the conditions of the water supply of the city indicate that while the water may give favorable analyses for some months of the year, none of them is at all times safe. At certain times of the year the waters are actually bad and capable of giving rise to water-borne diseases. We do not consider that any further analyses or examination of the waters are necessary to establish the above conclusions. It follows, then, that the future water supply of the city, whether it consists of unmixed St. Lawrence water from south of Nun's Island or not, must be purified by a thorough system of filtration before distribution to the public. To ensure the proper working of the plant, constant supervision of the filtered water by an expert water analyst, devoting his entire time to the work, is an essential part of such a system."

3. Calcium hypochlorite was employed as a temporary means of improvement of the quality of the supply (see *Engineering News*, April 9, 1910). The municipal board of control has been granted \$15,000 to make studies for a filtration system.

CAUSE OF THE MENSTRUAL FLOW

To the Editor:—What is the latest theory as to the cause of the menstrual flow?

W. H.

ANSWER.—According to the latest views, the menstrual flow is due to a congestion of the uterine mucous membrane which occurs under the influence of ovulation. Previous to the flow, the mucous membrane is thickened and it is believed by some authors that most of the membrane is thrown off and the blood escapes from the denuded surface mixed with pieces of the membrane. According to others, no material destruction of the membrane occurs, but the blood escapes by small capillary hemorrhages. It is believed that the ovaries influence the uterus by an internal secretion which is absorbed by the blood or lymph, and on reaching the uterine tissues serves to stimulate the mucous membrane to a more active growth.

WHY DOES THE GASTRIC JUICE NOT DIGEST THE STOMACH?

To the Editor:—What prevents the gastric juice from digesting the stomach during life?

W. P. H.

ANSWER.—Several theories have been suggested to explain the fact that the mucous membrane of the stomach is not digested by the gastric juice during life. One is that the acid is neutralized by the alkaline blood, so that the digestive agent has no effect; another is that the mucous membrane contains some substance capable of inhibiting the digestive action of pepsin; a third and more plausible theory is that the stomach is protected by the layer of mucus which covers its surface and prevents the access of the gastric juice which has been secreted.

WANTED: BOOKS ON THE GENITAL ORGANS FOR THE LAITY

A correspondent asks for a good book covering the female generative organs anatomically, physiologically and pathologically, treating also of child-birth, written in language easily understood by a layman. He desires to give copies to some of his young women patients.

We shall be glad to hear from our readers concerning any works that may be recommended for the purpose.

THE DRINKING OF SEWAGE BY COWS

To the Editor:—1. If a cow drinks fluid containing diphtheria, typhoid and other pathogenic germs from an open sewer or ditch in which the current flows at the rate of 60 feet a minute, can such germs be found in the milk and in consequence be a source of danger to those partaking of the milk?

2. Is an open sewer such as I have described a source of danger to a community, the contents not in any way contaminating either the food or water supply of said community?

A. I. LAWNAUGH, Calumet, Mich.

ANSWER.—1. When typical typhoid bacilli are fed to cattle in considerable numbers they do not appear in the feces, much less in the milk. Diphtheria bacilli also would probably be destroyed in

the alimentary tract. In regard to tubercle bacilli, as is well known, the matter is somewhat different. It is certainly conceivable that cattle might acquire tuberculosis from the ingestion of sewage.

2. An open sewer of the sort described is not without dangerous features. The precise degree of danger from flies, chance contamination, etc., is a matter about which opinions may vary in the absence of exact information. The danger ordinarily would not be considered great.

The Public Service

Medical Department, U. S. Army

Changes for the week ended Oct. 22, 1910.

Eastman, William R., captain, on expiration of his present sick leave of absence, will proceed to New York City for duty as attending surgeon.

Richards, Robert L., captain, relieved from duty in New York City, on expiration of his leave of absence, and ordered to the General Hospital, San Francisco, for duty.

Rich, Edwin W., captain, on arrival in the United States will proceed to Ft. Mason, Cal., for duty and will report to the Commanding General, Department of California, for duty as attending surgeon, San Francisco.

Sweazey, Verge E., captain, ordered to his home to await retirement.

Blanchard, Robert M., captain, ordered to Ft. Thomas, Ky., for temporary duty during the absence of Major W. M. Roberts, Medical Corps.

Murray, Wilson, first lieutenant, M.R.C., granted leave of absence for two months, about Nov. 4, 1910.

Nichols, Henry J., captain, will proceed to Newark, N. J., in time to lecture on Pellagra, before the Essex County Medical Society, about Nov. 22, 1910, and on completion of this duty return to his station.

Lambie, John S., Jr., captain, granted leave of absence to include Jan. 3, 1911.

Tasker, Arthur N., lieutenant, M.C., on being relieved as surgeon of the *Sheridan*, ordered to the Presidio of San Francisco for duty.

Kellogg, Preston S., first lieutenant, R.C., ordered to Ft. Yellowstone, Wyo., for duty.

Walker, Thomas C., first lieutenant, R.C., on expiration of leave heretofore granted him, will proceed to Ft. Terry, N. Y., for duty.

Weston, Henry R., first lieutenant, R.C., ordered to Ft. Strong, Mass., for duty.

Hogan, David D., first lieutenant, R.C., on abandonment of Ft. Schuyler, N. Y., will proceed to San Francisco and take the first available transport to the Philippines for duty.

Williams, Allie W., captain, M.C., ordered to New York City for temporary duty as attending surgeon.

Clark, John A., captain, M.C., ordered to Ft. H. S. Wright, N. Y., for duty during the absence of Captain Williams.

Hanson, Louis H., captain, M.C., granted ten days' leave of absence to take effect on his relief from duty at Hot Springs, Ark.

Maus, L. M., colonel, Medical Corps; Persons, E. R., major, Medical Corps; Allen, J. H., major, Medical Corps, detailed to represent the Medical Department of the Army at the meeting of the Association of Military Surgeons, at Richmond, Va., Nov. 1 to 4, 1910.

Woodall, W. P., captain, M.C.; Whitecomb, C. C., captain, M.C.; Crabtree, G. H., captain, M.C.; Davidson, W. T., captain, M.C.; Smith, H. M., captain, M.C.; Bartlett, C. J., captain, M.C., ordered to report on Dec. 5, 1910, to Lieut. Col. H. P. Birmingham, Medical Corps, president of the Examining Board, at the Army Medical Museum Building, Washington, D. C., for examination to determine their fitness for promotion.

Krebs, L. L., captain, Medical Corps; Howell, Park, captain, Medical Corps, ordered to report on Dec. 5, 1910, to Lieut. Col. J. D. Glennan, Medical Corps, president Examining Board, at San Francisco, for examination to determine their fitness for promotion.

Medical Corps, U. S. Navy

Changes during the week ended Oct. 22, 1910.

Sheehan, R. F., Kress, C. C., and O'Malley, J. J., commissioned asst.-surgeons on Oct. 5, 1910.

Iden, J. H., surgeon, detached from duty at the Naval Hospital, Annapolis, Md., and ordered to the *Georgia*.

Ames, H. E., medical director, detached from command of the Naval Hospital, Puget Sound, Wash., and ordered to the naval training station, San Francisco.

Norton, O. D., medical inspector, ordered to duty on board the *California* as fleet surgeon of the Pacific Fleet.

McCullough, F. E., surgeon, detached from the naval training station, San Francisco, and ordered to the *Georgia*.

Stuart, D. D. V., Jr., asst.-surgeon, ordered to the Naval Medical School, Washington, D. C., for instruction.

Lawrence, H. E., asst.-surgeon, ordered to duty at the Naval Hospital, Las Animas, Colo.

Norton, O. D., medical inspector, detached from the *California* and ordered to the *West Virginia* as fleet surgeon of the Pacific Fleet.

U. S. Public Health and Marine-Hospital Service

Changes for the seven days ended Oct. 12, 1910.

Wickes, H. W., surgeon, directed to proceed to New Orleans (quarantine) on special temporary duty.

Lumsden, L. L., passed asst.-surgeon, directed to proceed to Huntsville, Ala., on special temporary duty.

McClintic, T. B., passed asst.-surgeon, granted 14 days' leave of absence from Oct. 5, 1910.

McLaughlin, A. J., passed asst.-surgeon, directed to proceed to Chicago on special temporary duty.

Francis, Edward, passed asst.-surgeon, granted 30 days' leave of absence from Oct. 3, 1910.

Rucker, W. C., passed asst.-surgeon, directed to proceed to Baltimore on special temporary duty.

Spratt, R. D., passed asst.-surgeon, granted 4 days' leave of absence from Sept. 28, 1910, on account of sickness.

Alford, Neil, acting asst.-surgeon, granted 30 days' extension of leave of absence from Aug. 29, 1910, on account of sickness and 14 days' annual leave from Sept. 28, 1910.

Barelay, James, acting asst.-surgeon, granted 13 days' leave of absence from Oct. 10, 1910.

Bingham, E. O., acting asst.-surgeon, granted 15 days' leave of absence from Oct. 15, 1910.

Goldthwaite, Henry, acting asst.-surgeon, granted 7 days' leave of absence from Oct. 6, 1910.

Board of medical officers convened to meet at Stapleton, N. Y., Oct. 18, 1910, for the purpose of making a physical examination of a cadet of the U. S. Revenue-Cutter Service. Detail for the board: Surgeon H. W. Austin, chairman; Passed Asst.-Surgeon W. A. Korn, recorder.

Changes for the seven days ended Oct. 19, 1910.

Gassaway, James M., surgeon, granted 1 month's leave of absence from Oct. 7, 1910, on account of sickness.

Sprague, E. K., surgeon, granted 15 days' leave of absence from Oct. 28, 1910.

Mathewson, H. S., passed asst.-surgeon, granted 1 day's leave of absence Oct. 12, 1910, under paragraph 189, Service Regulations.

Goldberger, Joseph, passed asst.-surgeon, granted 4 days' leave of absence from Oct. 26, 1910.

McLaughlin, A. J., passed asst.-surgeon, directed to report at the Bureau on special temporary duty.

Bogges, J. S., passed asst.-surgeon, granted 1 month's leave of absence from Nov. 14, 1910.

Rucker, W. C., passed asst.-surgeon, directed to proceed to New York on special temporary duty.

De Valin, Hugh, passed asst.-surgeon, granted 30 days' leave of absence from Nov. 2, 1910.

Duffy, B. J., asst.-surgeon, relieved from duty at Buffalo, N. Y., and directed to proceed to Tompkinsville, N. Y., and report to the commanding officer of the Revenue Cutter *Seneca* for duty.

Jackson, James M., Jr., acting asst.-surgeon, granted 30 days' leave of absence from Nov. 1, 1910.

Tappan, J. W., acting asst.-surgeon, leave of absence for 20 days from Oct. 1, 1910, amended to read 20 days from Oct. 5, 1910.

Terry, M. C., acting asst.-surgeon, granted 30 days' leave of absence from Nov. 1, 1910.

Board of medical officers convened to meet at the Bureau, Oct. 20, 1910, for the purpose of conducting a physical examination of an officer of the Revenue Cutter Service. Detail for the Board: Asst. Surgeon-General J. D. Long, chairman; Asst.-Surgeon Paul Preble, recorder.

Medical Economics

THIS DEPARTMENT EMBODIES THE SUBJECTS OF ORGANIZATION, POSTGRADUATE WORK, CONTRACT PRACTICE, INSURANCE FEES, LEGISLATION, ETC.

THE PUBLIC'S ATTITUDE IN MEDICAL FRAUDS

Evidence of the increasing understanding of medical matters by the press is found in an editorial in a recent number of the Fresno (Cal.) *Republican* which is worth quoting in its entirety:

"CAN'T DO IT"

"The directors of the San Francisco Medical Association, aroused by the Eva Swan malpractice case, have instructed their secretary to take steps toward the prosecution of the numerous alleged 'doctors' practicing in San Francisco who are known to have no licenses, nor any qualifications on which to procure them. These men are of course all frauds, and are on the brand-order list of the United States postal department, but they are also in large part engaged in actual criminal practice, and the recent publicity given to these practices is the motive of the effort against them.

"It is a laudable effort, but we doubt its success. There is plenty of law against practicing medicine without a license, but there is very little sentiment, in or out of courts, to enforce it. Judges, lawyers, jurymen and laymen alike share the medieval superstition that medicine is some kind of magic, of which there are various sects and schools, as there are of religion; that there is no such thing in medicine as truth or falsehood, knowledge or ignorance, but only some kind of a mysterious knowledge what drug or treatment will 'cure' each of the recognized diseases. Every quack has 'cured' a lot of cases, and can prove it. Every legitimate practitioner has found a lot of cases which he could not 'cure,' and it can be proved against him. Plenty of people have been 'cured'

by the incantations of Indian medicine men, and by the more modern and refined forms of the same treatment. These facts of course are nothing to the point, but nearly every judge, lawyer and juror thinks they are. Also, nearly all the juries have the notion that a medical association is some kind of a labor union, and that its only objection to unlicensed practitioners is that they are 'scabs.' And, while in the trades which they can understand their sympathy is all with the union man against the scab, in the trade of medicine it is the other way. You see, the relation of the public to the physician is that of employer, and the unreasoning employer always prefers non-union labor.

"So, for all these foolish and ignorant reasons, the law against unlicensed healing is unpopular, and therefore unenforceable. It is particularly so because in this one case the judge and the lawyers are usually quite as ignorant as the most ideal juror a typical panel can show."

The editor of the *Republican* aptly summarizes the weaknesses of restrictive medical legislation when he says that "judges, lawyers, jurymen and laymen alike share the medieval superstition that medicine is some kind of magic of which there are various sects or schools as there are in religion." Until the public, including the bench and the bar, is sufficiently intelligent to see that there is no more possibility of "schools" in modern medicine than there is in modern chemistry or engineering, it will be impossible to secure a sane, rational interpretation and administration of medical police regulations such as is given to similar regulations in other lines. "Schools" of medicine are and ever have been the curse of the medical profession. There is danger of their also becoming a menace to the public.

POSTGRADUATE COURSE FOR COUNTY SOCIETIES

DR. JOHN H. BLACKBURN, DIRECTOR
BOWLING GREEN, KENTUCKY

[The Director will be glad to furnish further information and literature to any county society desiring to take up the course.]

Third Month—Third Weekly Meeting

INFECTIONS OF THE KIDNEY

VARIETIES: Pyelonephritis, pyonephrosis, pyelitis, abscess of kidney.

ETIOLOGY: Infection may be (1) hematogenous, descending, from pneumonia, typhoid, puerperal sepsis, etc.; (2) ascending, from inflammation or ulceration of ureter or bladder; (3) direct extension from adjacent viscera, liver, spleen, appendix, etc. Micro-organisms usually found.

SYMPTOMS: Hematogenous: General, history of preceding infection, chills, fever, prostration, pain. Examination of urine. Terminations. Ascending: History of lesion of bladder or ureter. Pain. General symptoms. Examination of urine. Terminations.

TREATMENT: Medicinal and general. Surgical, removal of primary lesion, and treatment of kidney. Indications for nephrotomy, for nephrectomy.

TUBERCULOSIS OF THE KIDNEY

ETIOLOGY: Frequency, age, sex, calculus, nephritis.

PATHOLOGY: Routes of infection. Primary and secondary. Miliary and caseous forms. Associated lesions in genito-urinary tract. Effect of mixed infection. Involvement of second kidney.

SYMPTOMS: Insidious onset. Irritable bladder, polyuria, colic, pyuria, hematuria. Examination of urine. General symptoms. Physical examination.

DIAGNOSIS: Early, dysuria, acid pyuria and occasional hematuria with absence of bladder and ureteral lesions; later, changes in bladder.

Differentiate from calculus, pyelonephritis, tumors, essential hematuria.

INFLAMMATION OF PARANEPHRIC TISSUES

FORMS: Fibrosclerotic, lipomatous, suppurative. Pathologic changes in each.

SYMPTOMS AND DIAGNOSIS.

State Boards of Registration

COMING EXAMINATIONS

ARKANSAS: Regular, Little Rock, November 8-9. Sec., Dr. F. T. Murphy, Brinkley; Homeopathic, Little Rock, November 11. Sec., Dr. P. C. Williams, Texarkana; Eclectic, Little Rock, November 8-9. Sec., Dr. G. A. Hinton, Hot Springs.

CONNECTICUT: Regular, City Hall, New Haven, November 8-9. Sec., Dr. Charles A. Tuttle; Homeopathic, Grace Hospital, New Haven, November 8. Sec., Dr. Edwin C. M. Hall, 82 Grand Ave.; Eclectic, Hotel Garde, New Haven, November 8. Sec., Dr. Thomas S. Hodge, 19 Main St., Torrington.

FLORIDA: Palatka, November 9-10. Sec., Dr. J. D. Fernandez, Jacksonville.

LOUISIANA: Homeopathic, New Orleans, November 7. Sec., Dr. John T. Crebbin, 1207 Maison Blanche Building.

MAINE: City Council Rooms, Portland, November 8-9. Sec., Dr. Frank W. Searle, 806 Congress Street.

MASSACHUSETTS: State House, Boston, November 8-9. Sec., Dr. Edwin B. Harvey.

NEBRASKA: State Capitol, Lincoln, November 9-10. Sec., Dr. E. Arthur Carr, 141 S. Twelfth Street.

NEVADA: Carson City, November 7-9. Sec., Dr. S. L. Lee.

TEXAS: Palestine, November 22-24. Sec., Dr. R. H. McLeod.

WEST VIRGINIA: Morgantown, November 14-16. Sec., Dr. H. A. Barbee, Point Pleasant.

Illinois April, May, and June Reports

Dr. J. A. Egan, Secretary of the Illinois State Board of Health, reports the written examinations held at Chicago, April 14-16, and June 9-11, and at East St. Louis, May 10-12, 1910. The number of subjects examined in was 16; total number of questions asked, 100; percentage required to pass, 75.

At the examination held in Chicago, April 14-16, the total number of candidates examined was 125 of whom 107 passed, 17 failed and one took an incomplete examination. The following colleges were represented:

College	PASSED	Year Grad.	Total No. Examined.
Howard University, Washington, D. C.	1	(1909)	1
Bennett Medical College	3	(1910)	3
Chicago College of Medicine and Surgery	35	(1910)	35
Coll. of Med. and Surgery, Chicago	5	(1909) (4, 1910)	5
Hahnemann Med. College and Hospital, Chicago	1	(1909)	1
Hering Medical College	1	(1910)	1
Illinois Medical College	2	(1910)	2
Northwestern University Medical School	9	(1899) (1909)	(7, 1910) 9
College of Phys. and Surg., Chicago	18	(1910)	18
Reliance Medical College	1	(1910)	1
Rush Medical College	21	(1892) (1909) (19, 1910)	21
Louisville Medical College	1	(1894)	1
Baltimore Medical College	1	(1906)	1
Detroit College of Medicine	2	(1896) (1901)	2
St. Louis University	1	(1909)	1
University of Missouri	1	(1908)	1
Univ. and Bellevue Hospital Med. College	1	(1903)	1
University of Pennsylvania	1	(1901)	1
Medical College of Virginia	1	(1907)	1
Royal College of Physicians, Ireland (1886), and Royal College of Surgeons, Edinburgh	1	(1889)	1

College	PASSED	Year Grad.	Total No. Examined.
University of Arkansas	1	(1909)	1
Bennett Medical College	1	(1909)	1
Chicago Coll. of Medicine and Surgery	1	(1908)	1
Coll. of Med. and Surgery, Chicago	3	(1908) (1909)	3
College of Phys. and Surg., Chicago	3	(1910)	3
Northwestern University Medical School	1	(1909)	1
Reliance Medical College	1	(1909)	1
Sioux City College of Medicine	1	(1906)	1
Hospital College of Medicine, Louisville	1	(1904)	1
St. Louis Coll. of Phys. and Surg.	2	(1906) (1908)	2
Mebarry Medical College	2	(1907) (1909)	2

At the examination held in East St. Louis, May 10-12, the total number of candidates examined was 116, of whom 100 passed and 13 failed. Two candidates did not complete the examination and one withdrew. The following colleges were represented.

College	PASSED	Year Grad.	Total No. Examined.
Denver and Gross College of Medicine	1	(1909)	1
Chicago College of Medicine and Surgery	1	(1909)	1
Northwestern University Medical School	1	(1909)	1
Rush Medical College	1	(1908)	1

Wisconsin July Report

Dr. John M. Beffel, secretary of the Wisconsin Board of Medical Examiners, reports the written examination held at Madison, July 12-14, 1910. The number of subjects examined in was 22; total number of questions asked, 100; percentage required to pass, 75. The total number of candidates examined was 60, of whom 54 passed, including 3 osteopaths, and 6 were conditioned. Eighteen candidates were licensed through reciprocity and one was licensed under the exemption clause. The following colleges were represented:

College	PASSED	Year Grad.	Per Cent.
Northwestern University Medical School.....	(1910) 82, 89,		90, 92
College of Phys. and Surg., Chicago.....	(1897) 82; (1910)		84, 87
Chicago College of Medicine and Surgery.....	(1910)		87
Hahnemann Medical College and Hospital, Chicago.....	(1909)		85
Univ. of Minnesota, Coll. of Medicine and Surgery.....	(1910)		87
Hahnemann Med. Coll. and Hospital, Philadelphia.....	(1907)		80

Book Notices

ERGEBNISSE DER CHIRURGIE UND ORTHOPÄDIE. Herausgegeben von Erwin Payr, Greifswald, und Hermann Küttner, Breslau. Erster Band. Paper. Price, 20 marks. Pp. 526, with 152 illustrations. Berlin: Julius Springer, 1910.

The editor, recognizing the increasing mass of literature relating to the various specialties, and the very scattered manner in which articles on related subjects are published, thus making it difficult or impossible for one to keep in touch with all of them, conceived the idea of publishing a series of volumes, of which the present one is the first, which should contain articles on present-day subjects in surgery and orthopedies, written by men of recognized ability and based on a critical review of the literature up to date.

The present volume of 526 pages contains 12 articles as follows: Vessel and Organ Transplantation; Myositis Ossificans Circumscripta; Opsonins; Free Transplantation, Exclusive of Transplantation by Means of Vessel Suture; Treatment of Fractures; Methods of Covering Bony Skull Defects; The Parathyroids; Basedow's Disease; The Present Status of Differential-Pressure Methods in Surgery of the Chest; Benign Tumors of the Breast in the Light of Recent Investigations; The Operative Treatment of Hernia of the Umbilicus, of the Linea Albæ and of the Postoperative Lateral Ventral Hernia in Adults; Hypertrophy of the Prostate. Each article is well-illustrated and is preceded by a rather extensive bibliography covering the last few years. From the very nature of the work, the number of volumes is unlimited, but nothing is said as to the frequency with which they will appear. The intention is to take up as nearly as possible those subjects which have a "live" interest at the time.

The idea is a novel one and the success of the undertaking will depend on the ability to maintain the same standard of excellence in the articles of the subsequent volumes as is found in those of the first volume.

LEITFADEN DER EXPERIMENTELLEN PSYCHOPATHOLOGIE. Vorlesungen gehalten an der Universität Leipzig. Von Privatdozent Dr. Adalbert Gregor, Oberarzt der Psychiatrisch-Neurologischen Klinik Leipzig. Paper. Price, 5 marks. Pp. 222. Berlin: S. Karger, Karlstrasse 15, 1910.

Those who are aware that abnormal psychology is rapidly becoming a separate branch of medicine will not be surprised that special text-books on the subjects are appearing. Though this work is in the form of lectures, it covers the ground well.

The subjects taken up are: the psychopathology of time conception; reaction experiments; pathology of perception; association experiments in health and in mental disease; memory and its pathology; expression; attention; will; the emotions and bodily expressions of psychic conditions as revealed by the sphygmograph, platysmograph, psychogalvanic reactions, etc.; the laws governing intellectual efforts and methods determining intellectual capacity. All of these subjects are thoroughly treated, the literature, particularly the German, thoroughly sifted and a wealth of original observations added. The specialist occupying himself with the neuroses and psychoses will welcome this exhaustive monograph, but the busy general practitioner will find it too lengthy and intricate.

THE NEW INTERNATIONAL YEAR-BOOK. A Compendium of the World's Progress. For the Year 1909. Editor, Frank M. Colby, M.A. Associate Editor, Allen L. Churchill. Cloth. Price, \$7. Pp. 702. New York: Dodd, Mead & Co., 1910.

This third number of the "New International Year-Book" is an improvement over the previous numbers, which should be expected, as the editors of the various departments increase in experience and profit from criticism and suggestion. Almost every subject of human thought and endeavor is treated; brief biographies of persons prominently in the public eye during the year are given; new inventions and great public works are described and illustrated; the articles on the achievements in medicine during the year seem well up to date. The work is informing, and is an interesting summary of the year's progress.

Medicolegal

Sadistic Insanity and Physical Examination of Defendant

The Supreme Court of Nevada says that in the case of *State vs. Petty* (108 Pac. R. 934) the defense relied on by the defendant for killing his wife was sadistic insanity. In support of this defense, he went on the stand and testified in his own behalf. He also called as a witness a Dr. Hepner, who qualified as an expert, and testified, among other things, to having made a physical examination of the defendant prior to the trial, and detailed certain physical conditions existing in the defendant, which, in part, formed a basis for his opinion that at the time of the killing the defendant was insane. For the purposes of rebuttal, counsel for the state requested the court to appoint three physicians and to order that the defendant be submitted to an examination by them relative to the physical conditions detailed in the testimony of Dr. Hepner. Over the objection of counsel for the defendant, the order as requested was made, and three physicians were appointed by the court for the purpose of making the examination. The examination was made in a suitable room in the county jail in the presence of counsel for the state and for the defendant. Each of the physicians so appointed by the court subsequently, on rebuttal and over the objection of the defendant, testified to the facts disclosed by their examination of the person of the defendant within the limits specified in the order of the court.

Exceptions to the order directing the examination, and to the testimony of the appointed physicians, were based on the contention that the constitutional guaranty that no person shall be compelled, "in any criminal case, to be a witness against himself," was violated. The court, however, holds that there was no error in the order or in the admission of the testimony.

In this case the defendant, the court says, had interposed the defense of insanity, had offered himself as a witness solely in support of this defense, had been physically examined by a physician for the purpose of enabling such physician to testify concerning his physical condition as bearing on his alleged insanity, and such physician had testified in regard hereto. He could not therefore interpose any legal objection to the state having the benefit of the same character of expert examination which he had through the testimony of his physician submitted to the jury.

Then counsel for the defendant further contended that it was an error to order the examination of the defendant's person or to permit the physicians appointed by the court to testify to facts disclosed by such examination, for the reason that the purpose of such examination was to contradict the witness Dr. Hepner for purposes of impeachment, and, as Dr. Hepner had, on cross-examination, testified that he had not based his opinion on the physical symptoms of the defendant testified to by him, "except the typical degeneracy written on his face and head," his testimony relative to the defendant's heart and genitals was as to an immaterial matter, and hence could not be contradicted for purposes of impeachment. But the court does not think that the testimony of the physicians appointed by the trial court could be regarded solely in the light of impeaching evidence. Dr. Hepner had testified at length as to the condition of the defendant's heart and genital organs, and it was not until cross-examination that he stated that he did not take into consideration the condition of these organs in reaching his conclusions as to the defendant's mental condition. Counsel for the defendant never withdrew this portion of Dr. Hepner's testimony from the case or offered to have it stricken out. It was all included in the hypothetical question propounded by the witness by the defendant's counsel.

Sadism is a mental disease in which the sexual instinct is abnormal or perverted. Where this character of insanity is relied on, the physical facts, here claimed to be immaterial, would very naturally be given some weight by the jury in the defendant's favor where it was shown by uncontradicted testimony that they were abnormal. The testimony of Dr.

Hepner was that the defendant's heart and genital organs were abnormal, while that of the physicians appointed by the court was that they were normal. The court in ordering the physical examination of the defendant was careful to limit it to the points testified to by the defendant's own expert. If counsel for the defendant deemed these physical facts immaterial, he should not have offered testimony concerning them, but, having offered testimony of the existence of certain physical characteristics of the defendant, he was not in a position to object to the state offering testimony in reference to the same physical facts, and, as before stated, such testimony could hardly be held to be governed by the rules relating to impeaching testimony. At the time the order was made, it could not be told whether the investigations of the physicians appointed by the court would confirm the testimony of Dr. Hepner or not. The purpose of making the order was to enable the court to arrive, if possible, at the truth of the existence or non-existence of certain physical facts, which the defendant had introduced into the case in his defense, and not to impeach the defendant's witness. The mere fact that one expert witness may reach a conclusion different from that of another expert witness does not of itself impeach the former witness.

The objection to the testimony of the physicians appointed by the court was general, and went to all of their testimony, without specifying any certain portion thereof that was claimed to be immaterial. The examination also went to the head, including the mouth, teeth, and tongue, of the defendant, which were conceded to be material points. No specific objection to the testimony relative to the other alleged immaterial points was ever made. If such objection had been made, its overruling could not constitute prejudicial error, unless the defendant withdrew or caused to be stricken out the testimony offered in his behalf concerning the same facts.

Impeachment of Medical Experts

The Supreme Court of Washington says that in the homicide case of *State vs. Newcomb* (109 Pac. R. 355), a physician was called as a medical expert by the defense, and the state in rebuttal called witnesses to impeach him on his general reputation for truth and veracity. The ruling of the trial court in permitting such testimony over the defendant's objection was assigned as error. This was untenable. A medical expert, or any other expert, is subject to the same rule of impeachment as any other witness. He occupies no higher plane than the ordinary witness, nor does he stand on any different footing. The only difference is that he may be interrogated along hypothetical lines; otherwise he is subject to the same methods of examination and must subject himself to the same test of credibility.

Society Proceedings

COMING MEETINGS

Am. Assn. for Study and Prev. Infant Mort., Baltimore, Nov. 9-11.
Hawaiian Territorial Med. Assn. Honolulu, November 26-28.
Ohio Valley Med. Assn., Evansville, Ind., Nov. 9-10.
Southern Medical Assn., Nashville, November 8-10.

MEDICAL SOCIETY OF THE STATE OF PENNSYLVANIA

Sixteenth Annual Meeting, held at Pittsburg, Oct. 3-6, 1919

The President, DR. THEODORE B. APPEL, Lancaster, in the Chair

Hospital Appropriations

The House of Delegates passed unanimously a resolution offered by Dr. John B. Roberts, requesting the legislature to appoint a commission consisting of members of the House of Representatives, the Senate, the State Board of Public Charities, two physicians and a lawyer, to investigate the subject of state appropriations to hospitals not under state control, and the management of all hospitals, and to report on a better method than the present of making hospital appropriations.

Pure Food and Public Health

The house reaffirmed its position taken last year on the question of pure foods, endorsing the work of the Federal authorities on this subject. It endorsed also the principles outlined in the Owen Bill, providing for the establishment of a department of health. Commissions were authorized to continue the study of malignant growths, the end-results in the treatment of fractures of the femur and the work concerning trachoma.

President's Address: Purposes of the Society

DR. THEODORE B. APPEL, Lancaster: Analyzing the purposes of this society as set forth in the ordinances we find that they cover a three-fold aim: organization, individual aid, and duty to the public, uniting in the one definite object of advancement of the medical profession in its usefulness as a distinct entity in the body politic. The development of this three-fold aim of our society forms an interesting study. The work of the committees on cancer and on tuberculosis, the work for the prevention of trachoma, and against the abuse of privileges by the refracting opticians, shows the progress in our work for the public. In our relation to the state in the matter of legislation our hope to unite all national efforts for the purpose of fighting disease seems near realization. The record of the sixty-two years of the society's life is a matter of medical history. Problems confronting us must be settled by cooperation of organized bodies with the people.

Infant Mortality

DR. SAMUEL G. DIXON, Harrisburg: Influences which are responsible for excessive infant mortality may be divided into prenatal and postnatal. Preventive measures must be educational and discreetly philanthropic. The problem is one which concerns the mental, moral and physical prosperity of all people throughout the civilized world, and to this extent every force and influence of individuals, societies, churches, schools, states and nations must be solicited and enlisted in a campaign of helpfulness which is the only solution.

Typhoid Fever in Pennsylvania—Past, Present and Future

DRS. SAMUEL G. DIXON and B. FRANKLIN ROYER, Harrisburg: Typhoid fever is preventable by prophylaxis and sanitation. Since the creation of the department of health much has been done, and a forecast shows that still greater advance is possible through hard work, much outlay of money and close cooperation between the family doctor and the health official.

Work of the Council on Pharmacy and Chemistry

DR. DAVID L. EDSALL, Philadelphia, gave a short summary of the problems the Council has met, the support received from the medical profession and from some manufacturers, and mention of the kinds of obstruction offered by other manufacturers. He also made a general statement of what has been accomplished with reference to its value to the profession, and consideration is given to future problems.

Oration on Medicine: Recent Progress in Medical Sociology

DR. CHARLES H. MINER, Wilkes-Barre: The medical profession in this country has probably done more for the benefit of the people and for its own reputation in the past few years through sociology than in any other field of their labor. In this connection may be mentioned the tuberculosis campaign, medical inspection of school children, the temperance movement, the prevention of cancer, and of venereal diseases. Social service in connection with hospitals has great possibilities. We may consider also in this connection the interest taken by the medical profession in industrial insurance and the employer's liability law, and the campaign for the prevention of infant mortality with special emphasis on the value of a clean milk supply.

Gall-Bladder Dyspepsia

DR. JOHN A. LICHTY, Pittsburg: The symptoms of the dyspepsia referred to are nausea, loss of appetite, flatulency,

pyrosis, distress or a gnawing feeling below the ensiform cartilage, at certain times relative to meals. The gall-bladder and gall-duct affections include catarrh of the bile ducts, acute phlegmonous and gangrenous cholecystitis, acute infections and catarrhal cholecystitis, cholelithiasis and cancer. The symptoms usually described as indicating cholelithiasis are found in only from 5 to 35 per cent. of all cases. Hyperchlorhydria was found in about 70 per cent. in 298 cases of gall-bladder and duct affections. From experiments on dogs it seems that hyperchlorhydria is secondary to affections of the gall-bladder and ducts and is a symptom of considerable value. In cases of hyperchlorhydria in which gastric and duodenal ulcer are excluded, before the diagnosis of nervous dyspepsia is made the presence of disease of the gall-bladder should be carefully considered.

The Treatment of Fermentative and Putrefactive States of the Intestines

DR. DAVID L. EDSALL, Philadelphia: In this type of cases attention is too often directed to the bowel to the exclusion of the stomach. Emphasis should be placed on the importance of examination of the feces as a routine measure. Test diets are often misleading, and the examinations should be made rather while the patient is taking the usual diet. Improvement of the general tone of the abdominal muscles, attention to the circulation and blood-pressure are highly important factors. The condition should be regarded less as a disease of the intestines than as a chronic affection situated in the intestinal tract, and should be treated from the standpoint of increasing the resistance. Long-continued use of active purgatives is harmful. Surgical intervention is sometimes indicated.

Gastric Manifestations of Non-Gastric Disease

DR. CLEMENT R. JONES, Pittsburg, discussed the symptom-complex of non-gastric disease as compared with diseases of true gastric origin.

Constipation of Colonic Origin

DR. JUNSON DALAND, Philadelphia: Patients with chronic constipation due to abolition of the rectal reflex may secure relief by a determined effort to secure a movement of the bowels each morning immediately after breakfast. This effort of the patient may be supplemented by the introduction of a properly prepared soluble glycerin suppository or the employment of an enema. Diet, exercise, other remedial agents, drugs or surgery are of value in constipation colonic in origin.

Discussion on Gastro-Intestinal Derangements

DR. I. J. MOYER, Pittsburg: Many beginning gall-bladder cases are due to modern habits of improper eating and nervous hurry. I agree with Dr. Edsall, that the cause of many of the gastro-intestinal conditions must be looked for outside of the intestine. I think the treatment of constipation by the use of irrigations has been abused.

DR. ERNEST LA PLACE, Philadelphia: If we do not find the cause of the trouble in the organ apparently the seat of the difficulty, we should look for it elsewhere and remove it, no matter how foreign it seems to the condition present. We are apt to forget the intimate relation of all the organs within the abdominal cavity.

DR. JAMES N. ANDERS, Philadelphia: I agree with Dr. Lichty that gall-stone dyspepsia is frequently overlooked even by competent observers. In obscure cases, if the symptoms do not yield to ordinary measures, we should at once suspect an anatomic basis, as a rule, outside of the organ implicated, particularly if it be the stomach or intestine. In conditions with an actual pathologic change, medical treatment will not suffice.

DR. J. A. LICHTY, Pittsburg: The object of my paper was to counterbalance the paper, which in the early part of the year was put out by another author, laying considerable emphasis on appendix dyspepsia. Much that is said of appendix dyspepsia can be said of gall-bladder dyspepsia. A point to be emphasized is the obstinancy of the symptoms,

DR. J. DALAND, Philadelphia: I agree with Dr. Moyer that too constant use of irrigation may be harmful, but by carefully determining the quantity, the time of injection and the temperature of the water untoward results may be avoided.

Significance of Transient Cerebral Crises and Seizures as Occurring in Arteriosclerotics

DR. JAMES D. HEARD, Pittsburg: The following are some of the possible causative factors in these cerebral crises: the action of a toxin on brain cells in localized areas; a spasmodic localized contraction of cerebral arteries sufficient to interfere with the function, but not to affect the integrity of a part; so considerable a decrease in a compensatory hypertension that certain areas of the brain are temporarily insufficiently supplied with blood through the sclerotic vessels which supply them; localized areas of edema in the brain substance. In the light of our present knowledge, a toxic basis may be assumed as a general underlying cause for all these conditions. The supposition that the condition is due to a localized poisoning of brain cells is that which Tanzi invokes to explain the closely allied, if not at times identical, seizures of progressive paralysis. A simpler possible factor may be an intermittent closure of the blood-vessels supplying the affected area, which theory has the adherence of Russell, Osler and others. The association of cerebral seizures of an apoplectic nature with migraine is now considered, and J. Mitchell Clark has observed apoplectic seizures in nine members in three generations of a migrainous family in which hemiplegia, usually accompanied with aphasia, was a constant feature. The importance of an appreciation of the nature of these crises rests on the fact that their proper interpretation may influence both prognosis and treatment. There is danger in having a routine conception as to the blood-pressure desirable in an individual of a given age. As the cerebral seizures are usually the result of toxic influences, prompt measures should be instituted aiming at the removal of circulating poisons and the limitation of their further production.

DISCUSSION

DR. T. DILLER, Pittsburg: There are causes of cerebral palsy other than those which most of us learned in our student days. We are sometimes in the presence of a palsy, a hemiplegia, or monoplegia, which is cerebral in character and transitory in duration, and difficulty arises in its explanation. Where we can exclude the three common causes—hemorrhage, thrombus and embolism—we are a good deal at a loss, and while some of the theories advanced are very plausible, it must be said plainly that the diagnosis of the exact situation is difficult. I have seen several of the cases to which Dr. Heard refers. They may be due to arterial spasm, to local edema, or to an occlusion of the artery stopping short of complete closure. In the presence of an apoplectic stroke in a man in the forties, the practitioner should consider the possibility of paresis. The mental condition and history of previous transient attacks are to be considered in this connection.

Clinical Studies in the Auscultatory Method of Determining Blood-Pressure

DRS. EDWARD H. GOODMAN and A. ALEXANDER HOWELL, Philadelphia: By studying the relation of the five phases to one another, much may be learned diagnostically from the auscultatory method. No particular phase is of the greatest significance, but the importance of each phase should be interpreted by its relation to the other phases and by its relation to the total pulse pressure. The length of the individual phase should be recorded and its percentage relation to the pulse pressure should be ascertained. We have formulated the following conclusions: For accuracy and simplicity, the auscultatory method of estimating blood-pressure is to be preferred to any clinical method. In diagnosing aortic insufficiency, absence of the fifth phase is almost pathognomonic. In the diagnosis of cardiac neuroses, the recognition of tonal arrhythmias and irregularities in maximal and minimal pressure, and variation in sequence relation will prove of much value.

Mitral Stenosis

DR. J. C. WILSON, Philadelphia: It is generally agreed that rheumatic endocarditis is the most common cause of mitral stenosis. Whooping-cough is probably the occasional cause of the primary endocarditis as a result of the great mechanical stress on the ventral valve in the paroxysm. That mitral stenosis carries with it some degree of immunity against pulmonary tuberculosis requires confirmation. The etiologic uncertainties are greatly increased by the numerous cases encountered in young women in whom none of the ordinary causes of endocarditis can be determined. Muscular or spasmodic mitral stenosis and the mitral stenosis of acute malignant endocarditis should also be mentioned under causation. Observation of the well-recognized types of anatomic lesions in mitral stenosis shows variations so essentially different in their circulatory effects as to constitute at least two valvular diseases having little else in common than a narrowing of the auricular ventricular orifice, the physical signs to which that narrowing gives rise, and a tendency to the transference of the blood-pressure from the arterial to the venous side of the circulation. In my experience hemoptysis in mitral stenosis, though often very alarming, is usually followed by abatement of the cardiac symptoms and sometimes by prolonged improvement. The prognosis is less favorable than in mitral insufficiency. Treatment must be carefully adjusted to the individual case.

Treatment of Cardiac Irregularities

DR. ALFRED STENGEL, Philadelphia: Following the more common classification the irregularities may be divided into three important types: juvenile; extrasystolic; nodal rhythm. Conditions which ultimately determine myocardial failure are: (a) progressive increase of the myocardial disease; (b) conditions outside the heart, finally causing incompetency. Measures of treatment designed to prevent the former condition are improvement in nutrition, regulated exercise, tonic treatment, antisyphilitic treatment. Measures to prevent overhardening of a damaged myocardium are correction of gastrointestinal troubles, relief of strain and undue blood-pressure, promotion of renal and dermal activity. I would emphasize that in many cases of beginning failure of cardiac power we had better devote attention to the gastrointestinal tract and external conditions. The time will come when we must resort to the final effort of remedies directed to the heart itself.

Blood-Pressure and Other Observations in Hypertrophy and Dilatation of the Heart

DR. JOSEPH H. BARACH, Pittsburg: The observations are based on studies in a series of over 50 young men who had practiced distance running for at least six months and have to do largely with the pure forms of hypertrophy and dilatation such as occur in the absence of valvular lesions and history of previous disease. I can only conclude that there is a usual occurrence of transitory dilatation following cardiac overstrain.

The So-Called Nodal Rhythm of MacKenzie

DR. JOSEPH SAILER, Philadelphia: MacKenzie and others find as an essential feature of the tracing of the venous pulse a wave which occurs before the time of the contraction of the ventricles, which has been pretty definitely ascertained to be due to the contraction of the auricles, forcing the blood back into the veins of the neck from which the tracing is taken. MacKenzie observed in many of his cases of persistent arrhythmia that this wave was lacking. He concluded, therefore, that there was a synchronous contraction or a paralysis of the right auricle. In trying to find the cause of this it occurred to him that the node of Tawara which is found on the wall of the right ventricle and is probably situated on the conduction fibers passing to the bundle of His, might be involved, and that its involvement would account for this condition. It has been shown by the electrocardiograph, that a series of fine contractions due to muscular effort take place in the right auricle between the ventricular contractions, so that complete paralysis of the auricular wall cannot be

present. This however does not necessarily invalidate MacKenzie's explanation. MacKenzie has applied the term "nodal rhythm" to this condition because he believes that the lesion is situated in the node. This view has not met universal acceptance.

Discussion on Heart Lesions

DR. LAWRENCE LITCHFIELD, Pittsburg: I want to emphasize the frequency with which mitral stenosis is overlooked. We make a diagnosis of mitral insufficiency and before the characteristic signs of the stenosis have developed we have ceased to examine the heart carefully enough and the condition is overlooked. I think the point is well taken that nitroglycerin may do much damage.

DR. GEORGE W. NORRIS, Philadelphia: I am willing to admit that nitroglycerin, under some circumstances, is a good drug, but I am strongly convinced that it is often much abused. As a rule it is not correctly given. Men in nitroglycerin factories develop headaches but become immune to the toxic effect of the nitroglycerin if they work long enough. Similarly if a man be given 1/100 gr. nitroglycerin for a week, you may at the end of a week have to give 1/250 gr. Without blood-pressure determination it is impossible to tell what one is doing.

DR. JAMES D. HEARD, Pittsburg: We must all realize the advantage of measures other than drugs to a great extent in the early stages of the conditions.

DR. A. STENGEL, Philadelphia: There is a certain relationship between polycythemia and cardiac disease. In the use of the saline baths the temperature is the most important thing. In a case under my observation the best results were obtained with the temperature at 94 F. Edematous patients do not respond so well as patients without that symptom.

DR. J. SAILER, Philadelphia: I think that nodal rhythm is interesting chiefly from the fact that it introduces to us a further refinement in cardiac diagnosis. I believe that our knowledge of cardiac disease is in an unsettled state. We merely know that the condition of nodal rhythm is one of those forms of cardiac disease in which the lesion seems to be in the conduction apparatus rather than in the valve or in the general muscular structure of the heart. The symptoms and reactions vary so greatly that it seems impossible to bring the cases into one clinical group. Treatment is largely experimental and will be directed according to the individual choice of the physician, by his experience and his impressions received from the experience of others.

(To be continued)

AMERICAN ROENTGEN-RAY SOCIETY

Eleventh Annual Meeting, held at Detroit, Sept. 29-Oct. 1, 1910

(Concluded from page 1491)

Pulmonary Manifestations of Syphilis

MR. H. W. DACHTLER, Toledo, O.: The patients presented the clinical picture of early pulmonary tuberculosis, but failed to respond to the tuberculin test, nor did the skiagrams show any evidence of tuberculous lesion. The history of syphilis was obtained in each case, and the pulmonary findings cleared up under specific treatment, except in one patient, who died from myocarditis. In the skiagrams of these cases there was an increase in density over the lower part of the lungs, more marked on one side than on the other, so much so in one case that the diaphragm shadow was obscured on the right side. These cases might go to prove that whenever mercury produces a favorable result in so-called cases of pulmonary tuberculosis, the case was probably a syphilitic one and not tuberculous.

DISCUSSION

DR. A. W. CRANE, Kalamazoo, Mich.: A positive tuberculin test does not always indicate tuberculosis of the lungs. The disease may be located elsewhere. If syphilis is present, the Noguchi or Wassermann test should be used. It is quite probable that syphilis of the lung is more common than we have supposed.

DR. HENRY HULST, Grand Rapids, Mich.: The x-ray should not be used to make a differential diagnosis between tuberculosis and syphilis of the lung. Other clinical tests should be used for this purpose.

DR. GEORGE C. JOHNSTON, Pittsburg, Pa.: I have seen many cases of syphilis of the lung in colored children. The physical signs were precisely those of tuberculosis, but tubercle bacilli were never found in the sputum.

Fluoroscopy of the Gastro-Intestinal Tract

DR. EDWARD H. SKINNER, Kansas City, Mo.: Fluoroscopy of the gastro-intestinal tract properly performed is of great diagnostic value, even more so than radiography. The fluoroscopic symptoms of pyloric stenosis are dilatation of the stomach, antiperistaltic waves passing from the pylorus to the greater curvature, and interference with the emptying of the stomach. The fluoroscopic symptoms of carcinoma are irregular outline of the stomach wall, abnormal peristalsis, and if the carcinoma involves the pylorus antiperistaltic waves are seen. When there is involvement of the middle portion of the stomach there is hour-glass contraction. There may be adhesions of the stomach to adjacent organs, and the lumen of the stomach is much smaller than normal, except when the carcinoma is at the pylorus. In gastric ulcer, the irregularity in outline of the stomach wall is not so apparent as in carcinoma, because the irregularity is caused by muscular action, and not so much by changes in the stomach wall. When the ulcer involves the pylorus, there is also interference with the exit of food. In the precancerous stage the stomach has a lessened lumen, is placed rather high in the left hypochondriac region, and there is a small *Magenblase*. The pylorus is frequently lost behind the stomach shadow, and the filling shadow of the stomach is funnel-shaped. It is an atrophied stomach, dependent on a certain degree of starvation.

DISCUSSION

DR. HENRY HULST, Grand Rapids, Mich.: While I feel incompetent to diagnose cancer of the stomach skiagraphically. I think that the x-ray is more likely to make the diagnosis than are the clinical findings. In stomach diseases there is a decided place for fluoroscopic work. We can determine the size of the stomach, its location, motility and even the presence of enlargements, such as tumor.

Skiagraphy of Pancreas

DR. A. W. CRANE, Kalamazoo, Mich.: I have attempted to study the anatomic relations of the head of the pancreas to the duodenum. Bismuth salts suspended in water are administered, and will be found to coat the walls of the duodenum. By this means, the position of the duodenum can be determined and thus also the greater portion of the head of the pancreas. I believe that by means of the x-ray we can diagnose diseases of the pancreas, including tumors and cysts of the head of the pancreas, gall-stone obstruction of the pancreatic duct and diabetes. The pancreas is inaccessible to the diagnostician, hence the skiagraph may be of assistance. In all cases of pain in the upper abdomen a skiagram should be made, because the pancreas may be the seat of the pain. I do not believe that the axis of the gland as usually given in the text-books is correct. The loop of duodenum increases with the increase in size of the head of the pancreas. I have been able in a number of obscure cases to make a diagnosis with a skiagram.

Value of the Roentgen-Ray in Early Diagnosis of Carcinoma of Bowel

DR. FEDOR HAENISCH, Hamburg, Germany: I am convinced of the value of screen work in the early diagnosis of carcinoma of the bowel. I have had three cases in which my assumption has proved to be correct by operation. I do not make the diagnosis of carcinoma, because the skiagram cannot show that, but I do say that there is something wrong in the bowel which should be looked after. I determine this by injecting bismuth into the bowel, and watching its passage upward by means of the fluoroscope. In cases of carcinoma

the flow of bismuth stops, the bowel bulges, and then suddenly a little finger-like process of bismuth passes onward again. That is the sign I look for.

Enlargement of Thymus Treated by the Roentgen-Ray

DR. SIDNEY LANGE, Cincinnati: In four cases of enlargement of the thymus in which urgent pressure symptoms were present, I gave *x*-ray exposures and promptly relieved the patient. I then studied the action of the *x*-ray on the thymus gland of young rabbits, and found that it produced a rapid involution of the gland, which was followed by complete atrophy. It is essential, however, in order to avoid any possible after-effects, that the treatment should be pushed only to the extent of causing a reduction in the size of the gland, and not a complete atrophy.

DISCUSSION

DR. H. K. PANCOAST, Philadelphia: The effect of the *x*-ray on the thymus in these cases would probably help to explain the structure of the gland. I think that it consists largely of lymphoid tissue. We must be extremely careful of the dosage, because the patients are usually infants or young children, and to set up a toxemia would be little short of fatal.

DR. W. F. MANGES, Philadelphia: In one patient, a child six or seven months old, the symptoms came on suddenly and were quite severe. A diagnosis of enlargement of the thymus was made by a prominent practitioner in Philadelphia, and I was asked to use the *x*-ray. I did so, and was much surprised to see the child improve, all symptoms disappearing. They recurred for a little while, but disappeared again under *x*-ray treatment.

DR. G. C. JOHNSTON, Pittsburg, Pa.: I saw one very interesting case, in which the father of the child, a physician, made a diagnosis of enlargement of the thymus. I was unable to confirm the diagnosis skiagraphically. The child grew progressively worse, however, and an operation was decided on. As soon as the incision was made, there was a rush of pus and a large postlaryngeal abscess was evacuated. The child made a rapid recovery.

The Roentgen Ray as Aid in Diagnosis of Gall-Stones

DR. GEORGE E. PFÄHLER, Philadelphia: Gall-stones can be shown with the *x*-ray only when they are composed of a substance of greater density than the surrounding tissue. This means that they must contain some cholesterol salts. Therefore, if the patient presents symptoms of gall-stones and the skiagraph fails to show stones, it does not mean that they are not present, but that they are devoid of lime salts and, therefore, did not throw a shadow. These pictures must be made quickly, and while the liver and gall-bladder are absolutely immovable.

DISCUSSION

DR. FEDOR HAENISCH, Hamburg, Germany: We must be very careful in making a diagnosis of gall-stones, because, as was pointed out, we may fail to get any shadow when the stone is of the same density as the film on the plate. However, with the technic Dr. Pfähler employs, I think better work will be done.

DR. HENRY HULST, Grand Rapids, Mich.: Putting a marker over the place where one expects to find a stone, as is done by some, is not wise, because the marker may hide the stone. The Mayos operated recently in a case of supposed kidney stone, seen in the skiagram, but failed to find it. The patient was turned over, the gall-bladder opened, and the stones were removed. That shows the difficulties of diagnosing these cases correctly.

DR. T. E. POTTER, Chicago: In three cases I obtained shadows on the right side which might indicate stone in the kidney, common duct or gall-bladder. Even the stereoscope did not help. Later I found stones in the kidney in each of these cases, with a gall-bladder infection.

DR. C. F. BOWEN, Columbus, O.: Making a skiagram an hour or two after a large meal, when the gall-bladder has emptied itself of bile, might help to give a picture of stone.

DR. PERCY BROWN, Boston: It is essential to have the large colon thoroughly empty; therefore, we should always give a good cathartic before making a skiagram. My percentage of positive diagnoses is about four, and I feel that is pretty good.

DR. E. H. SKINNER, Kansas City, Mo.: We can only expect to find stones containing calcareous material, and as only from 6 to 10 per cent. contain this material, we cannot hope to see the shadows of very many stones. My experience is limited to about 10 cases. One was rather interesting, because the plate showed 2 shadows, widely separated, which could be interpreted as a stone in either end of the gall-bladder. These 2 stones evidently were the only ones containing calcareous material.

DR. L. G. COLE, New York City: In one case in which I was sure stones were present, the skiagraphs failed to show a definite shadow, but I did see a peculiar small stellate shadow in the region of the gall-bladder. The patient was operated on and a soft cholesterol stone was removed. The nucleus of that stone corresponded to the stellate shadow shown in the plate.

Therapeutic Efficiency of Roentgen Irradiation

DR. G. C. JOHNSTON, Pittsburg, Pa.: The glandular affections wherein the *x*-ray has proved itself valuable are tuberculous lymphadenitis and goiter, except the cystic variety. In glandular disease, the results are permanent. In goiter, they are exceedingly gratifying, especially in the exophthalmic type, when seen sufficiently early. I have had twenty-four such cases, in which a cure seems to have been effected. In rodent ulcer, epithelioma and sarcoma of the skin, the Roentgen-ray is most effective; results are obtained in less time and at less expense than with any other method. Lupus, acne, chronic eczema and psoriasis are also tractable. Even in leukemia many good results have been obtained. Malignant tumors on or about the eyelids can be removed easily. Post-operative radiation should be employed as a routine measure after the removal of every breast for carcinoma or sarcoma, especially when there has been glandular involvement.

Roentgen-Ray Treatment of Carcinoma of the Breast

DR. RUSSEL H. BOGGS, Pittsburg, Pa.: In inoperable cases the ray will cause cessation of pain and hemorrhages, abolish discharge and offensive odors and arrest progress of the disease and bring about improvement in the general health of the patient. In some cases, the mass is reduced to such an extent that it will become operable. I have had twenty cases in which the results have been gratifying, but I would advise physicians not to depend on the rays alone, but to enlist surgical aid whenever possible, even in the inoperable cases. The pain in my cases was relieved for a period averaging a year, and in nearly every case the mass was reduced in size, the patient being free from pain and able to attend to her duties. Preoperative treatment is also of great benefit, and one surgeon has all his patients of this kind treated before operation. Postoperative treatment has been adopted by a large number of surgeons; it seems to insure a longer period of freedom from recurrence.

The Roentgen-Ray in Malignant Disease

DR. J. RUDISILCINSKY, Cedar Rapids, Ia.: My experience in the use of the ray in the treatment of malignant disease has been a satisfactory one. It not only often effects a cure, but in operative cases it prevents metastases. It is best to ray both before and after operation, because the infiltrated lymph channels and glands will be converted into fibrous cords and knots, thus preventing metastases. In the inoperable cases much good may be done.

DISCUSSION

DR. ALFRED L. GRAY, Richmond, Va.: The only trouble about preoperative treatment is that it may be given beyond the period when an operation will benefit the patient. This time no one can determine, and, therefore, it may be valuable time lost to proceed with Roentgen therapy. I am heartily in favor of giving a maximum dose just prior to the closing of the wound, while the patient is still under the anesthetic.

Aside from the physical benefit given in the inoperable cases, one of the greatest advantages of treatment by the Roentgen-ray is the comfort to the patient's mind. The patient feels that something is being done; this maintains his interest in life, and thus prolongs it for many days.

DR. W. F. MANGES, Philadelphia: I believe in the operative treatment mainly because so many surgeons are beginning to consider every breast carcinoma inoperable. The influence of such a procedure will be that in time patients having a lump of any size, however small, in the breast will proceed to the surgeon for advice. One surgeon advises Roentgen treatment if enlarged glands can be felt in the axilla, the treatment to be continued until such time as an operation seems indicated.

DR. H. K. PANCOAST, Philadelphia: In one case the breast was removed and the axilla cleaned out, but not the supra-clavicular region. Roentgen-ray treatment was begun soon afterward and administered for thirty or more days. The patient was told to return in three months, but returned before that time because of a ring of nodules, extending from the posterior axillary fold around almost to the sternal line. They were entirely outside of the area of exposure, showing that the ray was effective in preventing a recurrence in the area treated.

DR. GEORGE E. PFAILER, Philadelphia: I am more convinced than ever of the efficacy of Roentgen-ray treatment of malignant disease. In one case of ulcerating mammary carcinoma which was pronounced inoperable, I succeeded in reducing the lesion to an easily removable scar, an inch in diameter. The patient is perfectly well to-day. I feel that we should treat these patients until they are ready for operation; that is, until the disease has become localized. I do not agree to the giving of a large dose before the wound is closed.

Roentgen-Ray Treatment of Leukemia

DR. HENRY K. PANCOAST, Philadelphia: As a result of the observation and treatment of twenty cases, I am forced to the conclusion that the Roentgen ray seems to be no more than a palliative measure in leukemia—one which affords a prolongation of life for a variable period through inhibition of abnormal cell proliferation. It is necessary to ray the bones as well as the spleen. The direct exposure of the bone marrow seems to produce a more powerful and more lasting inhibitory effect on the leukocytic substances. The applications are made over the bones of the entire skeleton, each area being exposed regularly and systematically. Exactness in dosage is essential, so as to avoid a toxic reaction. Prolonged periods of rest from treatment are to be avoided. A symptomatic cure has in some instances been sufficient to prevent a relapse and ultimate death.

Bone Cysts

DR. F. H. BAETJER, Baltimore, Md.: The radiogram has assumed a place of importance in differentiating bone cysts from sarcomas, thereby saving many patients a mutilating operation. In the case of the bone cysts, the bone seems to be swollen, the cortex thinned out and the medulla replaced by a smooth, dark shadow of uniform consistency. The cyst is walled off from the rest of the bone and there is no evidence of an invasion of the shaft. The periosteum is not involved. These are the essential points of difference between bone cyst and other diseases of the bone. I have had six cases, in three of which a clinical diagnosis of sarcoma had been made. In one case the arm was amputated, and when the plate was sent to me afterward I pronounced it a bone cyst, and the pathologic findings confirmed this diagnosis. All that needs to be done in the case of a bone cyst is to open and evacuate it.

Stereoscopic Radiography

DR. EMIL G. BECK, Chicago: Stereoscopic radiography will help solve the problem of correct interpretation. I have employed this method almost exclusively for several years, and as a result I am convinced of its value. I am a strong advocate of stereoscopic work. It will enable even the general practitioner to interpret plates correctly. Shadows may be studied more profitably, and depth and size determined

more easily. In the study of fractures and dislocations, the location of foreign bodies, and in the study of diseases of the bones and joints, of sinuses and abscess cavities, stereoscopic radiography is exceedingly valuable.

Mental Disturbance Caused by Painless Dental Lesions

DR. HENRY S. UPSON, Cleveland: I have had some experience with mental cases, ranging from psychasthenia to dementia præcox and imbecility, in which the exciting cause proved to be some painless dental lesion, such as an impacted tooth. My attention was called to this fact accidentally, and since then I have made it a routine practice to have a skiagram made of all these cases, with the hope of finding some irregularity about the teeth and jaw. I consider the use of the Roentgen-ray in diagnosis as necessary as the stethoscope and the thermometer. Deep-lying lesions are usually painless, but are often disastrous as irritants. I am firmly convinced that in my cases the mental aberration was caused by impacted teeth, alveolar abscess, and other dental lesions.

DISCUSSION

DR. W. C. HILL, Cleveland: The ill effect of eyestrain and adenoids is well-known, and there is no reason why the teeth should not be considered in the same class. Marked irritation from a tooth is fully as disastrous as the irritation of eyestrain. I have seen some of Dr. Upson's cases and can verify his statements.

DR. H. K. PANCOAST, Philadelphia: During the past year I have made skiagraphs of several hundred dental patients, some of whom were Dr. Upson's. I am convinced that peripheral irritation often is responsible for obscure neuralgic pains; and there is no reason why mental aberration should not be produced in the same manner. Recently, I was asked to examine the head of a patient for possible brain tumor or old fracture to account for persistent headaches. The skiagram was made and showed the presence of an impacted molar in both upper and lower jaws, and evident disease of the antrum on the same side.

DR. FEDOR HAENISCH, Hamburg, Germany: I saw one very interesting case of severe trigeminal neuralgia. The patient had been subjected to several operations, but secured only temporary relief. I made several skiagrams of the head, but failed to find anything to account for the trouble. Finally, I made a skiagram of the mouth and found imbedded in the jaw a part of a root of a first bicuspoid. This was removed, the pain ceased within a week and never recurred, after having been persistent for almost seven years.

DR. C. E. COON, Syracuse, N. Y.: I had one case of persistent torticollis, in which the removal of a third molar, which was crowding the first and second molars, effected a speedy recovery.

DR. W. F. MANGES, Philadelphia: A case of persistent neuralgia, in which a bicuspoid had been extracted and later the root of this tooth removed, was shown by the skiagram to have been caused by a single little thread of gauze that had been left behind after the removal of the drainage. This thread was removed and was coated with calcareous material. The patient immediately recovered.

DR. G. C. JOHNSTON, Pittsburg, Pa.: I have seen a number of nervous wrecks among women in which the cause was an impacted tooth.

DR. GEORGE E. PFAILER, Philadelphia: A theologic student had been told that he was suffering from dementia præcox, and was advised to discontinue his studies. I made a skiagram of his mouth and found an abscess at the root of one of the molars. This was treated, and a month later the man had made a complete recovery. In another case, I found the roots of six teeth abscessed. We must make the physical examinations complete, and not limit ourselves to an examination of any one part of the body.

Chronic Joint Disease from Roentgenologic Standpoint

DR. ROLAND HAMMOND, Providence, R. I.: I wish to emphasize the importance of recognizing visceroptosis as a causative factor in chronic joint disease. It may be congenital

or acquired, the latter usually being the ease. It is due to faulty attributes of the body, relaxed conditions of the suspensory ligaments of the viscera, atony of the abdominal walls, skeletal deformities. The Roentgen-ray is particularly useful in determining the character of the changes in the joint. It discloses distinctly thickening of the synovial membranes, ligaments and tendons, change in bony structure, villous growths and accumulations of fluid. Atrophy and hypertrophy are easily recognized. In infectious arthritis the skiagram may not show any change in the joint, even though ankylosis may be present. These cases are probably due to the presence of toxins rather than bacteria. Gout and the various types of rheumatoid arthritides are easily recognizable in the skiagram. The careful use of the Roentgen-ray in the diagnosis of obscure joint affections invariably proves profitable.

Removal of Foreign Bodies Under Fluoroscopic Examination

DR. CHARLES F. BOWEN, Columbus: I have done considerable work with the fluoroscope in removing foreign bodies from the bronchi, trachea, esophagus and elsewhere. I use a special cable for this work, so that both the patient and I are sufficiently protected from the rays. The work can be done very quickly, and much more successfully, than can the average operation performed without the use of the fluoroscope. This method is applicable only in cases in which the foreign body is dense enough to cast a shadow on the fluoroscopic screen. By this means I have succeeded in removing foreign bodies from the esophagus and bronchi in cases in which the surgeons failed utterly. This work must be done under thorough antiseptic precautions, and by a roentgenologist who has surgical experience.

Tumor of Hypophysis

DR. HARVEY CUSHING, Baltimore: For the purpose of determining the exact configuration of the sella turcica, the x-ray is invaluable. It has become one of the most important adjuncts of our diagnostic measures. This is a matter of importance since surgery has found ways of approaching the gland with reasonable freedom from risk. The only cases in which operative measures are justified are those in which the local symptoms are pronounced, and in which the skiagraph shows an enlargement of the sella turcica.

Stereoskiagraphy of the Urinary Tract

DR. EUGENE W. CALDWELL, New York City: I have found the stereoscope almost indispensable in this work. Accuracy is of such great importance, that we cannot neglect any procedure which will be useful in occasional or unusual cases. It is imperative to make at least two complete sets of plates, using proper appliances and technic. A styleted ureteral catheter or an air-inflated bag in the rectum or vagina will aid in determining the exact position of the ureters.

MICHIGAN STATE MEDICAL SOCIETY

Forty-Fifth Annual Meeting, held at Bay City, Sept. 28-29, 1910

(Continued from page 1492)

Use of Carbon-Dioxid Snow

DR. ANDREW P. BIDDLE, Detroit, spoke on the use of carbon-dioxid snow, and demonstrated a new instrument for moulding snow.

DISCUSSION

DR. HENRY R. VARNEY, Detroit: In many of the small benign growths, and in nevi, especially of certain depth, and in lupus erythematosus and lupus vulgaris, this treatment is excelled by no other means of medication or operation. When we destroy a wart, mole, rodent ulcer, or epithelioma, and destroy the pathologic tissue and go through into the true skin, we must expect some discomfort, some pitting, some scarring, so that to promise the patient that there will be no effect following the application of the snow is to my mind a little

bit far-reaching, and I am afraid if we do that we will be a little disappointed. There is no pathologic condition, such as a mole or wart, that we cannot help by application of the snow if we avoid the healthy surrounding tissue. A number of these lesions will recur if other stimulants are not employed to encourage or stimulate the surrounding healthy cell, and replace the destroyed tissue.

DR. A. W. CRANE, Kalamazoo: Carbon-dioxid snow is a destructive agent. It does what an operation would do, namely, destroys the pathologic condition and a certain amount of tissue, and recovery occurs as a process of healing with the pathologic tissue in place. It may be possible that there are some products absorbed into the system so that there will be some blood serum reaction with carbon-dioxid snow. If that is true it would rival the x-ray. The x-ray treatment of a skin lesion, or epithelioma of the skin, is in the long run a blood reaction. It is not a process of local destruction. The skin lesion will heal in some cases even without local inflammation, but in a case of lupus, for instance, if the blood be examined, it will be found that the opsonic index will rise after every x-ray treatment just as though there were a vaccine of a tuberculous substance injected. In some way or other, by the use of the x-ray, we have introduced a vaccine into the circulation.

DR. M. L. HOLM, Lansing: In a case which had been diagnosed lupus, and in which the lesion tended to spread around the nose, the man was treated for three months with the x-ray, and the lesion continued to spread. The patient then went to Dr. Biddle, and within three weeks after the treatment with carbon-dioxid snow was begun, the lesion was practically healed. Whether there will be a recurrence or not, I do not know.

DR. F. W. ROBBINS, Detroit: We must not take too much into account the fact that the tissue has been destroyed, because those who have had experience before these two methods were mentioned apply caustic paste to an epithelioma, and after removing the paste from a tumor or growth an inch in diameter, they would find that healing had taken place.

DR. A. BIDDLE, Detroit: This treatment is not brought forward as a cure. Those who have watched the development of the x-ray know that its limitations in skin diseases have been very great. I know that in some cases the patients are better operated on by the knife, but I claim from clinical experience that there are patients who will not submit to the knife.

Points in the Management of Breast Feeding

DR. THOMAS B. COOLEY, Detroit: If successful breast feeding is to be as common as it ought to be, the general practitioner must give it more attention, and must become better versed in the detail of its management. Contraindications to nursing are not so numerous as some physicians seem to think; artificial feeding is often adopted for very trivial reasons. The contraindications may be summed up as follows: first, the possibility of transmitting a serious infection; second, the danger of a serious drain on an ill or exhausted mother. The last should not be too readily assumed. Under other conditions nursings should be attempted. Rational, normal hygiene and diet are essential for the mother. Unnecessary restrictions in the diet, or distasteful additions, may disturb her nutrition, and thereby the milk supply. Rational exercise and freedom from worry or excitement are important. Gruels and other supposed lactagogues are to be used when needed rather than as routine measures. The intervals between nursings should be at least three hours always, and four hours after the first few weeks. It gives the child's stomach rest and lessens colic and other annoying symptoms; the child also sleeps better and is more comfortable. Feeding by the clock is not advised. Within reason, the child should be fed when it is hungry. Colic is usually a result of fat indigestion; it is less frequent with the longer interval. Over-rich milk is a common cause, and this may be corrected often by diet and exercise, or by giving water before nursing. Over-feeding is also a cause. Even when persistent,

it is not an excuse for weaning if the baby is thriving. Variations in quantity and quality of milk are common. Quantity should be ascertained by weighing before and after feeding. There is no absolute standard of quality, and the best guides are the behavior of the child and the character of the stools. Mixed feeding is indicated by failing supply. The old method of replacing one or more nursings by the bottle is not so good as to supplement each nursing by a small bottle feeding. The supply of breast milk can be maintained longer in this way. Weaning for insufficient reason is altogether too common. Before the sixth month it should be done only on account of failure of the breast milk, serious persistent digestive disturbance, or failure of the child to gain under careful intelligent handling. The normal weaning at nine or ten months is best managed through a course of mixed feeding.

DISCUSSION

DR. H. McLAREN GALE, Bay City: First the essayist emphasized the regular and liberal feeding of the mother with plain food, and then insisted on feeding of the child at three to four-hour intervals in place of the two-hour interval. It is unnatural and cannot but be injurious. For colic in children care in the diet is the main thing, as the cause of colic is too frequent feeding.

DR. HERBERT M. RICH, Detroit: On one point I am sure Dr. Cooley will agree with me, and that is the use of wet nursing in substitute feeding. It can hardly be denied that if a very young child can be given mother's milk, it is the thing to do. In this country this method has not been employed to any extent as it is abroad, but we should encourage the practice of wet nursing.

DR. E. E. CURTIS, Saginaw: In regard to wet nursing, I would like to offer some suggestions that I have found of considerable value, and that is procuring for the baby two or three wet nursings a day. I have found that when bottle-fed babies a month or two old were failing if they could have one or two nursings a day some lives have been saved.

DR. JOHN H. CROSBY, Otsego: There are very few contraindications to breast feeding. Certain women have no milk at all, and they must be ruled out, but in most cases of so-called contraindications it is simply mismanagement of the feeding. If in these cases we pay attention to the management of the proper interval and the proper length of time of nursing much will be accomplished in saving the breast to the child, and every day that the baby takes breast milk its chances are so much the better for life. I had an opportunity not long ago to observe the methods of feeding in some of the clinics in Berlin, and I found that in the hospitals four-hour intervals are followed in every case for the first six weeks. The baby was fed six times in twenty-four hours, and after six weeks were up, the normal child was fed five times from 6 o'clock in the morning until 10 o'clock in the evening, and nothing from then until 6 o'clock. The results were uniformly good.

DR. M. L. HOLM, Lansing: From a laboratory standpoint, we find that if the milk is sufficient in quantity, and the child is not doing well, the majority of physicians think first of having the milk analyzed. I find that about two-thirds of the milk sent in for analysis is the first portion of the milk, and those who send it in are surprised to find that the fat contents will amount to 1.5 or 2 per cent. Invariably when milk is taken for analysis the entire amount should be taken. If less milk is collected it will be high in fat. As a general thing, I think the fat contents is a good indication of the quality of the milk. The entire milk of one breast should be collected, and even the whole, or a portion of it presented for analysis.

DR. T. B. COOLEY, Detroit: In my experience protein indigestion is very rare in a child at the breast except in case of overfeeding. If a child is overfed all around, and there is too much milk, there will be general indigestion; but otherwise protein indigestion with breast milk is a rare experience. Wet nursing is not so common as it ought to be in this country. It is one of the greatest helps in managing babies, and the general practitioner appears to be too confident of the success of bottle feeding.

Tuberculosis in Children

DR. HERBERT M. RICH, Detroit: The last word has not yet been said in regard to tuberculin tests. Von Pirquet himself does not claim that the tuberculin test is especially suitable for infancy, and I have used it up to the age of 2 years. If the Pirquet reaction is positive under the age of 2 years there is probably a tuberculous process which has not yet been quiescent very long. I have seen two cases of severe conjunctivitis at the children's hospital from the use of the Calmette tests, and the fact that tuberculous chorioiditis is not unusual in small children is an argument for care in its use. I have used the Moro test very little. I have tried it a few times, but have found the v. Pirquet easy to use and satisfactory. The points to be emphasized are that nearly everyone is affected with tuberculosis in childhood, and if physicians are to combat it successfully we must realize that. A number of cases of malnutrition, marasmus and some others which I have seen at autopsy showed broken-down glands, and this has led me to believe that the disease is much more common than we suspect. If we are going to make a great advance in the treatment of tuberculosis we must do it in children. The way in which we will finally conquer tuberculosis, if we do conquer it, will be to teach the children in school and to eliminate school children as the source of infection.

DISCUSSION

DR. VAUGHAN, Detroit: I was glad to hear Dr. Rich say that pulmonary tuberculosis is more common in children than is generally supposed. I was led to think that I could find tuberculosis where it did not exist. In connection with my work on the board of health in Detroit I have had occasion to examine many children of poor families, and have found them infected with tuberculosis to an appalling extent. Whereas the results of physical examinations are somewhat doubtful and dubious owing to the characteristics of the breast sounds in children, still certain of those do show signs not only of consolidation, but also of cavities which were apparent on very superficial examination. I have taken as a rule children of tuberculous parents, having subjected them to the tuberculin test. If they reacted positively they were transferred to the hospital for a period of observation, and without exception these small children have shown clinical evidence of active tuberculosis, as indicated by a rise of temperature to 100 F., and by rapidity of the pulse, both being combined at some stage during the day. My experience has been that these children do remarkably well.

DR. JOHANN FLINTERMAN, Detroit: We do not know where to seek the cause always, but if we investigate these cases and at the time the diagnosis is made take in the whole clinical picture, we would never fail to see that it is tuberculosis.

DR. THOMAS M. KOON, Grand Rapids: In the last two or three years I have used the v. Pirquet test extensively. I have now in the state sanitarium six patients whom I sent there, and in every one of whom I used the v. Pirquet test. The symptoms, the early history, and the findings in each case pointed to the individuals having tuberculosis. On top of that I gave the v. Pirquet test; they reacted, and I felt safe in concluding that I was dealing with cases of active tuberculosis. The Calmette test is considered dangerous by a great many workers, and there is a wide difference of opinion about it.

DR. JOHN H. CROSBY, Otsego: The v. Pirquet test is of value up to 6 months of age, and if a positive reaction is obtained up to that time one can say that the child has active tuberculosis. After that one can simply say that the child has or may have had active tuberculosis. The only positive contraindication for breast feeding in children is tuberculosis in the mother.

DR. FRANK SMITHIES, Ann Arbor: From personal observation of between 600 and 700 instillations of tuberculin into the eye, I may say that only in five cases have there been any serious results, and I may add, at the same time, that if careful examination of the eye had been made previous to the instillation, or if the patient had been kept under close observation it is extremely doubtful as to whether there would have been any deleterious effect whatever.

A Business-Man's Cold

DR. J. VERNON WHITE, Detroit, spoke of vocation and habits as etiologic factors in a common cold; how to prevent a cold; how best, and to what extent a physician can formulate a system of treatment by which a man can continue with his business without jeopardizing his health.

(To be continued)

MEDICAL ASSOCIATION OF THE SOUTHWEST

Fifth Annual Meeting, held at Wichita, Kan., Oct. 11-12, 1910

The President, DR. G. H. MOONY, San Antonio, Texas, in the Chair

Addresses of welcome were delivered by Hon. C. L. Davidson, mayor of Wichita, Dr. O. P. Davis, president of the Kansas State Medical Society, and Dr. E. J. Oldham, of Wichita, Kansas, and were responded to by Dr. J. Beeton, Greenville, Texas.

Colica Mucosa

DR. E. H. THRAILKILL, Kansas City, Mo.: I have chosen the designation colica mucosa from the long list of names that have been proposed for non-infectious diseases of the mucous membrane of the colon. It is most appropriate for it designates the passage of mucus and the attacks of colic. Formerly, this subject was considered a constitutional disease, owing to the lack of scientific knowledge of the etiology and pathology, but in recent years various views and opinions have arisen and have been published. I have adopted the following classification:

1. Those cases due to a motor and sensory neurosis I designate as simple colica mucosa.
2. Those due to extracolonic conditions, causing interference with the movement of the fecal discharges, I designate as colica mucosa reflexa.
3. Those due to an extension of the inflammatory process from the rectum or appendix, or when due to the retention of hardened fecal masses, foreign bodies, or to the prolonged use of cathartics, causing an inflammatory condition, I designate as mucosa colitis.

Each class requires a different treatment surgically and medically.

In chronic cases, or in those due to a mechanical interference or an inflammatory process, the mucus is thick, tenacious and attended with considerable pain, due to the strong peristalsis of the bowel in its effort to dislodge and expel it. The majority of these patients give a history of disturbed digestion or constipation, preceding the onset of this affection. I have had patients give a history of diarrhea preceding or accompanying this trouble. As a rule, the diarrhea was caused by a diet composed of a concentrated food and the lodgment of fecal crumbs throughout the bowels.

DISCUSSION

DR. ARTHUR E. HERTZLER, Kansas City, Mo.: The classification given is very sensible. The difficulty that has arisen in our conception of this disease has been due to confusing the various classes of cases. In some cases the condition is neurotic; in others it is not. We have not used so much care as we should have done in separating the different cases. A patient may present a history of some neurotic condition, and the natural inference is that the trouble is the result of nervous disease, and yet the disturbance may be secondary to some abdominal lesion which is obscured by the existence of the organic trouble. Unfortunately, we are not in possession of enough knowledge of the abdominal conditions which develop in these nervous states. Most of the cases of colica mucosa I have seen have been in neurotic subjects, who have responded to treatment by the neurologist. There are a number of cases attended by stomach disturbance, and in others by diverticular formations, and yet there is no definite pathologic lesion or defined symptomatology.

DR. G. W. ROBINSON, Kansas City, Mo.: My experience with colica mucosa has been confined chiefly to cases among the insane. This condition is more frequent among them than in any other class of patients. Constipation is common among insane patients, and we find that there is a disturbance of the

function of the cells of the central nervous system, and I believe this condition is chiefly a perversion of the secretory nerves as well as the motor nerves of the intestine.

Postoperative Care and Treatment of Suprapubic Prostatectomy

DR. D. W. BASHAM, Wichita, Kan.: Suprapubic prostatectomy offers a marked exception to the expectant plan of post-operative treatment. The after-treatment is fully as important as the operation itself. Many patients either would die or would recover without full functioning power of the bladder unless they had suitable treatment during convalescence from the operation. Suprapubic prostatectomy should not be performed outside of a hospital, unless an experienced male nurse can be left with the patient to attend to the details of after-treatment. Most of these patients are in an enfeebled condition, brought about by years of catheter life with infection of the bladder accompanied with pain and vesical tenesmus. Frequent attacks of urinary stasis may have resulted in an ascending pyelitis. These conditions may all be aggravated by prolonged and crude efforts to pass the catheter. It is possible for pyelitis to be provoked after operation, provided the drainage is not absolutely unobstructed. Drainage is indispensable in most cases of suprapubic prostatectomy. There are a few cases in which the bladder may be closed and urethral drainage depended on, but they are not numerous. The rubber tube having a diameter of not less than half an inch, fenestrated toward the end and having the edges pared to a feathery thinness, constitutes the best method of drainage. If the tube be even larger in caliber, it is still better. Hemorrhage may be controlled and treated through a large tube. The method of placing the drainage tube is important. Neither the drainage tube nor the bladder should be stitched to the abdominal parietes. It is better for these patients to get out of bed early. This facilitates both drainage and the early passage of the urine through the urethra.

DISCUSSION

DR. JABEZ N. JACKSON, Kansas City, Mo.: I am a strong advocate of the perineal route in removing the hypertrophied prostate rather than the suprapubic. In my early practice I resorted to the suprapubic method, but abandoned it subsequently for the perineal, as one of the great difficulties attending the former is the establishment of proper drainage through the suprapubic wound. If I were going to do a suprapubic prostatectomy as a routine measure, I should be inclined to employ the method of Senn, namely, do the operation in two stages, the first stage consisting of making an incision down to and exposing the bladder wall, followed by packing until the cellular space about the bladder is closed by granulations, then making an opening through the bladder. In this way, we do away sometimes with disagreeable infection which takes place in the freshly exposed cellular tissues and which ultimately interferes with the healing of the wound.

DR. BRANSFORD LEWIS, St. Louis: I have always advocated catholiticity in connection with this subject and freedom from being restricted to any one operation, still my preference is for the perineal operation in selected cases. I have never been converted to the use of a large tube, such as is used by Freyer and others, because I have not been able to see the advantage of it, particularly when drainage can be accomplished just as effectually and satisfactorily by a smaller tube which will entail a shorter time for convalescence and granulation than a very large tube. The formation of clots can be prevented by the siphonage apparatus of Bremerman, of Chicago.

DR. E. G. MARK, Kansas City, Mo.: While I favor the perineal route in most cases, yet there are instances in which the suprapubic is unquestionably the one of choice. The main thing after suprapubic prostatectomy is drainage, and patients with hypertrophied prostate requiring prostatectomy practically always have cystitis. To obviate the occurrence of hemorrhage, to secure efficient drainage, and to do away so far as possible with the formation of clots following cystotomy, nothing in my hands has proved so valuable as continuous irrigation for 24 or 48 hours.

DR. J. D. GRIFFITH, Kansas City, Mo.: I have done more suprapubic operations than perineal. While I admit the advantages of the perineal route, I think with Freyer that there are many cases in which a suprapubic cystostomy is demanded, and that efficient drainage is the thing *par excellence*. I believe in irrigating the bladder and in siphonage, and I believe in protecting the space of Retzius with gauze.

DR. HOWARD HILL, Kansas City, Mo.: I favor the use of a large tube through the incision after suprapubic prostatectomy, as I believe it is more advantageous than a small one. After the operation, continuous irrigation with hot water, with the patient propped up well and on the side, will control the hemorrhage. Hemorrhage is one of the serious objections to suprapubic prostatectomy, because it occurs from the time the operation is begun, and hemorrhage marks the first stage in the after-treatment of the patient. In regard to suturing around the tube to prevent leakage, one can secure the skin and bladder together.

DR. G. B. NORBERG, Kansas City, Mo.: My experience has been confined largely to operating on these hypertrophied prostates by the perineal route, and I prefer it to the suprapubic operation.

DR. D. W. BASHAM, Wichita, Kans.: It is evident that the last word on prostatectomy has not been said. Each speaker has voiced his own convictions in the matter, and that spirit is to be admired because it is in that way we advance our knowledge. This is an important operation and it behooves us to master all the details connected with it in order that we may increase its safety.

New Method of Cure for Pelvic Infections in Women

DR. J. F. KUHN, Oklahoma City: Peritoneal infections of the pelvis are easily controlled, because with the Fowler position the infectious material is confined to the pelvic cavity, where toxins are more slowly absorbed than in the upper peritoneal regions, and in consequence the system produces antibodies rapidly enough to counteract their effects. I wish to lay special stress on the treatment through the rectum with normal saline solution. By the method I suggest, the rectum is distended at six hourly periods with from one to four pints of the solution at 105 F., the quantity being gradually increased as tolerance for a larger amount is established. Intermittent periods of hyperemia are produced, thus hastening the destruction of the infecting organisms, inducing more rapid absorption of the resultant plastic lymph, and preventing the formation of dense adhesions so commonly seen in the neglected cases. It has all the other advantages of normal saline solution, stimulating and aiding the emunctories in ridding the system of the products of infection; fortifying the system during its struggle to produce antibodies and finally, by the action of heat locally, relieving the patient of the distressing pain which is the chief complaint. One patient suffering with streptococcus puerperal sepsis was delivered March 10, 1910, and 5 days later had a chill with high fever and great tenderness throughout the whole pelvis. She was placed on this treatment until March 31, when the saline was withdrawn for a few days, to be continued thereafter at twelve hourly intervals. She made a complete and uninterrupted recovery.

DISCUSSION

DR. A. E. HERTZLER, Kansas City, Mo.: In the first stage of gynecologic gonorrhea, the women are put to bed, their bowels are moved, and practically nothing more is done. The result of this line of treatment runs something like this: About two-thirds of the patients recover their health; about one-quarter of these two-thirds will conceive. The remaining third will come to operation. At the end of the first few days there will be a leukocyte count of from 15,000 to 25,000, which will drop down to normal in two or three weeks; this drop is preceded by a drop of the temperature to normal. The temperature falls to normal usually ten days before the leukocyte count does. I have obtained excellent results from the use of autogenous serum in chronic cases of gonorrhea; but experience with the stock serum has not been satisfactory.

DR. J. A. WALKER, Shawnee, Okla.: I have not tried the method outlined by Dr. Kuhn. Usually within a reasonable

time inflammation of the Fallopian tubes will subside and incarcerate itself by the adhesions of the fimbriae and, ordinarily, by occlusion of the uterine end of the tube. The pus cavity will thus be isolated from the general peritoneal cavity, though not sufficiently to prevent the formation of strong adhesions to the surrounding tissues. So long as adhesions are present the patients are going to have trouble. If the inflammation is of a streptococcus nature, the adhesions are more liable to be dense than if they are from the Neisser coccus; and when the adhesions are so strong and dense, I do not believe it is wise to be too conservative and wait too long before breaking them up and removing the foreign body, which an old collapsed occluded tube is bound to be. My practice has been to wait a reasonable time for the inflammation to subside and, perchance, for the pus after having become sterile to be reabsorbed. If I think such a thing has not occurred, I remove the tube, leaving all ovarian tissue possible.

DR. J. D. GRIFFITH, Kansas City, Mo.: We know how dangerous infection is from the Neisser coccus and how frequently we meet it. I have used the serum in these cases, and I have used the knife. I have resected the tubes and tried to save organs that I thought would functionate, but the treatment Dr. Kuhn has outlined in the acute stage of filling up the rectum with normal salt solution, with the patient in the Fowler position, I have never tried, but in the next case which presents itself, I am going to do so.

DR. J. F. KUHN, Oklahoma City: If in a community not larger than Oklahoma City I can treat a series of twenty-eight cases with the treatment I have outlined without a failure, Dr. Griffith and others can certainly achieve the same results in the larger communities in which they practice. I hope they will try the method.

(To be continued)

PHILADELPHIA COUNTY MEDICAL SOCIETY

Regular Meeting, held Sept. 28, 1910

The President, DR. HENRY LEFFMANN, in the Chair

Ehrlich's "606" in Syphilis

DR. HENRY W. CATTELL: I shall simply speak to-night on the technic used in Wechselsmann's wards of the Virchow Hospital in Berlin for the treatment of syphilis with Ehrlich's "606," and make no attempt to review the rapidly increasing literature on this subject. Toward the end of July, I saw five injections given and had the opportunity of examining about 100 patients in all so treated. Our knowledge in regard to syphilis has been increased by: (1) the discovery of the active agent, by Schaudinn and Hoffmann; (2) the diagnosis of the poison by means of the Wassermann reaction, or one of its various modifications; (3) the inoculation of apes, rabbits and guinea-pigs with syphilis. The capsule containing the yellowish compound, dioxidiamidoarsenobenzol, is broken and collected in a sterile mortar, and dissolved in from 1 to 2 c.c. of concentrated sodium hydrate. Methyl alcohol is no longer employed. After solution has taken place, the preparation is again precipitated by the addition of glacial acetic acid. From 15 to 20 cm. of sterile water are added, and the whole centrifugated, the supernatant water poured off, more water added, and the whole brought to neutral by the addition of either a decinormal solution of sodium hydrate or of a 1 per cent. solution of acetic acid. The dose used at the time I was in Berlin was from 0.5 to 0.6 gm. for an adult and 0.025 gm. for an infant. The preparation is injected in a large syringe beneath the scapula, in an area which has first been painted with iodine. One of the strong reasons for choosing the subscapular region is that, in case of arsenicalism, the location is easy of access surgically. A lump is formed which requires some time to disappear. The injections are sometimes followed by pain, fever or malaise, immediately afterward, or coming on after several days. The oldest case of inoculation is now between 11 and 12 months, and Ehrlich must have now nearly 8,000 records, with 7 deaths. It is

marvelous to see a patient come into the wards with pronounced evidences of the disease, and to observe the immediate improvement after treatment. The spirochetes begin to disappear the first day, and in from 48 to 72 hours they are no longer to be found. The Wassermann reaction may, however, remain positive for several weeks. A test similar to that employed in the Calmette or von Pirquet reaction must always be made to determine whether or not the patient has been treated before by arsenic or is peculiarly susceptible to the drug. Ehrlich insists that everybody, before being inoculated, should have the eyes examined and that the physician should ascertain that there are no complications, like grave heart or kidney disease present. This mode of treatment has been carried out by the best observers that Europe affords, and has been undertaken under control conditions, such as have never existed before. The results so far have been astonishing, though I saw three patients in Wechselmann's hands who had returned for a second treatment. The reason given for this was that theirs were some of the earlier cases, in which too small a dose had been administered.

DISCUSSION

DR. L. JAY HAMMOND: Is the preparation used in cases of definite lesions of syphilitic origin, especially in lesions of the central nervous system? My impression has been that Ehrlich advised against its use when such lesions were present, even though there was other evidence of syphilitic conditions.

DR. CATTELL: The users of this remedy are so enthusiastic that they advise it in practically every case. In one of the wards there were no less than ten syphilitic babies suffering from every manifestation of inherited syphilis.

SYMPOSIUM ON HOME TREATMENT AND MANAGEMENT OF TUBERCULOSIS

Home Treatment of Tuberculosis

DR. H. R. M. LANDIS: The necessity of home treatment becomes apparent when we realize that fully 95 per cent. of tuberculous patients must be treated in their homes at least some time during the course of the disease. Home treatment cannot be applied in every case. Simple as the requirements are, we must at least be sure of these if the treatment is to be successful: First, the patient must be willing to obey instructions faithfully; second, he must be able to obtain sufficient aid to get proper food and to be at rest, and third, the home itself should be hygienic. The advantage of home treatment lies in the fact that an individual who has recovered in the locality, and under the conditions in which he will continue to live, is more apt to remain well. The underlying principles in the treatment of tuberculosis are the same, no matter whether applied at the sanatorium, in a health resort or in the home. If there is any difference, it is in the strict attention to details which are so necessary in the home treatment of tuberculosis. Here nothing can be left to chance. What the patient learns he learns from the physician and the visiting nurse, not from the routine practice of the sanatorium. In addition to medical treatment, the problem is a hygienic, a social and an economic one, and all these factors should receive attention.

Rest, Exercise and Food in Tuberculosis

DR. A. P. FRANCINE: In the management of this disease nothing is more important than the proper adaptation of rest and exercise to the individual case. The importance of rest is generally understood; it is the strong arm of the treatment, and is the best agent in combating symptoms. In all moderately advanced cases in which there are fever, rapid pulse, cough, etc., the patient should be confined to bed until these symptoms are relieved. Most patients are better off for a preliminary rest cure, and in the beginning of treatment, even in incipient cases, the individuals should take as little exercise as possible. In poor patients, the necessity of earning a livelihood is an almost insurmountable obstacle to the rest cure, and for this reason such patients should be sent to a sanatorium or infirmary. In chronic cases in which the patients

have no fever or increased pulse rate, but suffer every morning with a coughing spell which may cause vomiting, it is advisable for them to stay in bed till after this attack is over. They should then eat breakfast in bed and after that rest for an hour or two before getting up. Properly regulated exercise is valuable during convalescence, and this point should be emphasized, as there is a tendency to overdo the rest cure. Neglect of exercise is especially liable to occur in sanatorium treatment; it is true that there is a growing tendency to make patients take graduated exercise, but in most instances it is incomplete or ineffectual. There is too general a fear of producing attacks of auto-intoxication, and too great a desire to maintain the patient's weight at the highest point possible. Increase in weight is apt to be looked on as the index of improvement; in a measure this is true, but the individual's strength and endurance must also be developed. The final object of treatment must not be lost sight of; that is, not to make the patient stay well under ideal conditions, but to fit him to lead a life of reasonable activity and usefulness. If this treatment is properly carried out, the patient should be able, if necessary, to go back to the old environment and employment and remain well. The system of graduated labor carried out at the Brompton Hospital Sanatorium is to be highly commended. The patients are nearly all doing outdoor work in the fields and gardens. The work is harder than anything most of them had ever done before, but they all look and feel well. If a patient has a reaction he is put to bed at once and is compelled to remain absolutely still; as soon as he is able to be up again, he is put back at the same work.

In the matter of food, the home treatment of tuberculosis resolves itself into a matter of domestic economies. Strictly speaking, it is a social and economic rather than a medical problem. With the average type of poor consumptive, the food question is a very serious one; it may be considered under the following phases: (1) The cost of food; how can we feed a family properly on five or six dollars a week for food? (2) The choice and selection of foods among the poor and ignorant. (3) The preparation of the food. No class of people lives so extravagantly as the very poor. Their means make it impossible for them to buy in quantity, and their ignorance renders them unable to buy intelligently. While in the aggregate they spend what would be enough money to heat their houses well and cook their food properly, yet two-thirds is wasted. Food is selected which will require the least cooking or which may be easily cooked, as, for example, by frying. They never bake, but buy baker's bread. Vegetables are little used on account of the trouble of cooking, and this applies also to cereals. Pickles and jellies are much used, often at every meal. Tea and coffee are frightfully abused, children often being sent to school without any other breakfast. All these problems could be solved if there existed in connection with philanthropic agencies, and particularly in connection with tuberculosis dispensaries and diet kitchens, where patients could be sent to learn how to economize in the choice and selection of food; where they could learn the simpler rules of cooking, and could be instructed in the use of the fireless cooker, and where the supervision of the physician could be supplemented by easily learned facts in regard to habits of eating.

Ultimate Results in the Treatment of Pulmonary Tuberculosis with Mercury Succinimid

This article, by Dr. H. J. Hartz, appeared in full in THE JOURNAL, Sept. 10, 1910.

Discussion on Tuberculosis

DR. LAWRENCE F. FLICK: The home treatment of tuberculosis contains really almost all of the essential features of the sanatorium treatment of tuberculosis—complete control of the patient; the greatest amount of comfort of life; the best and largest amount of food and the greatest freedom from worry. It is my experience that these essential features can be accomplished better in the home than under what is called climatic treatment. We should bear in mind also that

something can be done by medication. Too much stress has been laid on hygiene, rest and climate, without any regard to medication. Fresh air is good, but we may go to extremes in insisting that the patient must sleep out of doors. That is ideal, but for practical purposes, a room with windows on two sides, with the bed near the open window, is sufficient, if everything else is right. The most important one factor in the treatment of tuberculosis is a proper food supply, of the kind which is adapted to the individual. I believe that we should select carefully the diet of each patient, adapt that diet to the capacity of the individual to digest the food, and watch closely whether we have the right diet by the weight. There does not need to be a fabulous increase in weight, but there must not be much decrease below the normal. As a general proposition, I would lay down the rule of one solid meal, three quarts of milk and six eggs a day, as the place to start from. This diet can be varied one way or the other. The prevention of reinfection is an important element in treatment too often forgotten. It should be remembered that, as a rule, there is no complete immunity against tuberculosis. Exercise, though a valuable asset, is sometimes a dangerous one. When in doubt as to its value, it is safe to maintain complete rest. Exercise can be used profitably provided it is graduated. Graduated exercise, I may say in this connection, did not originate at the Brompton Hospital at Frimley, but at White Haven. Severe coughing is frequently due to an overloaded stomach and indigestion, and these attacks may often be avoided by regulation of the diet.

DR. WILLIAM G. TURNELL: Public education has reached such a point that there is little difficulty in dealing with tuberculosis among the wealthy classes. In the treatment among the poor it is important that we adapt ourselves to their circumstances rather than try to reach ideal conditions. Only by understanding the home life of these people, as Dr. Landis and Dr. Francine pointed out, can we hope to help them. We must find out what a patient can do, learn for ourselves the prices of articles of diet, their food values, and how they should be cooked. If then we give this information intelligently our patients will follow directions.

DR. MYER SOLIS COHEN: If a small portion of the many acres of Fairmount Park could be set apart for a public tuberculosis camp, much of the difficulty in the home treatment of tuberculosis could be overcome. There would be practically no expense to the city; the camp could be placed on the line of the park trolley; the Red Cross Society or other agency would probably furnish reclining chairs, etc. The Board of Health, of course, should have charge of such a camp.

DR. A. B. IIRSH: In connection with the outdoor treatment of tuberculosis, two facts stand out in regard to the building of houses: In the Latin countries we find verandas on the second and third floor, and the part of a house which faces the prevailing winds stands back 10 or 15 feet from the first floor. In Philadelphia, much good could be done through the newspapers by urging builders to change their architecture and follow to some extent this method. Builders should be told that the streets between the main streets along which they put their double rows of two-story houses should run east and west, so that the prevailing winds should be of use to the families. Another advantage noticed in the buildings in Europe is the French window, which not only gives fresh air but adds to the esthetic appearance of the room.

DR. JOHN H. MUGGETT: In addition to hygienic treatment of tuberculosis, I use tuberculin, and I have had very good results.

DR. ALBERT P. FRANCINE: I consider Dr. Hartz's results important, because they have the effect of checking the use of mercury as a therapeutic agent in tuberculosis. Personally, I have felt that there was just enough plausibility in Dr. Wright's theories to be likely to deceive, and I have further felt that the probability of syphilitic infection in his cases was one of the probable sources of error in regard to his own views on the efficacy of mercury. I would not say that in so far as syphilis may be a factor in a given case mercury may not do good. However, I have had a number of tuber-

culous patients who gave a markedly positive Wassermann reaction, but who were without tangible syphilitic symptoms, and whom I have treated with mercury without any apparent benefit. I wish that Dr. Wright might be here to speak for himself, because there seems to be an element of unfairness in criticising a man's work in his absence. I think, however, that Dr. Hartz has made a strong case, and in so far as it should combat what might prove to be a serious fallacy in the treatment of tuberculosis, I endorse every word of it and congratulate him heartily on his careful work.

- 6 Three Cases Treated with Antigonococcus Serum. M. Zigler, New York.
- 7 *Fracture of the Pubic Bone. T. Abbe, Washington, D. C.

I. Management of Poliomyelitis.—Taylor thinks that time is wasted in treating anterior poliomyelitis with massage and electricity. The prevention of deformities and their correction is of the utmost importance. After deformity has taken place it is important to correct it by apparatus and operations. Improvement may be obtained even in cases of long standing by these measures, and a fair amount of motion obtained by careful balancing of the muscles.

2. Treatment of Diseases Among the Aged.—Craig reports 19 cases of various kinds in persons from 60 to 85 years of age in whom reactions were obtained to vaccines, chiefly of the streptococcus and staphylococcus. The mortality in spite of vaccines was 13 per cent.; 13 per cent. of deaths were from cancer.

7. Fracture of the Pubic Bone.—In the case reported by Abbe, a fracture of the pubic bone on the left side was caused by a fall on the hip. The diagnosis was confirmed by Roentgen-ray examination. The symptoms were inability to turn over in bed, or to move the left leg fully from the hip, with tenderness over the ramus of the pubes on the left. Pressing together the great trochanters or the iliac crests caused pain in the pubes. Strapping the pelvis with an encircling band gave comfort and enabled the patient to turn in bed and to move the leg better. The patient recovered with good gait.

8. Acute Thoracic Empyema.—Cases of purulent pleurisy are divided into three classes by Robinson: Acute, subacute and chronic. Suction or siphon drainage aids in the reexpansion of the lung in all cases of the first group; in most of the second, probably in none of the third. Suction even though inefficient is better than no suction, provided suction is constantly applied. Prevention of leakage requires above all things an air-tight thoracotomy wound. This is best obtained by the rib-trephining method with the application of a threaded metal tube. The particular form of suction device applied to the air-tight wound will depend on the means at hand.

The importance of maintaining air-tight suction leads Robinson to advocate a method of rib-trephining, which he has employed in cases belonging to the first and second groups with greater success than with any of the other methods. He advocates local anesthesia, except in nervous patients, to whom it is not suitable. When first employing this treatment, after trephining the rib, he inserted a rubber tube selected to fit as tightly as possible, holding it in position by adhesive plaster and safety-pin or with a stitch through the skin. This prevented leakage for a number of days and was a great improvement on all other methods employed. Even this leaked too early, and to prolong the period of air-tight closure Robinson substituted a metal tube with a thread cut on one end and corrugated for the attachment of rubber tubing on the other. These tubes are made in different sizes and of different lengths to suit the individual case, depending on the size of the rib and the depth of the chest wall tissues to be traversed. The less the tube projects beyond the skin, the better, as it receives better support by the soft tissues and the skin. It is not necessary to allow the corrugated portion to project beyond the skin sufficiently to support the end of the rubber tubing, for this may be applied to a depth within the soft tissues before the latter are sutured around it.

The skin is anesthetized, incised for two inches over the selected rib, dissection is then carried on under further local anesthesia. With gentle retraction of the edges of the wound an anesthetic compress is applied to the periosteum with pressure for at least 30 seconds; this membrane can then be scraped away for a length of 2 cm. without causing pain. A cranial trephine of the exact outside diameter of the tube to be inserted is then applied directly over the center of the rib. Care should be taken to leave a bridge of rib at least 3 mm. in width above and below the trephine opening. When it is evident that the posterior periosteum is reached at any point in the trephine's circle, the needle should be inserted in the crack and the periosteum and over-sensitive pleura anesthetized, even if the solution is allowed to leak into the pleural cavity. Traction on the pleura caused by removal of the button is thus rendered painless, as is also exploratory puncture. After removing the button with mouse-tooth forceps, a Cabot trocar should be inserted into the pleural cavity to verify the selected point of drainage. This should be done with caution so that only a drop or two of pus escapes and does not come in contact with the superficial tissues. One of the metal tubes is then screwed with the fingers into the trephine opening. The muscles and skin, which should have been spared infection, are now sutured. A collodion dressing with a circular opening is then applied, and with the wound thus protected the complete opening of the pleura is indicated. This can best be done by the use of a pointed or blunt bistoury or a long-bladed scalpel, which is passed through the metal tube to the pleura. Great care should be taken to do more than merely incise the pleura, the knife being used for the purpose of excising a section of pleura the size of the tube. During this process, pus, of course, escapes freely, but runs directly into a basin and need not come in contact either with the skin or sterile sheet or even drench the floor. A rubber tube about 6 inches in length with a clamp at its outer end is then slipped over the corrugated portion of the metal tube and tied. No outside dressing or swathe is needed, and after sufficient removal of the pus contents at the time of operation the clamp is reapplied to the rubber tube and the patient sent to the ward.

11. **Test for Diarrhea Caused by Gas Bacillus.**—In order to throw light on the distribution of the gas bacillus in the stools of children with diarrheal diseases, Kendall and Smith have utilized the abundant material in the Boston Floating Hospital. The method employed in detecting the gas bacillus is simple, rapid and certain. It consists essentially in inoculating sterile tubes of whole milk with a small portion of the suspected stool, thoroughly emulsified in it, and immersed in a water bath to above the level of the top of the milk and heated to 80 C. for 20 minutes, incubating at body temperature for from 18 to 24 hours. As an alternative procedure, the infected milk tube may gradually be brought to the boiling point of water in a water bath, kept there for 3 minutes,

then incubated as above. By so doing, all bacteria not in the spore state are killed, and the development of the spores into vegetative cells is unrestricted by the presence of non-spore-forming organisms. Those cultures containing gas bacilli present at the end of the period of incubation three prominent features: (a) The casein is largely dissolved (usually at least 80 per cent.); (b) the residual casein is slightly pink in color and filled with holes, the result of the stormy fermentation; (c) the culture smells strongly of rancid butter, due to the formation by the gas bacillus of butyric acid. Gram-stained preparations made from such growths show rather thick, short bacilli with slightly rounded ends. Controls suitably studied culturally have shown that cultures presenting this complex are in reality gas bacilli.

The authors have examined by this method the stools from 231 infants presenting a variety of intestinal disturbances and a few other diseased conditions. It was possible to isolate the gas bacillus from 22 cases. Six of these infants had apparently normal stools; 2 had thin watery stools with a few curds and a little mucus; the remaining 14 showed blood and mucus and many of them pus in the stools. The clinical diagnosis in these 14 cases was uncertain, but suggested bacillary dysentery. It was not possible in any case in which the gas bacillus was recovered from the stools to isolate simultaneously the dysentery bacillus. The diagnosis of diarrhea due to an infection with the gas bacillus can be made by the means described within 24 hours, at the end of which time it is possible to begin treatment with a definite idea as to the etiology of the condition. The management of all acute diarrheas during this period of 24 hours while the cultures are developing and while the diagnosis is being made, is practically the same, namely, purging and starvation. So far, the application of the method as outlined and the subsequent treatment with buttermilk has been limited to relatively few cases, but the results obtained have been uniformly satisfactory and would seem to justify the belief that the gas bacillus is the etiologic factor in a small group of the acute diarrheas in infants.

14. **Nervous Affections in Relation to Adjustments of Eyes.**—Stevens presents a short series of studies of nervous affections in their relations to the adjustments of the eyes, the studies being based each on a single case of sufficient importance, observed with reasonable care, and sufficiently well defined in its character to afford opportunity for observing not only the phenomena, but the course of treatment and the results of such treatment. Such a series of studies would appear to be of more value than conclusions derived from a number of isolated and, perhaps, not fully correlated facts and surely of more value than attempts to theorize from principles which might or might not apply to the cases. The first study was made on a case of chronic progressive chorea. The boy was 16 years of age, was of about the usual height for his age, but was quite thin and pale. He was 3 years old before he walked, but when he was only 2 years of age he began to manifest the twitchings of chorea to a moderate extent. At the age of 6 the convulsive movements were very bad and his head tipped from side to side. As he grew older and somewhat stronger there were times when he was sufficiently quiet to attend school for a week or for 2 or 3 weeks at a time. He was an apt pupil and seemed to keep well along, though what he learned seemed to be more by the

ear than by the eye. At the age of 9, by the advice of physicians, he was removed from school and since that age he had never attended any school.

The nervous condition was manifested by a stamping of the heels against the floor, the clapping of the hands, the striking the head in its bobbing between the knees and up again, of the ejaculatory sounds. As he walked he stopped once in a few steps and gave a jerk of the shoulders backward and of the abdomen forward, making at the same time one of his characteristic sounds. His face was in perpetual motion and his body was never still. Occasionally as he walked he stopped for a general convulsive attack of a much more violent character than that just mentioned. Vision of each eye 6/6, right without glass, left with cyl. +1.25 axis 90°. Hyperphoria=0; esophoria=16°, deviation in exclusion corresponding to the esophoria shown by the phorometer. Rotations were all free and normal, but the rotation upward of 42° was in excess of the most favorable rotation in that direction. Declinations, right+1°, left+6°. The boy could see single, but images were confused when both eyes were open and the interposition of a faintly colored glass before either eye induced diplopia.

The correction of the declinations was the aim of all the efforts to correct the adjustments. No treatment was instituted directly against the esophoria, for in case the declinations could be corrected there was no reasonable doubt that the esophoria would correct itself. The treatment was surgical, consisting of operations to which Stevens has given the somewhat contradictory designation of "extendocontraction" of a tendon.

The time of observation of this case was rather more than a year, during which there was, at first, a rapid and then a steadily progressive improvement. While during the early weeks of treatment, moderate nervous attacks occurred from time to time, as the months progressed these days of restlessness became progressively less frequent until during the last few months no return of the malady was observed. A year later he was well, and later than that he was well and at work.

15. Treatment of Cancer.—Vaughn has made daily differential counts in 25 patients with various forms of cancer who were receiving injections of cancer residue. Within from 24 to 48 hours following a residue injection the percentage of polymorphonuclear elements falls from 5 to 40 per cent., while there is a corresponding increase in the percentage of mononuclear cells. These observations, when compared with the blood changes found in connection with the administration of cancer residue, are of particular interest, since the type of mononuclear cell which is found to take part in the most decided increase is the myelocyte, with a fairly dark staining nucleus surrounded by a larger amount of protoplasm than is found in the small mononuclear cell. Also the protoplasm of these cells seems to contain, in most instances, a greatly increased number of azure granules. The temporary conclusion that must be drawn from the blood changes noted is that the specific ferment which destroys the cancer cell is in all probability formed through a chemical reaction with the cells of the mononuclear variety.

25. Reaction Curve of Human and Bovine Type of Tubercle Bacillus. In several earlier publications Smith described a culture method for distinguishing the bovine from the human

type of bacillus, which consists in determining from time to time, over a period of from three to four months, the reaction of glycerin bouillon in which tubercle bacilli are growing. The curve resulting from such determinations can be plotted and it presents certain characters which under like conditions remain fairly constant for each culture. Several other investigators have applied this method in their studies of tubercle bacilli from human and animal sources. Their results impressed on Smith the desirability of going over the method again and determining more precisely the conditions which make uniform results possible. He therefore collated the new data obtained during the past two years and used these as a basis for further investigation.

He says that experience has taught him the need of applying certain uniform methods in following the reaction curve. In the first place, the depth of the bouillon and the size of the flask should be the same for all comparative tests. The amount of glycerin used also tends to modify the result. To make conditions uniform the glycerin should be entirely consumed or else a certain amount should remain unused. The initial reaction of the bouillon probably does not greatly influence the curve if the acidity be maintained within 1 to 2 per cent. of a normal acid. Great care must be exercised not to use figures obtained by titrating fluids from contaminated flasks. The faintest cloudiness of the fluid is suspicious. The question toward which nearly all the data tend is whether the process indicated by the reaction curves of the two types of bacilli are qualitatively identical or not.

In a former communication Smith endeavored to explain the differences in the reaction curves by assuming that the bovine bacillus utilized the glycerin without splitting it into acids, whereas the human type first split into acids. This explanation was not accepted by Griffith nor by Siebert, who regard the behavior of both types toward glycerin as the same. That the behavior is not identical is evident from the data Smith presents, but whether it is variable, inconstant and the resultant of essentially the same functional activities of the two types cannot be determined until much more work has been done. When cultures have been recently isolated, the difference in behavior of the two types is striking. With the continued artificial cultivation the bovine strains grow more abundantly and the reaction after two or three months becomes acid. Within this period the difference between the bovine and the human type is marked even in old cultures. After three months the culture fluid of many bovine strains is from 0.5 to 1.5 per cent. acid. It still remains to be determined whether this acidity coming on so late is not wholly to be ascribed to disintegrative changes. Smith says that the original distinction made by him will stand until overthrown by more thorough, analytic studies than have been made up to the present.

The reaction curve of tubercle bacilli in glycerin bouillon has proved of great value to Smith in studies of tubercle bacilli. Among the criteria for distinguishing the bovine and human type of bacilli, such as slow or rapid growth, high or low virulence for rabbits, Smith regards the difference in the reaction curve as the most interesting and at the same time the most puzzling phenomenon. It is closely bound up with vital processes of this species of which we know as yet very little. All claims of transformation by passages of the human into the bovine type, or *vice versa*, must, in Smith's estimation, pass the test of the reaction curve as well as others before such transformations can be accepted as accomplished facts.

26. Bovine and Human Types of Tubercle Bacilli.—This article covers 160 pages, and is based on a large amount of personal observation and experimentation, the data in each instance being carefully recorded and fully discussed. It is impossible to abstract the paper, valuable though it is.

27. Phenol as a Clearing Agent. DeWitt says that monophenol which fades the stains commonly used in histologic work, can be corrected by redistilling, stopping the distillation as soon as the temperature begins to rise above the constant boiling point of the phenol. The substances passing over at a lower point are not injurious to the stains. If

redistillation is not convenient, the carbol-xylo which fades the stains can be corrected by supersaturating it with a mixture of sodium bicarbonate, one part, and sodium-potassium tartrate, two parts. Often the sodium bicarbonate alone will correct it. It may also be partially corrected by the addition of from 0.5 to 1 per cent. of pyridin.

28. **The Viscosimeter.** It seems probable, according to Torrey, that with the aid of the Oswald viscosimeter the test for the liquefaction of gelatin on the part of bacteria may be reduced from 14 days, as at present, to 4 or 5 days. If this statement proves valid, a definite report on the presence of *K. Coli* in a sample of water may be given within a week instead of after two weeks as at present. Cultures which liquefy very slowly and at the same time produce a viscid substance may be unsuited for the test. As an aid in the biometric study of bacterial liquefaction this apparatus should prove of value.

42. **Treatment of Pneumonia in Children.**—Ludlum emphasizes the importance of fresh air, rest in bed, sufficient clothing to be comfortable, reduced diet. He says that a tepid bath should be given daily to maintain the proper function of the skin. In the early stage counter-irritation may be of value, the best form being the homemade mustard paste. Poultices and clay pastes are positively harmful to the infant and, to say the best of them, of very doubtful value in the older child. They should not be used. Similarly the formerly much-used pneumonia jacket is condemned as useless and harmful. Aside from its use as antipyretic and sedative mentioned below, the local application of cold is at times very valuable; when cyanosis is marked and respiration shallow nothing aids deeper respiration and clears up the cyanosis so well as a cold chest compress. If the fever is giving trouble, hydrotherapeutic measures should be employed. The simplest and, at the same time least effective, is cold sponging. If simple sponging is not adequate, the best way to secure more positive action is by the cold pack, with the greatest emphasis on the fact that coal-tar products are very rarely to be given, though Ludlum says that there is an occasional case in which a small dose of phenacetin works admirably to control fever and restlessness.

At the beginning of an attack, in addition to a cathartic, a refrigerant, such as potassium citrate, in dose of 1 grain to each year of the child's age up to 4, or liquor ammonia acetatis, 15 drops at 1 year up to 1 dram at 4, with tincture of aconite from ¼ drop at 6 months to 1 drop at 3 or 4 years, greatly adds to the child's comfort and has some value in reduction of fever. This is usually kept up for one or two days. An average case will frequently require no other medicinal treatment. Stimulants are usually not necessary, and should never be given till the occasion arises. If there is threatened failure of the heart, particularly at the crisis, the best drug is usually strophanthus, given in the form of

the tincture, 1 drop for a child of from 6 months to 1 year, 2 drops for a child from 3 to 5 years. Strychnin is occasionally called for in a heart weak and irregular and not very fast. For right heart failure nitroglycerin is indicated. Alcohol, if needed at all, must be used in good-sized doses, in the form of whisky or brandy.

In bronchopneumonia, Ludlum says, poultices, pneumonia jackets and their like are to be condemned, only more strongly than in lobar-pneumonia; for this is typically an asthenic disease and their damage is even greater. On the other hand, counter-irritation in the early stages is of decided value, because its influence is left on the accompanying bronchitis. The mustard-paste is a very satisfactory mode of application. The cold compress to the chest is useful under the same conditions as in lobar-pneumonia, but the child's condition must be watched with even more care; shock must be watched for and the extremities kept carefully warm; its value in selected cases and given with extreme care is very great. Inhalations are of great value while the secretion is still scanty; plain water, lime water or, best, water containing from 10 to 20 drops of creosote or 1 teaspoonful of compound tincture of benzoïn to the pint. The inhalation cannot be given with full satisfaction except under a tent, but there is some value in the free escape of medicated steam in the room. After free secretion has been established the inhalations are of no further use. A full sponge bath may be given daily for cleanliness and to keep the skin active. Hydrotherapy should be carried out just as in the lobar type, tepid or cold sponging or the cold pack; watch carefully for shock or cold extremities. Laxatives should be employed as needed, but the initial cathartic is not a routine measure as in the lobar form.

Expectorant drugs, so called, are of value because of the bronchial irritation. Ludlum most commonly employs ipecac in doses of 2 drops of the syrup for a 1-year-old child, from 3 to 5 drops for a 5-year-old or upward; with ½ grain of ammonium chlorid for the younger age, 1 grain for the elder; in these doses the stomach is rarely deranged. If cough is very distressing and unproductive, he uses codein 1/30 grain, or Dover's powder ¼ grain for a child of 1 year. After secretion is well established, if an ammonium salt is still needed to aid in its expulsion, the carbonate is the best and should be given in similar small doses or in the form of the aromatic spirits, from 3 to 5 drops at the age of 1 year, 10 drops at 5 years. Creosote in the form of the carbonate is useful in some cases in the later stages, but Ludlum rarely uses it in children under 4 or 5 years; at this age the dose is 2 or 3 drops. Stimulants are needed much oftener than in the lobar type, but by no means should they be used too early. Strychnin is the best if the pulse is weak and irregular and not particularly fast. If the pulse is rapid, i. e., 150 or more when the child is asleep, strophanthus is indicated, 1 drop at 1 year, 2 drops at 5. Alcohol should be left until late when, if needed at all, the dose required is large, 20 or even 30 drops of whiskey or brandy well diluted at the age of 1 year. In cyanosis, glonoin in dose of 1/200 grain to a 1-year-old child may be of value, and in extremely shallow breathing atropin 1/400 grain for the same age.

49. **Radical Cure of Inguinal Hernia.**—Gray believes that with the uniformly good results that are now obtained by operative procedure, that we should advise operation in all cases between 2 and 60 years of age, unless for some very good reason; for example, if the person be suffering from some

chronic ailment, such as diabetes, chronic interstitial nephritis or valvular disease of the heart, when operation, as a rule, should not be considered. All others, as a rule, should be promptly submitted to operation. Even individuals who fear a general anesthetic can be operated on under cocaine or other local anesthetic. Further, in view of the uniformly good results and the very small percentage of mortality attending these operations, it would seem utterly absurd at the present time, he thinks, for any physician to advise the young adult or middle-aged man or woman, or even one in youth or old age, to wear a truss, rather than submit to an operation.

57. **Syringoma.**—The lesions in Ormsby's case were very extensive. They were situated in greatest abundance over the breasts, arms, forearms, face, eyelids, thighs and legs. On the limbs the extensor surfaces were more considerably involved. The lesions were very numerous over the breasts and over the extensor surfaces of all the limbs. There were, however, many on the flexor surfaces and a few on the back, especially over the buttocks and on the upper part of the trunk around the shoulders. The palms, soles and scalp were free. Some lesions were fairly superficial and flat; others were deeper and not flat; while many were quite deep. Large numbers occurred as discrete nodules; others coalesced and formed lobulated plaques. On the arms the nodules were flattish, yellowish-brown, appearing much like xanthomatous lesions. Similar growths occurred on the forearms, but here many were smaller, having only the normal hue of the skin. On the lower limbs where they were numerous, the color varied; some were bluish-red, brownish-red or yellowish-red. In general, much more color was exhibited here than elsewhere. Over the breasts the color was pinkish and darker red. Over the neck and face large numbers were colorless. On the eyelids much deformity was produced by the protuberance of the nodules. Here some appeared translucent and some resembled fibromata.

Radiotherapy moderately applied caused appreciable diminution in the size of the lesions. Several of the latter, treated with a ten-second exposure to carbon-dioxid snow, completely disappeared. Apparently, they were especially susceptible to each of these forms of treatment. The wounds made by biopsies healed readily by primary intention. The lesions were much more extensive than in any previously recorded case, though the individual lesions are similar in many respects to those described in connection with cases of syringocystoma group. Histologically, the sections show the most marked pathologic changes at all times in the region of the sweat ducts, and strong presumptive evidence is obtained from the sections that the new growth is a proliferation-product of the cells of these ducts. A connection between the cells of the hair follicles or of those of the epidermis with those of the new growth could not be demonstrated, nor was it suggested.

- 68 Is Syphilis a Contagious Disease? F. Clift, Salt Lake City, Utah.

67. **Amputation of the Epiglottis.**—Extensive studies on the living and dead have shown that approximately one-third of all consumptives have, in greater or lesser degree, coincident involvement of the throat, and statistics prove that in over 20 per cent. of the laryngeal cases the epiglottis is involved. Lockard has had 961 cases of laryngeal tuberculosis, in 136 of which there were lesions of the epiglottis. Of 1,671 patients with lesion of the larynx, 127 had lesions of the epiglottis. In 4 cases, the laryngeal disease was limited to the epiglottis. Epiglottidean tuberculosis is practically always associated with advanced disease of other segments of the larynx and of the lungs, and to this fact, in large measure, Lockard says, can be accredited its appalling mortality, for even if the epiglottidean disease were capable of arrest or cure, the patient would usually succumb to these concurrent processes. Even when the pulmonary and other laryngeal foci are incipient or quiescent, their advancement is rapid after breaking down of the epiglottis, for the severe dysphagia and resultant cachexia soon destroy what little vitality the tissues have retained, and these conditions have generally supervened by the time the case comes under observation.

From such statistics as are available, it would seem that the general mortality of these cases, including both the incipient and the advanced, is in the neighborhood of 90 per cent. If one took into account the advanced cases only, those associated with severe dysphagia, it would be found that not more than 1 or 2 per cent. result in local healing. In addition to the failure to cure or even temporarily to arrest the process, little is achieved in the way of relief. Any method of treatment, therefore, that offers some hope of local cure in favorable cases, and promise of euthanasia in the incurable deserves serious consideration, and such a method Lockard thinks we possess in complete amputation. Of the 27 patients operated on by the author, 26 were completely relieved of pain; in 8 the larynx was cured, and in 5 the pulmonary process eventually became quiescent; 3 patients are still under treatment. In one case the palate was also involved, but even in this instance deglutition was greatly facilitated. Of the cured patients one has endured 5 years and 6 months, and one 4 years and 8 months.

71. Abstracted in THE JOURNAL, Oct. 1, 1910, p. 1220, and published in the *Lancet-Clinic*, Sept. 24, 1910.

74. **Wound of the Right Ventricle.**—The patient, a negro, aged 18, received a knife wound which entered one inch to the left of the sternal margin, and traveling beneath the skin, partly severed the costal cartilages of the fourth and fifth ribs, about half an inch to the left of the sternal edge. Entering the pericardial sac between the fourth and fifth cartilages, it penetrated the right ventricle near its center. The wound in the pericardium was just large enough to permit the tip of the index finger to enter, but did not allow

it to penetrate into the pericardial sac. The patient entered the hospital fifteen minutes after the injury, profoundly shocked, pulseless, and with a temperature of 97 F. The external wound was dry, and no perceptible hemorrhage was present. Percussion was performed with difficulty, because of the pain and restlessness of the patient, but it was thought that pericardial dulness was increased. The heart sounds could not be heard, nor could the apex beat be seen. She was placed in bed, surrounded with hot-water bags, and given morphin. Soon a faint pulse could be detected, and at 7:30 p. m., with a pulse of 160, and of fair volume, operation was advised and accepted. The original wound was enlarged and the fourth cartilage completely severed in the original knife wound and fractured distally. Blood was then spurting from the pericardial opening at each systole. The opening was quickly enlarged and the index finger of the left hand thrust into the opening to the right ventricle. A catgut suture was placed at the side of the finger and traction on this controlled the hemorrhage to some extent. In this manner the triangular stab in the ventricle was closed. Clots were removed from the pericardial sac by sponging and with the hand. A tube was placed in the sac and the opening sutured with a continuous catgut suture.

On the day following the operation a pneumothorax was detected and aspirated. The lung descended, but contained moist râles. On the fourth day the opposite lung became involved and moist râles appeared. The patient continued in this condition, with pulse ranging from 100 to 120 per minute and temperature registering from 99 to 101 F., until the night of July 21, seven days after the operation, when she died.

77. Hemorrhagic Form of Appendicitis.—In the cases cited by Torrance, the only abnormal condition found in the appendix was blood with organized clots, some of which were attached to macerated points of the mucous membrane of the proximal end of the appendix.

- 99 *Auscultation in Diagnosis of Fractured Ribs. S. T. Lipsitz, St. Louis.

94. Treatment of Cancer.—Wickham says that if a surgical extirpation cannot be made on account of untoward conditions, radium applied before the operation lessens the destructive process in the parts involved, and renders operable tumors which were not so before. Finally, there are a number of cases of extreme gravity in which surgery cannot intervene, but in which radium, without producing a particularly beneficial result, can at least relieve patients during long and tedious periods of pain (analgesic action of radium) and lessen hemorrhages and secretions. The special organ for radium therapy is the uterus. In fact, in cancer of the uterus, when it is employed before surgical intervention or simply to relieve the patient, radium plays a most useful rôle. The same result obtains in advanced cancer of the breast. Radium therapy must not be regarded as a means destined to cure patients afflicted with serious cancers, but may be employed by itself or in combination with other means to relieve the sick and prolong life during a period long enough to compel the thought that, at least, an apparent cure has been effected. Even when cures are absolute—results which Wickham says he has obtained relatively often—a relapse in the shape of a meta-stasis may take place.

Of all the malignant tumors, the giant-celled sarcomata are the most favorable to treatment because they are local. Moreover, in these cases the word "cured" is every now and then permissible. On the other hand, the lymphosarcomata, though they rapidly recede under the action of radium, are unfortunately only too often followed by a metastasis. Of all the lobular and tubular forms of epithelioma, those that are found in the mouth are the least tractable to radium.

99. Fractured Ribs.—Auscultation, in Lipsitz's opinion, will reveal fracture of a rib quicker than palpation will. He says that the sound obtained over a fractured rib is characteristic, is unlike the sounds of pleural rûles, air crepitation or râles and is therefore pathognomonic. Direct auscultation is not as satisfactory as the indirect method with the aid of the stethoscope. Have the patient inspire as deeply as possible. The sound is usually best elicited at the height of the inspiration or during the beginning of expiration. On listening in this way, it is with rare exception that any fracture of a rib can escape the examiner's notice. In two cases of the series there were multiple fractures. The exact site of each lesion was located without difficulty. In three cases the diagnoses were made by auscultation alone, palpation and manipulation giving negative results. This was explained by the knowledge that the severe pain produced by manipulation lessened the efficiency of this procedure, and that mere palpation was not sufficiently delicate. In all the other cases in which manual methods gave positive results auscultation was correspondingly successful. In a number of cases of suspected fracture not included in the series, careful auscultation was unsuccessful and invariably the results of palpation and manipulation were also negative. Other diagnoses were made. One may listen over almost any part of the affected side and elicit the peculiar hard, grating, breaking sound or the "click" which emanates from the site of the fracture. Once this sound is discovered over any portion of the chest, it can be followed in the direction of its increasing intensity, until, where it is most pronounced, the site of the fracture is located. As a rule, with practice, if more than one fracture is present all the lesions can be found in this way. This sign is so reliable that it is seldom necessary to send a patient away with a doubtful diagnosis.

105. **Foods Available for Infant Feeding.**—In the Philippines physicians are limited in regard to the variety of foods for the artificially raised child. The tinned milks and modified foods for sale on the market are perhaps the safest to use. The only raw milk available in any quantity is goat's milk. Caraboa milk has been used, but, owing to the scarcity of this animal, this source of supply has been cut off. Outside of the Government farm the cow is as yet almost an unknown quantity. Rice is perhaps the most common cereal used. The Igorrotes feed their artificially-raised babies almost entirely on sweet potatoes. Kneeder's experience with goat's milk has been rather satisfactory. One of the important advantages of the goat as a raw milk producer is that it is refractory to tuberculosis. It is not difficult to secure in Manila a fresh healthy animal for from four to ten pesos, which if properly cared for will give enough milk for one baby. This milk is especially recommended for infants because of its similarity in composition to mother's milk. Apart from its medicinal qualities goat's milk is far superior to the dairy milk ordinarily supplied. The taste is not disagreeable nor the odor bad, provided the animal is properly selected and kept. Each milking should be immediately prepared. A baby six months old should be given equal parts of raw milk and rice water with a little sugar added, and the nine months old child may take the milk unmodified.

107. **Food for the Poorer Classes.**—Calderson describes the methods pursued by the "Gota de Leche" (milk stations), an association instituted through the efforts of the late Dr. David Dougherty of Chicago. Its work is practically the same as that of the various milk commissions established in this country.

108. **Preservation of Vaccine Virus.**—During the past year some tests were made in the Bureau of Science comparing the relative value of the dry point; the emulsion in 3 parts of glycerin and 1 part of distilled water; the emulsion in 3 parts of glycerin and 1 of heated horse-serum; lanolinized vaccine and the dry powder. The preparations were kept at room temperature in a dark place, and at intervals of 7 days their efficacy was tested by the vaccination of monkeys. Dry points and dry powder gave good results after 3 weeks; the emulsion in glycerin and water retained its potency for 5 weeks; diluted with glycerin and heated horse-serum, the virus remained active for 8 weeks and the lanolinized vaccine was inactive after 7 weeks.

 126 Three Cases of *Tania Nana*. M. A. Wood, Houston

123. **Floating Kidney.**—In White's method the capsule of the kidney is incised longitudinally and to either side in the direction of the kidney pelvis, thus giving four triangular flaps from the fibrous capsule. Through each of the four flaps of the fibrous capsule, forty-day chromic catgut is passed at several points, folding the capsule on itself to give a firm hold for the sutures. The excess of fatty capsule is cut away on either side and from the upper kidney pole, leaving intact that portion of the fatty capsule attached to the lower pole of the kidney. This, with the peritoneum, is used as an anchor from below to hold the kidney up into the fixed position, it having been gathered up and sutured to the lower angle of the muscular wound. The ligatures in the fibrous flap are threaded into a curved needle, and passed high through the muscular structures on each side of the wound. With care the upper ones may be placed above the eleventh rib. The sutures from below are also directed upward, tending at all times to make upward traction on the kidney. The after-treatment of these patients is important. They should be kept in bed for three weeks, and in a dorsal position. White has performed this operation twenty-four times.

125. **Does Pterygium Cause Astigmatism.**—Hall reports one case which he believes demonstrates that a pterygium can and does produce astigmatism.

132. **Chronic Gastric Ulcer.**—The satisfactory treatment of simple, chronic ulcer of the stomach, according to Ebright, is a diet consisting for a few days entirely of from one to two quarts of milk with, as soon as possible, from two to twelve raw eggs. The patient may be allowed to follow his customary routine of living. Large doses of bismuth are of value in controlling pain. The patient must at all times be on such diet as will improve, first of all his general state of nutrition, in other words forced feeding within the capacity limits of the stomach. Inasmuch as rectal feeding, which has been advised that the stomach may be put at rest, does not cause complete arrest of peristalsis and since it is known retrograde peristalsis may be set up by it, and the food given by rectum actually found in the stomach, and since, at the best, rectal feeding is starvation diet, it would certainly appear that starvation and rectal alimentation are illogical procedures in the treatment of chronic gastric ulcer.

147. **Chemical and Mechanical Stimulation of Bone.**—The object of Meisenbach's work was to study the effects on bone growth by influencing the cellular structures of the epiphyseal cartilage, and to note the effects on ossification. His papers are based on the results of experiments on forty-two rabbits extending over a period of five months. Various substances were injected near the epiphyseal line, and as the animals grew in size the bony changes were noted and studied from a radiographic, anatomic, and microscopic standpoint. Four rabbits were injected with sterile water. They showed no pathologic changes in the injected limb either microscopically or radiographically. Five rabbits received sterile graphite pegs. None of the five rabbits showed any changes radiographically, the epiphyseal line being clear. Three rabbits received the injection of staphylococcus vaccine. Seven rabbits received sterile graphite pegs together with the staphylococcus vaccine. Six showed microscopic change, that is, increased proliferation of the endochondral and perichondral bone in the diaphyseal region. No special changes were noted in the epiphyseal lines. This seems to suggest that a toxin together with mechanical stimulation will produce active formation of the endochondral and perichondral varieties.

Eight rabbits received injection of pure tincture of iodine. None of the surviving rabbits showed any radiographic or microscopic changes in the injected limb. Pure carbolic acid was injected in two rabbits. They showed a slight change radiographically, and microscopically an increased vascularity only. One rabbit received 95 per cent. alcohol and lived eleven days, after which no pathologic condition was noted. Six rabbits received injections of pure formalin. All the rabbits, except one, showed radiographic changes in various degrees, thickening of the cortex, irregular epiphyseal line, exuberant growth of a portion of the diaphysis, and a general widening and thickening of the epiphysis and the diaphysis. All the rabbits showed definite microscopic changes in the injected region except one. In all of the pure formalin specimens the injected tibiae were enlarged at the diaphysis but somewhat shorter in the total length. The cortex in the region of the diaphysis was materially thickened and the entire diaphysis increased in circumference. The epiphyseal line was irregular and not as pronounced as the cortex. The entire length of the injected tibia was somewhat shorter. The diaphyseal line or the zone of provision calcification was widened in almost every instance, and the zone of calcified matrix increased. In one rabbit, portions of the epiphyseal line were replaced by new bone and ossification hastened. In another, ossification was hastened to such a degree that half of the epiphysis became united with the diaphysis, so that the epiphyseal line was entirely absent.

Six rabbits were injected with 2 per cent. formalin. The radiographic and microscopic changes were similar to those found with the pure formalin but were not so extensive. The radiographic changes were chiefly noted in the thickening of the cortex and the diaphysis with an early ossification. The microscopic changes were an increased amount of endothelial, endochondral, and perichondral bone with a corresponding increased zone of calcified matrix and a swollen and proliferating epiphyseal line, the latter being sometimes replaced by new bone. It is hoped that these experiments will act as a stepping stone to a new method of treatment in many bone cases which have heretofore seemed hopeless as regards helping the patient, such as congenital shortening of the limb, arrest of bone growth following infantile paralysis,

tuberculosis of the bone, osteomyelitis, obstinate non-union of fractures, and similar cases.

148, 149 and 150. Abstracted in THE JOURNAL, July 2, 1910, pp. 48, 50 and 51.

152. **Unusual Deformity of the Fingers.**—Four years ago, the patient, a miner, aged 56, met with an accident when a heavy piece of stone fell on the back of the fingers of the left hand. All the fingers were badly bruised, but the middle finger was so badly damaged that it had to be amputated. As soon as the patient began to use his hand again after this injury, he noticed that when he extended the proximal interphalangeal joints of his "ring" and "little" fingers there was a sudden "click," as he expressed it, and this also occurred when the movement of flexion from the fully extended position was begun. The "click" was felt on either side of the palmar surfaces of the proximal interphalangeal joints of the affected fingers. This clicking sensation was always associated with a movement of these joints in some respects similar to that seen in "trigger finger"—that is to say, the last part of the movement of extension and the first part of the movement of flexion took place with a snap or jerk and could not be performed slowly. The condition was considerably more aggravated in the "ring" than in the "little" finger, but in neither case did the joints jerk into apposition of more than normal full extension. This snapping movement, though slightly uncomfortable when it took place, apparently affected the usefulness of the fingers but little.

Cotterill says that so far as one can guess, the sequence of events in the case were as follows: At the original accident the fingers were probably forcibly hyperextended, causing tearing of the palmar portion of the capsular ligament of the proximal interphalangeal joint, while the tendon of the flexor sublimis was split in its long axis into two halves both above and below the point at which the tendon normally divides for the passage through it of the flexor profundus. This having occurred and the vaginal ligaments and tendon sheaths also having been stretched, it would allow of partial lateral displacement of the two portions of the flexor sublimis, giving rise to the condition seen in the little finger. At the operation a year ago on the ring finger, the vaginal ligaments and tendon sheaths were almost certainly divided in their long axis, and the already too mobile tendon slips were then practically unrestrained. This being the case, as the joint was extended the two halves of the tendon slipped gradually outward, finally making the "click" as they jerked from their normal groove to lie on the lateral aspects of the joint. In this position the tendon slips may possibly have come to act as extensors, much in the same way as the lumbrical muscles, but they certainly lost all their power as flexors with the result that the movement of extension, at the proximal interphalangeal joint, was practically unopposed, for the profundus tendon is merely a secondary flexor of this joint. Added to the condition of the tendon slips there must have been some weakness of the palmar part of the capsular ligament of the joint to permit of the amount of hyperextension produced and this was no doubt caused by the initial injury. The flexion of the metacarpophalangeal and distal interphalangeal joints was due, it is thought, to the tension of the flexor profundus over the hyperextended joint. The maneuver described, when the patient wished to flex the affected joint, was obviously performed in order to slacken the displaced tendon slips and to aid their return to the normal position. At the operation the diagnosis was confirmed.

2. **Absence of Fallopian Tubes.**—No case similar to Spencer's is said to be recorded in the literature. A single woman, aged 28, complained of attacks of pain in the right iliac region. She had never menstruated; she had never had a show of any kind. At about the age of 18 she first felt sharp pains in the abdomen around the umbilicus, and such pains have recurred with fair regularity every month, usually lasting three or four days. Gradually the attacks of pain became more severe. They began by a strange feeling in the right iliac region; then, as the pain increased around the umbilicus, she felt faint, trembled, sweated and had nausea. A very severe attack occurred in September, 1908, and another in the following November. Recently the umbilical pain had tended to spread round to the back and downward behind the left hip, the latter pain persisting between the attacks.

She was a well-grown woman with normal breasts, external genitals and hair. There was a well-defined normal hymen. By rectum a normal movable uterus with cervix was felt. To the right side there was felt bimannually an oval swelling in the ileocecal region resting on the psoas muscle. It was thought to be an enlarged appendix adherent to an ovary, separated from the uterus by a normal broad ligament. On the left side there was a smaller swelling, which was taken to be a tender ovary, while the left broad ligament seemed free. No further abnormality was discovered. The uterus was quite normal; in the place of each cornu was a pea-like knob. There was no sign of the main portion of the Fallopian tube on either side, but the round ligament was well-defined, and there was nothing else abnormal about the inner part of the broad ligament. Each ovary was enclosed in a pouch formed by peritoneal adhesions; the opening of the pouch into the general peritoneal cavity was directed backward; the peritoneal surface of the ovaries projected into the interior of the pouches. This surface of the ovary appeared normal, and on pricking one of the follicles fluid spurted out; but Spencer did not observe any sign of a corpus luteum of menstruation, nor any remains of blood clot or pigment whatever. In the wall of the sac where it was continuous with the broad ligament there appeared to be traces of the fimbriae of the Fallopian tube.

Spencer then went on to search for the Fallopian tubes. A uterine sound was passed quite easily, and to the normal distance. He then laid open the uterine cavity by cutting transversely on the point of the sound, and tried to pass a fine probe outward through the cornua. But the lumen of the uterus did not extend into the pea-like knobs previously noted. On the left side the knob contained a small dermoid cyst enclosing sebaceous material but no hairs. On the right the knob was a mass of fibrous tissue. Spencer next slit outward the upper free edge of the broad ligaments, and split the layers without finding any trace of a Fallopian tube, except

what appeared to be the fimbriated extremity fused in the wall of the ovarian pouches. The patient is now in very good health, has had no further attacks nor abdominal disturbance of any kind nor has she had any noticeable vaginal discharge.

6. **Rectal Cancer.**—Miles has been able to determine that a cancerous growth in the rectum spreads in three directions, and invades the tissues either in the nature of a direct permeation, or as separate metastases; at any rate so far as naked-eye appearances show. The directions of spread, he says, are downward, laterally, and upward, and take place in the zones of tissue traversed by the lymph vessels. The tissues in the zone of downward spread consist of the wall of the bowel below the growth, the external sphincter muscle, the perianal skin, and the fat contained in the ischio-rectal fossa. The zone of lateral spread comprises the levatores ani muscles, the fascia propria of the rectum, the presacral connective tissue, and its contained lymphatic glands. In the male, the capsule of the prostate gland, the vesiculae seminales, and the base of the bladder; and in the female the posterior wall of the vagina, the cervix uteri, and the base of the broad ligament with Poirer's gland. The zone of upward spread consists of the bowel above the growth, the pelvic peritoneum, the pelvic mesocolon, particularly the border attached to the pelvic parietes with the adjacent peritoneum and the lymph nodes situated at the bifurcation of the left common iliac artery.

Miles has found that:

A growth in the rectum, wherever situated, may lead to recurrence in the tissues comprising the zone of downward spread.

A growth in the rectum, wherever situated, may similarly lead to recurrence in the tissues comprising the zone of lateral spread.

A growth in the terminal portion of the pelvic colon may lead to recurrence in both the zones of downward and lateral spread.

Free extirpation of the tissues comprising the downward and lateral zones of spread generally prevents recurrence in the field of operation.

However free the extirpation of the tissues comprising the downward and lateral zones of spread may have been, recurrence will in all probability take place among the tissues of the zone of the upward spread.

The most extensive and complete perineal operation possible is, with few exceptions, quite inadequate for preventing a recurrence of the disease.

Up to the end of 1906, Miles had performed 59 perineal excisions, with 1 death, results which, from the point of view of mortality were quite satisfactory; but, of the 58 patients who recovered, 54 are known to have suffered from recurrence. Of the remaining 4, 1 died 7 years after the operation from some intercurrent disease and 3 remain well and are free from recurrence. Such an experience as the above decided Miles to abandon perineal methods of excision and to rely solely on an abdomino-perineal procedure. He therefore designed an operation which would enable him to extirpate the whole of the tissues comprising the zone of upward as well as those forming the zones of lateral and downward spread, for in this way only could one hope to check the tendency to recurrence. He has now performed this radical operation 26 times. Ten of the patients died within periods varying from 24 hours to 12 days after the operation, 1 is still in the hospital, 1 left too recently to make any statement about him, 1 died 13 months after operation without sign of recurrence, and 1 has not been since seen. This accounts for 14 out of the 26 patients. The remaining 12 are all still well and show no sign of recurrence after periods varying from a few months to over three and a third years. In 8 cases the period is over 18 months and in 4 is over 3 years.

23. **Disease of the Nasal Passages.**—Stuart-Low reports seven cases to illustrate the rather frequent occurrence of sarcoma and carcinoma in these localities. He says that pain

is not to be relied on as an indication of malignant disease in the nose. Increasing and persistent stuffiness, especially if unilateral, is an important point as regards diagnosis. Recurring and increasingly severe hemorrhage, especially if unilateral, is always a suspicious symptom. A combination of hemorrhage and increasing stuffiness is often a serious indication of the existence of a new growth. The making of an early diagnosis is of great importance. It is imperative to make a thorough and systematic examination in all obscure cases of nasal disease, and to remove early a piece of any obstruction in the nasal passages for a pathologic report. It is of great importance when there is malignant disease to operate as soon as possible after a diagnosis has been made to secure a successful removal. It is advisable to adopt the canine-fossa route in operating for the extirpation of intranasal tumors. Innocent and malignant polypi are likely to coexist.

24. Gastric and Duodenal Ulcer. Moullin says that acid of much greater strength than is ever secreted by the gastric mucous membrane may be swallowed with impunity and without causing pain, even when an ulcer is present; and while in many cases of ulcer hydrochloric acid appears to be in excess, this is certainly not so in all; there are many instances in which there is a decided deficiency. As a matter of fact, the excess of free hydrochloric acid, the so-called hyperchlorhydria, to which so much importance has been attached, is a secondary consequence of spasmodic contraction of the pylorus, or of hypersecretion of gastric juice, or of both together; and these are the result of the morbid condition of the mucous membrane induced by such causes as chronic septic poisoning or irritation spreading from an ulcer. The excess is due to accumulation in the stomach. There is nothing whatever to show that the strength of hydrochloric acid in gastric juice as secreted is ever raised in any way, though it may be lowered. So long as the epithelial lining of the stomach remains intact and uninjured, hydrochloric acid in any strength that can be secreted has no effect. But if from any cause, whether it is the cause that gave rise to the pylorospasm and hypersecretion or any other, the protecting epithelial layer of the stomach is injured or the deeper tissues exposed, the acid at once comes into play; the injured tissues are injured still further; inflammation sets in; the debris is digested, and an ulcer left. Ulceration does not occur except when hydrochloric acid is present, for digestion does not; but hydrochloric acid, whether it has accumulated so as to be in excess or whether it has not, cannot cause an ulcer unless there is some other agent at work to initiate the lesion. Given this other agent the effect of the acid, as Bolton has shown, is in proportion to its strength.

25. Physique of the Phthisical.—Several tables constructed by Woodcock are in part the result of study in morbidity rather than in mortality among phthisical subjects. No notice has been taken in them of the ordinary and universally recognized physical signs of phthisis, but an attempt has been made to call attention to certain other appearances coincident with phthisis, though not generally recognized. First, and most important of all, is the peculiar appearance of the soft palate, which Woodcock begins to look for with certainty in almost all cases of marked phthisis. The phthisical soft palate is of a pearly bluish-white tint, and is covered with a somewhat mucoid moisture. Woodcock places it as a sign of sinister import equal to the rapid phthisical pulse, or the temperature, pulse and respiration reaction to fatigue. The hand ratio is found by comparison of the length of the hand, from the ridge of the ulna in an oblique line to the end of the longest finger, with the breadth across the hand at the knuckles. Hyperextension of the fingers on the metacarpals or of the terminal on the penultimate phalanx is a sign commonly found in the cases of people in advanced or rapidly advancing phthisis. Clubbing as a means of diagnosis has, in his opinion, lost some of its value. Philip's glands, i. e., the enlarged deep glands just above the clavicle—are always found in phthisical children; but their presence does not necessarily indicate phthisis, since they are so frequently encountered in apparently normal children. In the same way, enlargement of the other glands of the neck is so generally found in all

classes of patients who consult the doctor for any and every illness that even if one found them in every phthisical patient the diagnostic value would not be great.

With regard to skin conditions of phthisicals, Woodcock recalls only one case of lupus in ten years among the patients under his care at Armley and Gateforth for pulmonary tuberculosis. Tinea versicolor is especially common at Armley Hospital, which harbors advanced cases, and not common at Gateforth, where only early cases are received. Marked acne is not common; indeed, it is hardly ever found among advanced phthisicals. Dilatation of the stomach is of common occurrence among tuberculous patients.

26. Ruptured Abdominal Hydatid.—The facts presented by Barling and Welsh have reference to a series of six cases of hydatid disease complicated by rupture or leakage of the cyst into the peritoneal cavity. In five cases the cyst was situated in the liver, in the remaining one in the spleen. The cases all occurred within a period of eighteen months. The symptom-complex to which they draw attention includes (1) eosinophilia, (2) peritonitis with effusion, and (3) urticaria.

29. Relief of Symptoms of Prostatic Obstruction.—The method of treatment employed by Bolton is to pass an electrode into the rectum and administer high-frequency currents. The electrode is so placed that it lies against the posterior surface of the prostate. The current is taken from the top of the resonator. Bolton's most successful cases have been those in which congestion and irritation rather than size of prostate have been the prominent features. While it is not possible to cure every patient, Bolton says that relief is experienced by such a large proportion as to make the treatment worthy of the trial in all uncomplicated cases. The results of the treatment may be summed up in a few words. Congestion in the blood-vessels and stasis in the tissues are relieved. The nerves are soothed. The intense irritability of the bladder which is such a marked feature of the disease passes away. The tone of the bladder muscles is improved, and as a consequence the size of the stream is increased and also the force of propulsion. The bladder becomes able to empty itself, and the urine returns to normal. The restoration of the confidence of the patient is no small help in lessening the frequency of micturition.

37. Leukemia Treated by the Roentgen Rays.—Clarke reports four cases which he believes confirm the experience of other observers, that although Roentgen-ray treatment does not result in cure in leukemia, it gives a greater measure of relief in most cases than is derived from any other form of treatment, and prolongs life. If ordinary precautions are taken, and a careful watch kept on the state of the blood as regards the red cells and hemoglobin, and on the condition of the urine throughout the period of treatment, it seems to be devoid of danger. The presence of a slight albuminuria in one case and of marked glycosuria in another seemed to form no contra-indication to Roentgen-ray treatment, as they gave no trouble. The Roentgen rays should be applied over the long bones and vertebrae as well as over the spleen.

56 Treatment of Nevi. J. L. Bunch.
57 Treatment of Certain Sprains. F. Romer.

45. **Varicose Veins of Leg.**—Barker says that many patients with congenital weakness of their vein walls could stave off operation indefinitely if they would or could adopt the proper measures to prevent the engorgement of the veins which leads to the changes described. These consist in active exercise and avoidance of prolonged standing, keeping the bowels open, and cold douching of the legs. Among these, active exercise, which unloads the vessels by the free play of the muscles and increased tone in all the tissues, is the most important. It is to those who, unfortunately, are unable to take active exercise, and who are condemned to stand long and are obliged to neglect their general health, that operation offers relief.

54. **Ringworm.**—For inveterate and extensive cases Abraham recommends the Roentgen rays. Other old as well as recent cases have done well with an ointment of pyrogallic acid, of from 5 to 10 per cent, or a phenol and salicylic acid ointment, of each \mathfrak{ss} . to the ounce; others, again, do well with cupric oleate. A composition that he has used much is:

R	Gm. or c.c.	
Cupri oleati	15]	\mathfrak{ss}
Acidi carbolicli liq.	4]	\mathfrak{ss}
Acidi salicylicli	4]	or \mathfrak{ss}
Paraffini mollis	15-30]	\mathfrak{ss} - \mathfrak{ss}

For very small patches he uses biniodid and other mercurial ointments. The alkaline and alkaline earthy sulphids, which have a depilatory effect, are also useful either in ointments or strong solutions, and Abraham believes that the solution of ammonium sulphid would be used far more frequently than it is to produce a temporary alopecia were it not for its evil odor. Abraham recommends that in addition to keeping the whole head shaved, or with the hair cut very close and, so far as possible, always covered with some germicide ointment, that the cheapest caps and hats be procured and burnt after a comparatively short use. In his opinion, a thorough washing with an antiseptic soap once a week, while under treatment with ointments, is quite enough—the ointment to be rubbed in all over directly the scalp is dry. Cataphoresis and the use of formalin he found too painful to the patient and even harmful, hence he has discarded these methods of treatment.

- 64 *Laceration of Mesentery with Strangulated Hernia. M. Guibé.
65 *Fracture of Scaphoid Bone of the Foot. J. Abadie and Rangé.
66 *Tendency to Dislocation of the Hip-Joint in New-Born Infants. (Hanches subluxables et hanches luxées chez les nouveau-nés.) P. De Lamany and J. Salget.
67 *Postoperative Parathyroopriva Tetany. X. Delore and H. Alamartine.
68 *Technic for Posterior Subcapsular Thyroidectomy. X. Delore and H. Alamartine.
69 *Subphrenic Abscesses. R. Piqué. Commenced in No. 5.

64. **Laceration of the Mesentery with Strangulated Hernia.**—Guibé had his attention called to this subject by a case in his own experience but he was unable to find in the literature more than seven similar cases and these were all reported by French writers. Vigorous taxis had been applied in four cases and moderate taxis in two others; in the seventh case taxis had been applied by the patient and two physicians in turn. The outcome of the case depends on the extent of the tear;

resection of the loop involved is necessary to prevent gangrene if its circulation is much impaired. Two of the patients died in the five cases in which the bowel was resected; another patient recovered after mere suture of the tear as it was comparatively insignificant. Laceration of the mesentery, Guibé remarks, is another evil to be charged to the account of taxis.

65. **Fracture of the Scaphoid Bone of the Foot.**—Besides a personal case reported the details of twenty-eight others from the literature are summarized and the point emphasized that none of the signs permits exact differentiation; this is possible only with the Roentgen-ray examination. If reduction under an anesthetic proves impossible, the region should be exposed and fragments removed and ligaments preventing coaptation pushed out of the way. It seems necessary to wear a plaster cast for a time even after simple reduction, although the cast need not extend more than even half way to the knee. Massage should be done systematically. A flat-foot insole is useful after removal of the cast; with old cases the measures should be those for inveterate flat-foot from the first, with wedge resections striving to restore the normal arch of the foot.

66. **Tendency to Dislocation of the Hip Joint in New-Born Infants.**—The clinical data and theoretical conclusions related compel the conclusion that congenital anthropologie—that is, not teratologie—dislocation of the hip joint never occurs in the uterus but develops after birth. But any malformation in the muscles, the nerve centers presiding over them or malformation of the pelvis is liable to induce congenital luxation. It frequently happens that new-born infants display a tendency to dislocation of the hip joint, "subluxable hip joints," as the authors call them, but this tendency subsides spontaneously in time in almost every case. Girls are more liable to have it than boys. Among the twenty-five illustrations are some showing four cases in which the congenital dislocation was due to dystrophy of the hip muscles. These muscular lesions should be suspected in every case of congenital dislocation of the hip joint in a fetus near term; and other malformations often accompany it. In his four cases there was spina bifida in three and multiple malformations in the other.

67 and 68. **Tetany and Thyroidectomy.**—In these articles Delore and Alamartine describe the best technic for operations on the thyroid in exophthalmic goiter and other conditions to prevent postoperative parathyroopriva tetany. The preferred method is by posterior subcapsular hemithyroidectomy. The details of thirty-two cases of postoperative tetany on record are tabulated, showing the interval after the operation before the tetany developed and the special technics which seem to be more liable to this complication.

69. **Subphrenic Abscesses.**—Piqué reports a number of unpublished cases and discusses those on record, emphasizing the necessity for differentiating the indications for the various types, localization and sources of origin, whether in the stomach, biliary apparatus, appendix, spleen or pancreas, and the pulmonary complications. The prognosis of the abscess left to itself is almost inevitably fatal. He distinguishes between the subphrenic pyopneumothorax and the pyothorax, and insists that the true subphrenic spaces are only those between the diaphragm and liver, between the diaphragm, liver and stomach, and, on the left, around the spleen. As these spaces are bounded by the diaphragm, abscesses in them simulate a thoracic lesion and are particularly liable to spread to the pleura and lung.

Semaine Médicale, Paris

September 28, XXV, No. 39, pp. 457-468

- 70 *Indications for Operative Treatment in Gastric Pathology and Pseudoneuroses. H. Vuillet.

70. **Indications for Operative Treatment with Gastric Symptoms.** Vuillet describes a few cases to emphasize that besides stenosis there are other mechanical causes of defective functioning on the part of the stomach. If they are not recognized and the patients are treated as for stenosis, not much harm is done, but if the trouble is classed as a neurosis the disturbance persists indefinitely. He protests against gastro-enterostomy as a routine measure; the surgeon and internist should study

the case together. The surgeon should be enough of a diagnostician to know what belongs to the internist and what to the surgeon. Among the typical cases he cites from his experience were some in which the pylorus and upper part of the duodenum were bound down by adhesions, the sole relief of some long-healed inflammatory process. The disturbances suggested a merely nervous trouble, but no treatment gave effectual relief until the adhesions were broken up. One patient had been treated for this gastric discomfort for years on the assumption of a neurosis but liberation of the perigastric adhesions relieved all the disturbance. Her little son, 10 years old, already presents gastric discomfort. Another patient had had gastric symptoms for thirty years and had taken all kinds of treatment without avail. There seemed to be nothing abnormal in the motor or secretory functioning of the stomach, but operation revealed an adhesion between the gall-bladder and the intestine; a small cicatrix was found on the liver. Breaking up the adhesions relieved the patient of all the disturbances and she soon increased nearly forty-four pounds in weight. This woman's son, 23 years old, had a callous ulcer of the stomach and required gastro-enterostomy; extensive adhesions were found throughout the region. In another case a woman of 45 had long suffered from the stomach but without distinct signs of an ulcer and the diagnosis of a neurosis had been considered established. The stomach was rather large and exploratory laparotomy revealed the gall-bladder and liver bound down with adhesions, fastening them to the duodenum. Release of the adhesions did not seem to benefit at first but now, two years later, the woman is in perfect health. In another case a year passed after the release of adhesions before the gastric discomfort was entirely banished. The symptoms in this case had suggested cancer but the stomach findings were negative, except for the pains, vomiting of bile and regurgitation, constipation and emaciation. In one case the adhesions formed again after nine months' freedom from symptoms. In two other cases the direct benefit from the operation was slight, but the patients declare that the operation relieved their minds as excluding gross disease.

72. Ehrlich's "606" in Syphilis.—Gennerich gives the details of thirty cases of syphilis in which "606" was applied, he says, with surprisingly good results. Signs of general disturbance were observed in only one case, although moderate acceleration of the pulse was regularly noted. In one case of complete paresis the patient could stand up and hold out his hand, the day after the injection, and the mind was clear for the first time in two months. In a case of total hemiplegia the arm could be bent to a right angle the next day and the improvement progressed afterward. A similar syphilitic hemiplegia in another case had proved refractory to a long and intensive course of mercurial treatment, while in another case of total paresis, three months of mercury were required to produce the improvement realized in twenty-four hours after the injection of "606."

73. The Wassermann Reaction in Human Milk.—Thomsen has found that the Wassermann test applied to the milk usefully supplements the serum test. There was always a positive reaction with the milk when the serum reacted positively; in fifty cases the reaction was more pronounced in the milk than in the serum. The milk of 200 non-syphilitic women gave the reaction in ninety-six cases, no reaction in ninety-eight and a positive reaction with a very small amount in six

cases. The test is therefore quantitatively specific when applied within the first two days after the child has begun to nurse. The absence of the reaction is important evidence against the assumption of syphilis as the reaction in the milk does not seem to be influenced by preceding mercurial treatment which may abolish the reaction with the serum.

74. The Urine Findings in Diagnosis of Carcinoma.—Salzkowski reports further research on the colloidal substances in the urine which seem to be materially increased in case of cancer. He describes his simplified technic. The findings in the cases tabulated show that the colloidal nitrogen averages 3.5 per cent. of the total nitrogen in normal urine and 7.75 per cent. with cancer.

75. Intratracheal Insufflation for General Anesthesia.—Unger reports two cases in which he applied Meltzer's technic. In the first case all went smoothly, but in the second case, two minutes after removal of the tube the young man seemed to be suffocating, with cyanosis; the respiration was purely abdominal and labored and an extensive cutaneous emphysema developed though the pulse remained strong and regular; the pupils were contracted. This condition lasted for half an hour but then gradually subsided although the emphysema persisted for three days. The introduction of the tube had been difficult in this case on account of chronic laryngitis.

76. Congenital Coxa Vara.—Drehmann explains this condition as the first degree of a congenital defect in the femur, and discusses the treatment.

87. Gastric Hyperacidity.—Piek summarizes the present status of knowledge in regard to hyperacid conditions in the stomach. He has encountered a number of cases in which persons whose occupation is particularly wearing on the nervous system, with much worry, experienced a sudden burning pain in the stomach region at certain regular times in the day. Examination revealed that it was due to copious secretion of a very acid gastric juice. In some cases the pain occurred an hour or so after dinner, in others before dinner or after breakfast; and the pain was relieved by taking a little food or alkali. The characteristic feature common to these cases is the fact that the attacks occur only when the patients are attending to business; this is most evident by the absence of the pain on Sundays and holidays. There is generally a tendency to nervousness and hypochondria, and the patients grow weak usually from unwise abstinence from food. In certain other cases, the hyperacid attack comes on when the meal is not taken at the accustomed hour; if the meal is on time there is no disturbance. In treatment of all hyperacid conditions and hypersecretion the diet should be such as to stimulate the gastric secretory glands as little as possible. Piek aims to regulate the diet according to the patient's

customs and what he knows he can bear, never forgetting that the causes of hyperacid conditions are liable to be manifold and that there may be disturbances in the sensory and motor functioning as well as in secretion. It is evident from his compilation the authors vary just as widely in their treatment as in their conception of the nature and development of hyperacid conditions. The hyperacidity is merely a symptom, a functional disturbance, the cause for which may differ in every case.

88. **The Spirometer in Emphysema and Heart Disease.**—Bruns comments on the close connection between the vital capacity and the functional capacity of the lungs. Treatment of emphysema should aim to increase the vital capacity, and he has found the spirometer a valuable aid in diagnosis and in estimating the effect of treatment.

89. **DiETING in Treatment of Psoriasis.**—Bloch reports a case in which a man of 40 had had for seven years typical psoriasis of the nails, hands, scrotum and parts of the body. The psoriasis had resisted all kinds of local treatment and arsenic. Bloch ordered him to drop meat from his diet and the result was surprising even in two weeks, and not a trace of the psoriasis was left by the end of three months. It was interesting to see the normal nail growth pushing off the abnormal parts of the nails. The dieting in such cases avoids the substances in the food which had previously modified the soil, permitting the unknown agent of psoriasis to get in its work. Dropping the meat from the diet seemed to put an end to this sensitization.

95. **Diagnosis of Typhoid and Paratyphoid.**—Minertz found that typhoid bacilli could be found in the blood early in the disease but less frequently thereafter, contrary to the experiences with the agglutination reaction which increases as the disease progresses. In the 167 cases which he reviews, the diazo reaction was positive in 65.2 per cent.; in 113 cases the leukocytes numbered less than 6,000 in 63.6 per cent., up to 10,000 in 32 per cent. and over 10,000 in only 4.4 per cent., including 2 convalescents and an infant. His experience, he says, thus emphasizes the diagnostic importance of the diazo reaction and of hypoleukocytosis. Bacteriologic examination of the blood with Kayser's bile tubes permitted an early diagnosis in 100 per cent. of the 16 cases examined during the first week. He regards paratyphoid as an entirely different disease from typhoid, his experience confirming the fact that infection is derived from meat, especially pork, or external contamination of foodstuffs, while typhoid is derived from human sources. The prevalence of paratyphoid bacteria everywhere, their saprophytic existence in man and animals, and other features resemble in many respects the behavior of streptococci.

96. **Diagnosis of Gastric Cancer from Hemolysis by Stomach Content.**—Grafe says that further research is confirming the importance of the hemolytic test as revealing gastric carcinoma; the findings of the test were constantly negative in 32 healthy persons and 111 patients with various affections but none involving the stomach, while the hemolysis was pronounced in 100 patients with suspected gastric cancer and in 56 an operation or necropsy confirmed the diagnosis. He has found that the presence of minute amounts of oleic acid in the stomach content in the cases of cancer is apparently responsible for the hemolysis. This discovery, he thinks,

much simplifies the test as the ordinary tests for oils can be applied. The patient takes as little fat as possible the evening before the test; the next morning the stomach is rinsed, with care not to aspirate bile into the stomach. Then the Ewald test breakfast is taken and 45 minutes afterward the stomach content is withdrawn and filtered. From 20 to 40 c.c. of the filtrate or even less are then treated by the Hübl iodine-absorption technic and the findings computed for 100, 200 or 300 c.c. of filtrate. The upper limit of normal iodine-absorption value is 9.5 c.c., while with carcinoma the value is from 11 to 20. As extensive ulceration in the stomach gives findings at times approximating those with cancer, the test is most useful for differentiation of cancer from achylia, gastritis, nervous dyspepsia and pernicious anemia. The findings were constantly negative in 9 healthy persons to whom the Hübl technic was applied and in 33 with a stomach affection that had nothing in common with cancer or ulcer and in 33 of 35 patients with gastric ulcer. On the other hand, the findings were positive in 19 out of 20 patients with unmistakable cancer, in 2 with presumptive cancer and in 3 out of 13 suspects. In 3 other cases the clinical data did not harmonize with the positive findings of the hemolytic test but time soon revealed the correctness of the latter, the clinical course soon falling into line. In a man of 40 the iodine absorption value of 11.4 per 100 c.c. of stomach content confirmed the suspicion aroused by discovery of blood in stomach content and stool although there was nothing otherwise to suggest cancer, and a movable tumor was found in the stomach, the microscope showing malignant elements in an old ulcer scar. This is one of the earliest diagnosed cancers on record. In two other cases the positive assumption of cancer was disproved by the negative findings with the test and necropsy later, showing encroachment into the stomach of an aneurysm in the aorta in one case and a callous gastric ulcer in the other. If intestinal juice or bile gets into the stomach the test is not reliable, but blood does not affect it. The hemolytic reaction, he reiterates, is not specific for cancer, but merely indicates the presence in the stomach content of oleic acid which normally is not found there.

98. **Changes in Drop-Forming Properties of Body Fluids.**—Schroen says that Aseoli's meostagmin reaction is practically the same as Weichardt's epiphan reaction with a little different technic—both indicate the presence of specific substances under certain conditions modifying the drop-forming properties of the organic fluids. The modifications observed have differential value in certain conditions; for instance, the curve with typhoid and colon bacilli infections is quite different. The biochemical reaction involved is extremely delicate, sensitive and constant with a large number of substances and body fluids.

101. **Gall-Stone Operations.**—Kerr remarks that since he has given up general surgery his results have been growing constantly better in his special field of gall-stone operations as there is no longer any chance of accidental infection from phlegmons, etc., on other patients. He has banished post-operative pneumonia entirely from his service, possibly by his insistence on having the teeth put in good order before he operates, and by the systematic breathing exercises enforced afterward. It is impossible, he declares, to determine by a single examination whether an operation is necessary, except in cases with vital indications. The patients have to be examined several times and kept under observation in the clinic for a few days. His mortality has not been over 1.4 per cent. in his series of 1,600 cases, restricted almost exclusively to patients with cancer or septic cholangitis.

102. **Evils of Forcible Dilatation of the Anal Sphincter.**—Mehlhor states that re-examination of a number of patients operated on years ago has revealed incontinence in some of the cases in which the sphincter fibers were cut or forcibly stretched. His operations were in eight cases for fissure of the anus, and in twenty-five the anus was stretched during an operation for hemorrhoids. In three of the cases the incontinence is far more disagreeable than the condition for which the operation was done. As the stretching of the sphincter causes no disturbances in the majority of cases,

he is inclined to explain the trouble in these cases as the result of stretching the anus before it was entirely relaxed under the influence of the anesthetic. In one instance the anus was stretched under primary ether anesthesia, which probably is not deep enough for these cases. The trouble is possibly the result of laceration of some of the sphincter fibers with secondary atrophy, although it is possible that the mere stretching alone might injure the fibers enough to lead to consecutive atrophy.

103. **Ascaris Poisoning.**—Goldschmidt relates that he and some of his assistants have attacks resembling hay fever and asthma when they are dissecting and working on ascarides. The peculiar pungent odor of the worms seems to irritate the mucous membrane, even without direct contact with the tissues. The ascaris found in the horse is much more toxic in this respect than the ascaris of man and pigs.

104. **Jerking Inspiration.**—Schaefer denies any pathologic significance to a staccato respiration, believing that it is merely the result of the propagation to the lung tissue of the concussion of the heart beat. It is similar to the vibration of the voice induced by tapping on the larynx during singing and whistling.

105. **Callous Gastric Ulcer.**—Kelling has operated in 51 cases of callous gastric ulcer with an interval since of over three years, and he discusses the diagnosis and treatment. The disturbances are inclined to be chronic, without the remissions observed with simple ulcer, and they continue without much change through months and years. About a third of the ulcers were palpable. The long duration of the lesion is the principal argument against cancer; a hemorrhagic tendency was evident in the majority of the cases, and an open ulcer was suggested by the intense pains especially during digestion. These callous ulcers do not heal under internal measures like simple ulcers, but, excluding the malignant cases, nine-tenths of the patients were cured of all disturbances by a gastro-enterostomy. In about one-third of his cases there was a malignant tendency and others have found it in up to 40 and even 50 per cent. Dietetic after-treatment is necessary when gastro-enterostomy has been done, and during the summer special care should be taken to avoid gastro-intestinal fermentations and to ward off intestinal catarrh. The danger of cancer with callous ulcer is over twice as great as with ordinary ulcer, but the ultimate outcome after removal seems to be more favorable with cancer developing in a callous ulcer than under other conditions. He has examined over 1,300 patients with various diseases to determine the frequency of a hemolytic reaction in the blood, and has found this reaction a useful guide as to the presence of malignant disease.

106. **Myoma and Glycosuria.**—Calmann reports two cases in which uterine myomas were accompanied by slight glycosuria without any other signs of diabetes. In the first patient the glycosuria disappeared entirely after removal of the myomatous uterus, but the glycosuria was not affected by the hysterectomy in the other case. He urges study of the connection between myoma and glycosuria, insisting that the urine should be examined again and again for two years at least after hysterectomy to learn the conditions in respect to elimination of sugar, and whether actual diabetes is influenced by the operation.

121. **Continuity of the Functioning of the Mammary Gland.**—Schein thinks that he has demonstrated that the mammary gland has an insensible internal secretion and that there is a continuous functioning of the gland not restricted to the production of a visible secretion.

122. **Pathologic Low Blood-Pressure.**—Münzer reviews the various groups of conditions accompanied by low blood-pressure aside from the acute or chronic infectious conditions. He gives a number of examples of low blood-pressure as the result of arteriosclerosis restricted to the large vessels. The maximal blood-pressure is low while the propelling force of the pulse wave is high—typical signs of changes in the large vessels. When the propelling force declines, this is a bad omen and should attract attention. In one of his cases this sign closely preceded sudden death and in two others it preceded severe cerebral hemorrhage. In another patient this sign was observed during a postinfectious cardiovascular disturbance and subsided under appropriate measures. In another group the low blood-pressure was due to status lymphaticus, and Münzer has found unusually low blood-pressure in his patients with exophthalmic goiter—contrary to statements in the text-books. His third group of cases includes patients with orthostatic albuminuria; in one case the low blood-pressure and low pulse force were observed with severe nephritic albuminuria which assumed the orthostatic form. In a case reported with the detailed findings the tendency to fatigue and apathy, the gastro-intestinal symptoms and the extremely low blood pressure suggested Addison's disease or severe functional disturbance in the chromaffine system. Herz has lately reported some cases of similar hypnotic bradycardia; it is possible that the assumption of defective functioning of the chromaffine system may explain orthostatic albuminuria. Münzer states further that vascular hypertonicity is the rule with nephritis; not until the vessels are injured by the effects of nephritis does the blood-pressure rise. Until the vessels are thus injured, the blood-pressure is normal or below. A case of paroxysmal tachycardia which he reports in detail shows that the pulse rate and blood-pressure are independent of each other. In conclusion he refers to the low blood-pressure in cachectic conditions.

Four months later he returned with an abdominal tumor which proved to be the undescended testicle, and this, likewise, was the seat of a sarcoma. The patient has been in good health during the eight months since. None of the glands seems to be affected. Sabella discusses the peculiar abdominal-lumbar location of the undescended testicle in this case and the occurrence of the sarcoma in both testicles with no apparent communication between them. He also reviews the literature on a constitutional tendency to neoplasms and the predisposition afforded by the undescended testicle.

THE PROPHYLAXIS OF CANCER *

CHARLES H. MAYO, M.D.
Surgeon to St. Mary's Hospital
ROCHESTER, MINN.

Among the great problems which confront the world to-day is that of cancer. The question of tuberculosis has been practically answered. The bacillus is known, as well as its modes of entrance to the body, its varying methods of attack and the causes of death from the disease. Up to a few years ago what the public learned of tuberculosis was through the advertising of interested dealers of patent medicines, promoters of health resorts and the exaggerated statements of irregular practitioners. To-day, with what may be called a world movement, tuberculosis is gradually being controlled and the percentage of deaths is yearly being lessened.

In view of the wonderful progress made in the prevention, care and curability of tuberculosis which has developed in the short time since the public was first taken into the work as assistants, is it not time that we should more generally diffuse what knowledge we have of cancer?

This world-wide disease is not confined to any certain people, but occurs among all races of mankind, and, indeed, is found throughout the vertebrate kingdom. Fish often have goiter, and in certain waters cancer seems to develop from these secondary changes in the thyroid. The disease also occurs in birds. In over a thousand instances primary cancer has been found in mice and thousands of cancers have been grown by inoculation (Bashford). Domesticated animals are somewhat more susceptible to it than animals in the wild state. This fact is explained as due to their longer life, the disease being more common in the relatively aged in both man and animal. While cancer is said to be uncommon in some countries, in Japan, for instance, there are 25,000 deaths a year from the disease in that country. In England it is estimated that, of individuals over 35 years of age, one out of every eight women and one out of every eleven men die of cancer, a greater death-rate for age period than from tuberculosis. We are not far behind in this country, with 80,000 cases constantly in progress and over 40,000 deaths each year from the disease.

It is undoubtedly true that the public is at present looking more anxiously for a specific or cure than for prevention of cancer, but it is in the line of prevention that the medical profession has assumed its present position of importance in the world. Practically all of

the acute diseases with which the population of the earth is afflicted are due to bacterial infection. It follows naturally, therefore, that the medical profession should search diligently for the germ of cancer, that an antagonistic remedy may be developed for its cure.

While it would be extremely interesting and useful to discover the parasitic origin, if such it be, of cancer, it is not vital. It requires but little judgment to decide that to prevent disease is better than to cure it. To prevent a case of diphtheria should be greater cause for elation than greatly to reduce the mortality by the use of antitoxin. The use of antibodies or serums as cures when the disease has been permitted to develop, and their use as vaccines for the prevention of disease, should by no means be discredited. It has been by such prevention and control of disease in children, and the reduction of mortality in adults, that the length of human life has been increased, and more people now than formerly reach a cancerous but not a proportionate old age. This fact, together with better diagnostic facilities and more carefully collected vital statistics, makes it appear that cancer is on the increase. The sooner this subject becomes one of general discussion, as tuberculosis has been in the various scientific meetings and in literature, the sooner may the adult hope to reach old age.

What is cancer? I shall not enter into a special description of cancer and its varieties beyond quoting briefly from Dr. L. S. Pilcher, who described the condition as follows:

It is in the lawless proliferation of preexisting epithelial cells in luxuriant, irregularly arranged masses that invade underlying and surrounding tissues, permeating, destroying them, and finally themselves attaining a mass which can no longer be adequately nourished by an accessible blood supply, and which itself then falls into central decay, while at the periphery the process still goes on, that cancer consists.

We must consider the irritation of groups of epithelial cells as the primary origin, and that such an arrangement occurred as a prenatal inclusion (this is questioned), or postnatally as a result of some mechanical or inflammatory condition. There is then a cell proliferation which becomes cancerous only when there is infiltration of the tissues.

From all the information which has been presented on the subject it is evident that there often exists a precancerous condition. The unproved type, that of prenatal displacement, we are unable to recognize. The postnatal type we recognize at least in the presence of tumors of a temporary, benign character in their more regular and uniform arrangement of structure and cells, such as warts of the skin, papillomata of the bladder and fibromata of the breast, as well as cell inclusions which occur in the scars of inflammations, or burns and the results of long-continued local irritation to tissues. These growths resemble the embryologic development of

* Chairman's Address before the Section on Surgery of the American Medical Association, at the Sixty-first Annual Session, at St. Louis, June, 1910.

cells merely in the power of cell multiplication and in the continuance of type in the metastasis and transplantation of the growth. Youth, because of the vigorous growth of the cells, is less subject to cancer, yet more susceptible to poisons, but the active lymphatics in youth cause rapid dissemination of disease when it occurs.

Bashford shows that, while no race of mankind is exempt from cancer, the predilection for the disease in certain countries is more from local irritation than from the peculiarities of climate, soil and diet. I shall mention only a few well-known sources of irritation as a cause of special cancer. For instance, carcinoma of the mouth is rare in European women but common in men, yet in Ceylon and India women suffer greatly from cancer of the mouth because of the chewing of betel-nuts and holding the plug in the mouth. In this country leukoplakia carcinoma is found mostly among those who use tobacco. Cancer of the skin of the abdomen, a rare condition, is common in natives of Kashmir, who wear abdominal charcoal heaters next to the skin. Lip or pipe cancer is an example of radiant actinic irritation, and there are numerous tumors from chemical and infective sources. Chimney-sweep cancer and innumerable other special forms are seen. It has been shown also that it may occur in a circumscribed area, and that any epithelial lining or covering may become cancerous. Why this is not still more common following chronic irritation or, if due to a special germ or parasite, why it does not occur after acute simple injuries it is impossible to say.

It is generally supposed that carcinomas often develop from severe single injuries, but there is no evidence that single injury does other than call attention for the first time to a preexisting tumor or hasten the growth in early or dormant malignancy. It is an apparent fact that in classifying the causes which may render precancerous conditions active we should include nerve-cell fatigue, such as is seen in the modern business world. The organs of convenience, *e. g.*, stomach, bladder and large bowel, which were added late to primitive life, have poor cell resistance and are prone to cancer degeneration.

Cancer of the stomach, bladder and large bowel undoubtedly often result from chronic local irritation. The tumor may often originate about the base of the appendix and in the wall of the cecum. It has been found by MacCarthy in a study by serial section of over 5,000 appendices which had been removed for so-called chronic subacute appendicitis, that 0.5 per cent. of them were carcinomatous, although the external appearance of these appendices did not always indicate such a condition. The diagnosis was made at operation in only 23 per cent. of the cases. It has been shown that diverticulum of the large bowel is sometimes the cause of cancer, and in such cases it is only in finding comparatively early growths which have not destroyed the diverticulum that the original location of the change can be shown. Therefore, in advising the early removal of chronic, inflamed appendices, we are avoiding the possibility of the development of a few cases of unrecognized cancer, not to mention the possibility of its development in some of the appendices which are removed in a precancerous condition.

Just at this time ulcers of the stomach seem to have taken a leading position as the cause of cancer development. It is not hard to understand how cell groups may become isolated by connective tissue development as a result of erosion or ulceration. This condition is becom-

ing more and more commonly recognized and it is estimated that a large percentage of the cases of cancer of the stomach have developed on ulcer. The trend of popular treatment in gastric surgery is to recognize the cancerous tendency of ulcers and excise them in their precancerous condition, reserving gastrojejunostomy for the cases of obstructed pylorus from closure or probable stenosis following excision of the ulcer. The question presents itself as to whether the supposed repeated medical healing of ulcers relieves the tendency to cancer.

Papillomata of the bladder are often found in the benign stage, yet we know that they develop cancer, and they should, therefore, be thoroughly removed as a precancerous condition.

It has been noted that the prostate gland is very subject to hypertrophy and hyperplasia, yet operation for its removal has been advised only when the distress and necessity become very great. Our present knowledge of the condition shows a high percentage of cancerous changes in the gland, which should be taken into consideration in deciding the advisability of operation before the proliferation of tissue becomes an infiltration, and some relief an absolute necessity. The mortality following operation in this early stage is low in comparison with that resulting from deaths of patients with symptoms who have not been operated on, to say nothing of the suffering which will have been avoided. Operation, however, is not advised merely because there is hypertrophy, which is common, but to avoid the changes incident to chronic irritation when it exists.

Patients with thyroid tumors who require operation, prove that chronic irritation of an adenoma may cause carcinoma in about one in twenty-five or thirty cases. A rapidly growing hard goiter should be looked on as a menace and early operation advised.

In a consideration of the irritative effects of the tumors of the body of the uterus, in which fibroids are common, we find $1\frac{1}{2}$ per cent. to be sarcomatous and 2.5 per cent. carcinomatous; yet the fibroid itself would be capable only of sarcomatous malignant change. In 1,000 hysterectomies for fibroids in women over 50 years of age, Sutton found that 10 per cent. of the tumors were cancerous. The condition will be found fifteen times in the cervix to once in the body of the uterus, yet in the cervix it is associated with fibroids in only $\frac{1}{3}$ per cent. Of the cases of cancer of the body of the uterus 40 per cent. are associated with fibroids, that is, over one hundred times more frequently than in cervical cancer. The first stage in such cases is adenomatous proliferation of the endometrium; the second, lawless cell-growth and invasion, or cancer. Fibroid of the uterus, while a fairly common condition, may often not be realized by the patient. Operation should not be advised in all cases, but in those which are giving symptoms; myomectomy in the young and hysterectomy in the older individual being the methods of choice. Chronic erosions are probably a greater menace than is commonly supposed, and they should receive attention.

A few years ago a tumor of the breast of a woman 35 or more years of age, which was not of infective origin, was considered malignant in proportion of four to one, and it seemed probable that nearly one-half of the tumors which were considered benign at the time of operation eventually became malignant. In the last ten years the increasing knowledge of the public, which has led to earlier operation, has reduced the proportion of probable malignancy at least 10 per cent. Tumors of the breast, not themselves malignant, may create a

change in the adjacent breast tissue by chronic irritation, or they may change within their own structure. Well-collected statistics show that the results following operations for cancer of the breast indicate that 80 per cent. of the patients remaining well three years were operated on within six months of the development of the tumor, and about an equal number, who had no palpable glands in the axilla at the time of operation, remained well. It is obvious that a patient should not be obliged to have the growth of a tumor watched for marked evidences of malignant change, a delay which might reduce the chances from the best average of cure; that is, about 50 per cent. for three years, to a possible 20 per cent. cure, or much less.

Considering that the mammary gland is very prone to cancer, are we justified in hesitating to advise early removal for examination of supposed simple tumors as freely as in those which are considered malignant? Physicians should not assume the responsibility of delay, but should inform patients that in retaining this source of chronic irritation they must do it at their own risk and responsibility. From a careful observation of the operative cure of cancer of the breast it appears quite probable that an early operation, even though incomplete so far as the removal of muscle, axillary lymphatics, fat and fascia is concerned, will still give better results than the most radical operation which is done late. I by no means wish to decry the late radical operation, but would urge, rather, that the radical operation be performed early in order to have the cures approximate 80 per cent.

Are there cures for cancer? At present we recognize none other than that obtained by removal from the body by means of knife, cautery, paste or destructive rays. All methods used to cause a disappearance by absorption within the body by body tissues or fluids are as yet failures as cures, although growths have been checked and even shrunk by such measures.

It must be admitted that there is a wide difference in the malignancy of cancer, in the character of its growth and the tissues involved, yet but little consideration is given to another important point—that there is just as wide a variation in the resistance of the individuals for the same type of cancer. Some patients who have this power of resistance and who remain well for several years after operation are often claimed by the surgeon as examples of the benefits of some particular method of operation or of some unusual cure which has been given them. Such patients do well with oft-repeated secondary operations, while others melt away with the disease or through metastasis.

A promising effort is being made to utilize cytotoxicity by using serums made from patients proved resistant to cancer, and from embryos of the same species, to create a destruction of the cells of embryonic type and character and power of regeneration, as seen in cancer.

Cancer is a disease of adult life. The patient is naturally the one most vitally interested, and he should be informed, in the precancerous stage, of his danger. We lose many opportunities for disseminating life-saving knowledge to the public by a mistaken regard for the sensitive feelings of the patients, until their condition has become practically helpless from an operative standpoint. The layman requires considerable explanation before he can be made to realize that the risk is not in surgery, but in delayed surgery. He considers all operations alike in their danger and severity, while in reality there is a very wide variation. It is a simple operation to remove stones from the gall-bladder. A delayed oper-

ation may require their removal from the cystic or even the common duct, and very often a pancreatitis will have developed. On an average, one in thirty of these cases has developed cancer as a local condition around a gall-stone which has chronically irritated some mucous area of the gall-bladder duct. In nearly all of the cases of primary cancer of the gall-bladder and liver ducts gall-stones have been found.

If surgery for cancer is in disrepute to-day it is partly because too large a proportion of patients are accepted without explanation for operation at a stage when there is no possibility of cure, and when their families, if not themselves, should have been informed of their hopeless condition. If they had been left they would have served as living examples of the results of delay instead of the unsatisfactory results of ill-advised surgery.

We can, however, say this: that we know nearly or quite as much concerning cancer as we do of other medical and surgical diseases. The danger of local irritation of a chronic character has been underestimated. Our present knowledge of the prophylaxis of cancer indicates that all tumors should have a medical examination and the majority of them a surgical consultation in order that we recognize the precancerous condition, and reduce mortality by prevention.

ETIOLOGY OF CANCER OF THE SKIN *

LEO LOEB, M.D.
PHILADELPHIA

In the following brief report on cancer of the skin I shall limit myself to a consideration of the epithelial forms of cancer. Even here I shall not be able to go into any detailed discussion and I must ask for indulgence in case I should express my opinions on certain questions without being able to give the data on the basis of which such opinion has been formed.

The etiology of cancer of the skin is, of course, on the whole not different from the etiology of cancer in other parts of the body, and the same principles underlie the formation of cancer in various organs. Cancer of the skin differs from cancer in other parts of the body inasmuch as the pathologic changes taking place in the skin are so much more accessible to direct observation. The clinicians have taken advantage of this circumstance, and to the clinicians we are indebted for some interesting discoveries concerning the causation of cancer of the skin.

EXTERNAL AND INTERNAL FACTORS

In following the origin of cancer of the skin we recognize most clearly the importance of external factors, and to me this is one of the most significant facts. Another conclusion that impressed itself on me in considering the various forms of cancer of the skin is the presence of a second condition which we may designate in a preliminary way as the internal factors.

Now, in the different varieties of cancer of the skin we see these two sets of factors associated in various combinations. If the external factor is very potent the internal factors can be dispensed with, and if the internal factors are very potent the external factors play only a subordinate rôle. There are intermediate

* Read in the Section on Dermatology of the American Medical Association, at the Sixty-first Annual Session, held at St. Louis, June, 1910

conditions in which a cooperation of the two agencies is of importance. To cite a few examples: In Roentgen ray cancer the external factor alone seems to be sufficient. An internal factor plays apparently a very negligible rôle in this case. It is perhaps similar but not quite as pronounced in the case of the chimney-sweep cancer of the scrotum. On the other hand, in xeroderma pigmentosum the internal factor is very potent and the external factor, although present, is without influence in normal persons of the corresponding age.

It is somewhat similar in persons affected with pigmented moles. The internal factor leading to the production of nevi is of preponderating importance, while in the case of normal people the external factor would be of a very trivial character. In the cancer developing in the skin of the sailors and in old people we are not in a position at the present time to know the relative distribution of the external and internal factors. We lack as yet statistical data sufficiently comprehensive to allow us to state what percentage of persons, in whom the external agency acted with a definite intensity over a certain period of time, became affected. Only on the basis of definite, we might call it, quantitative determinations, could we advance in this direction.

Let us now attempt to analyze those factors somewhat more closely. The external factors¹ of importance are (1) light rays, especially the short-waved and the ultraviolet rays; they play a part in the cancer developing in seamen long exposed to the rays of the sunlight; they determine the lesions in xeroderma pigmentosum, where the lesions are found in those parts that are more or less exposed to the light. They are in all probability also concerned in the causation of cancer which is found in old people on the basis of keratoma senile, or the so-called seborrheic wart. These changes are mainly found on parts of the body exposed to light. The Roentgen rays are of course responsible for the cancer of Roentgen ray operators. Next, certain chemical factors are undoubtedly the cause of a certain number of cancers. Soot, and especially hard coal soot, causes cancer in chimney-sweeps, and certain chemical products induce cancerous growths in paraffin and coal-tar workers. In these cases the irritating substance, the chemical character of which has not yet been ascertained, attacks the skin directly, reaching it from the outside. In persons taking arsenic over long periods of time this substance influences the skin after having previously been absorbed from the intestinal canal. Mechanical factors are also of importance. There is no doubt that mechanical irritation plays its part in transforming pigmented moles into cancer. And if we include the cancerous affections of the tongue and lip it is certain that the friction of imperfect teeth or the mechanical effect of a pipe may cause cancer. In the latter case heat may perhaps play a certain part, while a combination of heat and mechanical irritation, or either alone, acts in the case of Kangri cancer, observed in Tibet. Here a small stove carried near the skin of the abdomen causes a peculiar cancer of the skin. Among the external factors responsible for cancer we may also mention those conditions or organisms that cause affections, such as lupus, psoriasis, and leucoplakia of the tongue, and various chronic ulcerations and scars, as a sequel of which cancer sometimes develops in the skin and in the tongue. Of course, we

must realize that such a sharp differentiation between external and internal conditions does not do full justice to the complexity of nature, and that, *e. g.*, a condition that at one time acted as an external factor may later on become transformed into an internal factor and only after such a transformation has taken place it may act as a cause of cancer. And this is what some pathologists, indeed, assume to take place. A distinction between conditions outside the organism, conditions inside the organism but outside the epithelium and conditions inside the epithelium would be more correct.

In regard to the internal conditions our knowledge is much less definite. We know that melanotic cancer frequently starts from a pigmented mole and that the latter is a condition present at the time of birth or developing in very early life, and probably due to developmental abnormalities which may be hereditary. A certain localized congenital and also hereditary condition is therefore one of the internal factors leading to cancer.

In xeroderma pigmentosum some internal factor making the skin peculiarly susceptible to the action of light and ultraviolet rays is undoubtedly present. In the absence of positive knowledge we may propose the following hypothesis: We know that certain substances, especially fluorescent stains, are able to sensitize living cells as well as ferments to the injurious action of light. We furthermore know that cattle that feed on buckwheat (*Buchweizen*) become very sensitive to the influence of light rays, and skin affections follow if the cattle are exposed to the light. It is possible that in xeroderma pigmentosum a substance is produced internally that sensitizes the skin and certain mucous membranes to the action of light; the last stage of the light action in a sensitized skin is the development of cancer. Whether primary differences in the anatomic structure of the skin and mucous membranes are present in patients affected by xeroderma pigmentosum has to my knowledge never been examined. Nor is anything known, so far as I am aware, in regard to the sensitiveness of the skin in such patients toward the action of other than light and ultraviolet rays. Whatever the ultimate character of this internal factor is, it must in some cases have been indirectly transmitted through the germ cells of the parents, probably in the form of a preparatory substance, inasmuch as it is known to occur in sisters or brothers of the same family. Nothing definite is known concerning the existence of internal factors in the cancers of old age, cancer after use of arsenic, cancer in chimney-sweeps and other similar conditions. We might be inclined to believe in the presence of some predisposing internal factors in such cases inasmuch as we notice that only certain persons are affected by cancer or seem, at least, to become affected much more readily among a much greater number of people exposed to the same injurious influence. We must, however, be well aware of the fact that in such cases we cannot be certain that the same quantity of external injury, if we may thus express it, acted on all the persons exposed.

EMBRYONIC THEORY

There are other internal factors to which a great or, we may say, the almost sole responsibility has been attributed. I refer especially here to the views expressed by Borrmann. This author made extensive microscopic studies of early stages of carcinomata of the skin, and came to the conclusion that cancer of the skin is in almost all cases due to embryonic malformation which leads to complete separation of certain parts of the

1. Interesting observations concerning the action of etiologic agencies have been made in this country, among others, by Hyde (action of light), Harizell, Schamberg (action of arsenic), Wolbach (effect of Roentgen rays) and Councilman and McGrath (xeroderma pigmentosum).

epithelium from the rest of the epidermis and their transposition into the corium. Thus the corium carcinomata are produced which include, for instance, the cases of rodent ulcer. Or certain parts in the epidermis may remain in an undifferentiated condition and give rise later to the prickle-cell, keratinizing carcinomata, according to Borrmann.

It is impossible here to go into a detailed criticism of his observations and deductions. Suffice it to say that the results of histologic examinations of others, among whom I might mention H. H. Janeway, do not uphold his view. The typical carcinoma of the skin originates through a direct downgrowth of the surface epithelium or its appendages, and all the evidence at hand proves that, although perhaps in a few cases, carcinoma may take its origin in misplaced embryonal rests, embryonal displacements are of no or of very slight importance in the etiology of the large majority of the cancers of the skin.

RIBBERT'S THEORY AND THE CANCER CELL

In the last analysis Borrmann's views are based on the hypothetical conceptions of Ribbert, and, inasmuch as the views of this author had a dominating influence, at least for a certain period of time, we must briefly refer to the latter. In the course of time Ribbert changed his views considerably, so that at present little is left of what characterized his original conceptions. But the distinctive feature of his hypothesis was the following:

The carcinoma cell in its last analysis is nothing but an ordinary regenerating epithelial cell, such as is seen in wound healing. The only difference between cancerous and ordinary regenerative growth is to be sought in some secondary conditions which do not permit the epithelial cell to unite with its kin to form again a normal organ. In most cases the presence of the inflamed connective tissue is responsible for the separation of certain parts of the epithelium. This is the principal conception of Ribbert's theory, and the facts do not sustain it. The carcinoma cell is not an ordinary regenerating cell. The latter may be put into whatever environment we choose: it always follows the laws that are valid in the case of regeneration. The carcinoma cells remain carcinoma cells even if on both sides they are surrounded by its kin, the normal epithelium, or wherever they may be implanted. Indeed, the transformation of an epithelial into a carcinoma cell takes place, in many cases at least, at a time when the epithelial cell is still in union with the surrounding epithelial tissue. All the experimental evidence at our disposal admits of but this conclusion. Epithelium may grow in agar or blood-serum in the body or in intimate contact with connective tissue and the blood-vessels; the epithelial cells do not behave like carcinomatous cells; on the other hand, we may transplant carcinomatous cells and they will always grow as carcinomatous cells, if growth can be obtained.

This invariable difference between ordinary epithelial and carcinomatous cells induced some writers to seek for a preformed internal factor in the congenital constitution of the cell, and especially of their chromatin. This view appears to be as little justified as the opinion that as a rule cancers of the skin are due to embryonal misplacements. Nor would I recommend at the present state of our investigations the designation of carcinomatous cells as "new cell races" or the use of the term "anaplasia." I believe that all such terms are unnecessary, and that they frequently tend to obscure the real problems which consist in determining functional relations.

AGE AS A FACTOR

There remains another condition which might be classed among the internal factors, and on which great stress has been laid by various writers, namely, old age.

It is certainly correct to state that carcinoma occurs more frequently in advanced age and that certain cancers of the skin are especially found in the senile skin. If, however, we analyze more searchingly what is called old age in the case of its epidermis we will find that we have to deal with a complexity of factors, among which external injurious influences play directly or indirectly the most prominent rôle. The commonly assumed basis for old age is the conception of a certain deterioration in the machinery of the cell which is necessary to occur in the course of time and which is inherent in its structure. As I pointed out nine years ago, I believe this view to be erroneous, especially as far as the cells of the epidermis are concerned. There are weighty reasons why we should believe in the potential immortality of the epidermal cells rather than in their necessary aging. If the senile changes take place in the epidermis they are according to this view due to a long-continued cumulative action of injurious external agencies, as light, heat, mechanical insults, and so on, which acted either directly on the epithelial cells or on the stroma on which the latter live; injurious influences which made themselves felt continuously and from the effects of which no recovery was therefore possible. As far as the epidermis is concerned, old age is therefore a term designating the effects of long-continued external injurious factors. Instead of explaining various skin lesions as due to a premature senescence of the skin we should, it appears to me, take the opposite position and explain the senile changes of the skin as due to the action of injurious external influences.

MICRO-ORGANISMS

By what mechanisms do the external factors which have been enumerated affect the epidermis and how can they call forth a cancerous proliferation? In the first place we might think of the activity of micro-organisms that have an intracellular existence and are therefore constantly acting on the epithelial cells, stimulating them to active cell division and to invasion into the neighboring tissue, such stimulation being to some extent accompanied by changes in cell metabolism calling forth new enzymatic activities. We know, indeed, that certain micro-organisms as those of variola and vaccine and molluscum contagiosum call forth epithelial cell proliferation, and Borrell designated such a condition under the term epitheliosis in contradistinction to epithelioma. And there exist observations made in the course of the experimental investigation of cancer which could be readily explained by the assumption that micro-organisms have an etiologic significance. On this basis all the changes induced by the various external and internal conditions which we mentioned would only serve as means of introducing a certain micro-organism into the epidermis. Although at the present time we cannot deny, and although we must keep in mind such a possibility, we must confess that the probabilities of such a connection between external agencies and cancer appear exceedingly slight at the present time. No tangible indication of micro-organisms that withstood the test of later investigators could be found.

IRRITANTS

On the other hand, we see before us the prospect of an ultimate understanding of the connection of external irritants with cancer by a more penetrating analysis of

the biology of the various tissues, and especially will it be necessary to inquire into the influence which external agencies have on growth processes. Concerning the action of Roentgen rays and radium, considerable stress has been laid on their necrotizing effect. But especially, recent studies have shown that, independently of their necrotizing action, these radiations have a distinctly stimulating effect on the epithelial cells; we furthermore learned that under the localized influence of certain organic derivatives, especially aromatic amido derivatives a limited infiltrative growth of epithelium into the deeper connective tissue structures may take place. It was mentioned above that a combined action of internal and external factors caused carcinomatous growth in certain, probably in many, cases. Recently some advance has been made in the experimental analysis of formative stimuli which throws some light on such a combination of factors and makes it amenable to a quantitative analysis. It has been found that a substance produced by one organ of the body unites with the connective tissue cells of another organ, and that if such a combination has taken place mechanical stimuli can cause an extraordinary, though temporary, tumor-like tissue proliferation. In this case the chemical activity of an organ of the body represents the internal condition and the mechanical irritation the external agency. Such experimental means and studies will allow us to eliminate many variable factors which complicate the development of natural tumors. Although these experimental products which have just been mentioned differ from tumors, mainly in not being permanent, they nevertheless will throw much light on the conditions on which exuberant growth and infiltration of surrounding tissues depend, and will thus help to clear up the mechanism of cancerous growth.

ANATOMIC CHANGES

To this physiologic point of view of considering phenomena of abnormal growth may be opposed the anatomic point of view which undertakes to explain functional changes, such as variations of growth-energy as represented by tumor growth, on the basis of histologic appearances of tumors.

Thus in many changes in the skin due to long-continued external irritation we find more or less a similar sequence of anatomical changes. These typical anatomic changes have been termed "precancerous conditions." Cancers which are caused by the action of light and ultraviolet rays, and also by Roentgen rays and arsenic, and those found in senile skin, are preceded by hyperemia, pigment formation in the epithelial and pigment deposit in cutis cells; increase in the proliferation of epithelial cells, sometimes combined with the formation of epithelial giant cells; hyperkeratinization, formation of warts, and at last cancer formation. In certain conditions (*e. g.*, xeroderma pigmentosum) the hypertrophic processes in certain parts of the skin may be accompanied by atrophic processes at other places. In the later stages certain parts of the connective tissue show definite changes; they become hyaline while other parts directly underneath the epidermis may show a rarefaction. Many blood-vessels may be obliterated.

Now various writers attributed to these changes as such an etiologic significance in the development of cancer. Thus Unna ascribed to the overproduction of pigment some importance; a very improbable assumption, if we consider that on the whole colored races are less liable to cancer of the skin. The production of melanin in the skin depends in all probability on the activity of

certain oxidative ferments, and it is conceivable that under stimulating conditions, among other changes, a correlated change in certain oxidative processes in the cells may take place. Others held hyperkeratinization, as such, responsible; again a very unlikely assumption. Hyperkeratinization being merely the expression of atypical growth phenomena which are taking place in the skin, cannot be considered as the cause of these growth processes. Others accused the obliteration of blood-vessels; this condition, it was argued, forced the epithelial cells to obtain their food-supply from connective tissue cells; which latter process was said to act in a similar manner as the penetration of a spermatozoon into the ovum, a somewhat fantastic comparison with hardly any foundation of fact. Ribbert believed in the etiologic importance of a subepithelial cell-infiltration. But this is not always present at the commencement of the cancerous growth. Others assume that the chronic connective tissue changes liberate the latent energy of the epidermis. It is, however, difficult to see why very dense connective tissue should, as such, be favorable to epithelial growth. In all probability it would prove to be very resistant to the expansion of the epithelium. In many cases of cancer of the skin, moreover, no such connective tissue changes are present. Unna, for instance, especially noticed their absence in certain cases of sailor's skin cancer. On the whole, it is therefore more probable that epithelial proliferation and connective tissue changes are coordinate and that the latter are not to be considered as primary processes. In a few cases it was noticed, first, it seems, by Roessle and Spude, and recently also by Janeway, that in the early stages of cancer the epithelium grows down in the direction of dilated blood-vessels and in some way or other the presence of such dilated blood-vessels was held responsible for the development of cancer, without, however, any convincing reason being given for the validity of such an explanation. In many cases, moreover, such a relation between dilated vessels and epithelial proliferation is absent. We must realize fully the great difficulty in explaining functional phenomena on the basis of certain histologic appearances, however, frequently the latter may be found. There are many variable factors present in such phenomena and the chances are so great that only indirect connections exist between a certain histologic picture and the functional condition it is called for to explain, that it is not safe to use it as the basis of a more or less elaborate hypothesis.

CONCLUSION

Through experiment alone we can eliminate the variable factors one after another, and slow as the experimental procedure may appear, it will ultimately prove to be the only safe guide in our work. I do not, however, underestimate the value of histologic investigations, which in many other directions have proved to be of inestimable value, and which are also necessary as an adjunct in the etiologic study of cancer, but in the latter only in a subsidiary way. Until further experimental investigations shall enable us to discriminate with greater accuracy between the various factors and their mode of action, one must be content to state that in many cases of cancer long continued external irritation is of the greatest etiologic significance; that long-continued stimulation of the epidermis may lead to the formation of cancer; that it is, however, at the present time not possible to state how much of this stimulation is exerted directly on the epithelial cells through the

external agency, and how much is an indirect effect caused by changes in the organism as a whole or in the underlying connective tissue. But even if these latter changes should prove to be of greater significance, and not to be merely coordinated changes, they must be assumed to stimulate by physicochemical processes the overlying epidermis. Until we know more of the more distant effects which long-continued external stimulation may exert on cells, and which may find expression only after a very protracted period of latency, we must beware of too detailed explanations. We can, however, be certain that as the result of long continued irritation the epithelium changes in its proliferative power and that such changes are transmitted to the following cell generations apparently indefinitely.

TREATMENT OF MALIGNANT GROWTH OF THE SKIN FROM A DERMATOLOGIC STANDPOINT*

WILLIAM ALLEN PUSEY
CHICAGO

In considering the treatment of malignant diseases of the skin from the dermatologist's standpoint, the topic assigned to me, I shall take up only cutaneous carcinoma. I shall use the term "epithelioma" as synonymous with primary carcinoma of the skin and shall make no distinction in principles of treatment between rodent ulcer and squamous epithelioma confined to the skin.

The successful treatment of carcinoma of the skin, as of other tissues, requires, in the present state of our knowledge, the complete local destruction of the growth. The future holds out possibilities for the relief of carcinoma by systemic treatment, but at present we have no systemic methods that have any definite effect on the course of carcinoma. None of the agents used empirically has proved of value, and the agents which have been assumed to have a rational foundation, as cancerin, the cancer serums, and trypsin, have all proved totally useless.

INTERNAL REMEDIES

The only one of the internal remedies that seems to be entitled to the slightest consideration for its claims even to inhibit the growth of carcinoma, is arsenic. Arsenic, administered in large doses, undoubtedly has a definite effect on the nutrition or growth of the skin, and equally certainly some cases of sarcoma of the skin have been cured by the persistent and usually heroic use of arsenic. Some very careful observers, as Sherwell, and Abraham Jacobi, believe it is of benefit in carcinoma, and I believe when we are taking stock of our remedies for carcinoma, arsenic is entitled to mention as having a possible effect on the course of the disease—an effect not radical, but inhibitory.

We then are compelled to face the fact that the only way we can treat carcinoma successfully is to destroy it locally; and the practical question is, How can this best be done?

Obviously there are many ways in which living diseased tissues can be destroyed, and there are a number of methods of destroying carcinomatous tissue which are available for therapeutic application.

EXCISION

The most popular method and the one of preference among surgeons is excision. Excision is the only method practicable in many carcinomas, as those of the internal structures of the body, and in such situations we must avail ourselves of the one resort we have. But there are broad objections in principle to excision in carcinoma. In a large sense it is the crudest method of treatment. It removes an entire part, in the hope of removing with it diseased tissues which form only a fraction of the whole. It takes no account of the ability of the tissues to assist in the defense against carcinoma. A clean excision, healing practically without inflammatory reaction, must remove every cell of carcinoma to be successful. If it fails in this, no reaction has been excited in the tissues that may destroy remnants of the disease, on the contrary, lymphatic spaces have been opened up, and other opportunities given for the more favorable growth of any part of the carcinoma left. So, if clean excision fail in absolute removal *en masse*, the procedure has shot its one and only bolt, and the disease remains.

These are not the objections of one opposed to operations in carcinoma; they are inherent difficulties in the principle of treatment of carcinoma by aseptic excision which if they could be avoided in all cases, would simplify the problem of successful treatment. Surgery recognizes these difficulties in constantly devising more radical and still more radical operations. It also recognizes the great danger of clean incisions which go into carcinomas, whether through the body of them, or through the peripheral offshoots. Thus Meller¹ in a statistical study of the result of surgical treatment in carcinoma of the head, neck, and face in Hochenegg's clinic in Vienna observes that local recurrence in and about the scar (after operation for cancer of the lip) is very much more frequent than glandular recurrence; which is another way of saying that the greatest difficulty in operative removal is to get all of the local growth. From the study of this series of cases he also calls attention to the often observed fact that operations which are not complete hasten the fatal termination of the disease by favoring extension along the opened channels and in the mutilated tissues. And he concludes: "May these figures be a warning to all those who face this disease without sufficient equipment; the knife of the unpracticed, untrained surgeon does more harm than good."

These facts are, of course, well known, and the statements from Meller are not quoted for themselves, but because of the corollary to them. The corollary is that the dangers that arise from clean excisions in and about carcinomas should be avoided when the complete destruction of the carcinomatous mass is possible without resorting to such procedure.

Again, W. S. Halstead, in writing on the operative treatment of carcinoma of the breast, emphasizes the danger of incisions into carcinoma, even for material for diagnostic examination, as follows:

It was my practice at one time in making the exploration in doubtful cases to excise a portion of the breast tumor with the Paquelin cautery to prevent the wound inoculation which I feared might take place if the knife were used. The excision of a specimen for macroscopic or microscopic examination is never resorted to except just before operation. If the actual cautery for any reason is not used the wound is immediately cauterized with carbolic acid. All incomplete operations for

* Read in the Section on Dermatology of the American Medical Association, at the Sixty-first Annual Session, held at St. Louis, June, 1910.

1. Meller: *Ztschr. f. Krebsforsch.*, 1907, p. 64; reviewed editorially in *THE JOURNAL A. M. A.*, Nov. 16, 1907, xlix, 1677.

cancer should, when feasible, be made with the Paquelin or actual cautery.²

These dangers from the use of the knife obtain with equal force in carcinoma of the skin, in which, especially on account of the necessity of sacrificing as little tissue as possible, there is often presented a difficult problem in getting beyond the borders of a growth. To put it in another way, if it is dangerous to cut into a carcinoma, why should excision without canterization be the method of preference in epitheliomas in which one usually is compelled to save as much healthy tissue as possible, and often cannot be sure whether his knife has gone through carcinomatous tissue or not?

OTHER METHODS OF DESTRUCTION

This brings us to the question, Are there any available methods for destroying carcinomas other than excision? As I have already said, for internal carcinomas there are none; for carcinomas of the skin there are several which compel consideration by the open mind.

Let me say at the outset that I would exclude from consideration among non-excision methods all measures which are not vigorously destructive. Superficial caustics, like silver nitrate and phenol, are dangerous. They do not cause deep destruction of tissue themselves, nor do they produce a reaction sufficiently intense to destroy carcinomatous tissue, and, like all other irritants which fall short of destruction, they tend to make the growth more rapid. Equally ineffective for curative purposes are substances like pyoktanin, which promote epidermization and healing of ulcerated surfaces; they are especially dangerous in inexperienced hands, because the deceptive healing of the surfaces which they promote may be regarded as evidence of cure and valuable time thus be lost in making the radical attack.

The attempt to treat cutaneous carcinoma by high-frequency sparks or brush discharges, in the way this treatment is carried out in epithelioma, should also be included among the less vigorous and effective methods; it is not a method of treatment by actinic energy, like radiotherapy, and, when used with sufficient intensity to be effective, is a very awkward and painful way of doing a simple thing. In the same group of ineffective methods I would include simple curettage, no matter how vigorously done, and, except in cases most carefully selected by men of large experience, electrolysis and the new method of refrigeration, either with liquid air or with solid carbon dioxid.

Electrolysis, which is occasionally used for treating minute epitheliomas, does not destroy the tissue in sufficiently large masses to be a desirable method of treatment.

Refrigeration by liquid air or solid carbon dioxid, because of its ease of application and relative painlessness, is useful in very superficial rodent ulcers; but neither liquid air nor solid carbon dioxid is sufficiently destructive to rely on without great care, and they should only be used, if at all, in carefully selected cases; which is another way of saying that they should be used only by one who is thoroughly familiar with what he is doing.

CAUSTICS

There still remains a group of agents which, experience has shown, are vigorously destructive of carcino-

mas. These are the strong chemical caustics, like caustic potash, zinc chlorid, arsenous acid, and the strong mineral acids, the actual cautery and highly actinic forms of radiant energy in the form of Röntgen rays and radium rays.

The advantage which comes from the use of strong caustics, like potassium hydroxid, in treating carcinoma is that one is using an agent which not only promptly destroys the cancer tissue into which it penetrates, but at the same time blocks lymph-channels, and produces a violent inflammatory reaction that extends widely beyond the area actually destroyed—a reaction that offers a good prospect of destroying outlying diseased cells and that builds up a strong barrier of inflammatory connective tissue. A. R. Robinson³ has for years insisted on the usefulness of caustics in cutaneous epithelioma; and it is but fair to quote his description of the reasons why they are advantageous in the treatment of these lesions.

HOW CAUSTICS ACT

For the purpose of simplicity and clearness of description Robinson assumes that an epithelioma may be divided into three zones: a central area, A, which represents the epithelioma visible to the naked eye; around A, a zone, B, in which carcinoma cells exist, but are not macroscopically evident; around this a third zone, C, in which perhaps some carcinoma cells exist, but beyond whose outer border it is highly unlikely that the disease has extended. Then describing the effect on an epithelioma of a caustic such as arsenous acid, he says:

All of the tissue within A has been destroyed, deprived of its vitality, and also some of the tissue beyond A on account of the very intense inflammatory process there, the tissue being much more vulnerable than normal tissue on account of the injury received from the epithelial invasion; hence the completely necrosed tissue always appears to embrace a larger area than the epithelioma seemed to occupy when seen by the naked eye. Beyond this completely necrosed area the inflammatory process becomes less and less intense the less the tissue is invaded by the epithelial cells, but if the caustic has been applied for a long period the inflammation will be sufficiently intense to destroy all pathologic epithelia as far as B, and almost without exception as far as C; that is, the disease is removed as completely as if the incision by the knife had been made at C, although the normal tissue has been destroyed not even as far as B. Of course the favorable action extends in depth as well as outward in all directions from a center. The proof that the outlying epithelial cells are destroyed consists in the fact that the disease rarely reappears after such a condition of necrosis and inflammation has been produced.

The destruction of these outlying cells depends, in my opinion, first, on the existence of the acute inflammatory process destroying the pathologic tissue quicker than it does normal tissue, according to a general law in pathology, and especially so in this instance, as the pathologic epithelia lie in the lymph-spaces and can, therefore, be vigorously acted upon by the inflammatory lymph, thus changing quickly and very greatly the previous condition under which they lived. . . .

To repeat somewhat: from the proper action of this caustic, the same result as regards removal of the disease is obtained as if all the tissue within C had been removed by the knife, although normal tissue has been taken from a less area than that included within B; that is, that the caustic is in suitable cases a much more conservative agent than the knife, and therefore it should be employed in all cases in which it is an efficient one and deformity is to be avoided as much as possible, as in all face cases, for example, especially in cases of nose epithelioma. It must not be forgotten also that this method of treatment enables the surgeon to destroy the sometimes deep-lying cancerous tissue that cannot be excised for some reason or other.

2. "I was greatly pleased to note during a visit to Rochester, Minn., that Drs. William and Charles Mayo make extensive use of the actual cautery in operations on cancers incurable by the knife, and to have them endorse the view, so long maintained by me, that there is relative immunity from local metastasis with the employment of the cautery." W. S. Halsted: *Tr. Am. Surg. Assn.*, 1907, xxv, 61.

3. Robinson: *Med. Rec.*, New York, March 31, 1900, p. 355.

In conclusion he calls attention to the fact that it is not desirable for these wounds to remain aseptic, but that the usual moderate infection from the pus organisms of the skin aids in making the inflammatory process more intense, and of longer duration, and stimulates the growth of the granulations which are of benefit in lessening deformity.

That the theoretical advantages to which Robinson calls attention do actually exist, and are of practical benefit in the treatment of epitheliomas which are amenable to caustic treatment, has, I believe, been shown to those who are familiar with the results obtained with these methods of treatment. The scarring which results in these cases, when the treatment is carried out by experienced hands, is relatively very slight in proportion to the amount of destruction of tissue that may be required, and the results, I am convinced, will bear favorable comparison as regards permanency with the results of the treatment of similar lesions by clean excision. The impression as to the radical character of the results of caustics in carcinomas involving superficial structures, is not confined to dermatologists. Note, for example, the following quotation in regard to the treatment of carcinoma of the breast with caustics:

I am indubitably convinced that the local and regionary recurrences after incomplete operation, which come, as a rule, with amazing rapidity when the knife has been used, are, to say the least, relatively late in making their appearance when chemical or actual cautery has been employed. I have several times had occasion to operate on cancers which had been vigorously and repeatedly treated with caustics, and to note the relatively admirable condition, the freedom from cancer permeation of the surrounding tissues and of the axilla; whereas, after incomplete operation with the knife the local manifestations of recurrence were almost invariably deplorable and the prognosis, of course, invariably hopeless.

This statement of the excellent character of the results of caustics in carcinoma tissue is not from a dermatologist, but from one of the foremost authorities on the operative treatment of carcinoma—Dr. William S. Halsted. The favorable effects of caustics on carcinoma, which he summarizes so admirably, apply with especial force in the treatment of localized carcinoma of the skin. I have had occasion, in a few cases, to observe the results from the use of caustics in the total removal of the breast, in one case, of both breasts, and I can confirm Dr. Halsted's statement as to their character. They fully bear out the claims made by Dr. Robinson, as to the radical effects of caustic treatment, when thoroughly applied in the treatment of carcinoma. I have also had occasion to see surprising radical results in extensive epitheliomas, which had failed of surgical cure, and were apparently beyond check. The man, like myself, who is called on to see the late cases of carcinoma in patients who have sought all sorts of methods of relief, regular and irregular, cannot but be impressed with the value of caustics, sometimes in the hands of irregular practitioners; and to feel the misfortune that surgery, as a rule, has not been able to keep an open mind in judging of treatment by caustics, with the result that their use has been left largely to irregular practitioners, most of whom are ignorant and who do much harm, but who, in spite of this, occasionally produce with caustics amazing results in cases which have been signal surgical failures.

CHOICE OF CAUSTICS

The choice of chemical caustics for the treatment of epitheliomas lies practically between arsenous acid, zinc chlorid, caustic potash and acid nitrate of mercury.

Robinson prefers, as a rule, arsenous acid; Van Harlingen, caustic potash; Sherwell, acid nitrate of mercury. All of these are agents which totally destroy cancer tissue with which they come in contact, and all, except arsenous acid, produce immediate destruction of healthy as well as diseased tissue. Arsenous acid, in proportion of 50 to 75 per cent., with powdered acacia 50 to 25 per cent., mixed with water to form a paste, requires for the destruction of a mass of superficial carcinoma of the skin from six to twenty-four hours. It may be said to possess some selective action in the destruction of carcinomatous tissue. The others progressively destroy all tissues with which they come in contact and require for the destruction of an epithelioma an application of only a few minutes' duration—from five to twenty. The technic of the application of these agents, into which I cannot go fully here, is easily available in the detailed writings of Robinson, Sherwell, Van Harlingen, Gottheil and others. The successful treatment of epitheliomas with caustics requires knowledge of the methods, and one should familiarize himself with these methods before undertaking to use them. In the use of caustics, as in operative procedure, knowledge and judgment are needed. No one method is applicable to all cases and no one technic. In the use of a caustic there is required the exercise of judgment and the adaptation of means to ends, quite as definitely as they are demanded in treatment by excision.

THE RÖNTGEN RAY

No one who is not blind to facts can doubt, if he will take the trouble to investigate, that carcinomatous tissue in the skin can be destroyed with *x*-rays. On the basis of a large experience in primary and secondary carcinomas of the skin, I am willing to maintain that carcinoma tissue in the skin can be destroyed by exposure to *x*-rays as certainly as by any mechanical or chemical method; that the method, therefore, can be used with assurance, and that the results as regards permanency are fully as good as those obtained by any other methods. There are certain theoretical advantages which the use of the *x*-ray offers over other destructive methods.

First.—It is painless and avoids the ordeal of operation. This is an advantage not only of humane consideration, but of practical importance, because it enables one to treat early lesions in cases in which the patient will not at the time accept the gravity of the situation and submit to operation or any other method of gross destruction.

Second.—The method may be so used as to destroy carcinoma cells, but leave in large part the connective tissue stroma intact and in condition to repair itself.

Third.—Accordingly it leaves small scars.

Fourth.—It can be used in cases in which the surrounding healthy tissue cannot be sacrificed. This means that:

Fifth.—It is valuable in certain cases in which ordinary methods are objectionable, because they involve extensive operations and serious subsequent disfigurement, as, for example, about the eye and nose. This means further that:

Sixth.—It has a field of usefulness in some cases in which ordinary methods are impossible, because of the amount of destruction of tissues which complete removal would require; in other words, it may be used to produce a radical result in some inoperable cases and to improve and inhibit the course of other inoperable cases.

These theoretical advantages of the use of *x*-rays are a practically verbatim quotation of a statement of mine published seven years ago, and my subsequent experience confirms me in the belief that their accuracy has been established by practical results.

I have written so much on the use of x -rays in epithelioma that I do not feel that I should impose on your patience by an extensive consideration of this subject on this occasion. In brief, I may say that except in those cases in which I think the only proper treatment is excision and a radical surgical operation, to be considered later, treatment by x -rays is my method of preference in epithelioma. As a rule, but not always, the method is slower in results than the older methods, but this is its one disadvantage. As to the radical character of the results, they may court comparison with any other method of treatment. In a paper read before the Sixth International Dermatological Congress in September, 1907, I gave a detailed report of the results in 111 consecutive cases which had been treated three years or more before. In this list there were 72 per cent. of successful results; of the patients not incurable by other methods, practically 100 per cent. were successfully treated. Without entering into statistical considerations here, I believe I may say fairly that in an experience now numbering hundreds of cases of epithelioma treated with x -rays, I have not had occasion to regret that I had used x -rays; and I say this with, I trust, a fair appreciation of the results obtained in the treatment of epitheliomas by other methods. The disappointments at failure radically to relieve operative epitheliomas by treatment with x -rays have been very few. I have had a very much larger number of disappointments at failure greatly to benefit hopeless cases. Nevertheless, the most valuable use, perhaps, of x -rays in carcinomas of the skin is seen in the palliation and temporary relief of the cases which are hopeless of other benefit.

I trust I may be pardoned for basing my remarks on the use of Röntgen rays in carcinoma solely on my personal experience, on the ground that in a comparatively new field, like the use of Röntgen rays in carcinoma, one can speak with the most assurance from his own experience.

Excellent results in cutaneous carcinomas have been obtained by F. H. Williams, Abbe, Wickham, and others with radium. In a previous paper I have indicated my belief that there is no essential difference in the form of energy concerned in treating epitheliomas with radium and with Röntgen rays. I know of no results obtained with radium which have not been duplicated with Röntgen rays, and in my opinion there is little ground for choice between the two methods. The obstacles to the use of radium lie in the difficulty in obtaining it and the fact that it exists in such small quantities that it is impossible to obtain more than a minute fraction of the quantity of actinic energy which is furnished by the ordinary x -ray apparatus.

COMPARISON OF METHODS

In referring to the comparative advantages of different methods of treatment in cutaneous carcinoma, I would emphasize as strongly as possible the importance of a sharp line of distinction between the cases which are suitable for treatment with caustics or x -rays and those which should be treated by excision. I would make no distinction on their histologic structure—between squamous-cell epitheliomas, which are apt to be deeper, and the superficial lesions of the rodent ulcer type, the so-called basal-cell carcinomas of the skin. I do this fully understanding that there is often a marked difference in the clinical course of rodent ulcers and alveolar epitheliomas, but I am, nevertheless, fully convinced that the treatment of rodent ulcers should be

carried out on exactly the same principles and as vigorously as that of other carcinomas of the skin; that they occasionally have metastases; and that if left untreated or treated badly, while they will likely pursue a slower course, from that very fact they often cause more disfigurement and more suffering than more rapidly growing carcinomas.

For the purpose of treatment, I divide epitheliomas into two classes: First, those in which rational treatment requires only the complete destruction of the growth *in loco*; second, those in which rational treatment requires removal of contiguous glands, or—having in mind in this connection the orbit—the deep removal of underlying tissue.

In the first group of cases—those in which treatment requires only the destruction of the growth in its primary location—I believe that as a rule the x -ray is the best method of treatment; that after that the use either of a caustic or of a mechanical method of procedure, like curettage, always to be followed by a strong caustic, is the second method of preference. This condition, the necessity for the removal of contiguous glands, eliminates from this method of treatment most lesions occurring on the mucocutaneous junctures. It requires that most epitheliomas occurring at the anus, and on the penis and scrotum, and perhaps most epitheliomas occurring on the vulva, should be immediately submitted to radical operations. Perhaps there are some cases of epithelioma about the external genitals which do not require a radical operation, but my experience is so small in all but late epitheliomas of the external genitals that I should want some one of wider experience than myself to decide before I would undertake the treatment of any epithelioma of these parts by its local destruction. This condition also demands a radical surgical operation for most epitheliomas of the lower lip—not of the skin surface of the upper lip—but it is indubitably true that there is a type of superficial epithelioma of the lip which the expert can recognize as such, and whose radical cure does not require the removal of the glands beneath the jaw. These lesions are very superficial epitheliomas, usually occurring in old people and perhaps lasting for years without deep involvement of the lip. They begin in most cases—I am not sure not in all—in patches of hypokeratosis or of leukoplakia of the lip. These, after continuing without manifestations of irritation for years, perhaps finally show an irritated base with some excoriation of the surface, and then there is slow progression along the surface of the lip. I have treated perhaps forty consecutive such patients, most of them referred by surgeons, without a single development of carcinoma in the lymphatic nodes of the neck.

But the selection of the treatment applicable to these cases requires the greatest caution, and their treatment should not be undertaken unless one fully understands what he is doing. Because of the danger of the abuse of any method of treatment of epithelioma of the lip which does not involve the removal of the glands beneath the jaw, I should be glad not to mention the practicability of the treatment of any epithelioma of the lower lip by methods of local destruction, were it not for the fact that there are some cases in which this less radical procedure is highly desirable or the only resort possible. There are other situations in which the decision of the question as to the removal of the contiguous glands requires the exercise of mature judgment; but it is in epitheliomas of the anus, of the external genitals, and of the lower lip that this question

is of most importance. In the treatment of epitheliomas about the eye the question of attacking the orbit surgically arises. In lesions beginning on the upper or lower lids, involvement of the orbital tissue is slow to occur and the x-ray offers the ideal method of treatment. When epithelioma palpably involves the orbital tissues, the radical cleaning out of the orbit is indicated. This danger is greatest with epitheliomas occurring near the inner canthus, and in such cases local destruction should be undertaken with the utmost caution. Lesions occurring on the temples and near the outer canthi do not nearly so frequently call for destruction of the eye by radical operation, and are often amenable to treatment with x-rays.

72 Madison Street.

THE SURGICAL TREATMENT OF CUTANEOUS MALIGNANT GROWTHS *

JOSEPH C. BLOODGOOD, M.D.

Associate Professor of Surgery, Johns Hopkins Medical School
BALTIMORE

Before any surgical treatment for a cutaneous growth is planned or carried out there must be an accurate diagnosis. I cannot go into the details of such diagnosis for the different lesions, but I wish to emphasize in the beginning of this discussion the importance of a definite diagnosis. In some instances the diagnosis can be made from the clinical appearance of the visible cutaneous lesion. Palpation of the dermal or epidermal tumor should always be combined with careful inspection, and in many cases the recognition of carcinoma is possible by palpation when inspection leaves a doubt in the surgeon's mind.

When the diagnosis is impossible or doubtful from the clinical history, combined with inspection and palpation, a surgeon who has the requisite special training can differentiate the various pathologic processes by making an incision and thus exposing to the naked eye the freshly cut lesion. The operation follows immediately. Such an exploratory incision should be disinfected either with pure phenol or the Paquelin cautery. When the surgeon has not this special training, a small piece can be excised at the exploratory incision for a frozen section, and the diagnosis can be made almost immediately by the pathologist connected with the surgical clinic. It is unfortunate when a piece is excised for diagnosis and some days elapse before the operation is instituted. In the benign, and perhaps in some of the less malignant, skin lesions there is no danger from such a course, but, as far as my investigations have gone, it is distinctly contraindicated in the more malignant lesions, both carcinoma and sarcoma. If circumstances are such that the surgeon is compelled to excise a piece for diagnosis and then wait a few days before carrying out the operation indicated by the pathologic report, he should attempt to cut out the area from the tumor proper, without carrying his incision into the border of uninvolved tissue, and, in addition, the raw surfaces should be immediately treated with pure phenol or the Paquelin cautery. It is my opinion, however, based on a large experience and con-

firmed by the expressions in the literature, that the diagnosis can and should be made immediately. It is the hope that it may be possible to train ourselves to such a degree that even the exploratory incision for gross inspection or frozen section may become less and less frequent.

This positive diagnosis is necessary; because for the different skin lesions the magnitude of the operation varies, even involving considerable mutilation. It is especially in those cases where the extensive operation would be mutilating that the positive and immediate diagnosis becomes more and more essential. When the more extensive operation would be no more mutilating than the restricted local operation, I should advise the extensive operation if there be any doubt.

The extent of the local operation, and whether it should be combined with the removal of neighboring lymphatics, or deeper tissues, muscle and bone, varies not only with the nature of the lesion, but with its site. In general, it may be stated that for sarcoma a local operation is sufficient, while in carcinoma of the squamous or spinal-cell type, the local operation should, in the majority of cases, be combined with the dissection of the neighboring lymphatic glands and surrounding tissues. But to-day, no such general statements are sufficient. Experience has taught us that the nature of the operation must vary not only with the different varieties of tumors, but with the same tumor in different localities and different tissues.

So much to emphasize the importance of a positive diagnosis.

CLASSIFICATION

In the Surgical Pathological Laboratory of the Johns Hopkins Hospital I have developed a scheme of classification which has been found of practical value for teaching purposes and for investigating the question of the proper operation for the different tumors in the same locality.

In this investigation I have borne in mind the question, what operation will give the patient the best assurance of a cure with the least mutilation, and when and where is extensive mutilation justifiable in an attempt to accomplish a permanent cure?

The facts of this paper are based on a study of the following cases which include only lesions of the skin:

Malignant pigmented moles.....	65 cases
Sarcoma of the derma.....	45 cases
Epithelial tumors of the skin and mucous membrane	812 cases

These figures demonstrate that the most common malignant lesion of the skin is of epidermal origin; sarcoma is relatively rare.

MALIGNANT PIGMENTED MOLES

The study of this malignant dermal tumor of congenital origin, and of its benign prototype, brings out better than the study of any other group of neoplasms a conception of what may be called the preventive measures for treatment for malignant tumors. I look on a preventive measure as the recognition of those benign tumors and conditions which have a tendency to later become malignant, and their removal in the benign state.

I was the first, or at least one of the first, to call attention to the importance of the removal of certain forms of benign congenital pigmented moles, some seven years ago.¹ The statements then made, which were

* Read in the Section on Dermatology of the American Medical Association, at the Sixty-first Annual Session, held at St. Louis, June, 1910.

¹ Because of the space required this article is abbreviated in THE JOURNAL, but it appears in full in the Transactions of the Section and in the author's reprints

based on a relatively small experience, have been confirmed by the greater experience of the seven succeeding years. I now have careful personal notes of 65 cases of malignant pigmented moles. These cases have been collected from various sources. In every instance the diagnosis has been confirmed by a pathologic examination. Up to the present time there is not a definitely cured case amongst them. Now, it is to be remembered that in every one of these cases there had been a tumor visible to its host for many years. Such tumors can be removed under cocaine or local anesthesia without difficulty. It seems, therefore, worth while, to educate the public, to call the attention of the physician to such apparently innocent tumors, and to educate the physician to recognize when their removal should be urged. Of course, no harm can be done by the removal of any such tumor, although it may be practically impossible to remove all the pigmented areas which are to be found on some individuals.

In my experience with 65 malignant cases, in only three or four were the patients covered with such pigmented areas. In the majority, the individual had but one, or at most but a few, congenital pigmented moles. The mole which had become malignant was never a flat pigmented area, not elevated above the epidermis, but was distinctly a projecting tumor. It is my opinion that all such moles should be removed, especially when they are in localities exposed to trauma. Pigmented spots are entirely different from the definite, projecting, sessile or pedunculated, warty or smooth, pigmented mole. This information should be given publicity. During the same period in which I have collected 65 cases of malignant pigmented moles, I have accumulated in the laboratory 76 benign, the majority of which have been removed by myself, because of my attitude toward such apparently innocent tumors. As to the present result in all these cases, I have a record with but few exceptions, and there have been no local recurrences and no deaths from internal metastases. The largest number of moles removed from any one individual was five. In every case the mole has been removed with the knife, and not an individual finds any fault with the scar.

I emphasize this point, because there are other methods employed to remove different types of benign skin lesions—the x-rays, radium, carbon-dioxid snow, liquid air, the Paquelin cautery, the electric needle, and different caustic pastes. As I have had no experience with these methods of treatment, I am not justified in condemning them, but I am inclined to the view that the more dermatologists familiarize themselves with the simplicity of removing small skin tumors with the knife, under local anesthesia or nitrous oxid gas, the more they will employ this method.

For certain tumors and in certain situations the above methods have a distinct place, but for the benign mole I would urge complete excision with the knife. With the other methods there is not the same certainty that all these congenital residues of cells are destroyed, and when the method is employed incompletely it may act as a stimulant. In a number of my personally studied 65 cases of malignant congenital pigmented moles, one of these methods had been first employed. Of course, it is impossible to say that this tinkering with the mole was the factor which produced its malignant growth. Nevertheless the observation is suggestive.

The excision with the knife may be just as dangerous if the tumor is not given a sufficient berth. I am confident that it is better to leave a mole alone than to ex-

cise it incompletely. When the mole is situated on the face there is a temptation in the hands of an inexperienced surgeon to limit the area excised, but as a matter of fact the scar is no more conspicuous when sufficient margin is given than otherwise.

The public and physicians should be impressed with the importance of the immediate and complete removal of any congenital mole which suddenly shows any growth, superficial ulceration, or scab formation. The sudden appearance in the skin of a tumor resembling a congenital pigmented mole should be looked on as an indication for its immediate removal.

I trust that the subject of the relation of benign or innocent tumors to later malignant transformation will be more often considered in the dermatologic and other sections of the American Medical Association. There is great need for publicity. It is true that the relative number of individuals to be saved is small, but certainly large enough to justify the time and trouble.

The first problem in regard to our attitude towards the apparently benign or innocent mole, I think should be looked on as settled—the tumor should be removed.

The second problem is by no means settled; that is, what should be the extent of the local operation, and should the neighboring lymphatics be included in the dissection when the patient comes with a mole which shows, clinically, definite signs of malignant growth?

In my 65 cases and, as far as I can ascertain, in the literature, surgeons have confined themselves to the local operation when the neighboring lymphatics were not visibly involved. Many of the patients, before there is any evidence of general metastasis, return with enlargement of the neighboring lymphatics, and now the more complete operation is performed. In many cases, if glandular enlargement is evident, the complete local and glandular operation has been carried out in the first instance. But there have been no permanent cures. In view of this evidence it seems to me I am justified in urging that in the future surgeons perform in every instance, whether there be visible glandular enlargement or not, a larger local operation combined with the complete dissection *en bloc* of the neighboring lymphatics, and such an operation should be planned along lines similar to Halsted's complete dissection for carcinoma of the breast. That is, the tumor should be removed with a zone of uninvolved skin and a wider area of subcutaneous fat, and with this should be included at least the fascia, and, in some cases, the muscle itself, then the neighboring lymphatic glands and surrounding tissue. It is my opinion that we are distinctly justified in the future in attempting such an extensive dissection, although at the present time we have no evidence that the results will be any better.

But, as I study critically the 65 cases of which I have records and the available literature, I am impressed with the conclusion that the surgery of moles in their malignant state has been incomplete. There is therefore room for improvement in two directions: The education of the public and the profession in such a way that we may get the mole either in its benign state or very quickly after the first signs of local growth, and, second, in the later malignant state we must give the tumor a wider berth and combine the dissection with the removal of the neighboring fascia and lymphatic glands.

SARCOMA OF THE DERMA

In this group, in which there are 45 cases, there is generally a history of a congenital nevus, an acquired or

congenital fibroma, or the tumor has originated in scar tissue. The type of the tumor, when there has been a history of a nevus, is one that would naturally be expected—angiosarcoma. With a few exceptions the malignant connective-tissue tumor which has its origin in a scar or fibroma is of the type of the fibro-spindle-cell tumor. Among 14 cases of the former type (angiosarcoma) I have observed but one cure, and it is important to note that in this case a more extensive local and glandular operation was performed than in any other. Among 26 tumors of the latter type (fibro-spindle-cell sarcoma) 20 patients have been permanently cured by a local operation only.

Angiosarcoma.—Among 14 cases in which the gross and cellular pathology of the tumor has been practically identical, in 6 cases the malignant neoplasm has arisen in a congenital vascular nevus; in 8 there was no such history.

During the same period I have observed 109 cases of benign hemangiomas. The tendency, therefore, for the congenital nevus to become malignant is distinctly less than in the congenital pigmented mole.

All of the 109 cases of benign hemangioma have not been confined to the skin; for example, there are 7 situated within muscle—the so-called intermuscular angioma. Here the differential diagnosis is not a problem of dermatology.

Granulation-Tissue Tumors.—Here the differential diagnosis is more difficult. I have records of six cases. The age of the patients varied from 9 to 25 years, the duration of the tumor from two weeks to three months. In every instance there was the history of an injury, and the little tumor composed of red, vascular granulation tissue has grown from the scar. On account of the situation of these tumors a correct diagnosis is important, because if they be looked on as sarcoma a complete local operation, in some instances, would result in unnecessary mutilation. In two instances the tumor was situated at the site of the toe-nail; in one of these cases an unnecessary amputation was done. In three instances the tumor occupied the palm of the hand, once the finger and once the skin of the axilla. In these cases, if the surgeon is not able to make a differential diagnosis clinically, a trained pathologist should do so from the frozen section. When complete excision would cause mutilation these areas should be treated with the Paquelin cautery. The difficulties of differentiating sarcoma from granulation tissue is an old problem in the history of pathology, but it can be done and often saves the patient disfigurement.

Hemangioma of Skin.—Among my 87 cases of hemangioma the majority have been dermal tumors, and most of these of congenital origin, although in many cases the tumor was first observed later in life. My figures by no means give an idea of the relative frequency of this tumor, but represent only the type which, on account of local growth, has caused its host to seek surgical aid. During the last twelve years there have been sent to me for examination, from various sources, ten cases with the diagnosis of sarcoma. In all of these cases the dermal tumor in its growth had caused the destruction of the epidermal covering and given rise to a very vascular granulation-tissue mass. When I compare these cases clinically with true sarcoma I find a distinct difference: in sarcoma the compressibility of the tumor beneath and around the granulation area is lost, while in the benign tumor the characteristic feature of angioma—compressibility—is present. The differential diagnosis from a frozen section should not be difficult: in the angioma the

blood-containing vessels are always present and the cellular tissue between these vessels resembles ordinary cellular granulation tissue, while in sarcoma no such picture is observed. The differential diagnosis is important, because the complete excision of the benign lesion would frequently be mutilating, and a cure can be accomplished by partial excision in conjunction with the Paquelin cautery, liquid air or carbon-dioxid snow. In view of the comparative rarity of sarcoma and the frequency of the hemangioma simulating sarcoma one should look on these lesions as benign until they are proved, by microscopic examination, to be malignant.

Sarcoma of the Skin with a History of a Congenital Nevus.—I have six cases in one of which the patient was cured. They are as follows:

In all of these cases the sarcoma was of the prithelial type. The cells were small and round, very much like those of lymphosarcoma. This tumor, wherever I have encountered it, has shown a very high grade of malignancy, and up to the present time I know of no permanent cures.

The two points which I wish to emphasize in regard to congenital tumors of the skin are well brought out in the study of this small group of cases. Any growth in a congenital dermal tumor should be considered as a symptom of an acute disease. A diagnosis should be made at once; if the histology shows that the growth is still of an innocent character a restricted local operation will be sufficient. As has been pointed out, the congenital angioma may show growth of a benign character, and the nature of the local operation will vary with the position of the tumor; if complete local operation would cause mutilation one is justified in using the Paquelin cautery or carbon-dioxid snow for these cases. In other situations I should recommend excision. If the histology shows the picture of sarcoma the local operation should be very extensive, and I am quite confident, if this is done, the number of cures will be increased. When the patient is seen later in the malignant stage of the disease it seems to me it is justifiable to make an attempt at a most radical dissection *en bloc*. The chances of a cure, however, are relatively small for the cellular type of sarcoma.

Angiosarcoma of the Skin with No History of a Nevus.—These 8 cases differ from the previous group only in the absence of a history of a congenital tumor. The age of onset has varied from 4 to 54 years of age; the duration of the tumor from six weeks to twenty years. In five of the cases the duration of the tumor has been over one year. In none of these cases has a cure been accomplished. All of them have been of the most malignant form of sarcoma—small-round-cell, and most of them of the prithelial type. All of the tumors first appeared as subepidermal nodules; in a few ulceration with fungus formation was present at the time of the operation. Three were tumors of the scalp, clinically resembling the ordinary wen, which is an epithelial cyst; two of these were blood-cysts; the third blood-cyst was situated between the mucous membrane and skin of the cheek. All of the important problems of the surgical treatment of tumors are represented in the study of this group. In the first place, the sudden appearance of an epidermal nodule, even if it has all the signs of a benign tumor, should be looked on as an acute disease. In view of the fact that in this earlier period a differentiation between the benign and malignant cannot be made, except at the exploratory incision, the surgeon should be prepared to make the differential diagnosis.

Of the three tumors of the scalp resembling wens, in every one such a clinical diagnosis was made, and the incomplete excision sufficient for the wen was performed for the more malignant tumor. In all there was immediate local recurrence. Subepidermal blood-cysts are not always malignant; I have observed a benign blood-cyst in the cheek and one on the tongue. Both were recognized at the exploratory incision and a cure accomplished without mutilation.

Sarcoma of the Skin in Scar Tissue.—I have personally studied 19 cases, in which 16 patients have remained well. In all of the cured patients the tumor was of the fibro-spindle-cell type. Tumors of this character must be looked on as on the border-line between benign and malignant. One pathologist may call them sarcoma, another a cellular fibroma. The important surgical fact is that these tumors are curable by a local operation, and such an operation need not be extensive.

When such a tumor is observed in a scar it is essential to differentiate, in the gross or in the frozen section, this fibro-spindle-cell tumor from the more malignant round- and spindle-cell sarcoma, and the latter must be differentiated from the carcinoma. I wish to emphasize this, because very frequently the operation which should be performed for the carcinoma, and in some instances for the spindle- and round-cell sarcoma, would be unnecessarily extensive and mutilating for the fibro-spindle-cell tumor. The differentiation can be often made by an experienced surgeon clinically; if this is not possible an exploratory incision or frozen section should settle the question at once.

The relation of scar tissue to various pathologic processes is an important one. The most common, non-ulcerating neoplasm is the keloid. I have studied 42 cases. It is important to differentiate the keloid from the fibro-spindle-cell sarcoma in scar tissue. There are cases in which there is little doubt as to the keloid on one hand and the sarcoma on the other. The keloid confines itself to the scar proper, reaches a certain size and ceases to grow; it rarely ulcerates. The sarcoma quickly infiltrates beyond the area of the scar, grows more deeply, and not infrequently ulcerates. The histologic differentiation from a frozen section in some cases is impossible, in my opinion. If there is any doubt in the diagnosis between a keloid and a sarcoma I should advise that the treatment be planned as for a sarcoma. Among the fibro-spindle-cell sarcomas in scar tissue I note a few cases in which cures have been accomplished after one or more recurrences, and the question naturally arises, Are these tumors sarcomas or keloids? Perhaps later Dr. Mallory, who is making such important and interesting investigations into the cellular and intracellular structures of tumors, may throw light on the differential diagnosis. But at the present time there are many cases in the group of fibro-spindle-cell tumors in which the surgeon should not depend on the frozen section, but should be influenced more by the clinical picture and gross pathology, and when there is any doubt it is best for the patient to treat the lesion as sarcoma, because the necessary local operation is not of sufficient extent to cause mutilation.

I wish to emphasize here again that for this border-line fibro-spindle-cell tumor the local operation need not be very extensive. However, if the lesion is situated in a position in which a more extensive local operation will cause no greater mutilation I would advise its performance.

The granulation-tissue tumor I have already discussed under angioma and angiosarcoma. The more malignant

spindle- and round-cell sarcoma in scar tissue is relatively rare. The three cases which I have studied died of local recurrence and internal metastasis. All of them were, in the modern sense, neglected cases, because the growth in the scar tissue had not been subjected to treatment until a period of from three months to two years had elapsed, and in all of the cases the first operation had been incomplete; two were later subjected to second operations of a more extensive character without avail. The investigation of the cured cases in this group shows in a few instances that the operation has been unnecessarily extensive. For example, in one in which the lesion was situated on the heel, amputation of the foot was performed.

The epithelial tumor which may form in the epidermis of scar tissue will be discussed later.

The study of scar tissue is therefore a very interesting and important problem, both to the dermatologist and to the surgeon. A wound is an irritant and the injured tissues throw out or give rise to a new tissue which is at first very cellular, and is called granulation tissue, and later changes into scar tissue. If there is a defect in the skin or mucous membrane we have, in addition, an ulcer and the process of epidermization of such an ulcer. There is unusual activity, therefore, on the part of both connective tissue and epithelium.

During the early healing of a wound, if the inflammatory reaction is excessive, we have what is called a granulation-tissue tumor. In later periods an excessive scar tissue gives rise to keloids. If the wound is associated with a break in the skin we may have, during the epidermization of the ulcer, atypical down-growths of epithelium, or over-growths giving rise to a papillomatous surface at the ulcer edge. The malignant epithelial tumor—the carcinoma—is observed only after an ulcer has been present many years, but the sarcoma, apparently, may form at a much earlier period.

It is important, therefore, that every attempt be made to encourage the proper and prompt healing of a wound, and nothing should be done unnecessarily to increase the inflammatory activity of the cells.

This is not the place to discuss the relation of wounds and other lesions of the skin which keep up a form of chronic irritation, but if surgery of to-day is not to be the forlorn hope of an operation at the late stage of a disease, it must demand that it be given the opportunity, not only to apply its art in the early stage of neoplastic growth, but even at an earlier period, which might be called the precancerous period. At this period surgery advises the removal of all skin tumors and proper healing of all skin lesions.

Sarcoma and Fibroma of the Derma.—One is confronted with the same difficulty of differential diagnosis between fibroma and sarcoma as between the fibro-spindle-cell sarcoma of scar tissue and keloid.

I have classed 9 cases as sarcoma in tumors which have been present a number of years and which might be called originally benign fibroma. Four patients have remained perfectly cured since the complete local excision of the dermal growth. In every one of these cases the histology of the tumor exhibits the picture of fibro-spindle-cell new growth. In the three patients who were not cured the histology of the tumor was entirely different; they were round-cell sarcomas, and the round or spindle cells were found in alveoli, the mesh-work of which appeared to be the remains of the fibrous tissue of the old fibroma.

It is very important to call attention to the fact that in all of these cases there was a history of an apparently

innocent dermal tumor which had been present from one to eighteen years. The actual duration of the tumors was as follows: one (2 cases), three, four, eight, ten and eighteen years. There was no difference in the local growth in these two types of tumor. In every case there was a quiescent period, then a local growth with superficial ulceration, in many cases associated with trauma. The cause of death in one of the cases was internal metastasis. In this instance the local growth of the tumor was insignificant; in the other two cases which succumbed to the disease there was, first, local recurrence after an incomplete operation, then again local recurrence and internal metastasis after an attempt at complete operation.

As compared with keloids the true fibroma of the skin is a less frequent lesion. I have recorded as true fibroma of the skin 28 cases; many were small nodules with adherent epidermis of from 5 mm. to 2 cm. in diameter, the majority about 8 mm. In many of these there was a history of a trauma, or the hard nodule was secondary to a pimple. That is, in almost every case there was an etiologic factor. So perhaps these tumors should be really classed as keloids. Among the 9 cases classed as sarcoma 3 in their onset were small subepidermal nodules, 4 pedunculated tumors.

It seems to me that this evidence is sufficient to justify the immediate removal of the small subepidermal or pedunculated fibroma during its innocent stage. This should be done by a local operation. If the patient seeks advice after such a tumor has begun to grow the extent of the local excision should be relatively greater. I have already called attention to the fact that in two of the fatal cases of sarcoma the first operation at an apparently fairly early period was followed by local recurrence, due probably to a restricted local operation.

Fibromyxoma of the Derma.—Von Recklinghausen's disease is not very frequent, and the tendency of one or more of the dermal tumors to become malignant is unusual. I have one such a case. It is quite impossible in many of these cases to excise all of the tumors, but if the tumors are few in number, or if one begins to grow, I would urge the immediate removal by a local operation.

I have never observed a fibromyxoma or a pure myxoma occurring as a single tumor to be situated in the derma, nor have I observed a myxosarcoma of the skin.

Connective-Tissue Cysts.—Among 30 cases of this type in only 2, one of the cheek and one of the tongue, were the cysts of dermal origin. Both were blood-cysts, and I have already discussed their differential diagnosis from sarcomatous cysts.

Lymphangioma of the Derma.—These are relatively infrequent lesions. All the cases which I have studied were benign. The diffuse form seen in the lip and tongue (macroglossia and macrocheilia) is not difficult to recognize. I have observed a small subepidermal tumor of the tongue of this type, and here the proper differential diagnosis from early epithelioma saved the patient from a mutilating operation. Another case is very rare: the tumor, 2 cm. in diameter situated in the skin of the thigh, had been present fifteen years in a male aged 47; it was encapsulated and showed a calcification and ossification. In a third case there was a diffuse growth in the groin which, on account of the accompanying papillary overgrowth of the epidermis, might have been mistaken for carcinoma. Gilchrist, who saw this patient first, has reported the lesion as lymphangioma circumscriptum.

Among the rarest benign tumors of the skin I have seen one case of xanthoma.

EPITHELIAL TUMORS OF THE SKIN AND MUCOUS MEMBRANE

Whether Krompecher's³ classification be accepted or not, I am firmly convinced that a classification along the lines established by him is of practical importance.

There is a lesion of the skin which may appear as a wart, a subepidermal nodule, an ulcer or a fungus, and, microscopically, differs from the squamous-cell epithelioma. These tumors practically never give metastases and can be and are permanently cured by a somewhat restricted local operation. The opposite is true of the so-called squamous-cell epithelioma, in which the cells show hornification and pearly-body formation.

As with the benign and malignant connective-tissue tumors of the skin and the benign and malignant pigmented moles just discussed, so with the epithelial tumors, the extent and plan of the surgical operation should be controlled by the character of the tumor. As has been stated before in this paper, the same tumor when situated in different localities sometimes can be treated along different lines. For example, a squamous-cell epithelioma of the lip should always be removed locally, and this local operation should be combined with the complete dissection of the glands of the neck. But for the same tumor situated on the scalp the glandular operation is apparently unnecessary.

In 1904 I contributed my experience⁴ with epithelial tumors as based on 468 cases, and adopted, to a certain extent, the classification of Krompecher. With an increased experience—684 cases—I am still favorable to Krompecher's views.

In the breast, no matter what the variety of the carcinoma may be, there should be no restriction of the complete dissection, but experience has taught us that in the skin and mucous membrane the well-known different types of epithelial tumors, with their differences in local growth and tendency to local infiltration and metastasis, allow us to vary the operation according to the site and character of the tumor. This is important from the standpoint of the patient, because if the principles applied to the breast were found to be necessary for cancer of the skin and mucous membrane, many patients, in order to be cured, would be subjected to mutilation, which experience up to date has demonstrated to be unnecessary. It is fortunate for the patient with cancer of the breast that the most extensive operation is little if at all more mutilating than the restricted operation. In cancer of the breast there is the same variability in the character of the tumor, and, while for some tumors the probability of a cure is 80 per cent., in others only 20 per cent., experience has demonstrated that a restricted operation in the most favorable form of cancer of the breast will reduce its probability of a cure to that of the most malignant form of cancer subjected to the most complete operation. It is this evidence that prohibits any restriction of the operation for cancer of the breast.

In cancer of the skin and mucous membrane we are accumulating experience which forces us to change the plan of the operative technic. In some cases the operation must be considerably extended. For example, in carcinoma spinocellulare (squamous-cell cancer) of the extremities, which rarely occurs except in wounds, ulcers

3. Beitr. z. path. Anat. u. z. allg. Path. (Ziegler's), 1900, xxviii; Der Basalzellenkrebs, Gustav Fischer, Jena, 1903.

4. Progr. Med., December, 1904, p. 134

or warts, it has been the rule in the majority of surgical clinics to confine the dissection to a local removal only. But to-day the majority of authors who have investigated the ultimate results emphatically conclude that the local operation should be combined with glandular dissection. In cancer of the tongue, it is my opinion that to-day the glandular operation is unnecessarily extensive, while the dissection of the floor of the mouth is too restricted.

Table I illustrates the relative frequency of epithelioma of skin and mucous membrane in the different localizations. In the first column appear the figures of carcinoma spinocellulare (squamous-cell epithelioma). In the second column are recorded the cases of carcinoma cubocellulare, which is composed of transitional cells; this variety is relatively unimportant, as the malignancy of this tumor is practically identical with that of the spinal-cell tumor, and the treatment should be the same. In the third column appears the carcinoma basocellulare; in the fourth, the malignant warts, irrespective of their cellular type, and in the fifth column, the benign warts. In the sixth column the number of inoperable cases, or those in which there was no pathologic examination, is noted.

TABLE I.—EPITHELIAL TUMORS ACCORDING TO SITE AND PATHOLOGIC VARIETY

Site.	Pathologic Variety.					No. Note.	Total
	Spino-Cellulare.	Cubo-Cellulare.	Baso-Cellulare.	Malignant Pigmented Wart.	Benign Wart.		
Lower lip	100	2	4	12	1	42	161
Upper lip	4	..	9	6	21
Face, cheek	1	3	24	5	5	28	74
Chin	2	2	4

Penis	13	..	4	1	7	12	37
Skin of body	2	..	5	1	3	1	12
Total	246	27	125	44	49	193	684

For the basal-cell tumor and the benign wart a local operation is sufficient. There have been many reported cures of basal-cell ulcers and fungi after treatment with the x-ray, radium, caustics and carbon-dioxid snow. I have had no personal experience with these methods. I have operated on a number of cases in which these methods of treatment had failed in the hands of competent dermatologists and roentgenologists. I have never observed a recurrence after proper excision in operable cases. If the small rodent ulcer (basal-cell tumor) is situated in a position where the local excision would produce more or less mutilation, for example, the eyelid, the ala of the nose or the lobe of the ear, my experience teaches me that there is no danger in attempting a cure by the methods just enumerated, provided the patient is carefully watched. The chances of a permanent cure by local excision after a failure from any of these methods are not decreased. When the rodent ulcer has reached a huge size, practically prohibiting its removal with the knife, the other methods should be attempted, and now and then cures have been reported. I wish to emphasize the fact that experience demonstrates that an incomplete excision with the knife is more dangerous than a failure from the other methods, and if on account of the position of the epithelioma the

surgeon feels that it would be less mutilating to give the lesion a somewhat narrow margin the knife should be supplemented by the cautery.

In my own experience, when these tumors have come to me in their early stage, I have no difficulty whatever in accomplishing a cure without mutilation, no matter what their situation, by excision with the knife, and I have followed the ultimate results in my cases most carefully.

For the malignant wart a local operation is sufficient, but when the original wart has practically been destroyed and its position is occupied by an ulcer or fungus it must be treated according to the character of the cells of which it is composed. The great majority of warts are spinal-cell tumors. The basal-cell tumor rarely has its onset in a papillary wart; it appears as a subepidermal nodule, at first covered with brownish epidermis, and then, as it grows, with a scab; beneath the scab an ulcer forms which may remain an ulcer no matter how extensive, or may produce a fungus no matter how small the ulcer. We never observe fungus growth in an ulcer larger than a silver dollar.

STUDY OF EPITHELIOMA ACCORDING TO SITE

Epithelioma of the Lip.—Carcinoma of the lip is the most frequent of the malignant lesions of the skin and mucous membrane.

The public must be educated to the life-saving importance of immediately consulting the physician for any ulcer, induration, wart or scab at the mucocutaneous border of the lower lip. The surgeon, with the rarest exception, must never vary from the rule to remove the glands of the neck as well as the primary tumor of the lower lip. The experience in the study of 161 cases, of which I have notes, demonstrates the appalling neglect on the part of the patient and the profession of lesions of the mucocutaneous border of the lower lip. On the whole, surgery has been much less neglectful in restricting its operation. A lesion at the mucocutaneous border of the lower lip in the majority of instances is a carcinoma spinocellulare. I have observed but one benign wart, twelve malignant warts and four basal-cell carcinomas. In these 17 cases a local operation would have been sufficient; all have been cured.

Among 32 cases of carcinoma spinocellulare of the lower lip in which, for some reason, the tumor only was removed, I can find only two definite cures. In a few cases the patients were apparently well six years and then returned with carcinomatous glands in the neck. When these results are compared with those in which both the local and glandular operations were performed at the same sitting there is a tremendous difference. If we take the cases in which six years have elapsed we find at least 50 per cent. of the patients well, as compared with less than 10 per cent. when the glandular operation was not done. What the results will be when patients seek surgical aid earlier I am not prepared to say, but I think it would be a mistake, with the evidence in hand to-day, not to combine the glandular operation with the local, even when patients present themselves in the early weeks of the lesion. In one of my own patients, who has been cured, the epithelioma was so small that the section can be viewed in its entire extent under the low power of the microscope. Yet this patient had metastatic glands. When the epithelioma of the lip has involved bone I have not a record of an accomplished cure, even after the most extensive dissection.

Upper Lip.—With the exception of four cases the lesion was situated on the skin and was either a basal-

cell epithelioma or a malignant wart. Local excision accomplished a cure. In the spinal-cell tumor the same operation should be performed as when the tumor is situated on the lower lip. The differential diagnosis, therefore, is important.

Face and Cheek.—The majority of lesions here are of the basal-cell type, but the tumor must be differentiated from the less frequent spinal-cell carcinoma, because in the latter, if a larger local operation combined with the glandular dissection is not performed, there will be no hope of a permanent cure.

On the chin, eyelid, ear and nose the problem is the same as on the face and cheek; here also the less malignant basal-cell tumor is more frequent. But if the tumor is of the spinal-cell type the local operation must be more extensive, and, my experience teaches me, also combined with glandular dissection.

Scalp and Forehead.—The local operation is apparently sufficient in early cases for all types of tumor. In the spinal-cell tumor one should also remove the pericranium, and, if this is apparently involved, some bone.

The lesions of the *skin of the neck, body, upper and lower extremities* may be considered together. The problems are apparently identical. As to why carcinoma spinocellulare is so frequently observed at the mucocutaneous border of the lower lip, and in the tongue, we seem to have no definite explanation. It is difficult to bring together cause and effect. In carcinoma of the gum the cause stands out prominently. The frequency of basal-cell epithelioma of the areas just mentioned without the history of a wart, of a wound or ulcer, or of some chronic inflammation of the skin, eczema, psoriasis, x-ray burn, etc. Here carcinoma never begins with the same spontaneity as apparently happens in the lower lip and tongue. There is therefore a distinct precancerous lesion which can and should be eradicated in that stage. When the fully developed tumor presents itself surgeons should not be content with the restricted operation of the past. For carcinoma spinocellulare in its fully developed ulcerous or fungous state the operation should be along the lines employed in the breast; a wide area of skin, a broader area of subcutaneous fat, fascia always in some cases muscle, and always the neighboring lymphatics. Infiltration of bone may be encountered, indicating amputation.

The surgical treatment of carcinoma and sarcoma of the extremities emphasizes the deplorable fact that surgeons have had a wrong notion of the local growth of these two neoplasms; for sarcoma amputation has been the rule, while for carcinoma a less radical operation has been performed. As a matter of fact the reverse should be the rule. But this is not a question for the dermatologist.

904 North Charles Street.

Principles of Treatment of Gonorrhoea.—The fruitful principles on which we base our urethral therapeutics in gonorrhoea are: (1) precise diagnosis of the nature of the lesions; (2) knowledge of their local position; (3) direct interference in the case of superficial lesions; (4) mechanical action to reach even deep lesions; (5) mechanical transport of medicinal particles.—L. Wickham, in the *Practitioner*.

PATHOLOGY OF MALIGNANT DISEASES OF NON-EPITHELIAL FORMATION *

F. B. MALLORY, M.D.
BOSTON

There are some fourteen different types of simple tumors. Each is due to the proliferation of one variety of cell. The epithelial tumors form the largest group of the simple tumors and their pathology has already been presented to you. The remaining tumors are often called the connective tissue tumors because many of them are of mesenchymal origin. The broader and better term to designate them when placed in contrast with the epithelial tumors is the non-epithelial tumors. It remains for me to present to you as dermatologists certain points of interest concerning the pathology of this large variety of tumors, some of which you see frequently, others rarely or not at all.

CLASSIFICATION AND TYPE OF CELL

A word first in regard to the classification of tumors. Under every recognized variety of tumor should be grouped both the slowly and the rapidly growing tumors built up by the multiplication of the same type-cell. In no other way is it possible fully to understand each variety of tumor and find out its characteristics. The type-cell is the one important element in every tumor. From it the tumor should be named; not from some peculiarity of minor importance, such as method of growth, arrangement of cells, or form of retrograde change. I shall speak briefly of some of the type-cells and of the tumors built up from them, and shall illustrate my remarks with pictures.

The fibroblast, the ordinary connective tissue cell, is in general a flat cell with a flat, oval nucleus. It is characterized by the production of two kinds of fibrils, fibrogia and collagen fibrils, which may be stained differentially and which distinguish it from all other cells. The fibrogia fibrils are in intimate contact with the cytoplasm; the collagen fibrils form a true intercellular substance.

The slowly growing tumors arising from fibroblasts are called fibromata; the rapidly growing ones, fibrosarcomata. These terms represent extremes in rate of growth; all gradations between them exist. No matter how rapidly these tumors grow the cells tend to differentiate as do the normal fibroblasts.

The tumors known as keloids are formed by the proliferation of fibroblasts, but the cells tend to arrange themselves in thin sheets between broad layers of collagen fibrils, so that a striking and characteristic microscopic picture results.

The so-called myxoma and myxosarcoma develop from fibroblasts. They do not differ from the fibroma and fibrosarcoma except in the presence of fluid containing a variable amount of mucin between the collagen fibrils. The same holds true of the cells in the umbilical cord. These tumors do not deserve, therefore, to be regarded as a special type of tumor but should be looked on as a variety of the fibroma and fibrosarcoma.

The so-called giant-cell sarcoma, usually occurring in connection with bone, deserves special mention. At least two types of giant cells occur in tumors. One type is due to multiple mitoses, and occurs in a variety of tumors, for example, glioma, fibrosarcoma, lymphocy-

* Read in the Section on Dermatology of the American Medical Association, at the Sixty-first Annual Session, held at St. Louis, June, 1910.

* From the Pathological Laboratory of The Boston City Hospital.

toma. It is a true tumor-cell with the characteristics of the other tumor-cells and signifies usually rapid proliferation under very favorable nutritive conditions. Tumors containing these giant cells are rarely or never called giant-cell sarcomata. That term is reserved for tumors containing giant cells of another type which are not due to multiple mitoses but to fusion of endothelial leukocytes to form foreign-body giant-cells. The leukocytes are attracted into the tumor usually by bone injured in some way by the growth of the tumor. They form foreign-body giant cells (osteoclasts), just as they do around bone requiring removal under normal and pathologic conditions. Their occurrence in tumors signifies usually erosion of bone, rarely the presence of free fat and fat crystals or other substances. They occur most commonly therefore in fibromata and fibrosarcomata involving bone. They occur also in inflammatory processes. Epulis, the term commonly applied to giant-cell formations about the jaws, is probably often only an inflammatory new-formation, not a true tumor. The presence of the giant-cells leads to a wrong diagnosis. This view is favored by the simple treatment needed to get rid of most of these lesions. Giant-cells of this type are therefore not true tumor-cells, and hence should not be mentioned in naming the tumor. That must be diagnosed and named from a study of the rest of the tissue minus the giant-cells.

The smooth muscle cell is a long spindle-cell with a rod-shaped nucleus. It is characterized by having longi-

Fig. 1.—Fat cells of embryonic type.

tudinal striations or fibrils in the cuticle. These fibrils fuse together at each spindle end of the cytoplasm to form a fairly coarse fibril of considerable length. From the smooth muscle cell arise slow and rapidly growing tumors called leiomyomata. These tumors occur occasionally in the skin, both single and multiple. The rapidly growing tumors are rare.

The fat-cell is characterized by the storage of fat within its cytoplasm. It is a cell of mesenchymal origin which produces no intercellular substance and which in the embryo and in young emaciated children resembles to some extent a liver-cell, with finely granular cytoplasm. (Fig. 1). In this early stage the fat when present is usually in small droplets and the nucleus remains centrally located. In the adult type of cell the fat is in one large drop and the nucleus is pushed to the periphery.

The ordinary tumor, the lipoma, resulting from uncontrolled growth of fat-cells, is composed of fat-cells of the adult type and is too well known to require description. Rarely, however, a rapidly growing lipoma may arise in which the cells (Figs. 2 and 3) are all, or for the most part, of the embryonic type with granular

cytoplasm in many of the cells and the fat in small droplets surrounding the nucleus, which is situated in the center.

Neuroglia-cells are characterized by the production of but one kind of fibril, the neuroglia fibril, which is in intimate contact with the cell producing it. Gliomata, the tumors arising from neuroglia cells, occur ordinarily only within the central nervous system, but they may arise rarely in the nasal sinuses and over the coccyx beneath the epidermis; in the latter region from remains of the neural canal. Two cases arising in this situation and carefully studied were distinctly infiltrative in their manner of growth and in one case metastases took place into both groins.

The pigment-cell (chromatophore) occurs in the skin, the eye, and the membranes of the central nervous system. In the skin the cell is of mesenchymal origin. It varies much in shape, that is, it is polymorphous, produces no intercellular substance, and is characterized by the property of producing a brownish pigment. Abnormal collections of pigment-cells in various stages of development, with and without pigment, frequently occur in the skin. They are known as congenital nevi.

Fig. 2.—Lipoma composed of fat cells of embryonic type.

The tumors arising from pigment-cells are generally called melanomata. The cells composing them vary much in shape, from spindle to round, and also in size. The pigment varies greatly in amount. Many cells and clumps of them contain no pigment; others have so much that it is difficult to find the nuclei. The arrangement of the cells varies also; some tumors, composed of bundles of spindle-cells running in different directions, suggest a fibrosarcoma, especially if pigment is slight or absent. In other tumors the cells may show more or less of an alveolar arrangement, but usually little stroma is developed. Frequently by necrosis, dissolution, and absorption of cells at a distance from the blood-vessels, sheaths of tumor-cells are left around the blood-vessels suggesting a perithelial type of growth.

The endothelial cell is poorly characterized except by the lack of distinguishing features other than that of lining vessels and spaces. Three varieties are recognized, those lining blood and lymph vessels, which are nearly related and perhaps identical, and those lining the subdural space. I shall speak here only of blood-vessel endothelium.

The tumors arising from endothelial cells should be called endotheliomata. Most pathologists at present, however, reserve this term for the rapidly growing tumors and speak of the slow growing ones as angiomas. To distinguish this group of endotheliomata from the two other types the term hemangioendothelioma is advisable. Two varieties are recognized, the capillary and the cavernous hemangioendotheliomata.

The capillary form always grows infiltratively, not expansively. It invades fat and muscle-tissue, nerves and blood vessels. In spite of its growing in an infiltrative manner, I know of but one case on record in which metastases took place. These tumors are prone to recur, however, because the surgeon does not remove a sufficiently wide margin of apparently normal skin.

Fig. 3.—Lipoma composed of fat cells of embryonic type.

These tumors may grow slowly or rapidly and may be very destructive locally. Certain peculiarities of structure deserve mention. The endothelial cells may thicken up so as to form several layers around the lumen and mitoses may occur in any of these layers. If the lumen becomes obstructed in any way from hemorrhage or pressure the endothelial cells continue to multiply, forming whorls; less often they form irregular masses suggesting the alveolar arrangement of a carcinoma; lumina are not reformed. The connective tissue cells around the blood vessels of the stroma, in part grow in between the endothelial cells, in part deposit collagen fibrils between them so that the tumor may come to resemble fairly closely a fibrosarcoma; but the whorls of cells and the lack of fibroglia fibrils betray it. Moreover, the tumor in typical form may be found invading the fat tissue outside the tumor nodules.

Rarely all the vessels are surrounded by several layers of endothelial cells so that a perithelial type of tumor is suggested. Still more rarely papillary masses of endothelial cells may project into the lumina of vessels. Direct growth of this tumor itself within blood-vessels is not so rare.

The cavernous type of the hemangioendothelioma is not very common. It consists of large blood-spaces separated by thin partitions of connective tissue lined on each side with endothelial cells. These tumors may spread and give rise to different nodules, which follow in a chronologic sequence and yet seem to have no direct relation to each other. The explanation of the sequence of events is simple. The tumor grows within blood-vessels, extending along them and dilating them. In places it destroys or ruptures them and forms the large nodules so evident macroscopically.

There are many varieties of nerve-cells in the central nervous system. The one common and distinguishing characteristic of them all is the production of nerve-fibrils.

Tumors arising from nerve-cells are called neurocytomata.¹ They are probably not so rare as commonly supposed. They arise most frequently in the adrenal glands and may give rise to multiple metastases within the skin, bone marrow, liver and lymph nodes. The tumors in general suggest a lymphocytoma of the large cell type but they have one distinguishing feature—bundles of delicate fibrils running parallel. The nuclei of the cells are relatively large and the cytoplasm is small in amount and poorly defined. Occasionally, apparently when the fibrils are poorly developed and short, small clumps of fibrils are found with the cells arranged more or less in a circle around them to form a sort of rosette.

CONCLUSIONS

In conclusion I wish to say that it is advisable so far as possible to discard certain loose and indefinite terms frequently used in connection with tumors and strive for definite diagnoses and exact terms. For example, "spindle-cell sarcoma" refers only to a tumor with cells of a certain shape. The commonest tumor which grows rapidly with cells of this shape is the fibrosarcoma, but other tumors which may have cells of this shape are the chondrosarcoma, the osteosarcoma, the hemangioendothelioma, the leiomyoma, the rhabdomyoma, the glioma.

A round-cell sarcoma is most often a lymphocytoma, but other tumors which may have round cells are the osteosarcoma, the leiomyoma, the glioma, the myeloma, and the neurocytoma.

The so-called perithelial angiosarcoma is in my experience most commonly a melanoma, but other tumors which may grow in this form as the result of malnutrition (necrosis, dissolution, and disappearance of cells at a distance from the blood vessels) are fibrosarcoma, glioma, neuroma, and carcinoma (of breast and epidermis).

True tumor giant-cells occur in many tumors, glioma, fibrosarcoma, lymphocytoma. In the so-called giant cell sarcomata, the giant-cells are foreign-body giant-cells due to the fusion of endothelial leukocytes. They are not tumor-cells and should not be named in the diagnosis. The tumor itself is usually a fibroma or a fibrosarcoma. It may be only inflammatory tissue full of giant-cells. Probably the so-called epulis of the jaw is frequently of this nature, and not a tumor.

THE PATHOLOGY OF MALIGNANT EPITHELIAL GROWTHS OF THE SKIN *

JOHN A. FORDYCE, M. D.

Professor of Dermatology and Syphilology, University and Bellevue
Hospital Medical College

NEW YORK

The presentation of this subject as a lantern exhibition permits the demonstration of a large number of slides showing the usual and unusual features of the two main types of cutaneous epitheliomata and some of the conditions which precede their growth. As it is obviously impossible to reproduce all, either pictorially or graphically, in a paper of this scope, only a few selected ones will be introduced to emphasize certain features, and in the text reference will be made to those of interest which have been published elsewhere.

PATHOLOGY

There is perhaps no field in tumor pathology which offers such facilities for the study of diversity in histologic structure as the growths of the skin, nor one which furnishes the opportunity for investigating such a variety of mediate causes. In the vast majority of cases a tumor when first seen is beyond its first inception, malignancy is already established, and its genesis and initial changes left to speculation. In the skin, however, owing to the ease with which changes can be noted, and the slower rate of growth, it is possible frequently to obtain material which shows early transitional stages. In addition, we have a group of conditions which are so definitely associated with tumor forma-

tion that on a clinical basis alone we do not hesitate to prognosticate their outcome. These affections, classified as precancerous and highly important from a dermatological standpoint, permit us not only to draw deductions as to the etiologic and biologic factors concerned in malignant proliferation, but they confirm the view that a

Fig. 3.—Xeroderma pigmentosum (Zeiss 8 mm., C.O.4). Small warty growth, showing hypertrophied horny layer and rete. Many cells of latter show degenerative changes, are vesicular and have large deeply staining nuclei. Corium degenerated and dense infiltration occupies upper layers of cutis in close juxtaposition to epidermis.

plurality of causes is operative in the etiology of cancer. While admitting the contention of Borrmann and other adherents of the Cohnheim theory, that in certain case-tumors have their origin in embryonal cell rests, as in those springing from certain nevi, the weight of evidence in the majority of cutaneous epitheliomata is not in favor of this view. In the examination of early growths, especially the superficial epitheliomata which arise on a seborrheic base, single or multiple foci of proliferation can be seen proceeding directly from the epidermis. These areas are usually sharply delimited from the surrounding surface and appear as swellings bulging toward the corium. The cells are smaller, more closely and less regularly placed than normally and the basal layer has lost its symmetry. They are, furthermore, to be distinguished from the surrounding cells by their larger and deeper staining nuclei. In some of the superficial epitheliomata of the Paget type edema of the affected area is the characteristic early

* Because of the space required the article is abbreviated in THE JOURNAL, by the omission of some of the pictures and part of the text, but it appears in full in the Transactions of the Section and in the author's reprints.

change; the cells increase in volume and their pale bodies stand out in sharp contrast with the neighboring normal ones.¹ Findings like these and the evidence offered by the precancerous class of diseases, it seems to me, negative the view which incriminates isolated cell groups, in the skin at least.

production of a slight scar. Not infrequently in the same individual we can see lesions in all stages of development—the telangiectases, brownish or blackish discolorations not appreciably raised above the surface, flat seborrhœic warts and those showing considerable elevation, with the adherent crust above referred to.

ILLUSTRATIVE CASES

Sections from a patch of keratosis from the cheek of a man 60 years old showed a thickened horny layer, with nuclei fairly well preserved; attached to its under layers were cornified plugs, which distended the mouths of the pilosebaceous apparatus. The granular layer was missing. The rete was irregularly thickened and thinned and had areas of degeneration which stained badly and contained vacuoles. On the whole the cells were smaller than normal and the sharp contour of the basal layer was lost. The connective tissue in the upper corium was degenerated, its fibrillary character was lost and it had acquired a homogeneous appearance. The majority of the vessels had very thick walls and small lumina. A mild inflammatory infiltration was present in the superficial part of the cutis. In addition to numerous pigmented, telangiectatic and keratotic lesions on his face and hands, he had three active squamous-celled cancers, one over the bridge of his nose, another under his left eye and the third over the left parotid region.

A senile keratoma, removed from a patient 47 years old, who presented a squamous-celled epithelioma of the index finger, several warty growths on the backs of his hands, as well as telangiectases, atrophic and pigmented lesions, showed, under the low power, a striking resemblance to the warts seen in xeroderma pigmentosum. The higher power showed principally the degenerative changes in the cells. From hyalin

Fig. 6.—Arsenical keratosis (Zeiss S mm., C.O.4). To show degenerative changes in cells and clumping of nuclei probably due to amitosis.

PRECANCEROUS AFFECTIONS

Of the precancerous conditions senile keratosis comes first in order of frequency. Its sites of predilection are the face, neck, and backs of the hands, the parts of the body exposed to the influence of light. It is not infrequently accompanied by seborrhea of the face and scalp, so that it is difficult to know just how much weight to attribute to the infection of the epidermis and how much to the influence of light. The various stages of its development are frequently seen coincidentally. The first noticeable change is the brownish discoloration of the skin. This is followed by a slight thickening of the epithelial cells and practically corresponds to the seborrhœic wart. As the lesion develops it increases in depth, its warty character becomes more pronounced and it is in this stage that we have virtually an epithelioma. These lesions differ from the ordinary verrucae in that they are more pigmented and less elevated, and in their later stages they are covered by a greasy friable crust which is not so adherent as the epidemic layers of the ordinary wart. It can be detached with little effort and then reveals a bleeding papillomatous condition. At this stage the lesion can be readily removed by curettage and caustics and heals with the

Fig. 7.—Basal-celled epithelioma developing in a lupus scar (Spencer 1 1/2 in., Zeiss Proj. Oc. 2). Tumor consists of irregularly rounded, oval and elongated masses of small cells with central degeneration. There is no connection with the surface epithelium.

1. Paget's Disease of the Gluteal Region, Jour. Cutan. Dis., 1905, xxiii, 193.

Fig. 8.—Squamous-celled epithelioma (Zeiss Planar 20 mm., C.O.4). An epithelioma which developed in the scar following a burn received 40 years previously. The scar broke down and healed several times during this interval. The slow course of the tumor, which was relatively benign, probably finds its explanation in the cicatricial capsule-like connective tissue resisting the epithelial growth.

and hydropic changes they had become voluminous, lost their prickles and assumed a more or less rounded form with a well-defined periphery, as though encapsulated. In the older portions they had become confluent and their outlines were no longer visible. The nuclei in many had entirely disappeared or only shrunken bits of chromatin remained, surrounded by a clear space, or were connected with the cell by radiating protoplasmic threads. In addition free cells were found appearing as spheres of hyalin with a dense nucleus and a vacuole. The connective tissue beneath the wart, and especially on either side of it, was degenerated and rarefied. It is this rarefaction of the subepithelial tissue which Thiersch considered the necessary or determining element in tumor growth. By bringing about a disturbance in tissue tension the restraint to epithelial invasion is removed.

Figure 3 is an example of xeroderma pigmentosum from the tissue of a young man, aged 21, with the typical features of the disease developed on his face, neck, hands and lower portions of the forearms. He also had a well-advanced epithelioma of the lip. The horny layer is markedly thickened, very dense and firmly adherent below. The granular layer is absent. The rete

is very irregular, consisting in places of only two or three layers of stretched cells and in others of irregular processes, whose cells vary in shape and size, but have atrophic bodies and conspicuously large nuclei. The prickles are not distinguishable as the cells are more or less welded together. Hyalin degeneration is a marked feature. The basal layer is in a state of disorganization, with the tissue immediately below it vacuolated. The corium is atrophic and degenerated; the papillary and subpapillary regions are occupied by a dense infiltration of lymphocytes and plasma cells.

Figure 5 illustrates telangiectases. The tissue is from a patch of dilated capillaries which followed an x-ray burn. The horny layer is considerably thickened, the rete flattened and hollowed out by the dilated capillaries. The cells are smaller than normal and many of them contain vacuoles. The papillary bodies have been entirely obliterated and the corium changed by hyalin degeneration. The tortuous ectatic capillaries extend from the middle two-thirds of the cutis to almost beneath the horny layer. Some of the sections contain partial thrombi.

Arsenical keratosis (Fig. 6). This tissue came from a patient kindly referred to me by Dr. Jackson. He had taken Fowler's solution for five years. On his body and hands were numerous scaling, pigmented and warty lesions. The section from one of the keratotic areas shows the thickened horny layer dipping down into the rete, producing a marked undulatory line between the two. In some of the layers the nuclei are well preserved; in others as the result of dyskeratosis there are large ballooned bodies which appear like double-contoured organisms. The granular layer has almost entirely disappeared, the horny layer proceeding directly from the Malpighian layer. In the latter the points of interest are acanthosis and edema, causing a widening of the intercellular spaces. Here and there the cells have disintegrated, their remains lying in cystic spaces or several have fused to produce large, deeply-staining, irregular bodies connected by cytoplasmic threads to the sur-

Fig. 9. Paget's disease. Disease began about nipple two years previously. Condition shows an eroded moist surface, with defined somewhat polycyclic border; nipple retracted. Extending from primary lesion and covering almost entire surface of breast a lymphangitis is present. Over this area were scattered lesions similar to primary one. The mammary gland was the seat of a diffuse carcinoma. Axillary node enlarged.

rounding cells. Nuclear degeneration is as common as cytoplasmic. Some of the cells contain central clumps of chromatin; in others it is dispersed through the cell, and a further sign of degeneration is the presence of clumped nuclei, due probably to amitotic division. The basal layer is disorganized at points where the corium is more or less rarefied. The superficial part of the cutis has a granular appearance and the connective tissues cells stain only faintly. Aside from this a slight lymphocytic infiltration is seen about some of the capillaries.

Leukokeratosis produced by syphilis or tobacco, or occurring independently of either, is probably the most common antecedent change in mucous membrane epitheliomata of the mouth.³

In addition to the foregoing, which represent a group of conditions whose natural history includes a termination in epitheliomatous formation, there is another class of diseases which offer a favorable base for the development of malignancy. They are chronic skin diseases, as syphilis, lupus vulgaris, lupus erythematosus, Darier's disease, psoriasis, scars from various causes, etc.

Cancers secondary to tuberculous lupus are, in the majority of cases, classed as scar cancers or are attributed to the use of x-ray in treatment. However, they also develop on an active lupus and are usually of the squamous-celled variety, in which case both processes appear coincidentally under the microscope.

The case illustrated is of peculiar interest in its departure from the usual type seen in connection with tuberculosis or scars. It was originally reported as an endothelioma,⁴ but a greater familiarity with the basal-celled growths and

their degenerations has led me to include it in the latter group. The tumor, which developed in a lupus scar, occupied the entire corium as large and small cellular masses, irregularly rounded, oval or elongate (Fig. 7). The cells, many of which are spindle-shaped from pressure, have rather large oval

Fig. 10.—Paget's disease of nipple (Zeiss 8 mm., C.O.4). The epidermis shows characteristic change which begins at basal layer and extends to the upper layers, viz., edema, vacuolization and degeneration of protoplasm. At the surface of epidermis is a marked collection of polynuclear leukocytes where erosion has taken place. In the corium cross-section of lymph space showing infarct of tumor cells. Infiltration of lymphocytes, plasma and mast cells in the papillary and subpapillary layers.

Fig. 11.—Lymphangitis in Paget's disease of nipple (Zeiss 8 mm., C.O.4) Section from circumcised area radiating from disease of nipple. Shows lymph space containing an alveolus of cancer cells.

nuclei, rich in chromatin and contain numerous mitotic figures. The central portions of the cell masses from degeneration are cystic and contain detached cells and detritus. There is no connection anywhere with the surface epithelium, and no evidence of the tuberculous process is present.

In a case of epithelioma following a burn, which was previously reported,⁵ the tumor developed on a chronic ulcer of the thigh following a burn received forty years previously. The ulcer healed and broke down several times, eventually passing into neoplastic formation. The slow development probably finds its explanation in the histologic structure (Fig. 8), which shows the sharp limitation of the growth by the underlying sclerotic tissue, which, capsule-like, retarded the epithelial invasion.

The coexistence of epithelioma and psoriatic patches is a rare occurrence, but through the kindness of Dr. George T. Jackson I had an opportunity of seeing such a case several years ago. Multiple tumors of the basal-celled type were present. The patient subsequently developed metastases in the mediastinal glands and internal organs and died of

3. For a description of the character of these lesions the reader is referred to *Affections of the Mucous Membranes and their Relation to Skin Diseases*, Jour. Cutan. Dis., 1904, xxii, 397.

carcinosis. The tumors were made up of masses of small, deeply-staining cells with scant stroma and numerous foci of degeneration of a mucinous character in the cellular aggregations.

The slides demonstrating epithelioma and Darier's disease were made from specimens kindly loaned me by

marked acanthosis of the epidermis the line of demarcation between epidermis and corium is preserved, and in a series of cases that I have examined downgrowth did not occur. In these cases there was concomitantly a mammary carcinoma and the corium was infiltrated solely with growth from the lactiferous ducts below.

Fig. 14.—Rodent ulcer (Zeiss 8 mm., C.O.4). An early rodent ulcer near ala of nose, taking its origin from the lanugo hair follicles.

Dr. Grover W. Wende from his case of multiple squamous-celled epitheliomata consecutive to Darier's disease. The interesting feature in connection with these growths was the degenerative forms and cell inclusions.

The subject of malignant growths secondary to nevi, with illustrations, has been previously discussed by me.^{5, 6}

Paget's disease of the nipple is regarded by many authors as a superficial epithelioma, and this view is probably justifiable on clinical grounds, since we find in other portions of the body superficial flat epitheliomata having an eroded granular center and a slightly rolled polycyclic margin, strongly resembling the nipple lesion. Histologically, however, some points of difference are to be noted, especially in the older portions of the extra-mammary cases. If the edge of these lesions is examined, the picture in many instances bears a very close resemblance to the mammary disease. The cells are edematous, vacuolated, and show the peculiar degenerative changes of the affection. There is, however, evidence of proliferation, and if the central portion of the area is examined, true epitheliomatous formation of the small basal-celled type will be found.^{1, 5} In the nipple region, while there is a

The photograph (Fig. 9) is from a Russian woman about 55 years of age, referred to me by Dr. Keene. The patient stated that the condition of the left breast had existed about two years. It presented the typical features of Paget's disease, a dark red, granular, exuding surface with sharply defined periphery, with here and there evidence of beginning cicatrization in the center of the lesion. She also presented a group of small secondary ulcerated and encrusted lesions outside of the original patch. These lesions suggested autoinoculation or the breaking down of a lymphangitis, which radiated for a distance of about 3 inches from the periphery of the patch. The entire breast was the seat of a carcinomatous tumor, which was not sharply circumscribed, but seemed to involve the entire gland, probably due to the simultaneous infection of the lactiferous ducts. She also had an enlarged node in the axilla.

Tissue from the nipple region (Fig. 10) shows the epidermis riddled, as it were, by some destructive agent. The process has proceeded to complete autolysis in some areas, or only distorted nuclei and fragments of the cell body remain. The surface of the epidermis is eroded and covered by a crust of polynuclear leukocytes, remains of epidermic cells and fibrin, and below this there are military collections of leukocytes.

The specific degeneration in Paget's disease begins in the deepest layers of the rete and causes the cells to become paler and increase in volume. From swelling the

prickles become indistinct or disappear entirely and vacuoles make their appearance. In this way there may come to be left only a ring of protoplasm separated from the nucleus by a clear space, or the latter may be distorted or pushed aside by one or more vacuoles. Even-

6. Melanomas and Some Types of Sarcoma of the Skin, THE JOURNAL A. M. A., Jan. 8, 1910, p. 91.

tually the cells are separated and lie free in cavities and assume most bizarre forms and appearances. The basal layer, although degenerated, still sharply marginates the epidermis from the corium. In the cutis, with the beginning epidermic changes, an infiltration of mast and plasma cells appears in the papillæ, later becoming more diffuse and extending to the subpapillary layer and the tissue below. In the case under consideration the superficial lymphatics contained cancerous infarcts.

The histologic findings from the area of lymphangitis are shown in Figure 11. The tissue immediately about the cancer embolus is denser than elsewhere, owing to the reactive fibrosis which has taken place. The cells are large, irregular and show pronounced degenerative changes. Their protoplasm is coarsely granular, and in going through the sections seriatim all types of so-called cancer bodies, dependent on cellular and nuclear origin and aberrant mitosis, are to be met with.

These curious changes are, however, not peculiar to malignant growths but are also found in chronic inflammations, and irregular mitotic figures have been produced experimentally in various tissues. Degenerating cells may also divide by amitosis, giving rise to a clumping of nuclei.

Illustrations and report of lymphangitis in cancer *en cuirasse* will be found in my paper already referred to.

CLASSIFICATION

Cutaneous carcinomata in the great majority of cases take their point of origin from the epidermic covering of the sheath of the follicles, the glandular epithelium only exceptionally proliferating primarily. Although there are many classifications based on the microscopic or macroscopic appearances, relative malignancy or genesis, the histologic division of cutaneous epitheliomata into two great groups, according to certain prominent characteristics is the most practical, namely, the prickle-cell group, and the basal-cell group of Krompecher. In the former, the tumors are composed of large cells which have retained their prickles; they are early destructive, metastasize and have a general malignancy. In the basal-celled group the tumors are made up of small cells which possess no prickles and have relatively large nuclei; they do not as a rule metastasize and have usually only a local malignancy. While recognizing the validity of the criticism made by Adami that all cells originate from the basal layer, it is nevertheless a fact that in the one case only one type of cell continues to proliferate while in the other differentiation goes on. As a rule, too, these two types conform more or less with distinct clinical pictures, though occasionally cases are seen in which a positive diagnosis can only be made by the microscope. Patients with multiple epitheliomata sometimes present the two types with not sufficient clinical difference to tell them apart.

Histologically the typical feature of squamous-celled growths is the solid prolongations or downgrowths from the epidermis, which spread out in different directions or on section give rise to masses of alveoli of various shapes and sizes lying in a connective tissue stroma. In the characteristic members of this group the epidermal characters are preserved and result in epithelial pearls.

The alveoli which go to make up the tumor have one or more centers of pearl formation; their periphery corresponds to the basal layer, consisting of small cells with deep-staining nuclei. Within this are several rows of prickle-cells with a concentric arrangement; the majority have lost their prickles and are in various stages of

keratinization, appearing as more or less flattened or rounded plates, anuclear, or with nuclei undergoing disintegration. As a rule the activity of pearl formation is an indication of malignancy. In the corium or supporting stroma is usually found an inflammatory reaction of varying grade. Not infrequently a mucinous degeneration has taken place, or the tissue is porous, or shows other signs of loss of vitality.

In tissue undergoing malignancy certain changes take place which indicate the vegetative activity of the cells. These are a smaller cell with oval or rounded cell body, clear cytoplasm and a relatively large, deeply staining nucleus; the relations of the cells to one another become changed; they become crowded and occupy a much smaller space than under normal conditions. This is especially true of the basal-celled tumor and it is not so difficult to make a diagnosis in these cases of early epithelioma. In the squamous-celled type, however, particularly those which develop on ulcerated surfaces, it is not so simple to say whether one is dealing with tumor formation or only atypical proliferation. In chronic ulcerations there is a marked tendency for the epithelium at the edges of the ulcer to grow irregularly downward and infiltrate the tissue beneath. These processes may become snared off and sometimes develop pearls, when it is practically impossible to determine from the histology the exact pathologic condition.

Of the basal-celled epitheliomas the rodent ulcer may be taken as the type, as it is the form most frequently encountered. These tumors are made up of an undifferentiated type of cell, yet, contrary to the rule, are the least malignant of epithelial tumors. Various degrees of anaplasia are encountered and a more or less spherical, polygonal or even spindle-shaped cell may be encountered. Not only the cellular morphology but the general structure of these basal-celled tumors varies and has led to the recognition of certain well-defined types. It has been suggested by Darier that this varied architecture might be explained as the attempt on the part of the basal layer to functionate, as during embryonic life, in the production of the appendages of the skin.

Descriptions and illustrations of cylindroma and tricho-epithelioma will be found in a paper previously published,⁵ and of benign cystic epithelioma and other forms of growths in papers likewise already published.⁷

The picture of the ordinary rodent ulcer differs a great deal in appearance and may, in one instance, appear as a solid downgrowth from the surface epithelium, with little tendency to branch; in another the larger masses may show central cystic degeneration and peripheral budding, or fine or coarser processes of cells bifurcate throughout the cutis. Figure 14 illustrates a rodent ulcer near the ala of the nose originating from the hair follicles and forming solid tubes or cords of cells which give off lateral processes. Tricho-epithelioma, which also develops from lanugo hair follicles, has a somewhat different structure, which may be due to an attempt on the part of the cells to differentiate. These growths clinically may appear as morphea-like lesions, as already described.⁵

A frequent concomitant of the basal-celled tumor is the hyalin or mucinous degeneration, which affects either the cells or the connective tissue, or both. Degeneration is considered by some authorities, as Adami, to indicate malignancy, but in the skin we find the tumors most

7. Clinical and Pathological Observations on Some Early Forms of Epithelioma of the Skin, *New York Med. Jour.*, June 9 and 23, 1900; and *Cancer of the Skin*, *Jour. Cutan. and G. U. Dis.*, 1902, xx.

prone to degenerate are of a benign type. In mucinous or pseudo-mucinous degeneration the cells appear indistinct and poorly differentiated, in areas breaking down and forming cystic cavities which contain the products of degeneration. Aside from these changes there may occur a central autolysis of cells (Adami) which may be due to lack of nutrition or to metabolic products of the tumor cells themselves. Extractives or diffusible products *in vivo* may have the same effect in producing this autolysis as the introduction of a vaccine from a tumor.

Many multiple epitheliomata in the early stages closely resemble Paget's disease. They present all grades from pale and red scaling patches, the size of a split pea or smaller, to patches as large as the hand. They have sharply defined, scalloped margins showing very slight tendency to elevate or pearly rolled edge. Some of them maintain their red and scaling appearance and others become the sites of fungating growths (Fig. 16). These tumors often develop on patches of seborrheic dermatitis, which suggests some infectious agent. It is possible that the bottle bacillus, in combination with the staphylococcus, stimulates epithelial proliferation. Even in the early stages, before any apparent thickening of the epidermis is present, proliferation of the basal layer can be determined by histologic examination.

CONCLUSIONS

A study of skin cancers suggests to the observer, if it does not demonstrate absolutely, that no one agent is concerned in the malignant proliferation of epithelial tumors and that cutaneous carcinomata have a multiple etiology. The development of epitheliomata following exposure to sunlight, x-rays or other radiant energy is a strong argument against the parasitic nature of the disease. Likewise, the occurrence of epitheliomata in xeroderma pigmentosum and allied conditions of the skin which come on in old age or middle life is an additional argument against this theory. These conditions are preceded by changes identical with those met with in xeroderma pigmentosum, such as a dry atrophic skin, telangiectases, warty growths and, finally, malignant transformation. Furthermore, the action of chemical substances on epithelium, for which they have a special predilection, such as arsenic, tar, scarlet R., tobacco, etc., demonstrate that a variety of agents have the power to stimulate epithelial mitoses which may pass into malignancy. Cancers which develop on scar tissue or antecedent conditions of the skin like lupus, syphilis, etc., suggest that we are dealing with misplaced cells in some cases and in others with degenerative processes which lead to the abolition of the functional activity of the cells, which is followed, as a consequence, by vegetative activity, according to the theory of Oertel, Adami and others. In primary multiple epitheliomata we have several foci in which an infectious agent or some internal sensitizing agent may have acted on the cells and rendered them susceptible to a local factor.

ABSTRACT OF DISCUSSION

ON PAPERS OF DRs. LOEB, FORDYCE, MALLORY, BLOODGOOD AND PUSEY, CONSTITUTING A SYMPOSIUM ON CANCER*

DR. E. R. LECOUNT, Chicago: There seems to be a subsidence of belief in the parasitic origin of tumors and a diminution during the last few years of investigations to find such para-

sites. The prevalence of the former belief in a parasitic origin of tumors may be accounted for by the conspicuous place which the infectious diseases occupied in investigative medicine during the last few decades. With the lessening of search for a "cancer parasite," opportunity has been offered for researches in other directions. In general these have been of two sorts, one of them the old and well-worn subject of the histogenesis of tumors, still capable of yielding valuable information; the other, the newer study of transplantable spontaneous tumors of animals. In regard to the last of these, the results have been the development of a new branch of medical literature, new journals and the founding of special institutions by both private and public funds. Some of the articles dealing with phases of tumor transplantation are as difficult for the average physician to comprehend as many of the contributions to the problems of immunity. In both fields of investigation there is a great deal which needs collating for the physician with average equipment. In general the results which have so far occurred from study of these transplantable tumors are: 1. Learning that only a relatively small percentage of the transplantations lead to successful growing grafts. 2. The belief in a continuity of tissue growth—that all the successful grafts represent direct ancestry of the tumor with which the experiments began. 3. The undoubted experimental production of a malignant tumor which has been observed a few times when metamorphosis of a carcinoma into sarcoma has taken place. 4. The altered tactics among these investigators very recently in now attempting to modify, control or prevent processes of tumor growth which they are able to bring about; in other words, to produce an immunity. 5. The gradually growing suspicion, now almost a conviction in the minds of some, that the growth of malignant tumors is largely dependent on processes of metabolism not understood at present, but which may eventually be found analogous to those which are concerned with normal growth.

DR. F. B. MALLORY, Boston: I should like to say a word in connection with the paper of Dr. Fordyce in regard to epidermoid carcinomata. In the ordinary epidermoid carcinoma the cells differentiate like those of the epidermis. The cells of the rete Malpighii are cubical to cylindrical in shape and have considerable cytoplasm. These cells show a slight fibrillation of the cuticle. In the prickle-cell layer the fibril formation is much more marked. The fibrils are numerous and short. Finally the cells undergo a homogeneous transformation with cornification which leads in the tumor to the formation of the so-called epithelial pearls. In the non-cornifying type of carcinoma of the skin, the so-called carcinoma baso-cellulare, the cells vary from cubical to spindle in shape, have little cytoplasm and do not lead to prickle-cell formation. Instead these cells often produce numerous very definite straight and wavy fibrils of considerable length. The only cells in the skin which differentiate in this way are the cells leading to the formation of a hair shaft. These cells are spindle in shape, have little cytoplasm and produce numerous long, wavy fibrils which gradually undergo a homogeneous transformation and form the shaft of the hair. Judging from the cell differentiation they undergo this tumor arises from the hair matrix.

DR. J. W. VAUGHAN, Detroit: It is interesting to note that the results of the treatment with the x-ray in some cases are apparently far superior to the use of purely surgical measures. I will attempt to give a possible explanation for this fact. The late Dr. Hodeppl of New York cured a cancer of the liver by the use of injections of ascitic fluid; the ascitic fluid gave good results in other cases. In addition to that we have the work of the experimenter who injected a suspension of cancerous cells into patients with beneficial results. In my own experiments I split up the cancer cells with a 2 per cent. solution of sodium hydrate in absolute alcohol. The non-toxic residue is insoluble, and I injected this portion with apparently beneficial results. Now, how does this apply to the better results we get with the x-ray, as compared to purely surgical measures? If you take cancer tissue and expose it to the x-ray for fifteen minutes it splits up the cancer tissue the same as the caustic sodium hydrate solution, into its toxic and non-toxic portions. The good results following the use of the x-rays, I believe, are due to the fact that the rays

* Another symposium on cancer appeared in THE JOURNAL last week, the one which took place in the Section on Pathology and Physiology at the St. Louis session.

form an active ferment within the body of the patient, which in itself splits up the cancer cell, and is not due wholly to the destruction of the cancer cell.

DR. WILLY MEYER, New York: In the treatment of skin affections by radium it is necessary, in the first place, to have radium of great strength. The application and treatment is comparatively simple and nothing that I know of can be compared to the results obtained by it. In cases of tumor of the skin, warts, epitheliomas, etc., Dr. Abbe proposes to make these radium applications for a period of half an hour and then send the patient away. I have obtained good results by using it in such cases at close range for five minutes the first day, adding to this time one minute for three successive days, and then on the fifth day allowing the radium rays to exert their effect on the immediate surroundings of the tumor for ten minutes. Then the patient is sent away and is not seen again for three or four weeks. By this method, in three different cases, I have seen the marvellous effects of radium, similar to those described by Dr. Able in his oration on surgery at this session. The patients with what we formerly called epithelioma or rodent ulcer, especially when located about the nose and eyes, where they are unusually disfiguring, come back to us after this method of treatment with a scar which, while it is somewhat below the level of the skin, remains a healthy scar, without showing any evidence of recurrence. In one of my cases two years have now elapsed without a recurrence; in two others the interval is shorter. There is nothing, in my experience, that can be compared with the wonderful effect of this method of treatment, which often acts where the α -ray fails. The only drawback is that radium is very scarce and very expensive. It is to be hoped that pitchblend will soon be found in large quantities in one of the many mines of our country. In that case I am sure dermatologists would be the first to make more frequent use of this apparently wonderful remedy.

DR. WILLIAM T. CORLETT, Cleveland: I believe that the ideal treatment for cancer is not yet known. During the last twenty-five years I have worked with my colleagues, the surgeons, in handling many cases of cancer, and I believe if one acts honestly and studies his cases well he will not adopt any one method of treatment to the entire exclusion of others. The main thing that has been brought out in the discussion thus far in the treatment of cancer is the early eradication of the disease. The method of this eradication, I believe, is of secondary importance, but it is the early recognition and thorough eradication that is followed by the best results. Everybody who sees many of these cases must be impressed with the fact that many patients are allowed to go on for months and years, receiving only dilatory or insufficient treatment, until the case is beyond the scope of operative measures. Every clinician must have observed, too, that there are different degrees of malignancy, as has been pointed out in the histologic presentation. There are cases of cancer of the skin in which the knife is the only means that can be employed, but in many cases the knife is not the best means. When it is, it is advisable in many instances to follow it by a thorough course of α -ray treatment. In regard to the use of caustics, we are familiar with the work of Robinson, and, while I have had little personal experience with caustics, I believe they are effective and in selected cases are good. One objection to them is that they are painful, and personally I believe in most instances there are better methods. The Roentgen ray in some cases is the best and only method, and in others the knife is not only the best but the only method. The Roentgen ray, I believe, is not the most efficient, for after this method of treatment only a certain number will remain free from the disease for a period of years. The method that I have adopted very largely for at least twenty-five years at the Lakeside Hospital is electrolysis. Of late this method has received attention by Brocq of Paris, and some Germans have spoken of it favorably. When I first adopted this procedure I did it at the request of the surgeons in cases in which the use of the knife was not deemed advisable. In these cases and in many others since then the results have frequently surprised me. They have been very favorable, and I hope some time in the near future to present a tabulated report of my results. That

the procedure is indefinite, as stated by Dr. Pusey, I refuse to concede. My method is to introduce both electrodes around the malignant growth, penning it in, and afterward to introduce them into the growth itself. It is advisable, I believe, to go beyond the margin of the growth and produce a decided retraction. Many of these patients, to my personal knowledge, have gone from nine to fifteen years without a recurrence; others have died of old age, but I have no detailed statistics to present at this time. Finally, the method to be selected in the treatment of cancers of the skin should depend on the nature of the case. In some the knife is best, in others the Roentgen ray, while in suitable cases, before metastases have occurred, electrolysis is followed by excellent results. Of course, where glandular involvement has already taken place, it should not be considered; then the knife is imperative.

DR. A. RAVOGLI, Cincinnati: I was very glad to hear Dr. Mallory speak of the possibility of micro-organisms finding an entrance through the opening of the sebaceous glands, and to listen to Dr. Fordyce's remarks regarding the precancerous changes in the skin and the development of epitheliomas on certain dermatoses; that it was possible that a micro-organism might be the cause of this preceding disease of the skin, and then the causation of the cancerous changes. I have always believed in the parasitic origin of cancer, and still incline to that view. The success of the transplantation experiments, I think, point to the correctness of that theory. There must be something which produces the changes and the proliferation of the cells. I find that liquor formaldehydi gives me very good results in superficial epithelioma and carcinoma. My usual procedure is to curette the lesion and then apply a 40 per cent. dilution of liquor formaldehydi. The pain that this method gives rise to can be allayed by a 5 per cent. solution of cocain. After two or three days the surface of the lesion begins to harden into a whitish or yellowish eschar, and when this falls off, a second application is rarely necessary. I have had perhaps 40 or 50 cases in which my results with formaldehyd solution have been very satisfactory. I also wish to mention the use of Coley's fluid, especially in fibrosarcoma. I have seen cases in which the growths were so extensive as to be practically inoperable improve under the injections of the *Streptococcus erysipelatis* and *Bacillus prodigiosus*, as advised by Dr. Coley, and I think this remedy should be borne in mind in extensive cases that are not amenable to other methods of treatment.

DR. J. A. FORDYCE, New York: I was very much interested in what Dr. Mallory said in regard to the infiltrating angioma. This seems to bring it into connection with the angiosarcoma of Kaposi.

DR. WILLIAM A. PUSEY, Chicago: I am glad to see from this discussion that we are not so far apart in our views on this subject. I think the consensus of our views is that the proper treatment of carcinoma is to destroy it. It does not make so much difference how you do it, providing you do it. For this purpose I prefer to use vigorous measures. I do not like formaldehyd solution or pyrogallie acid. As to any antibodies or ferments being produced when you treat carcinoma with the α -ray, I have looked for such an effect as longingly as anybody, and I am compelled to say that I have seen no such effects. I have seen great masses of sarcoma and carcinoma disappear under the α -ray, but as far as my experience goes I have not been able to see a glimmer of hope that by this method of treatment any antibodies were formed that were of any value. We must depend on the destruction of the cells by the α -rays. As to the comparative value of radium and the α -ray, I believe that the results of these two agents are very similar and that in both instances we are using practically the same agent.

Radium in Urology.—We distinguish three kinds of action of radium of which use can be made in urology: (1) bactericidal action; (2) action on the surface of tissues, consisting especially of decongestion and cellular modification; (3) alternative action on deeper tissues and on glandular organs.—L. Wickham, in the *Practitioner*.

PRELIMINARY REPORT ON THE CLINICAL SIGNIFICANCE OF INDICANURIA

BASED ON TEN THOUSAND EXAMINATIONS FOR INDICAN *

G. BAAR, M.D.
PORTLAND, ORE.

In the last four years I have made it a routine practice to examine the urine of every patient for indican. Jaffé's test, carried out as follows, has been employed:

The urine was precipitated with lead acetate (moderate quantity), filtered through a dry filter-paper, and an equal quantity of fuming hydrochloric acid with ferric chlorid (50 c.c. hydrochloric acid, with 8 to 10 drops ferric chlorid) added to the precipitate. This was shaken thoroughly for two minutes, then shaken with 1 c.c. chloroform for the same length of time.

The depth of the blue discoloration of the chloroform was taken as indicating the quantity of indican present; thus designating the quantities as "very excessive," "excessive," "considerable," or "moderate." Traces of discoloration were not taken into consideration. In 10,000 urine examinations I found indicanuria present in about one-third of the cases, mostly, however, temporarily only and I designated these as "accidental indicanurias." The cases, however, in which there appeared constantly excessive indican, which formed the most conspicuous clinical symptom of the case, I called "*indicanuria par excellence*." Cases in which the examination of the whole body, the stomach contents, the feces and blood did not yield any abnormal findings, but in which indican in the urine appeared constantly in excessive quantity I considered "intestinal auto-intoxication," provided the complaints of the patient pointed, even though uncertainly, to the digestive apparatus. I wish to state here in advance that true cases of intestinal auto-intoxication are rare. This statement, I am well aware, places me in direct opposition to the general profession as held to-day. Such patients present clinically the following symptoms: pale complexion, dry skin, cold hands, and feet, dizziness, headaches, insomnia, nervous depression, neuralgias, migraine, rheumatic pains in the extremities, emaciation, fetor ex ore, often acne, seborrhea, furunculosis, and urticaria. The excessive amount of indican in the urine of these patients indicates simply the large increase in the sulpho-ethers and aromatic substances of the urine.

The indoxyl compounds are not toxic in themselves. So far as we know they are not capable of producing any such pathologic symptoms as enumerated above. The true toxic substances are the ptomaines. The "aromatic bodies" (phenols, cresols, indol, skatol), however, develop in parallel degree with the former in intestinal putrefaction. While we do not possess a simple clinical procedure to estimate the ptomaines, we do possess one in the above-mentioned Jaffé's test, which permits a practical estimation of the aromatic bodies and thus gives valuable information as to the metabolism of the body; for it is a proved fact that whenever ptomaines are absorbed from the intestinal tract sulpho-ethers of the aromatic bodies are absorbed simultaneously, and by measuring the quantity of the sulpho-ethers we obtain knowledge of the intensity of the putrefactive processes within the bowel. There are but two exceptions to this rule: (1), individuals taking aromatic

drugs internally, i. e., salol, phenol, naphthol; (2), organic suppurations. In this manner the excessive excretion in the urine of sulpho-ethers and aromatic compounds serves as an indicator of an abnormal formation and absorption of the products of microbial nitrogenous putrefaction. The intestinal anaerobic flora being one of putrefaction, we find it always predominant in cases of intestinal putrefaction.

It is not, however, the quantity of putrid substances formed in the bowel, but the quantity of those putrid substances entering the blood which causes the symptoms of auto-intoxication. This accounts for the fact that, on the one hand, we may find in cases of marked intestinal putrefaction many toxins in the stool but few only in the blood. Diarrhea, for instance, or mucus covering the intestinal mucosa, diminishes their passage into the circulation; and so also will perfect function of the other organic lines of defense, to wit, liver, kidney, pancreas, prevent their absorption. On the other hand, however, even a feeble intestinal putrefaction will cause auto-intoxication if the lines of defense are broken, owing, for instance, to deep ulcerations of the mucosa or insufficient function of the antitoxic organs. Thus we may explain the case of a young girl, who suffered with a bloody purulent diarrhea for eight months, not showing any indican in the urine but frequently excessive amounts in the feces. When an appendicostomy was performed on this patient for the purpose of irrigating the colon, the urine, which never before showed indican, showed excessive amounts of indican on the four days following the operation, together with distinct traces of bile.

These findings prompted me to examine urines of patients to be operated on, before and after operation. The following are some of the conclusions I reached:

1. Ether narcosis has no influence whatever on the excretion of indican.
2. In all gastro-enterostomies, entero-anastomoses, appendectomies—in all operations, in short, in which the intestinal wall was cut, we found excessive indican and distinct traces of bile in the urine for a week or more following the injury.
3. Moderate handling of the intestines during the course of an abdominal operation did not cause any indican to appear in the urine, while prolonged handling of the intestines did cause excessive indican in the urine.

These findings offer the quasi-experimental evidence for my assertion that the trauma to the intestinal wall with the subsequent inflammatory and functional changes of the latter cause the impairment of the absorptive powers of the mucosa, thereby increasing intestinal putrefaction; an indicator for this increased putrefaction is the amount of indican excreted in the urine. The clinical evidence for my claim is given by the fact that the majority of my chronic appendicitis cases showed excessive amounts of indican in the urine, more especially during the recurrent attacks. The same did all mucous colitis cases. The mucous coating of the colon in these cases inhibits the toxicolytic functions of the mucous membrane, favoring, thus, intestinal putrefaction.

The thought that mechanical trauma to the intestinal wall is sufficient to produce indican was instrumental in my diagnosing four cases of pericholecystitis adhesiva, in which the diagnosis was corroborated by the surgeon. One case was that of a man aged 45, who had suffered almost constantly for twenty years with ill-defined pain-

* Read in the Section on Practice of Medicine of the American Medical Association, at the Sixty-first Annual Session, held at St. Louis, June, 1910.

ful sensations in the right and upper abdominal region. The examinations of the urine made frequently after such attacks showed always the presence of considerable indican and distinct traces of bile. On further inquiry the patient remembered an icterus he had had about twenty years before. The operator found the suspected adhesions between the right flexure of the colon and the gall-bladder. The severance of these adhesions brought a complete recovery of the patient, who had been considered all his life a neurasthenic only. The very same condition existed in another case, that of a middle-aged woman whose gall-bladder was found completely adherent to the colon. The excision of the gall-bladder effected a cure. Similar pathologic conditions existed in the two remaining cases. In one of them there was also present an adhesive chronic appendicitis. For the explanation of the constant presence of distinct traces of bile during the painful attacks, I merely suggest the kinking of the bile-duct, brought about mechanically by the peristalsis of the colon adherent to the gall-bladder, thus causing a temporary entrance of bile into the circulation.

The same principle of prolonged mechanical trauma to the intestinal wall through coprostasis explains the asthenic condition present in more than 300 cases of enteroptosis I tested repeatedly for indican. While it must be admitted that gastropstosis and enteroptosis are primary conditions, as Glenard and Stiller have proved, it will be easily understood that the "transverse festoons" of the intestines predispose to coprostasis. As long as the latter takes place in the rectum alone—either by its atonic or its spasmodic condition—on account of the dryness of the feces and consequent diminution of the number of bacteria, it will not cause putrefaction. This is proved by the cases of constipation in adults as well as in children, with periods of three to ten days between bowel movements, without the appearance of any of the phenomena of putrefaction, including no indican in their urine. If the coprostasis, however, takes place in the cecum or ascending colon, where there is not yet dryness of feces, but humidity and often alkaline reaction, the most favorable conditions for exaggerated putrefaction are created. The toxins, ammonia compounds and sulphuretted hydrogen, which then enter the portal vein from the intestinal tract, destroy red blood-cells in the portal system. The hemoglobin thus liberated is carried into the liver where it is found deposited in the hepatic cells as blackish granules, containing iron from the blood pigment. Thus we could find in almost all cases of enteroptosis anemias of about 70 per cent. (Sahli) and 4,500,000 red blood corpuscles. By applying a well-fitting abdominal supporter to these patients, rendering better defecation possible and at the same time fattening them, most of these patients became free of indican and attained normal blood again.

Quite conspicuous was the constant finding of indican in those cases of constipation, which were complicated by cardiac insufficiency. This latter must needs produce an insufficiency of digestive juices which can explain the formation of enterotoxins from the undigested residua attacked by bacteria. The same explanation holds true in all the accidental indicanuria cases, including febrile diseases, cachexias, nervous diseases (tabes, cerebral tumors, meningitis).

Schmidt's "intestinal dyspepsia"—a functional disease of the small bowel, in which the carbohydrates are not utilized—is very rare. In many hundreds of stool

examinations I have found only a few instances in which exaggerated fermentation was obtained in the first twenty-four hours in Schmidt's apparatus. In none of these cases was there any indican present in the urine.

Among the chief emunctories for those products of intestinal putrefaction which are circulating in the blood (like indoxyl, skatoxyl, phenol, leukomains, etc.) rank the kidneys. Any renal insufficiency therefore should—according to Combe's opinion—lead to a retention of the above mentioned products, i. e., "auto-intoxication." It is noteworthy that in a few thousand of indican tests made on patients with acute and chronic diffuse nephritis, pyelonephritis, tuberculosis of the kidneys, indican was found relatively rarely, and there were hardly any symptoms of the much-dreaded "auto-intoxication" present. Interesting in this respect was the case of a young woman with pyuria, due to a tuberculous abscess in the left kidney. For many weeks prior to the excision of the left kidney her urine never showed any trace of indican; since the removal of her diseased kidney, however, the urine—though practically free of pus—shows constantly considerable amounts of indican, while the woman herself feels perfectly well in every respect.

The liver is credited with the exercise of a powerful toxicolytic function against the enterotoxins entering the same through the portal vein. Diseases of the liver cells, should favor intestinal putrefaction, thus increasing the aromatic bodies in the urine. About a hundred cases of liver diseases like hypertrophy, cirrhosis, syphilis of liver, cholangitis, and carcinoma hepatis were studied in regard to their relation to indican excretion. I have come to the conclusion that indicanuria exists only in extreme hepatic insufficiency, when the latter is indicated not only by the decrease of urea in the urine—"hypo-azoturia"—but by the simultaneous presence of leucin and tyrosin in the same. While a marked increase in the sulpho-ethers and aromatic bodies always indicates auto-intoxication to a certainty, its hepatogenous origin should be asserted only by considering the amount of urea and leucin in the urine at the same time; for we know that urea is formed in the liver from the amino-acids and ammonia carried into it through the portal vein from the intestines; and uric acid is similarly formed in the liver from the nucleins and xanthic bases. Hepatic insufficiency, therefore, implies decrease in urea and uric acid. If urea was not decreased, we should have to think of some other origin for the auto-intoxication. If, however, in addition to a decrease of urea I found that 150 gm. of glucose produced alimentary glycosuria, my assumption of a general hepatic insufficiency would be strengthened. Thus I could see—though rarely—"auto-intoxication" brought about through hepatic insufficiency in cases of normally functioning intestines.

Normal gastric juice is supposed, under normal conditions, to either destroy or at least diminish the number of bacteria which cause putrefaction. In more than five hundred examinations of the gastric contents I found that hyperacidity quite frequently was coupled with indicanuria. If there was simultaneously present ulcer of the stomach or duodenum, indicanuria was always present. Hyperacidity coupled with indicanuria indicates an extragastric lesion, like chronic cholecystitis or appendicitis, provided ulcer of stomach or duodenum can be excluded. More than twenty laparotomies corroborate thus the value of indicanuria for the differential

diagnosis between gastric and extragastric lesions. Cases of anacidity and hypacidity showed indicanuria only in half their total number. Whenever these conditions were accompanied, however, by carcinoma ventriculi, indicanuria was always present.

The insufficiency of pancreatic juice (the tryptic action of which neutralizes many toxins) with its consecutive increase of intestinal putrefaction was shown in two cases of carcinoma of the pancreas with ever-present excessive indican.

Bile insufficiency is supposed to cause intestinal putrefaction, partially owing to the absence of the antitoxic action of taurocholic acid, partially because it leaves a larger alimentary residua for the bacteria to prey on. About fifty cases of icterus, with complete occlusion of the common duct, caused either by gall-stones or catarrhal icterus, showed indicanuria in but ten cases. Among these fifty cases there were three, in which all the bile was draining through a cholecystostomy wound, with absolutely acholic stools. There was no indican in spite of the much-spoken-of "bile insufficiency."

Conspicuous was the indicanuria in several cases of ozena and caries of the teeth in patients who exhibited no other signs of pathologic condition. Evidently the patients swallowed in their sleep more or less virulent pus which furnished the source of intestinal infection and putrefaction, the stomach being empty and not containing any hydrochloric acid.

I have endeavored to remove this indicanuria, which I have considered for these four years as only an indicator of intestinal putrefaction, by all means advocated heretofore: I have placed my patients on a vegetarian diet, mixed diet, proteid diet, lactofarinaceous diet. There appeared, however, no perceptible change in the excretion of indican in any one of the twenty cases of "intestinal auto-intoxication," I observed. I administered gelatin, lactic acid culture tablets, chologestin, calomel, menthol, ichthoform, ichthalbin, benzonaphthol, ichthyol, hydrochloric acid—without avail. I combined oil injections simultaneously with this internal and dietary treatment, and in another series of cases salicylic acid irrigations of the colon—all with no success whatever. I imported and used in many instances Metchnikoff's lactobacillin, with not the slightest reduction of indican in the urine. I used all makes of lactic tablets with which any manufacturer could supply me—but the "commercially so well-advocated antiputrefactive action exercised by lactic ferments, when applied to the treatment of intestinal disorders" proved a complete failure! Not the slightest influence on the excretion of indican in the urine could be seen from any of these preparations. At last I resorted to high enemas of 1 per cent. ichthyol with the patient in knee-chest position. I think the case in which I first applied the latter noteworthy enough to be reported.

A man aged 72 with pernicious anemia (the blood-picture showing poikilocytes, megalocytes and megaloblasts, the hemoglobin 30 per cent. (Sahli), red blood corpuscles 2,700,000) showed excessive indican for two weeks previous to the treatment. The physical examination of the body, and the examination of the feces, and of the urine revealed nothing further. The patient was put on lactofarinaceous diet, combined with daily high colonic lavage with 1 per cent. ichthyol. The indican disappeared from the urine, and the blood increased in the course of four weeks from 30 to 65 per cent. (Sahli). The megaloblasts disappeared from the blood. The patient is at present much improved.

Startled by the efficiency of ichthyol irrigations, I advised the same treatment for another patient, a middle-aged woman with depressive neurasthenia symptoms, with no other clinical symptom but persistent indicanuria. The indican disappeared, and the patient's whole mental attitude at the same time brightened conspicuously.

While I am aware that two cases are not sufficient to allow of any further general deductions for the therapy of this rare disease "intestinal auto-intoxication" I thought them noteworthy enough—in view of my numerous therapeutic disappointments in the treatment of that disease—to report.

806 Oregonian Building.

ABSTRACT OF DISCUSSION

DR. DELANCEY ROCHESTER, Buffalo, N. Y.: I had a case of pernicious anemia in which the injections were used as described by Dr. Baar, with only slight temporary improvement. The patient finally died. Although the injections were used for a long time, indican did not disappear from the urine. I do not agree that these patients with pernicious anemia can be cured, when these large quantities of indican appear in the urine, by washing out the bowels with these ichthyol injections. I think, however, that Dr. Baar's general observations are true. Indican is present in the urine in a large percentage of these cases, but it is not necessarily due to intestinal putrefaction. We certainly do not get relief by the employment of lactic acid bacilli used in any way, as in buttermilk, or lactic acid tablets.

DR. JUDSON DALAND, Philadelphia: As already stated, indican is non-toxic; but inasmuch as materials are manufactured during the process of putrefaction which are toxic, and as indican is an indication of their production, the presence of this substance in the urine may be of some value to us.

So far as pernicious anemia and the type of blood picture referred to is concerned, I also have had an interesting case. This experience was with a child about 12 months of age, who presented a persistent and excessive indicanuria. The colon was irrigated with normal saline solution, and this was followed by a rapid recovery. In this case certain materials remained in the blood and were active until destroyed, and we were able to recover from the urine cadaverin and putrescin. I believe that where there is an indicanuria which will not yield to treatment, often we will find tuberculous ulceration of the intestine, and also that any interference with the integrity of the intestinal canal will bring about indicanuria. Of course, the extent of the intoxication is exceedingly variable. I think the suggestion made as to the treatment of these cases is a valuable one; thorough and complete irrigation of the colon with normal saline solution should prove to be very efficient.

DR. JAY I. DURAND, Atlantic City, N. J.: During the last four years I have examined 5,000 specimens of urine, making the indican test as a routine measure. I have found indican, in definite amounts, in at least two-thirds of the specimens; if we accept the teachings that any trace of indican is pathologic, then at least two-thirds of the cases were pathologic. I agree with Dr. Baar regarding the difficulty in removing the excess of indican in a large number of cases. There are many cases in which I have been unable permanently to reduce the quantity; I have used Metchnikoff's bacilli, in many preparations, and have never been able to convince myself that they had a marked effect on the indicanuria. It seems to me that, if Metchnikoff's theory were to be substantiated, the indican should be profoundly affected by the use of the bacilli.

DR. C. SHATTINGER, St. Louis: I should like to make a report of a case recently under my observation. This case was, and still is, a puzzle to me so far as a correct interpretation of the symptoms is concerned. The patient was a boy of 18 years and he had been ill for 2 years. The symptoms were somewhat vague—mainly abdominal pain and progressive emaciation. He had had an appendectomy, and had made a

good recovery from the operation, but improved slowly. He afterward lapsed back again and the emaciation became extreme. When he came under my observation his weight was 79 pounds and he looked like a candidate for death from tuberculosis. The suspicion of a tuberculous lesion in the intestine was strong. The feces were examined for tubercle bacilli, but none were found. The von Pirquet test was twice negative. The blood was carefully examined. Except for a reduction of about 20 per cent. in hemoglobin the blood was found to be normal. All the organs were examined carefully, and with negative results. Examination of the urine showed it to be normal, except for the presence of indican in what would be called considerable quantities. I took that as a clue and an endeavor was made to remove the indicanuria. I have had a similar experience as Dr. Durand in the use of the different medicinal agents and the bacillary preparations. I used all, but without avail. In the want of better indications I fell back on what seemed to be common sense view of the indications. I wanted to improve the nutritive condition of this patient, and so I fed him to the utmost. I felt that he should derive benefit from the employment of hydro-electric baths, viz., sinusoidal baths, to stimulate metabolism. By using hydrotherapeutic measures, tonics, salines and carefully selecting the diet, I found it was possible after 7 months to bring his weight up to 132 pounds and apparently to make him a strong and healthy individual. But he still has indicanuria.

DR. GUSTAV BAAR, Portland, Ore.: Intestinal toxemia is a very uncommon disease; among 3,000 cases examined there were only about twenty in which I could not find the cause for the constant presence of excessive indican in the urine. Where there was a renal, gastric or liver insufficiency I have not called such cases "intestinal" toxemia. I want to avoid the expression auto-intoxication; this is a term that should be avoided, as should the term malaria. I noticed that those who took part in the discussion agreed that the lactic acid tablets show no influence on the excretions of indican. If we need any such nostrums let us have something that is less expensive than these lactic acid tablets. Here is another point: the excessive secretion of indican in the urine occurs in cases of hyperacidity; this is something of diagnostic value. Cases of hyperacidity point more to the neurotic conditions, or ulcer of the stomach; cases of hyperacidity associated with persistent indicanuria, however, point to extragastric lesions (gall-stones or appendicitis), and they belong to the surgeon.

THE COMPARATIVE EFFICIENCY OF SOME COMMON GERMICIDES

WILBUR E. POST, M.D.

Instructor in Medicine, Rush Medical College

AND

HOMER K. NICOLL, M.D.

Fellow in Medicine, Rush Medical College

CHICAGO

In the case of an obstinate gonorrhoeal arthritis in a hospital, the advisability of injecting argyrol into the joint arose and the question was asked, What is the germicidal power of this preparation? The literature seemed indefinite and various in its answers and tests were accordingly made. The results were so unexpected and so much at variance with the prevalent opinion that the tests were repeated and extended to protargol, and silver nitrate, and from these to a considerable number of germicides in ordinary use for clinical purposes in a large well-regulated hospital. As a consequence of the evidence produced, many solutions previously in use in that hospital have been discarded and in their place more effective ones substituted. Because of the daily interest of clinicians, as well as the importance of the subject to patients, a summary of these investigations is here presented.

The development of methods for testing the efficiency of germicidal solutions affords us practical knowledge as well as historical interest. From 1750 to 1881 the most extensive experiments were concerned with the value of different substances to hinder putrefaction in such media as infusion of tobacco leaves, meat broth, and vaccine lymph. Robert Koch, in 1881, was the first to compare the germicidal value of various disinfectants on pure cultures of bacteria. He instituted the so-called "thread method" by marking with emulsions of organisms dried on silk threads. The drawbacks of Koch's method are, first, that the organisms are dried, and, second, that a certain amount of the disinfectant is carried with the thread and continues to act on the organisms after being removed from the disinfecting solution. It is in part owing to these drawbacks that various workers reported the high germicidal power of mercuric chlorid, creolin, the cresols and higher phenols.

Krönig and Paul (1897) devised the "garnet method," by which emulsions of organisms were dried on garnets. These garnets were immersed in the solution of the disinfectant, and the disinfectant carried over was gently removed by washing. These workers were the first to emphasize the importance of:

1. Constancy of number and species of bacterium used.
2. Constancy of temperature.
3. Constancy of nutrient media for test cultures.
4. Absence of other organic matter.

In 1903 Rideal and Walker published their "drop method," by which a definite small amount of a broth-culture of constant species and age was added to a constant volume of disinfectant solution. In the opinion of many this method suffers from the disadvantage that whereas, in the majority of cases of practical disinfection, organic matter of some sort is present, there is no attempt to realize this condition during standardization. To overcome this objection modifications of the Rideal-Walker method have been described and may be found well discussed in a comprehensive paper by Chick and Martin.¹

The method by which the following results were obtained may be briefly described:

Half a cubic centimeter of the solution to be tested was placed in a small test-tube. Into this solution was placed one platinum loopful of an emulsion (in culture broth) of a twenty-four-hour culture (on blood-agar slant) of the organism used. After one minute, ten minutes, thirty minutes, and twenty hours, a loopful of contaminated test solution was thoroughly mixed into a tube of blood-agar and plated in the ordinary sterile petri dishes. These were incubated at 37° C. and observed after twenty-four, forty-eight, and seventy-two hours. In the case of large numbers of colonies the figures are approximate, and if the number of colonies was too great to permit of approximate estimation, the sign of infinity (∞) was used. The streptococcus was obtained by blood-culture from a case of puerperal septicemia; the pneumococcus from blood-cultures in a case of typical lobar pneumonia; the gonococcus was isolated from a urethral discharge; the *Bacillus typhosus* was obtained directly from blood-cultures. All of the organisms were grown only on blood-agar after being obtained.

Objections to this method will be raised: first, the emulsions of the various organisms were not standardized to represent a uniform number of bacteria per cubic

1. Chick, H., and Martin, C. J.: Standardization of Disinfectants. Jour. Hyg., London, November, 1908, viii, No. 5.

millimeter; second, by immersing the bacteria directly in the disinfecting solution a condition is obtained which is more favorable to the destruction of bacteria than is found in ordinary clinical conditions; third, errors may arise from accidentally striking the platinum loop on the side of the test-tube, leaving some of the bacteria outside of the solution and later picking them up when inoculating the blood-agar plates; and fourth, the intervals between the different times of exposure may be too long for minute comparison of effects of the various disinfectants. To the first and third of these objections we find the practical answer in the uniformity and consistency of the results in a series of tests necessitating nearly 2,000 different inoculations. To the second objection it is not necessary to say that if the solutions are not effective against bacteria immersed directly into them they are far less likely to be effective against bacteria in the presence of protective substances such as blood, serum, mucus, etc. To the fourth, we wish to say that the chief purpose of these tests was to obtain a broad guide in the choice of disinfectants in those conditions demanding effectiveness in a brief time, such as cleansing wounds, fields of operation, instruments, etc. Attention is also called to the possibility that on account of the thorough mixing of the bacteria in the blood-agar the action of the germicidal solution was promptly checked. At the same time their growth and detection is enhanced. This latter is especially emphasized in the case of the streptococcus with its hemolytic powers, which makes detection of organisms living in the blood-agar plate very easy. The various drugs were obtained as the best in the open market and were such as are used widely by the profession. The accompanying tables show our results:

TABLE 1.—SILVER PREPARATIONS

Silver nitrate 1-10,000	Pneum.	5,000	10	0	0
	5,000	10	0	0	

Table 1 shows the results which were so unexpected that they led to further tests. We see that 10 per cent. and even 50 per cent. argyrol, and 10 per cent. protargol failed to kill the gonococcus, streptococcus or pneumococcus after they had been exposed directly to the fluid for one-half hour. At the same time it is seen that silver nitrate even in a dilution of 1 to 5,000 was much more effective. These results were not all obtained at one time but represent the compiled results of tests made at different times and with disinfecting solutions made up at different times. The uniformity of results is striking.

In therapeutics, then one should keep in mind that argyrol and protargol are expensive and not so active in concentrated solutions as the ordinary silver nitrate in 1 to 5,000, or even 1 to 10,000 solution, which costs almost nothing. The action on the typhoid bacillus is more favorable for the argyrol and protargol and less favorable for high dilutions of silver nitrates.

* Broken.

The important lesson from the tests with solutions of the mercury salts is that the action is slow, but that it is effective even in high dilutions. The solutions of bichlorid of mercury were made up according to directions from Bernay's tablets, because these are so widely used by the profession. Organisms immersed in a 1 to 500 solution were still living in large numbers at the end of ten minutes and one colony of gonococcus was obtained after thirty minutes. In 1 to 2,000 solution there was almost no apparent effect in thirty minutes, although disinfection was complete after twenty hours. Contrary to a prevalent opinion, then solutions of bichlorid of mercury made up from Bernay's tablets are absolutely ineffective where prompt disinfection is required, as in the disinfection of hands and fields of operation.

The combination of the biniodid of mercury, potassium iodid and sodium bicarbonate are sold by Parke, Davis & Co., under the name of "germicidal discs." The following claims are made for the preparation: A 1-to-5,000 solution is as effective as a 1-to-1,000 solution of bichlorid of mercury. Coagulation of tissues at the site of application is prevented. It causes less irritation and in proper dilutions instruments are not injured by it. The first claim seems to be approximately

confirmed since the 1-to-2,000 solution is as effective as the 1-to-500 bichlorid. It is possible that the increased efficiency of this preparation over bichlorid may be due in part to the increase of iodine in solution. Attention is directed to the efficiency of iodine solutions. In general, however, it is seen that with the biniodid solution too, the time is needed to make sure of complete disinfection; and in the dilution of 1 to 5,000 the effect is not appreciable after thirty minutes, although disinfection is complete after twenty hours. In the case of the mercurial salts, the typhoid bacillus again seems to be more easily destroyed than the streptococcus, gonococcus, or pneumococcus.

TABLE 4.—SOLUTIONS OF IODIN

Solution.	Organism.	Number of Colonies in one loopful of test solution after exposure :			
		1 min.	10 min.	30 min.	20 hrs.
Iodin 1	Strep.	0	0	0	0
	Potassium iodid. 1	0	0	0	0
	Water 100	0	0	0	0
	("Senn's solution")	0	0	0	0
Iodin 1	Strep.	0	0	0	0
	Potassium iodid. 1	0	0	0	0
	Water 400	0	0	0	0
	B. typh.	0	0	0	0
Tincture of iodin.	Strep.	0	0	0	0
	Potassium iodid.	0	0	0	0
	Water 400	0	0	0	0
	B. typh.	0	0	0	0

The solutions of iodine (Table 4) were tested, the first two in the table being those warmly advocated by the late Professor Senn, and called, locally at least, the Senn solutions. Both of these, as well as the tincture of iodine, killed all organisms in less than one minute.

To what extent these may be diluted and still be effective was not determined. The weaker solution is extensively used by some in irrigating wounds, both on account of its germicidal power and its stimulating effect in producing granulations.

TABLE 5.—SOLUTIONS OF LIQUOR FORMALDEHYDI

Solution.	Organism	Number of Colonies in one loopful of test solution after:			
		1 min.	10 min.	30 min.	20 hrs.
Liquor formaldehydi (U. S. P.)	Strep. ...	0	0	0	0
	Gon. ...	0	0	0	0
	Pneum. ...	0	0	0	0
	B. typh. ...	0	0	0	0
Liquor formaldehydi 1%	Strep. ...	10,000	2,000	500	0
	Gon. ...	4,000	2,000	1,000	0
	Pneum. ...	5,000	3,000	200	0
	B. typh. ...	∞	4,000	50	0
Liquor formaldehydi 1 to 1,000	Strep. ...	10,000	10,000	2,000	0
	Gon. ...	6,000	6,000	6,000	0
	Pneum. ...	4,000	4,000	4,000	0
	B. typh. ...	4,000	4,000	3,000	0
Liquor formaldehydi 1 to 10,000	Strep. ...	10,000	10,000	10,000	1,000
	Gon. ...	4,000	4,000	5,000	2,000
	Pneum. ...	5,000	5,000	5,000	2,000
	B. typh. ...	∞	10,000	8,000	2,000
Liquor formaldehydi 2% Glycerin 98%	Strep. ...	∞	∞	10,000	0
	Gon. ...	10,000	10,000	4,000	0
	Pneum. ...	10,000	8,000	6,000	200
	B. typh. ...	10,000	50	0	0

Liquor formaldehydi (Table 5) also afforded unexpected results because of the slowness of its action in a solution as strong as 1 per cent., which did not completely kill in thirty minutes, and because the 2 per cent. formalin in glycerin acted more slowly than 1 per cent. aqueous solution. In the former 200 pneumococci in 1 loopful of test solution were still living after twenty hours. The solution in glycerin is of the strength frequently injected into infected joints.

TABLE 6.—SOLUTIONS OF ALCOHOL

Solution.	Organism	Number of Colonies in one loopful of test solution after:			
		1 min.	10 min.	30 min.	20 hrs.
Alcohol 1 %	Strep. ...	400	300	300	100
	Gon. ...	300	300	300	2,000
	Pneum. ...	∞	∞	∞	∞

	Gon. ...	500	300	10	20
	Pneum. ...	10,000	10,000	10,000	5,000
	B. typh. ...	2,000	2,000	2,000	2,000
Alcohol 10 %	Strep. ...	300	300	400	0
	Gon. ...	200	4	0	0
	Pneum. ...	10,000	10,000	10,000	6,000
	B. typh. ...	8,000	8,000	3,000	3,000
Alcohol 20 %	Strep. ...	300	200	3	0
	Gon. ...	300	0	0	0
	Pneum. ...	8,000	8,000	8,000	4,000
	B. typh. ...	4,000	6,000	2,000	1,000
Alcohol 30 %	Strep. ...	25	0	0	0
	Gon. ...	0	0	0	0
	Pneum. ...	2,000	2,000	1	0
	B. typh. ...	300	0	0	0
Alcohol 50 %	Strep. ...	0	0	0	0
	Gon. ...	0	0	0	0
	Pneum. ...	0	0	0	0
	B. typh. ...	0	0	0	0
Alcohol 70 %	Strep. ...	0	0	0	0
	Gon. ...	0	0	0	0
	Pneum. ...	0	0	0	0
	B. typh. ...	0	0	0	0

Alcohol (Table 6) seemed to kill the gonococcus more readily than the other test organisms; a 20 per cent. solution killed all gonococci in less than ten minutes. With the exception of one single colony of pneumococcus, cultures from 30 per cent. alcohol were entirely negative after thirty minutes. Alcohol in 50 per cent. and 70 per cent. solution killed all organisms in

less than one minute. Many methods of disinfecting hands or fields of operation may owe their good results largely to the use of alcohol at some time in the process.

* Broken.

Table 7 includes the results with a miscellaneous lot of solutions which were tested for various reasons. The tincture of green soap showed a very high germicidal power, killing all organisms in less than one minute. This may also be an important factor in various methods for disinfecting hands, etc., and certainly is to be recommended especially when used in conjunction with alcohol. Whether the effectiveness of the tincture of green soap is due to the alcohol in it was not determined.

The hydrogen peroxid (10 per cent. Mallinckrodt) is said to contain 4 parts in 10,000 of acetanilid. This

killed all typhoid bacilli in less than one minute and the other organisms in less than ten minutes.

Thiersch's solution (salicylic acid 2 drams, boric acid 12 drams, and water 1 gallon) was formerly much used in irrigating wounds. The results show it to be a fairly good germicide.

Potassium permanganate was only mildly active in the dilutions used, but even a 1-to 4,000 solution killed the organisms fully as rapidly as a 50 per cent. argyrol solution. Its wide use as an irrigating disinfectant seems, then, to be justified.

Cupric sulphate shows a slight, although distinct effect after thirty minutes and kills entirely in less than twenty hours, in a dilution of 1 to 1,000. This was tested largely because of its use in the dressing of lesions in blastomycosis and actinomycosis.

Boric acid in saturated solution (1 to 18) was only slightly germicidal after twenty hours.

Potassium chlorate in saturated solution (6.6 per cent.) has but little germicidal action, many living organisms still being found in one loopful of it after twenty hours. If, then, it has any special value as a gargle or mouth wash, for which it is so much used in weak solution, it must depend on some other property than its germicidal power.

Glycerin was tested by this method because the question was frequently asked whether other solutions containing glycerin did not owe their activity to the glycerin. The results indicated almost no germicidal power. The same was true with distilled water under like conditions.

TABLE 8.—IMMEDIATE COMPARISON OF RESISTANCE OF STREPTOCOCCUS GROWN ON BLOOD AGAR WITH THAT OF STREPTOCOCCUS GROWN ON PLAIN AGAR FOR FOUR GENERATIONS

Solution.	Media on which culture was grown	Number of Colonies in one loopful of test solution after:			
		1 min.	10 min.	30 min.	20 hrs.
Silver nitrate 1-5,000	Blood agar	200	50	0	0
	Plain agar	0	0	0	0
Silver nitrate 1-10,000	Blood agar	4,000	40	0	0
	Plain agar	2,000	3	0	0
Liq. formaldehydi 1-1,000	Blood agar	8,000	5,000	3,000	0
	Plain agar	6,000	4,000	2,000	0
Liq. formaldehydi 1-10,000	Blood agar	10,000	6,000	5,000	0
	Plain agar	8,000	3,000	2,000	0

It occurred to us that the apparent slowness of action of some of the reputed germicides might be due to the unusual resistance of the test organisms employed. Consequently the same strains of streptococci and *B. typhosus* were transplanted from their media containing blood, and grown for four generations on plain agar slants. Both organisms were then used in testing fifty-two of the solutions mentioned in the tables. The results were compared with those already given and indicated a moderate lessening of resistance of the organism when grown on plain media and consequently an apparent increase of germicidal power of the various solutions. In order to demonstrate this more conclusively tests were made at the same time, with equal portions of the same test solution and with the same strain of streptococci except that in one case it was grown on blood-agar and in the other on plain agar. The results are shown in Table 8 and indicate a lower resistance on the part of those streptococci grown on plain agar. This factor should be considered in establishing any standard method of testing the efficiency of germicides.

The results establish under these conditions the following points:

1. The reliability of the prompt action of a few simple germicides such as tincture of green soap, alcohol in solutions above 50 per cent., silver nitrate solutions as dilute as 1 to 1,000, the iodine solutions either as the tincture or in aqueous solutions with potassium iodid, phenol in 5 per cent. solution.

2. The unreliability of many agents prevalently supposed to be effective germicides.

3. The slow action of solutions of mercuric chlorid, although when given hours to act it is effective in high dilution.

4. The economic importance in the choice of germicides. This is of special interest to the managers of hospitals since there is great difference in expense between furnishing the much-advertised high-priced (yet less effective) articles in concentrated solutions, and the simple cheaper (yet more efficient) articles in higher dilutions. In one hospital alone, where advantage has been taken of this difference the saving has been several hundreds of dollars a year, and efficiency has been increased at the same time.

We take this opportunity to express the urgent need of a standard method of testing the comparative values of disinfectants. We hope this will be established in the near future by some recognized, suitable authority such as the laboratory of the Marine-Hospital Service at Washington, D. C., or by a committee of the American Medical Association. It will be then less common to find the wide usage of so-called germicides based on advertising literature and other unreliable data. The benefits will be appreciated throughout the profession.

150 Michigan Avenue.

THE PRINCIPLES OF HYDROTHERAPY *

THOMAS McCRAE, M.D., F.R.C.P.

Associate Professor of Medicine and Clinical Therapeutics, the Johns Hopkins University

BALTIMORE

It must be confessed that the discussion of the principles of any subject is apt to smack of the didactic and requires some resolution both on the part of the reader and the writer. We are all apt to look askance at principles and to carry the mental attitude, which characterized many of us as students, of preferring "pointers" to "principles." "The Principles and Practice of Medicine" is the title which adorns many text-books; we all grant the importance of the principles, but show more interest in the practice.

Hydrotherapy has suffered from a curious lack of appreciation from the days of Naaman the Syrian down to the present. Perhaps its simplicity and the fact that the remedy lies easily to hand has had something to do with this and many of us need to have the question asked of us: "My father, if the prophet had bid thee do some great thing, wouldst thou not have done it?" The reasons for this neglect are various, one important one being undoubtedly that instruction in hydrotherapy has not received its proper place in medical teaching, a reproach which, however, is rapidly being removed, for which those who have earnestly striven in this matter deserve our thanks. I remember well being impressed

* Read in the Section on Pharmacology and Therapeutics of the American Medical Association, at the Sixty-first Annual Session, held at St. Louis, June, 1910

by the remark made some years ago by an examiner regarding the answers he had received to a question in the paper on treatment, in an examination for the license to practice, which asked for the uses of water as a therapeutic agent. He commented on the almost absolute ignorance of the students on this question. Certainly the majority of us are better informed regarding the principles of digitalis therapy than on the principles of hydrotherapy. Yet we might with advantage use hydrotherapy much more frequently than any special drug therapy. Another reason for the neglect may be that the advantages which are claimed for hydrotherapy sound too good to be true. How many men—without having learned by actual experience—would believe the statement that cold compresses to the chest and throat are the best means of treating acute bronchitis? How many men would believe if they received a special note of advice to that effect printed in an attractive form? Yet a great many are ready to believe any similar bulletin as to the effect of some new drug preparation. The unknown and the new have an attraction for us; the use of water is an old story.

It is not the intention in this article to classify the effects of water or to discuss all its uses, but rather to try and place emphasis on some of the reasons why hydrotherapy is useful. The special effect of certain springs and their particular virtues are not considered, as they hardly belong here. The principles of hydrotherapy may be discussed under three headings which exemplify to a considerable degree the main uses. These are (1) internal hydrotherapy, (2) local hydrotherapy and (3) general hydrotherapy.

INTERNAL HYDROTHERAPY

In this connection the use of water is considered apart from any question of mineral constituents. That is a wider question and we cannot always administer some special water, while *water* itself is always available. It should not be necessary to draw attention to the necessity of being certain that the water which a patient drinks is pure. To have a patient drink contaminated water and so contract typhoid fever would be a serious misfortune. The purposes which may be fulfilled by the internal administration of water are too numerous to go over in detail and certain examples are chosen. When we remember what amount of the body weight is composed of water, the need of it in the daily economy of the body is evident. It is an important agent, both in absorption and in assimilation.

In disease perhaps one of the most marked examples of the benefit of its use is furnished by the acute infections. In these the greatest danger to life lies in toxemia. As a general rule it may be considered that the kidneys are the great eliminating channels of toxins and to cause a large excretion of water by the kidneys is our chief way of aiding this elimination. We are all aware of the importance of the amount of urine as an aid in prognosis in such diseases as typhoid fever and pneumonia. To some extent the greater the amount of urine the less the toxemia. Some would have it that in thus flushing the kidneys we run the risk of injuring them, but this view is held largely on theoretical grounds and lacks proof. Certainly as a clinical question, there is no doubt as to the general opinion. In a disease such as scarlet fever it is the toxins which are responsible for damage to the renal cells and not the fluids. When acute nephritis exists, it is very true that an excessive amount of water may do harm, but the kidney then is unable to excrete water or anything else. In many

lesser infections—or so generally regarded—as tonsillitis, for example, the effect of active internal hydrotherapy is marked. Then, again, in another group of cases, the chronic forms of arthritis, which in many cases are apparently of toxic origin of some kind, the influence of the drinking of large amounts of water is usually evident. It is easy to extend the list as, for instance, many of the cases of functional nervous disturbance or of mental disease of certain kinds are greatly helped by large amounts of water. That this principle is well recognized is shown by the increasing frequency with which saline infusions are given in many diseases characterized by more or less toxemia. In some cases water is so given because it is not possible to persuade the patients to take a sufficient quantity by mouth but in many others it is used to increase the quantity taken in. The frequency with which water is given by the bowel is another proof of the value of the internal use of water. Much of this is so evident as to require no mention.

Notice should be taken of one mistake which seems so evident that one would suppose its absurdity would be apparent did not experience show that it is made too often. This is the giving of diuretic drugs to increase the amount of urine when water is not being administered in even ordinary amounts. This seems an absurd mistake, but the fact that water must be given internally before it can be excreted is often forgotten. To give diuretic drugs without administering water and to expect large amounts of urine to be passed is like trying to make bricks not only without straw but without clay.

When we consider the amount of water which enters into the composition of the body and how great is the constant interchange in the constituents of every tissue of the body, the importance of the passage of considerable amounts of water is evident. This is true of health, but much more of acute infections in which so many of the cells of the body may be injured. The amount of water which should be given in any particular case of infectious disease must depend on many factors and the state of the circulation and kidneys should be kept in view. Still as a general rule it may be said that these systems are more likely to be injured by toxins than by internal hydrotherapy. In typhoid fever, for example, the effort should be made to have the patients pass each day at least 3,000 c.c., and better 5,000 c.c. of urine. In pneumonia such amounts can rarely be reached and perhaps 2,000 c.c. of urine is as much as can be hoped for in the ordinary case. In septicemia again we may hope to obtain the larger amounts. A certain amount in these cases is excreted by the skin and must be kept in mind in estimating the total output of water. The benefit of these large amounts of water in infection has not been generally utilized, even if recognized. We fail to carry into practice the knowledge that in the treatment of typhoid fever nothing which can be given to the patient in the way of food or drugs can be at all compared with water. It is altogether likely that to-day throughout the country there is nothing for which typhoid fever patients are suffering more than for water. The direction so often given, "Let him have all the water he wishes," does not do enough; he may not want any, but in almost every case water should be forced and the amount be specified just as we would in the case of a drug.

Some hospitals have found that when they had to care for a large number of typhoid fever patients, it was great economy in the amount of nursing required for these patients if one nurse in a ward did nothing else

but give water to the patients. To the doubters one can only suggest that they give internal hydrotherapy a trial. But some are like Naaman and ask, "Are not our antipyretics and intestinal antiseptics better than all the hydrotherapy?" One observation on this question was furnished by an orderly who had been working with typhoid fever patients. He had noticed that the patients who drank large amounts of water and voided corresponding amounts of urine did much better than those who did not take much water. He had been impressed by the fact that they required fewer tub baths and had shorter courses of fever as a rule. Taken ill himself with typhoid fever he carried his water-drinking rather to excess, for in twenty-four hours he voided the enormous amount of 26,000 c.c. This was not kept up, of course, but his confidence in water-drinking was fortunately supported by a short and satisfactory course.

In certain diseases, such as gout, arteriosclerosis or chronic arthritis, we advise the ingestion of considerable amounts of water as a routine measure, regard being always had to the state of the circulation. In these diseases there are several factors; metabolism is probably helped and also the excretion of toxins is aided. Then, too, the influence on the digestive tract must be kept in mind. Here again, as in the circulation, attention must be paid to the local condition of the gastrointestinal canal, especially the stomach, for the condition of an atonic stomach might be made worse by too much water. In hepatic cirrhosis large amounts of water are beneficial, perhaps largely through the effect on the digestive tract.

The general effects of internal hydrotherapy may be summed up as especially shown in toxic states of all kinds, whether due to acute infection, some disturbance of metabolism or the more elusive nervous states; in conditions in which a diuretic action is demanded; in local conditions of the digestive tract and its associated organs; and the best performance of the ordinary bodily functions is brought about by the ingestion of considerable quantities of water.

LOCAL HYDROTHERAPY

In discussing the principles of this we have to do with processes which are closely allied to those which operate in counter-irritation and the local use of heat and cold. There are two systems involved in the action of local hydrotherapy, the circulatory, using the term in its widest sense, and the nervous. In many cases, especially those in which the process is superficial, it seems probable that the effect on the circulation is the more important; in other cases it seems that both systems must be influenced. It is often difficult to decide which plays the more important part.

In the use of water locally, as is well exemplified by the application of compresses, there are several factors at work. One of the most important of these is the effect on the blood flow through the vessels in and near the affected area. The rate at which fluid flows through a tube is markedly influenced by the temperature, and with increase of this the rate of flow is made slower. Hence a reduction in the temperature results in a much-increased blood flow through the vessels. With this, of course, other influences are associated, especially the effect on the vasomotor system, which varies with cold or hot applications. Another factor is the effect of the application on the osmotic pressure of the tissues and fluids. This is markedly altered in tissues which show inflammatory changes, and in its restoration to normal local hydrotherapy has an important influence.

Again in some cases applications to the surface may have an important effect on deeper structures. We are all familiar with this in the case of counter-irritants and accept it as a matter of course, yet in many cases the influence of local hydrotherapy is quite as marked. A familiar example is the use of cold compresses to the thorax in cases of bronchitis. No form of treatment can equal this in the certainty and promptness of its action. When we remember that acute bronchitis is due to an infection in the great majority of cases it seems reasonable to suppose that the circulation is definitely affected, as otherwise it is difficult to understand the effect produced. Applications to the thorax in pneumonia probably have both a local and general effect. The influence of compresses to the abdomen is seen in their employment in the meteorism of acute infections and also in various nervous disturbances such as mucous colitis.

The effect on the local nervous influences is well seen in the relief of pain by the use of cold or hot compresses. The use of cold to a degree which produces anesthesia is not carried out by hydrotherapeutic measures, but the principle is the same. Certain associations—call them reflex if you will—may also be markedly affected, as for instance in the use of cold compresses to the abdomen in meteorism. In this case probably several things occur. The cold causes contraction of the abdominal walls which, as has often been pointed out, has a marked effect on the abdominal contents and probably influences the circulation as well as the muscular contractions. The circulation in the viscera is probably influenced also as is seen in the effect of hot application to the loins on the renal secretion in acute nephritis. Then, too, it may be that the sympathetic system is affected by external applications. So that altogether the mechanism at work is a complicated one.

GENERAL HYDROTHERAPY

As essential examples of the use of this form of hydrotherapy we may take the employment of tub baths and wet packs. They are particularly useful in two great groups of disease, infections both acute and chronic and various nervous disorders. Perhaps it is in cases of infectious diseases with toxemia and marked mental features that we find the best examples of the favorable results which can be obtained from general hydrotherapy. In these again the coincident use of internal hydrotherapy adds greatly to the effect.

Of its value in infectious disease we find no better example than in typhoid fever. The discussion of the reasons for the giving of tub baths in this disease is such an old one that to go over it again seems like playing an old tune too often, but the need of repeating it constantly was emphasized while this was being written by reading an article presented at a society meeting which criticized the use of tub baths in typhoid fever because they did not keep the temperature down. It is one of the principles of hydrotherapy in this connection that it is not employed to keep the temperature down. When employed in typhoid fever it may reduce the temperature, but whether it does or not is not necessarily of special importance. The mere reduction of temperature, except in cases of hyperpyrexia, is of no special advantage in the course of an infection. The explanation of the value of tub baths in typhoid fever is a complex matter and many points have to be considered. Its great result is in the reduction of mortality and this comes largely from saving patients who otherwise would have died

from toxemia and it is to the influence on this that we must turn. The effect of the baths comes largely through two systems, the circulatory and the nervous, by which the whole body is influenced. Increased excretion of toxins there must be; otherwise the influence on toxemia is hard to explain. Yet apart from this there must be some direct effect also on the nervous system as is shown by the marked beneficial effect on delirium and other nervous symptoms which sometimes is evident for an hour or so after a bath. This is perhaps due to the effect on the circulation. The influence on the circulation is especially seen in the effect on the vasomotor tone and secondary to this on the heart itself. Given a better circulation and the nervous system is better supplied with blood, while the kidneys can work to more advantage in the excretion of toxins. This in turn means less toxic effect on all body cells, especially those of the nervous system and the centers are better able to carry on their work. The vasomotor paresis is diminished and so we have a beneficial circle of events, each part helping the other and all intimately connected. Then, again, respiration is greatly improved and this results in better aeration of the blood and a better oxygen supply to the tissues. As a result of the deep breathing during each bath the lungs are thoroughly expanded—a condition which in a toxic patient it may be impossible to bring about in any other way—and as a consequence hypostatic pneumonia is almost unknown in typhoid fever patients who are being given the bath treatment. With the improved circulation the digestive tract is better nourished and less disturbance results, perhaps in no particular better seen than in the lessened occurrence of meteorism. It is evident that the effect on the circulation influences everything, the state of the nervous system, the excretion of toxins, digestion, and metabolism generally.

In the functional nervous states, especially when there is insomnia, one of the best therapeutic measures is the use of wet packs. What is the explanation of the effect of this on the central nervous system? It must be through both the circulation and peripheral nervous systems. Doubtless the early shock—if the pack be cold, as is usually best—with the following reaction causes a marked influence on the whole circulation, usually affected in these patients, and this doubtless influences the nervous system. But there is probably more than this. In the various functional nervous disorders, as in the severe attacks of acute infections, there is usually disturbance of the peripheral vasomotor system and probably of the central vasomotor system as well. The effect of general hydrotherapy is to lessen this and make the control more normal. This probably is partly brought about through giving the whole vasomotor system proper exercise. Given a normal vasomotor response it seems reasonable to suppose that for a time the working of the vasomotor system will be improved. It is a training in the normal performance of a function for which it is necessary, however, that a proper response be obtained, as too much vasoconstriction of the surface vessels without any reaction is harmful. Therefore comes the importance of friction, especially in the administration of tub baths. Constant active surface friction is a very essential part of the bath, a point which is sometimes lost sight of, especially by critics. In the use of wet packs friction may also be advisable but is not so important, as the reaction is more easily brought about. This exercise of the vasomotor system is one of the great helps we get from hydrotherapy.

Again the influence through the surface circulation on that in the deeper structures plays an important part. We use this frequently in certain methods of counter-irritation to influence the circulation in a particular area. By general hydrotherapy we can do this for the body as a whole. It is probable that an affected circulation means more to the function of various organs in acute infections than we usually realize. Witness the disturbances which follow in the train of a loss of compensation of the heart. Consider the rapidity of the improvement under digitalis therapy in many cases: cough and dyspnea lessen, vomiting ceases, and the kidney resumes activity. Hydrotherapy may influence the circulation in the viscera to an almost equal degree, perhaps if not with an equal rapidity.

Of the influence of general hydrotherapy in individuals who are not ill we have abundant personal proof. How much the cold morning tub adds to the working ability of the world is hard to estimate. It is difficult to know how many patients, whose nervous systems are only just about equal to the daily demands, are kept up to the mark by it. Of its effect in the prevention of "catching cold" we are all aware, perhaps forgetting sometimes that this is through its effect on the vasomotor system. Of these two great results from external hydrotherapy in health—the general brace to the nervous system and the decrease in the liability to various infections—most of us take daily advantage. It sometimes causes wonder why many men are not willing to give to their patients who stand in need of it the opportunity of obtaining the same results in disease and of being helped by one of our most useful therapeutic aids—hydrotherapy.

935 St. Paul Street.

ABSTRACT OF DISCUSSION

DR. DAVID PAULSON, Hinsdale, Ill.: The painstaking experiments that have been made by Winternitz and other workers have served to put hydrotherapy on a much more scientific basis than even electrotherapy. Winternitz showed that for several hours following a general cold application, there was an increase of 10 to 20 per cent. of red and white blood cells in the circulation, as well as a marked increase in hemoglobin. We are only beginning to appreciate the possibilities in hydrotherapy. It was a great day for physiologic medicine when Dr. Baruch was invited to give instruction in hydrotherapy in the College of Physicians and Surgeons in New York. Only recently a department of hydrotherapy has been added in the Chicago Postgraduate Medical School. All this shows that we are making progress. As you all know, hydrotherapy has completely revolutionized the treatment of typhoid fever. It is important to appreciate that it is equally valuable in other acute infections, and for that matter in all the chronic diseases.

Early Sign of Pott's Disease.—Angelescu has noticed that caries of the spine generally begins in the anterior segment, and consequently that traction on the anterior longitudinal ligaments is painful in these cases even when there is nothing else to suggest the vertebral process. He has the patient lie on the back and arch the body, resting only on the back of the head and the heels. This position induces pain in the diseased area or the pain is so severe that the patient is unable to assume this attitude. According to the *Deutsche med. Wochenschrift*, another Roumanian writer, N. Athanesescu, has recently reported positive findings with this sign and thus early differentiation of the disease before there was any local tenderness on pressure, stiffness of the spine or prominence on the part of any of the vertebrae.

TEACHING THE STUDENT THE OPERATION
OF PARACENTESIS OF THE DRUM-HEAD

HARRY FRIEDENWALD, M.D.
BALTIMORE

As a teacher of otology, I have long experienced the difficulty of all teachers of this branch to properly train the medical student to perform the operation of paracentesis of the drum-head, an operation which I think it is agreed that every general practitioner should be able to perform. I have solved this difficulty by a little device which I have put to use for several years in my classes at the College of Physicians and Surgeons of Baltimore. It consists of an addition to the

TETANUS SUCCESSFULLY TREATED WITH
LARGE QUANTITIES OF ANTITOXIN

A. J. CAFFREY, M.D.
MILWAUKEE

History.—G. S., a young man 18 years old, was running a foot-race barefooted at one of the lakes near Milwaukee and ran a splinter about an inch long in the big toe of his left foot. The splinter buried itself under the phalanges and acted as a splint, preventing motion of the toe and causing the toe to swell. Not knowing of its presence, he thought the toe was sprained and applied poultices. The accident occurred August 24, and the splinter was not discovered until September 4, on which date it was removed.

Treatment and Course of Disease.—On Tuesday morning following its removal, the patient came to my office complaining of "ear-ache" and pains in his chest. I immediately injected 1,500 units of tetanus antitoxin; the symptoms continued getting worse, and the next morning I injected 3,000 units, but there was no abatement of the symptoms, and that evening he went into tetanic convulsions. I could procure no more antitoxin until Thursday morning. Then I started giving him injections into the body of 3,000 units of tetanus antitoxin every three hours. The disease continued without any abatement until Friday evening about six o'clock, when I could see a slight improvement in the patient's condition. At nine o'clock the injection seemed to have a soporific effect on him and his muscles relaxed. Subsequently he would be relieved for a half hour or so following each injection, after which the convulsions would come back with sudden snap, causing him to bite the edges of the tongue and assume the opisthotonos position. The condition was so painful that I had to resort to chloroform. The patient would relax and fall asleep, but only for five minutes, when again the contractions would return. At this time, Friday night he had taken about 45,000 units of the serum, and while the chloroform would only relax his muscles for from five to ten minutes, he would show a relaxation for from one-half to three-quarters of an hour following the injection of the serum. This gave me confidence that the serum was beginning to show its effect on the toxins, and I pushed it every two hours during Saturday for about fourteen hours, every dose giving the patient rest.

After using the chloroform at intervals to control the exacerbations, I resorted to a rectal injection of chloral hydrate, 20 grains. This also had a quieting effect, but I was afraid to repeat it on account of the depression of the patient, although the result was good and he fell into a deep sleep.

On account of the retention of urine on Friday, I was afraid of uremic coma. He woke up after three hours with the spasms, but they did not seem so severe. I resorted to diuretics, including sweet spirits of niter and digitalis, with good results. He began to pass a sufficient quantity of urine, but trouble began with his bowels. Under the influence of large doses of castor oil, the contents of the descending colon when they reached the sphincter would throw it into tetanic contraction and would not pass. Then regurgitation would take place, and when the contents reached the transverse colon it would again throw him into a violent spasm. This condition kept up for about twenty hours. I injected olive oil and glycerin, but he would retain it. I had the same result with soap and water enemas. This kept up until Sunday morning, when he finally had an evacuation. By this time, Sunday morning, the pains were not so severe in the chest, but were frightfully bad in the abdominal muscles, during the spasms the patient crying out that he was ruptured, which was not the case. I continued the serum all through Sunday at intervals of three and four hours, until Tuesday, September 13, when he had taken in all 112,500 units. I might state that the trismus and the pains in the chest subsided partially during Sunday, but on and after Tuesday, September 13, the exacerbations disappeared gradually and the patient made a complete but gradual recovery. His urine showed on analysis a condition similar to acute nephritis.

The temperature never ran higher than 103 F. A rash, not unlike that of scarlatina, with an intense pruritus appeared,

Fig. 3.

Fig. 1.—The schematic ear model of Bacon for teaching manipulation of the speculum and head mirrors.

Fig. 2.—Diagrammatic representation of drum-head showing handle of malleus.

Fig. 3.—Same as Fig. 2, with paraffin paper stretched over it to represent drum membrane, for teaching method of paracentesis.

well-known schematic ear model of Bacon (Fig. 1). This model is supplied with a large number of brass plates into which colored pictures of the normal and diseased drum-heads are placed for the purpose of "teaching manipulation of the speculum and head mirrors." I have had made double brass plates of a general form similar to those made to hold the pictures, but provided with an opening of the size and shape of a drum-head, one of the plates having a little stem to represent the handle of the hammer (Fig. 2). The two plates are held together by a screw which allows one to separate them and place between them a piece of thin paraffin paper, such as is used by florists, and which well represents the drum membrane (Fig. 3). This device is then inserted in the model and the student, supplied with a head-mirror, speculum and paracentesis knife, is allowed to practice the operation many times. I may add that this device has been of the greatest help to teacher and student.

Morphin was resorted to with good effect, but to me it appeared that it was the antitoxin that effected the cure, and without it I believe that the patient would have died on Friday, September 9, as on that day the dyspnea was intense, and the patient became cyanosed, but after each dose he regained his color and got the needed rest.

It is my opinion that great quantities of the antitoxin must be used in these cases; if the toxins in the blood are to be destroyed the blood must be saturated.

I saw no ill effects from it outside of the rash. It seemed to support the heart by raising the blood-pressure. I do not doubt that in a case in which there is arteriosclerosis there may be danger of apoplexy, but in this case the patient was a young man with resilient vessels.

600 Grand Avenue.

THE MUFFLED ROOM IN THE TREATMENT OF ACUTE INSANITY

SANGER BROWN, M.D.
CHICAGO

By the muffled room I mean an apartment constructed in such a way that any noise made by the occupants may not be heard without it, and conversely, any noise made from without may not disturb those within. It should be large enough so that by employing forced ventilation the air may be kept pure in it at all seasons of the year. Its principal purpose is to facilitate individualization in the treatment of acute insanity.

By "individualization" in this connection I wish to imply that the physician in the treatment or management of a given case may be relieved from any obligation or necessity of making concessions to other cases. One of the most perplexing features a physician has to reckon with in the institutional treatment of acute insanity is to prevent the various manifestations of excitement incident to the disease from injuriously interacting on patients whose quarters are adjacent to each other and unless muffled rooms be available, on the principle of the greatest good to the greatest number, he is often compelled both by night and by day to prescribe "quieting" medicines for, or to employ other methods of sedation on, a patient who would be better off without them, especially when they have to be carried far enough to produce and maintain quietude over a considerable period of time.

As acute insanity is a disease for which no specific is known, and which under the most favorable circumstances usually runs a course of several months, measures calculated to promote and conserve the patient's bodily health are of cardinal importance in its treatment, for it is by maintaining the bodily forces in the most perfect condition that the chances for the brain to resume its normal functions are most favorable. Hence it seems peculiarly unfortunate for the physician to feel under the necessity of resorting to measures which he believes are in any way prejudicial to the best interests of his patient.

In a patient of delicate constitution, the prolonged excitement incident to the disease may bring about a critical situation in which only by the most judicious care and management can the patient survive, and the desirability in such cases of not having to reckon with the interests of others seems very obvious. It not infrequently happens that this tendency to noisy excitement continues more or less constantly through a period of

many weeks and the artificial maintenance of a sufficient degree of sedation to insure quietude over so long a period, by reducing the strength and causing disorder of the secretions, might bring about a very deplorable condition of bodily health, which, it is not difficult to conceive, might result either in a fatal issue or an incurable condition, when under more favorable circumstances recovery might have ensued.

When one has the opportunity of studying the natural history of these cases, as he may do when he has muffled rooms at his disposal, he learns that the patient's condition may be in every respect very much better at the end of a given period of a week or two, for instance, when medicinal sedation is not employed at all than if a patient be kept in a state of quietude by its use. My purpose, however, on the present occasion is not to discuss the value of different kinds of remedies in the treatment and management of acute insanity, but to draw attention to what I regard as the very great advantage to be gained when, in treating a patient in an institution, the physician has a free hand to employ such measures as he feels will best promote the comfort and recovery of a patient without in any way doing prejudice to the interests or comfort of others.

Lest I be misunderstood, having spoken of the benefits which I believe sometimes result from withholding chemical sedation in a case of acute insanity altogether, I wish to say that I think I fully recognize the value of the various remedies and do not hesitate to use them when I think they would be of benefit. I am maintaining, however, that they should be prescribed only for the sole benefit of the patient to whom they are administered.

Though perhaps this principle has not been stated quite so definitely as the term "the muffled room" might imply, it has been recognized for many years in the construction of public hospitals for the insane. So far as my observation has gone, however, even in them it has been very imperfectly carried out and in many of the smaller private establishments it has been entirely disregarded. In public hospitals, wards for excited patients are usually placed as far as possible from the apartments of those who are not disorderly, and in some there are a few rooms which are separated by a hall or corridor with the view of confining the noise; but in my opinion the principle has not been recognized and carried out at all as it deserves.

In some private establishments a separate building for excited patients is provided, but there are usually few if any special provisions made in it for preventing the dissemination of noise, and hence it not infrequently happens that conditions in this building are, to say the least, not such as might be desired; and it is not good practice, on the particular days or hours when the excitement for the time being has subsided, to transfer a patient to the building where the quiet patients are kept, only to send him back when he again loses self-control.

It will not be disputed, I think, that these rooms are well-nigh indispensable to insure the best treatment of acute insanity, no matter what attitude one takes in regard to chemical, mechanical or personal restraint, hydrotherapy, occupation or what not. I have had a number of them at my disposal now for a period of about five years and find them eminently satisfactory.

In the erection of a fireproof building, its equipment with well-muffled rooms throughout in the manner here proposed, might add 25 per cent. to the cost. The requirements of the situation would, however, in my opinion, be fairly well met in an establishment devoted

mainly to the treatment of acute cases if one-quarter of the rooms were muffled. The question of satisfactory muffling depends on the treatment of the doors, windows, floors, ceilings and partitions, and is a problem for the practical architect and the engineer to solve. So far it has not been satisfactorily worked out. This is probably owing to the fact that such construction has not been urgently demanded. In the institution in which I have gained my experience with the method, when the building was being erected, since it was not fireproof, I simply had several layers of Cabot's sheeting quilt placed in the partitions in the floors and ceilings, and had double doors and windows put in, and then placed a fan in the outlet flue (each room in the house has an independent inlet and outlet flue for ventilation) to provide for forced ventilation, and this later provision has been entirely satisfactory. I found, however, that while by this device the manner and the degree of muffling was considerable, it was far from what one would desire in certain instances. I have further thickened the walls in some of the rooms in various ways; that which has proved most satisfactory has been to line the walls and ceilings with tiling such as is used in partitions for fire-proof building. The matter of muffling could certainly be very well worked out by practical experiment. Indeed, this may already have been done, but if it has, I am ignorant of the methods employed.

100 State Street.

Therapeutics

DIPHTHERIA

(Concluded from page 1557)

TREATMENT AFTER DIAGNOSIS OF DIPHTHERIA HAS BEEN MADE

1. If the diagnosis seems positive, do not wait for culture proof, but inject antitoxin immediately.
2. If there is doubt and the culture proves positive, then immediately inject antitoxin.
3. If possible, seek the source of infection.
4. Report the case to the board of health.
5. Use the gargles as recommended.
6. Nutrition becomes of much greater importance, as diphtheria is depressant, and the disease must last at the best a week and perhaps two weeks, and the average time that the bacillus has been found in the throat cultures is three weeks. The diet should be a well-chosen, mixed diet that is easy of digestion. The character of the food should depend on the temperature and the behavior of the stomach. A diet should consist of oatmeal gruel or other cereal, a small amount of milk, toasted bread, one or two eggs a day, meat juice, mutton broth, sufficient salt, ice cream, gelatin, orange juice, lemonade, and plenty of water. The proper diet for the individual patient can be readily selected from the above. The manner of administration and the amount must depend on the condition of the patient, but some positive nourishment should be administered every single day. The frequency of the nourishment should generally be about every three hours in the daytime, and some little nourishment in the middle of the night. The nourishment should be given about five or ten minutes after the gargling, never just before it, as the gargling may nauseate the patient. Also, after the gargling there will be less possibility of swallowing germs into the stomach. While it has been shown that the gastric juice ordinarily

kills the Klebs-Loeffler bacillus, and it is perhaps never found in the intestines, still, it would be possible for this infection to do harm in the stomach, if the stomach wall had been injured or if the gastric secretion were insufficient. It has also been shown that after the use of antitoxin the gastric juice is even more active in killing the germ.

7. Diphtheria seems to interfere with the red blood-corpuseles, and the patient becomes readily anemic from the intensity of the disease or if the depression is prolonged. Therefore, from the beginning, whether the patient apparently needs it or not, iron should be given, and iron in its best and strongest form, viz., the tincture of the chlorid of iron. It is well to give it in 5 drop doses once in six hours, and is well administered in fresh lemonade, or it may be given as follows:

R	Gm. or c.c.	
Tincture ferri chloridi	5	fl.ʒiiss
Glycerini	10	or fl.ʒiij
Syrupi acidi citrici	25	fl.ʒi
Aquæ	ad 100	ad fl.ʒiv

M. et sig.: A teaspoonful, in water, every six hours.

The solution of iron may be taken through a glass tube or a straw or the mouth may, after its administration, be cleansed with water.

8. The heart and character of the circulation should always be watched in every case of diphtheria. As patients formerly frequently died, and now not infrequently die, of sudden heart failure in this disease, the physician should be emphatic that the patient with this disease should remain in bed, even if he is an adult and apparently not very ill. When he rises to gargle or for movements of the bowels he should rise slowly and carefully and should not exert himself any more than is absolutely necessary. A child must be watched constantly lest he exercise too much in attempting to play about the bed. As soon as the pulse feels too soft or becomes rapid, or before it gets to this point, small doses of strychnin should be administered, either 0.002 gram (1/30 of a grain) from once in eight to once in six hours, or 0.001 gram (1/60 of a grain) once in three or four hours. If the patient feels suddenly faint, the nurse may administer a proper dose of brandy or whiskey, or some aromatic ammonia. If there is an attack of heart failure, a hypodermatic injection of strychnin (1/30 grain) and atropin (1/150 grain) will generally be sufficient. Occasionally if the patient is not receiving sufficient nutrition, a small amount (not sufficient to flush the patient or cause the odor to remain on the breath) of whiskey or brandy may be administered regularly as fuel. It should not be considered that the alcohol is a cardiac tonic, as it is not. If a patient is at any time weak and collapsed, hot water bags and other methods of applying dry heat should not be forgotten.

9. The urine should be frequently tested for albumin. Not that a slight albuminuria would ordinarily need any special treatment, but that the physician should know the condition of the kidneys, as with an albuminuria the physician should take meat out of the diet, and perhaps modify the medication. Antitoxin is not a cause of albuminuria. Diphtheria can cause albuminuria, and may consequently cause it after antitoxin has been administered.

10. The convalescence after diphtheria should be prolonged. The gargles should be gradually used less frequently, first omitting the night gargling. The feedings

should be less frequently administered and more in amount. The patient should gradually sit up and as gradually get about. The first gargle to be stopped should be the peroxid, as it becomes an irritant and may keep the throat red and even swollen. The boric acid should be persisted in, and the potassium chlorate is one of the most soothing of gargles. For the liquid iron preparation the above capsule suggested for follicular tonsillitis convalescence may be substituted. Often the glycerophosphates of lime and soda are the best of tonics. If the patient does not rapidly recover strength, massage should be given, fresh air, drives, and all the other adjuncts to hasten or complete a convalescence. Severe exercise should not be attempted for some time if the patient has been seriously ill with diphtheria, as the heart is unable to stand much strain for some time.

11. Paralysis of the palate is much less frequent than formerly on account of antitoxin so rapidly inhibiting the disease. However, it is largely due to the absorption of toxins from the local inflammation, and consequently the greater the cleanliness of the throat, the less likelihood of this paralysis. This neuritis of the nerves of the palate may occur in the latter part of the disease, but often does not occur until during convalescence. A multiple neuritis rarely occurs from diphtheria. For paralysis of the palate there is no special treatment other than a prolonged use of strychnin, country or seashore fresh air, and a more prolonged convalescence. For multiple neuritis the treatment is the same with the exception that electrical treatment of the paralyzed muscles is added.

12. After the patient has apparently recovered, the throat should be swabbed, several hours after the last gargling, and another culture made to ascertain if the Klebs-Loeffler bacillus is absent. Until this germ has disappeared, the patient should remain isolated.

13. As soon as the culture is reported negative, the board of health is notified, and the patient's hair is washed, he is properly bathed, clean clothes are put on in an adjoining warm room, and the infected room or infected part of the house should be fumigated.

LARYNGEAL DIPHTHERIA

Whenever a child, especially a young child, is taken ill, the physical examination is never complete until the throat has been examined. If there are any symptoms pointing toward the nasopharynx or toward the larynx, even though the pharynx and tonsils are clean, the possibility of diphtheria infection in these regions should never be forgotten. A swab specimen from these regions should be sent to a bacteriologic laboratory. If by means of the laryngoscope a suspicious epiglottitis or larynx is seen, antitoxin should be immediately given without waiting for the bacteriologic report. It should be remembered that laryngeal diphtheria (membranous croup) can occur without fever and can cause occlusion of the larynx in from twenty-four to thirty-six hours; consequently, antitoxin must be used immediately.

A tent should be made over the crib or bed, and the child should frequently inhale steam-laden vapor. This will keep the larynx moist and allow the membrane to be coughed or raised.

The throat of a young child may be sprayed, but it is practically impossible to spray the larynx in young children, especially when they are readily strangled by it. The sprayed solution should be diluted and non-irritant.

A physician who has in charge a laryngeal diphtheria patient should be in touch with the physician or surgeon in his immediate locality who is able to do intubation. An intubated child should have a nurse always instantly at hand to remove the tube if it is coughed up if the child is strangling, and to send for the physician immediately in order that the tube may be quickly replaced or that tracheotomy be done.

The general care of laryngeal diphtheria and of the convalescence is the same as for tonsillar and pharyngeal diphtheria.

ANTITOXIN

It is not necessary to discuss the value of the antitoxin treatment of diphtheria. Its value has been proved clinically daily and statistically yearly. It should be administered immediately if the diagnosis is clinically positive without waiting for the culture report. It should be administered in doubtful cases as soon as the report is positive, unless the disease is already found aborted by the time the report is returned. In this instance the isolation should persist as usual. The prognosis in every case of diphtheria is so much better and the duration is so much shorter when the antitoxin is early administered than when later administered that there can be no longer any discussion on this point.

It should always be remembered that antitoxin combats nothing but the toxins of the Klebs-Loeffler bacillus and does not combat the toxins of secondary infection. Therefore, when secondary infection is present the antitoxin must not be relied on to save the patient, but every means at our command must be used to remove the secondary infection, to reduce the toxemia, and to support the patient.

The diphtheria antitoxin has apparently no direct bactericidal effect. Whether it chemically neutralizes the toxin, or whether it stimulates the cells to tolerance of the toxin, or stimulates the production of opsonins, it does generally arrest the spread of the local infection, apparently inhibits the growth of the bacillus, and hastens the loosening of the membrane.

Apparently the only contraindication to the use of antitoxin is in a patient who is an asthmatic or a hay-fever subject who is especially susceptible to the odor of horses or the emanations from stables. Such patients have been found to be particularly susceptible to this serum prepared from horses, and deaths have occurred after its administration, largely due to swelling of the bronchial mucous membrane, similar to asthma and urticaria, and death is caused by suffocation and oppression. These patients should not receive antitoxin. Patients who are not so afflicted and who acquire diphtheria should receive the antitoxin.

The only unpleasant symptoms that can occur are a slight increase in temperature, slight skin eruption possibly, either urticaria or erythema, and some local swelling, heat and burning over the region of the injection. Such symptoms rarely last twenty-four hours and generally do not occur at all, except possibly a slight local reaction. Albuminuria attributed to the injection is probably generally an albuminuria caused by the disease. That a lung congestion can be caused by the antitoxin is exceedingly doubtful, and in the rare instances in which such congestion has occurred it was probably due to the severity of the disease.

The dose of antitoxin has been gradually increased in size. Perhaps the best immunizing dose for a child under 5 years is 500 units. For over 5 years the immunizing dose should be 1,000 units. Under 5 years of age

the first dose for treatment should be from 2,000 to 3,000 units; over 5 years from 3,000 to 5,000 units, depending on the severity of the infection. If there is no improvement in the condition in from 12 to 15 hours, a second dose should be administered, generally one-half the size of the first dose, and this repeated again in 12 hours if needed. Rarely will more than 3 doses be required, and generally but the one. If, however, on successive days the disease does not abate, the patient's immunity to the diphtheria toxin is not established, and the antitoxin may be repeated for several days. It has not been shown that antitoxin, except in the instance of idiosyncrasy to horse serum above described, has produced death. However, it should be emphasized that it is better judgment to give the first dose of sufficient size to combat the severity of the infection rather than to give small doses more frequently repeated which will make the sum total of units required for such divided treatment larger than a properly estimated initial dose.

Antitoxin is now furnished in aseptic containers ready for subcutaneous administration.

PREPARATION OF ANTITOXIN

The substance itself, antitoxin, is at present derived from horses which have been rendered immune to the action of the diphtheria toxins through repeated injections. The toxins are the products of the Klebs-Loeffler bacillus and are set free in connection with its growth. Their action on the living cell is a coagulation necrosis, as evidenced in the so-called diphtheritic patches seen in the throat, the necrotic foci in the internal organs, and general systemic poisoning and prostration.

The first step in the manufacture of antitoxin is the production of toxins in various strengths. These are gotten in the following way. From a diphtheritic throat is obtained a culture of the Klebs-Loeffler bacillus, which, after freeing from contamination is planted in bouillon and allowed to grow in the dark in 37° C. for some time. As the bacilli multiply, their products ultimately inhibit their own growth, and there remains a solution, in the bouillon, of these toxins with a few germs only. This product is now filtered through glazed porcelain, and to it is added a small amount of an antiseptic. Then the toxicity is ascertained by injecting it into guinea-pigs, weighing 250 grams, until the minimum fatal dose has been ascertained. This marks the toxic strength of this particular product. A small amount of toxin prepared as above is injected subcutaneously into a horse, and for this purpose the horses are absolutely healthy and in fine physical condition. As a result there is a rise in temperature, some loss of appetite and of weight, but in a few days these effects all pass away. When the effects have passed away the horse receives another dose of toxin slightly larger and when the effects of this wear off, another, still larger, and so on until the animal becomes tolerant to a large dose of the toxin. At this time it may be assumed that the blood of this particular horse contains a considerable amount of antitoxin, and the next step in the process is to determine just how much. This is done by withdrawing a small amount of his blood, preparing the serum from it, and measuring this against a toxin of known strength by means of the guinea-pig. If it does not show sufficient antitoxic strength, further amounts of toxin are introduced into the horse to cause a better antitoxin to be produced, and the serum is again tested.

When repeated tests have demonstrated the required strength, the horse is bled from the external jugular vein, every possible aseptic precaution being observed.

The next step in the operation is the preparation of the serum from the drawn blood. This is done under the most elaborate system of asepsis. Small samples are taken to ascertain its toxic strength and its freedom from bacterial contamination. These are verified, the product is put up in containers and stored for a length of time under suitable conditions. They are then re-examined prior to being put on the market.

As for the horse, he soon recovers, as the amount of blood withdrawn is not enough to harm him, and he is ready to be used over again, which process can be kept up for a long, long time.

As regards the standard of strength, the first fact to remember is: the standard of diphtheria toxin sufficient to kill the standard guinea-pig is 0.1 of a cubic centimeter.

A normal serum is one possessing such potency that 0.1 c.c. will completely counteract the effect of 0.1 c.c. of toxin. In other words, 0.1 c.c. of normal serum will save ten guinea-pigs from the fatal dose of toxin. 1 c.c. of normal serum will counteract 100 fatal doses, or 10 c.c. of toxin, and this constitutes a normal unit. Or, to repeat, the antitoxin unit is that strength of serum, independent of its bulk, which will counteract the effect of 100 times the fatal dose of toxin for the standard guinea-pig.

The various preparations of antitoxin that have been on the market have differed considerably in the bulk requisite for a given strength, but at the present time they are practically uniform, and while necessarily varying slightly, have been much reduced in bulk. Antitoxin is now offered in all strengths from 500 units to 10,000 units.

ADMINISTRATION OF ANTITOXIN

The injection of antitoxin should be made only after the skin has been cleansed. The part selected should be first washed with soap and water, then thoroughly cleansed with alcohol, and a piece of cotton or gauze soaked in alcohol laid over the part while the syringe is being prepared. Previous to this the hands of the physician should be thoroughly cleansed, and the syringe and its various parts placed on a clean towel on a table near at hand. When the syringe is ready for use and the needle cleansed with alcohol, the skin should be dried with sterile cotton and the injection made into the subcutaneous loose fascia. The injection should be given slowly, and when finished the needle should be rapidly withdrawn and a piece of absorbent cotton wet with alcohol placed over the point of injection and an adhesive strap placed over it.

There are various suitable parts of the body for injection, but preferably one selects that where the skin is less firmly attached to the fascia and muscles; in other words, a part where the distention from the fluid will cause the least pain. This is in the wall of the abdomen. Often the injection is made into the back, between the scapulae.

Venous injection of antitoxin, while it has been done, is probably not necessary, and there is always some danger attached to it.

Tablets made of antitoxin to be administered by the mouth are said to have been used successfully, but this method of administration is not to be recommended.

THE PERSISTENCY OF CELL FUNCTION AND ITS BEARING ON PATHOLOGY

Under the foregoing title Professor Leube¹ of Würzburg emphasizes certain properties of the cells which seem to have important relations to various morbid conditions and to recovery therefrom. The underlying principle is that there is a well-defined tendency for each kind of cell to continue its work along certain characteristic lines which are determined for it during its organization and development. This is shown, for example, by the fact that many different kinds of stimuli acting on a cell will all cause the same effect; thus the mucous-gland cells secrete mucus when stimulated by heat, cold, toxins, chemical or mechanical irritants, while a muscle cell responds to these same stimuli by contracting. The difference in the effects produced by the several stimuli is quantitative rather than qualitative, for qualitative changes in cell function rarely occur; therefore injurious influences cause disease chiefly by producing quantitative alterations in cell action. If this quantitative change persists long enough the altered power of function eventually is acquired as a permanent character of the cells, and a persistent condition of disease results. Usually any persistent change in the direction or degree of cell activity is harmful; seldom is it useful except in the phenomena of immunity, and here study of the persistence of acquired characteristics of cells becomes of much practical importance.

Stimulation of cells, particularly those of the blood-forming tissues, by bacterial products causes a reaction which results in the formation of various antibodies. Thanks to the tendency toward persistency of cell functions, after each dose of bacterial products the cells react more quickly and more energetically; thus an animal which has been immunized to typhoid bacilli so long previously that most of the antibodies have disappeared from its blood will be found to react to a single minute dose of typhoid bacilli, too small to cause any appreciable reaction in a normal animal, with the production of large amounts of antibodies. It is probably this acquired character of reacting strongly to small stimuli which explains many instances of immunity in

men and animals whose blood contains no demonstrable protective substances, as is especially exhibited by persons who have had typhoid. The so-called accelerated reaction to foreign serums, which is exhibited as one of the forms of serum intoxication, would seem to be another instance of the development of a persistent tendency to a certain line of reaction by the cells.

That the reactive capacity of the cells which have acquired an increased power of forming antibodies is a real example of persistency or tenacity of function, is shown best by the fact that this increased capacity is exhibited in response to all sorts of stimuli, which may be entirely unrelated to the natural specific stimulus which originally was the only thing that could cause this particular reaction. For example, if a person has typhoid, the power to form typhoid agglutinins is so increased that the blood contains greatly augmented quantities of this specific antibody, but after a time the excessive agglutinins disappear from the blood until its agglutinating power may be little or no greater than that of a normal person. In such an individual, however, many quite indifferent stimuli, such as hot baths, stasis hyperemia, or even merely a hearty meal, will commonly cause the cells to react by secreting into the blood the specific typhoid agglutinins which they have acquired a persistent habit of forming in large amounts. That raising the body temperature by means of hot baths is a most effective method of arousing this reaction, is an interesting bit of corroborative evidence in favor of the doctrine that fever is of itself a helpful influence in increasing the reaction against infection.

Presumably this "tenacity of cell activity" plays a part not only in immunity reactions but also in the diseases of metabolic nature. For example, adiposity may be looked on as a condition, sometimes congenital and sometimes acquired, in which certain cells have an unusually developed capacity for storing fat, so that they persistently react in this way to influences which have no such effect in normal persons. In gout we find that in spite of long-continued purin-free diet the blood always contains free uric acid, which is never present in the blood of normal persons who are on a similar diet; here a certain persistent tendency of cell metabolism may be brought out by such varied stimuli as alcohol, lead, overeating, exposure to cold, certain articles of diet, and the countless other things that can stimulate gouty attacks in those whose cells react in this particular way by abnormal metabolism of purins. Pathologists, after much discussion of the underlying principle of cancer etiology, at least in many instances, have come to ascribe the unlimited growth capacity of cancer cells to the acquirement of a specific character as the result of long-continued stimulation to multiplication. The cells which generation after generation have their reproductive capacity stimulated without corresponding stimulation of their other functions, eventually lose these other functions in large measure and in place have an over-developed power of multiplication; hence to any and all

1. Leube, W. von: *Ztschr. f. klin. Med.*, 1910, lxx, 359.

stimuli they react by cell division. Von Hanseemann calls such cells "anaplastic," while Adami would say that they have acquired the "habit of growth"; at any rate we have here another striking illustration of Leube's doctrine of tenacity of cell activity, in which any sort of stimulus causes the dominant function of the cell to be performed, in the case of the cancer cell the dominant function being that of reproduction.

UNTOWARD EFFECTS OF THERAPEUTIC SERUMS

From time to time there appear reports of sudden death following the injection of therapeutic serums. The usual sequence of events is that within a few minutes after the injection of the serum the patient has difficulty in breathing, the respiration being similar to that of a person suffering with an acute attack of asthma. Along with the respiratory involvement there is an anxious expression, sometimes itching and burning of the skin, and frequently acute edema of the mucous membrane of the pharynx and upper larynx. In fatal cases, the patient usually dies in convulsions. The heart as a rule continues to beat some time after respiration has ceased.

These cases, which fortunately are extremely rare, almost invariably follow a first injection of serum, only a very few instances being reported in which a second injection has caused death. Second injections after an interval of from fourteen days to four months are sometimes followed by the so-called immediate reaction of von Pirquet and Schick, in which the symptoms of the syndrome described and named by von Pirquet the "serum disease" appear within twenty-four hours. The symptoms of the serum disease, while sometimes very distressing to the patient, are, as a rule, not of an alarming character, owing to the non-involvement of the respiratory system. When a second injection is given after an interval of four months, then the reaction appears within from four to six days instead of after the normal incubation period of from eight to thirteen days. When individuals are given repeated injections of serum extending over a considerable time at intervals of two or three days, alarming symptoms may occur, sometimes during treatment. In some instances death has been reported when the serum was used in this manner. From this it would seem that the reaction of man to injections of serum is more analogous to the reaction of the rabbit than of the guinea-pig.

A significant fact has been noted, attention to which was first drawn by Rosenau and Anderson,¹ that the majority of the cases of sudden death following the first injection of serum in man were in asthmatics or in persons who experienced discomfort when in the neighborhood of horses. A number of serums used in such cases were studied by Rosenau and Anderson, who found them to be no more toxic for sensitive guinea-pigs than other

serums which had caused no untoward symptoms in man. These authors suggested the possibility of a relation between asthma in man and hypersusceptibility to an injection of serum; and a recent paper by Meltzer² on "Bronchial Asthma as a Phenomenon of Anaphylaxis" brings forward considerable evidence in support of this possibility.

It would seem that the unfortunate accidents that sometimes occur following a first injection of serum in man depend on an inherent susceptibility of the individual and not on the toxicity of the serum injected. How this susceptibility is acquired we do not know, though it is hoped that the studies on anaphylaxis and asthma may throw light on this point.

It is greatly to be deplored that there seems a tendency in the minds of some physicians to hesitate to use therapeutic serums, particularly diphtheria antitoxin, on account of the possibility of untoward results following the administration of the serum. While this fear has been augmented by recent studies on anaphylaxis, it would not seem to be well-grounded. The knowledge of the fact that, in asthmatics or persons who have an idiosyncrasy to horses, the injection of horse serum may be attended with danger, should cause no hesitancy in the administration of therapeutic serum in others when the indication arises. However, when serum is administered it should be explained to the patient or to the family that the administration may sometimes cause unpleasant or alarming results, and the physician should remain with the patient for a little time following the injection.

The percentage of fatalities following the injection of serum is very small; for, in spite of the thousands of persons to whom serum is administered, only a small fraction of one per cent. suffer from serious ill effects, this percentage being less than that of fatalities following the use of anesthetics.

GLUTEN FLOURS AND DIABETIC FOODS

Two common misconceptions exist regarding gluten flour and various proprietary gluten foods on the market. One is that gluten flour is practically a starch-free flour; the other, a corollary of the first, is that any gluten flour or gluten food is a safe food for a diabetic patient. As regards the first proposition nothing could be much farther from the truth—at least so far as the great majority of American gluten products is concerned; and this fact in itself makes plain the fallacy of the second. It is probable that, proprietary medicines excepted, in the exploitation of no other products prescribed by physicians has there been so much misrepresentation and downright humbug as that indulged in by the manufacturers of gluten flours and foods.

The federal standard for gluten flour prescribes that it shall contain at least 35 per cent. protein (5.6 N X

1 Bull. Hyg. Lab., No. 50.

2. THE JOURNAL, Sept. 7, 1910, p. 1021.

6.25). Nothing is said about the starch-content and yet from the standpoint of public health the percentage of starch—or more broadly, of carbohydrates (starch, dextrin, sugar)—is of more importance than the proportion of protein.

As the Food and Drugs Act is now interpreted, an anomalous state of affairs exists. A firm that puts on the market a so-called gluten flour containing 20 per cent. of protein is permitted to label—or, at least, does label—its product “gluten $\frac{4}{7}$ standard” because, forsooth, twenty is four-sevenths of thirty-five and 35 per cent. protein is the standard set for gluten flour. The absurdity of this proposition appears when it is remembered that ordinary flour contains from 10 to 11 per cent. of protein and that, on the same grounds it could be legally labeled “gluten $\frac{1}{3}$ standard.” The fallacy of giving such an interpretation to a law, the primary object of whose enactment was the protection of the public health, is evident.

The important and essential fact is that in ninety-nine cases out of a hundred a gluten flour or a gluten food is prescribed for a diabetic patient, to whom the ingestion of carbohydrates is fraught with danger. Gluten products are prescribed by physicians, not because they are richer in nitrogen (protein) than other foods, but because they are believed to be poorer in, if not actually free from, carbohydrates (starch). Most of the manufacturers of gluten flours and foods in this country carefully avoid stating in their advertising matter or on the labels, what percentage of starch their preparations contain. The reason for the omission is that their products contain dangerously high percentages of carbohydrates. Yet the physician is misled by the term “gluten” into prescribing these worse than worthless preparations for his diabetic patient.

THE RISE AND FALL OF THE SEPTIC TANK

Starting with the famous Exeter experiments of 1895, the treatment of sewage by the septic tank method enjoyed for a period wide popularity among sanitarians. Recently signs have multiplied that the vogue of the septic tank is well-nigh over. Roughly speaking, the principle of the septic tank consists in holding the sewage in bulk under such conditions that anaerobic decomposition occurs and the amount of suspended organic matter is considerably reduced, partly by sedimentation, partly by digestion. For a time it seemed as if this treatment possessed not only the great advantage that the amount of solid matter in the sewage was diminished, but also the advantage that the organic matter was brought into such a state that it could be more readily oxidized. In a word, it was believed that “septic sewage” could be more easily purified by contact beds or by intermittent filtration than crude sewage.

The event has not justified this belief. Some experimenters, finding results at variance with the opinion

commonly held, drew the cautious conclusion that it was not necessary to use the septic tank as a preliminary to the purification of sewage by trickling beds or intermittent filtration. Others more frankly confessed to finding the septic tank effluents distinctly harder to treat than crude sewage. Evidence is now at hand which strongly supports the latter contention. It is becoming more and more the practice of the engineers in charge of sewage purification works to shorten the period of holding the sewage in septic tanks until little more than a slight settling out of suspended particles actually occurs. Indeed, the avoidance of septic action has now become an object of serious endeavor, whereas a few years ago it was the aim to further in every way the process of anaerobic putrefaction.

One cause of the now recognized injurious outcome of septic action appears to be that the gases arising from the sludge in the septic tanks dislodge masses of solid matter, both from the bottom and from the surface scum, which pass off into the oxidizing beds, where they produce clogging of the beds and interfere with the oxidizing action. A second disadvantage is the fact, apparently now demonstrated, that the organic matter which has been acted on anaerobically is in even less favorable condition for further destruction than it was in the crude sewage.

All this means that foul sewage cannot be as easily and effectively treated as fresh sewage. It has also been found that septic sewage requires much more chlorine to disinfect it than crude sewage, so that with the hypochlorite treatment the expense of handling the effluent from septic tanks would be notably greater. Altogether the decline of the septic tank as a method utilizable on a large scale seems likely to be as rapid as its rise.

Current Comment

INVESTIGATION OF NORMAL OR AVERAGE HUMAN BEINGS

A recent writer,¹ in connection with the bill to establish a federal laboratory for the study of criminals, remarks that, while the anthropometric study of criminals is desirable, “more important still is the anthropometric study of all sorts and conditions of men. . . . Crime conceived of as a social phenomenon should be studied in connection with the social group, and not merely the individual criminal.” Conclusions on this subject, therefore, can be profitably drawn only after consideration of data “derived from large series of observations in connection with the facts of sociology, history and ethnology.” This seems like a sane and reasonable suggestion. The exact and scientific study of the criminal at present, while we lack an exact standard of measurement derived from the normal, seems about as promising as would be the study of the path-

1. Lindsey, Edward: Bill to Establish a Criminological Laboratory at Washington, *Jour. Am. Inst. Crim. Law and Criminology*, May, 1910, p. 103.

ology of any organ concerning whose normal condition only vague and unorganized ideas were available. What is a normal human being? How close an approximation to this ideal type is to be found in the average or ordinary member of society? What deviations from the normal or from the average may an individual present and still be a functioning member of ordinary society? What is the percentage of deviations among the mass of members of ordinary society? When we have reasonably precise answers to a few questions such as these, founded on reasonably extensive and exact observations of unselected material, we shall perhaps be in a better position than at present to judge of the value of the elaborate theories of the nature of the criminal which are offered to us to-day. We shall then have a standard by which to judge of the nature, the degree and the comparative number of the deviations presented by those individuals whom society rejects as detrimental to its structure.

TOMATO CATSUP AND SODIUM BENZOATE

In discussing the use of benzoate of soda as a food preservative the question has almost universally been limited to the manufacture of one product—tomato catsup. This has been due to the fact that probably no other industry offers so wide a field as does catsup-making for the sophistication of foodstuffs by the employment of this preservative. Those who are opposed to the use of this chemical in food have urged that one of the chief objections to it is the fact that it permits the manufacturer to use an inferior grade of material and also to have less regard for cleanliness in making the catsup. The proponents of sodium benzoate, on the other hand, have not only strenuously denied that the use of the chemical would permit such frauds but they have gone still further: they have insisted that the only method by which low-grade tomatoes could be made into presentable-appearing catsup was by the use of the vinegar and spice method of preserving. This seemed to put the matter on debatable ground, but light has been thrown on the point in an eminently practical way. The United States Government has brought suit and obtained judgment in five cases against firms which make a business of using the waste material of canning factories—tomato pulp screened from peelings and cores of tomatoes—for making tomato catsup. In every case the catsup put up by these concerns was labeled as containing benzoate of soda! It is reasonable to suppose that if the only way to make a presentable catsup out of tomato refuse was by means of the vinegar-spice method these concerns would not have used the sodium benzoate method: especially, too, as the term "benzoate of soda" has become more or less of a reproach.

PUBLIC OPINION AND THE PUBLIC DRINKING-CUP

The abolition of the public drinking-cup is a sanitary measure of real importance that has been adopted rather widely within a short time. At least eight states have by statute prohibited the use of the public cup; the boards of health of forty states have recommended its abandonment, and, in addition, numerous city govern-

ments have banished the cup from the public schools and parks. This removes from a considerable proportion of the population an undoubted prolific source of danger to public health. But gratifying and important as this fact is, it is not the only source of gratification in this connection. Another feature worthy of comment is the practically unanimous manner in which this measure has been supported and advocated by the public press, and the intelligent manner in which it has been presented to and received by the people. In a large number of press comments, from many states and sections, only one was found which was in any way adverse, and that was only mildly so. This paper said: "The use of public cups or glasses is a practice not wholly nice, and most persons deplore it, still the practice is a matter of one's own personal like or dislike, it would seem." With a little more reflection, this lone objector would see that it is not at all "a matter of one's own personal like or dislike," but distinctly and eminently a matter for public regulation. The hearty support, advocacy and adoption of this measure by health, municipal and school authorities, and by the press and the people, are the best evidence that the importance of sanitary measures is recognized, and that, where reasonable and when properly presented, they will receive the sanction and support of the people, whose best welfare, of course, forms their sole reason for existence.

STATE SOCIETY BUILDS A HOME

After years of homeless wandering, the Rhode Island Medical Society, one of the oldest of our state associations, is about to erect a permanent home and library building, thus realizing the dreams of many of the older members. At the last meeting of the state society, the house of delegates authorized the building committee to purchase, in Providence, a tract of land containing 8,000 square feet. The plot is admirably located, facing the extensive grounds around the state capitol building and bounded on one side by the state normal school grounds. It is near to the union railroad station and is conveniently situated for the members of the state society. Plans are now being made for securing the necessary money for a building. As has been frequently pointed out, either the man or the organization that is homeless is hampered and is prevented from doing the best work possible. The tendency on the part of our state associations and some of the larger local societies to establish permanent homes and to secure buildings of their own is most commendable. Too often, in the past, in our efforts to be of public service, our own interests have been overlooked. It is a cardinal duty of every man, whenever possible, to provide a home for himself and for his posterity. This duty is also incumbent on medical organizations. In no way can the stability of our medical organizations in future years be so well assured as by acquiring real property and erecting permanent homes. This may not be possible or practicable for all state associations, nor even for all of the larger local organizations, but it is a splendid achievement whenever it can be accomplished and greatly strengthens the organization.

Medical News

COLORADO

Personal.—Dr. Charles F. Shollenberger, Denver, has returned from a trip around the world.

State Society Meeting.—The annual meeting of the Colorado State Medical Society was held in Colorado Springs, October 11-13, under the presidency of Dr. Leonard Freeman, Denver. The following officers were elected: president, Dr. Will Howard Swan, Colorado Springs; vice-presidents, Drs. Thomas E. Carmody, Denver; Madison J. Keeney, Pueblo; J. H. Cole, Yampa, and Samuel French, Meeker; secretary, Dr. Melville Black, Denver (reelected), and councilors, Drs. Edgar Hadley, Telluride; Jacob C. Chipman, Sterling; Charles F. Gardiner, Colorado Springs, and Edward A. Whitmore, Leadville, and delegate to the American Medical Association, Dr. Edward Jackson, Denver, and alternate Dr. Howell T. Pershing, Denver. The next meeting of the society will be held in Steamboat Springs.

ILLINOIS

Personal.—Dr. S. S. Wilcox, Charleston, was seriously injured by falling from his carriage recently.—Dr. Alexander F. Stewart, Oneida, has resumed practice after undergoing an operation at Augustana Hospital, Chicago.

Changes at Hospital.—At the annual election of officers of the Graham Hospital, Canton, Dr. Paul S. Scholes was elected president; Dr. Harrison C. Putnam, vice-president, and Dr. Charles N. Allison, secretary. The retiring members were Drs. Willis T. Zeigler, James E. Coleman, and Leroy Chapin. According to the annual report the hospital has had a successful year.

Medical Practice Act Upheld.—The State Board of Health won a victory October 28 when the Supreme Court, in the case of Board of Health vs. Wilson, sustained the validity of the medical practice act, and upheld the contention made by the board that an itinerant vender who sold a medicine accompanied by a circular exploiting the virtues of the remedy, and giving directions for its use, "professed to the public to cure or treat disease," even though he remained mute. The court also held that the State Board of Health is clothed with broad discretionary powers, and that the medical practice act is not subject to the objection that it confers legislative or judicial powers on the State Board of Health. Further the court emphasized its previous rulings that the regulation of the practice of medicine is clearly within the police power of the state.

Conference of Charities and Corrections.—At the meeting of the Illinois State Conference of Charities and Corrections at Galesburg, October 25, that body recommended, among other things, that the two state penitentiaries and the reformatory be placed under the supervision of the state board of administration; that political qualifications be eliminated in appointments and that civil service be established in the several institutions; also that short terms and small salaries be abolished; that the legislature enact an adult probation law, increase the number of parole agents, transform Cook County Hospital for the Insane to a state hospital, establish a true psychopathic hospital in Chicago, and a state inebriate institute, appoint a commission to take the census of the blind in Illinois, furnish more experienced care for the education of the feeble minded, and furnish two state schools for delinquent boys and girls; that infant mortality be studied in Illinois through a committee; that a state board of children's guardians be provided for by law.

Chicago

Fenger-Senn Memorial Lecture.—The council of the Chicago Medical Society, October 8, paid a high tribute to the names of Fenger and Senn, by instituting the "Fenger-Senn Memorial Lecture," to be given annually under the auspices of the society. The sum of \$200 was set aside as a fund.

To Study the Insane.—A meeting of physicians of the state was held at the University Club, October 27, and an organization perfected for the study of the diseases of the insane. Meetings will be held from time to time in different cities. Representatives of the medical staffs of the state hospitals attended the meeting.

Urges Teaching of Anatomy and Physiology in Schools.—The Federated Woman's Clubs of Chicago, at a meeting October 27, was addressed by Dr. Rose D. Howe on "The

Moral Problems of Education," and passed resolutions advocating a scientific course of anatomy and physiology in the public schools under the instruction of regularly licensed physicians.

Surgical Society Meeting.—At the meeting of the Chicago Surgical Society at the University Club, October 25, which was the occasion of the annual dinner, the following officers were installed: Dr. Jacob Frank, president, succeeding Dr. Arthur Dean Bevan; vice-president, Dr. P. Charles Davison; secretary, Dr. Frederiek A. Besley; treasurer, Dr. Dean D. Lewis; and members of the council, Drs. Albert J. Oschner and A. E. Halsted. The first scientific meeting of the year will be held November 10.

To Abolish Midwives.—At the meeting of the Conference of Jewish Women's Organizations, October 27, Dr. Alice Hamilton advocated the abolishment of midwives because they are not properly trained. She said that out of 500 licensed midwives in Chicago, scarcely 30 per cent. are capable and efficient, and one-third are willing to take criminal cases. In this country the license issued to a midwife means nothing. The practice is scarcely controlled at all. We give them the stamp of approval which only deceives those who do not understand.

Two Weeks of Clinics.—During the two weeks from November 7 to 19 a large number of physicians and surgeons of the city will hold clinics in the various medical schools and hospitals for the benefit of visiting physicians. A regular schedule of daily clinics has been prepared. A number of social affairs will also be provided for the entertainment of physicians during this time. An information bureau will be maintained at the LaSalle Hotel; full details may be obtained by calling there or by writing to Dr. Franklin H. Martin, 103 State street, Chicago.

Medical Health Officers Organize.—The Chicago Medical Health Officers' Association, composed of ninety-five graduate physicians employed in the City Health Department, was organized October 28. The following officers were elected: president, Dr. John A. Riley; vice-president, Dr. F. S. Windell; secretary, Dr. A. H. Jones, and treasurer, Dr. W. H. Falkenstein. The meeting deplored the small salaries paid city health officers, whom they assert are the poorest paid employees under the civil service. They also pledged hearty support to Health Commissioner Evans in his fight against contagious diseases.

INDIANA

Memorial Hospital.—The Gilbert Memorial Hospital of Evansville will be ready for occupancy Feb. 11, 1921. It will be four stories in height, built of reinforced concrete, and cost \$50,000. Dr. W. H. Gilbert will be the surgeon in charge.

Drug and Liquor Legislation.—The State Board of Pharmacy of Indiana, at its annual meeting at Indianapolis, October 23, selected a committee to devise more stringent laws to regulate the sale by druggists of intoxicating liquors and deleterious drugs.

Diphtheria.—An epidemic of diphtheria has closed the schools at Loogootee, and the State Board of Health has put Dr. W. E. Shimer in charge of the situation. Out of 194 throat cultures, eighty patients were found to have the germ of diphtheria present.

District Society Election.—At the semi-annual meeting of the Thirteenth District Medical Society, held in Rochester, October 18 and 19, Dr. Irvin J. Becknell, Goshen, was elected president; Dr. William H. Thompson, Winamac, vice-president, and Dr. C. Norman Howard, Warsaw, secretary (reelected). The next meeting will be held at Elkhart.

Deaths from Diarrheal Diseases.—The City Board of Health of Indianapolis has prepared a statement for the four summer months of 1910 of the deaths of infants due to digestive diseases. Of a total of 156 deaths, a personal investigation was made of 135. Of this number only thirteen were fed on mother's milk, while 122 had been given baby food, bottled milk, canned corn, etc. The statements emphasize again that the bottle-fed baby is less resistant to disease than the breast fed.

Arrest of Medicine Venders.—Dr. George D. Colburn of Toledo, Ohio, was arrested at Logansport on the charge of peddling medicine without a license. He was fined \$50 and permitted to leave the city on a suspended sentence. A Dr. William Hope of Indianapolis was also arrested at Logansport on October 8 for peddling medicine without a license. The local medical society has asked a change of venue, as Mr.

C. H. Stewart, the special judge, is an Eddyite, which is prejudicial to justice when the science of medicine is involved.

Preventing Ophthalmia Neonatorum.—A committee of the Indiana State Medical Society, in a meeting at the State House October 20, of which Dr. George Keiper of Lafayette was chairman, has advised the passing of a law making it compulsory on the part of attending physicians to use the Credé treatment on each infant at birth. The penalty for failure to comply will be revocation of license. It has been estimated that one-third of the total number of blind persons in the state of Indiana have lost their sight on account of the failure of the obstetrician to use this method of treatment.

Personal.—Dr. J. E. Talbot of Ruth, Nev., has moved to Indianapolis to practice.—Dr. J. I. Rinne has moved from Indianapolis to Lapell.—Dr. Urbana Spink, Indianapolis, sailed for Europe October 15 for study.—Dr. Lewis R. Thompson, Jr., of Lafayette, has been appointed an assistant surgeon in the United States Public Health and Marine-Hospital Service.—Dr. Charles C. Haskell, Indianapolis, who has been in New York for 3 months studying diseases of infants, has returned.—Dr. Edward A. Willis, Indianapolis, has been appointed guardian for Dr. Henry B. Fitts, U. S. Navy, retired.—The State Board of Medical Registration and Examination decided on October 18 that the charges made by Dr. Eli L. Schlatterback, health officer of Ligonier against Dr. Max C. Van De Venter and wife did not contain sufficient facts on which to base action.—At the same session the charges against William M. Thompson, Ligonier, were summarily dismissed by the board, and a license to practice was issued Dr. Thompson.

IOWA

Personal.—Dr. Joseph W. Armstrong, Des Moines, was seriously injured while on a hunting trip in northern Minnesota, October 18.—Dr. William W. Hunter, Monticello, who has been seriously ill, is now convalescent.

Epileptic Colony Needed.—The State Board of Control has sent out circular letters asking that concise statements be sent to the board giving the number of cases of epilepsy in the various localities in the state. The superintendent of the Mount Pleasant State Hospital believes there are 4,000 epileptics in Iowa, that 10 per cent. of these become insane, and that 3 per cent. commit crimes. The board urges that an epileptic colony be established in Iowa similar to the Craig Colony at Sonyea, N. Y.

KANSAS

Students to be Vaccinated Against Typhoid.—Dr. Mervin T. Suddler, head of the Medical Department of the University of Kansas, announces that all students who so desire may be vaccinated against typhoid fever free of charge.

Infected with Rabies.—Dr. William K. Trimble, bacteriologist of the University of Kansas, Medical Department, Rosedale, was infected with rabies, October 20, while making an examination of the brain of a dog sent to the laboratory for diagnosis.

Medical Department to be Moved.—The regents of the University of Kansas are reported to be seriously considering the removal of the medical department now located in Rosedale to some other city, possibly Kansas City, Kan., which has more abundant hospital facilities.

KENTUCKY

Personal.—Dr. John Todd has been elected health officer of Newport.—The residence of Dr. William D. Howe, Carlisle, was destroyed by fire, October 13, with a loss of about \$10,000 partially covered by insurance.

Visiting Staff Organized.—The visiting staff of the City Hospital, Louisville, met October 18, to form a permanent organization. Dr. Joseph B. Marvin was chosen chairman of the meeting and Dr. Henry Enos Tuley, secretary. Dr. J. W. Fowler, superintendent of the hospital, delivered an address, explaining the object of the meeting.

Testimonial to Dr. Bodine.—In appreciation of the devotion and services to the interests of the Medical Department of the Louisville University of Dr. James Morrison Bodine, its dean and president of the faculty for 45 years, his many friends and pupils have arranged for a testimonial dinner to Dr. Bodine at the hotel Seelbach, Louisville, December 16. Dr. Bodine is now in his 80th year and is still active in the cause of medical education. Dr. Lewis S. McMurtry is chairman of the committee on arrangements.

LOUISIANA

Charity Bed Endowed.—The first charity bed in the Presbyterian Hospital, New Orleans, has been endowed by the widow and children of Mr. Charles Weiss, in his memory.

Refuse New Trial.—It was announced October 18 that the supreme court had refused a new trial to Dr. Emmett C. McKowen, Jackson, charged with the murder of E. K. Judson, a patient in the State Asylum for the Insane, Jackson.

Sanitarium Transferred.—The formal transfer of the New Orleans Sanitarium property to the Presbyterian Hospital was made October 5. The new management intends to install a free clinic at once, and a little later free wards will be opened.

Noted German Physician in New Orleans.—Prof Dr. E. Grawitz, Berlin, who has been visiting in New Orleans, lectured, October 14, before Tulane Medical Department on "Pernicious Anemia, Its Definition and Treatment," and on the following evening before the Orleans Parish Medical Society on "The Causes of Leukocythemia."

Personal.—Dr. James M. Adams, St. Joseph, president of the Tensas Parish Board of Health, has resigned and has been succeeded by Dr. Louis A. Murdock.—Dr. Frederick J. Mayer, New Orleans, formerly special medical inspector of the State Board of Health of Louisiana, sailed for Liverpool from Galveston, October 5. He is making the trip in the interest of the State Board of Health of Texas.

MARYLAND

Personal.—Dr. Edson M. Glidden, assistant superintendent of the Maryland Tuberculosis Sanatorium, has resigned that office to become superintendent of the new Georgia State Tuberculosis Sanatorium.

Hagerstown Hospital.—The plans and specifications for the new hospital building, to be erected in Hagerstown, under the supervision of Dr. Henry M. Hurd, superintendent of Johns Hopkins Hospital, have been completed. It is for the Washington County Hospital Association, and the cost of construction will be about \$75,000. It will be two and three stories high, of brick, stone and stucco and will be fireproof.

Washington County Health Report.—Dr. J. E. Pitsnogle, health officer of Washington County, reports expenses of the year \$2,320. There were 795 deaths and 1,062 births (males 546, females 516). Many school buildings are said to be improperly ventilated and overcrowded. The teachers are complying with the vaccination law. Child labor permits were issued in 300 cases and 40 refused on account of educational or physical defects. He urges a compulsory education law, appointment of a food and meat inspector, a health officer in every election district, and that the county health office be taken out of politics. Hagerstown is in this county.

Baltimore

Address to Medical Students.—Dr. Charles P. Emerson, superintendent of the Clifton Springs Sanatorium, New York, and formerly resident physician of the Johns Hopkins Hospital, addressed the students of Johns Hopkins Medical School, October 28, on the good medical students can do by working in conjunction with charity organizations. Dr. Emerson organized the Social Service Department of the Johns Hopkins Medical School.

University Graduate Assassinated.—News has been received at the University of Maryland of the assassination of Dr. Taoufik T. Rassey, of Singa, Soudan, a surgeon in the Egyptian army, who graduated at the institution in 1902. A native ran a sword through his back, penetrating his right kidney and intestines and lodging against the ileum. There was no other medical man at the post to render assistance, and he lived but a few hours. He did not know his assailant or any reason for the assault. Dr. Rassey distinguished himself while a student here and stood high in his native country.

MASSACHUSETTS

Personal.—Dr. Allen G. Rice has been elected school inspector of Springfield.—Dr. Eliza J. Dadmun, Boston, has returned from Vienna.

State Society Proceedings.—At the regular meeting of the Council of the Massachusetts Medical Society, October 5, Dr. Orland J. Brown, North Adams, was elected delegate to the Vermont Medical Society, and Drs. Daniel E. Keefe, Springfield, and Elliot P. Joslin, Boston, were elected delegates to the Medical Society of the State of New York. Dr. Charles H.

Cook, Natick, gave a report of the meeting of the National Legislative Council of the American Medical Association with particular reference to the value of a national department of health. Dr. Walter P. Bowers, Clinton, was elected to succeed Dr. George W. Gay, Boston, as a member of the committee on state and national legislation. It was voted to revise the list of medical colleges and schools whose diplomas should be accepted by the Massachusetts Medical Society. Attention was called to the power of the Massachusetts Medical Society to regulate medical expert testimony as provided by its present by-laws. Dr. Horace D. Arnold, Boston, made a report of the last meeting of the House of Delegates of the American Medical Association at St. Louis, and dwelt on its great value to the constituent state societies.

MICHIGAN

Personal.—Dr. James A. Ashbaugh has been reelected president of the medical staff of the Hotel Dieu, Detroit.—Dr. Silas B. Frankhauser, Hillsdale, has been reelected physician of Hillsdale County.

Leper's Children May Attend School.—The State Board of Health has decided that the four children of Maurelius Jensen, a Calumet resident afflicted with leprosy, may attend the public schools without being a menace to public health. They will be kept away from their parents during the school term.

New Society Officers.—The Detroit Oto-Laryngological Society, at its meeting held October 18, elected Dr. Ernest L. Shurly, president, and Dr. Emil Amberg, secretary-treasurer. Dr. Shurly, in his address, urged a broader conception of specialism.—At the annual meeting of the Huron County Medical Society, held in Bad Axe, October 10, Dr. Frank E. Luton, Kilmanagh, was elected president; Dr. Alford E. W. Yale, Pigeon, vice-president; Dr. Daniel Conboy, Bad Axe, secretary-treasurer; Dr. Bernhard Friedlander, Sebawaing, delegate to the state medical society, and Dr. Dugald D. Munro, Kinde, alternate.—Tuscola County Medical Society, at its annual meeting, held in Caro, October 12, elected Dr. James H. Hays, Cass City, president; Dr. Albert J. Howell, Deford, vice-president, and Dr. Wynne C. Garvin, Millington, secretary-treasurer.

MISSOURI

Honor Old Member.—The Ralls County Medical Society held its meeting in Center, October 20, in honor of Dr. Nathan A. Foster, who has been practicing in that place for 50 years.

Hospital for Negroes.—The colored population of Springfield have decided to build and maintain a hospital for negroes, to be known as the Dunbar Hospital. An association has been organized to collect the necessary means.

Open Clinics to All.—A resolution has been adopted by the common council of Kansas City directing the hospital and health board to admit representatives of all schools of medicine and surgery to the clinics at the Kansas City General Hospital.

License Restored.—Dr. W. Earl Williams, Higbee, whose license was revoked by the State Board of Health on account of failure to comply with the regulations regarding the prescribing of liquor, is said to have had his license restored by that body.

Board of Charities to Meet.—The State Board of Charities and Correction will hold a meeting in Chillicothe, November 11 and 12. On the evening of November 11 the subject for discussion will be tuberculosis in the state. The St. Louis Commission on Tuberculosis will send its exhibit to this meeting.

Jefferson Alumni in Missouri.—Missouri graduates of Jefferson Medical College have organized the Jefferson Alumni Association of Missouri, with provision for corresponding members in Illinois, and invite the alumni of Jefferson in these states to become members. Dr. William Porter, St. Louis, is president and Dr. A. T. Muench, St. Louis, secretary.

Personal.—Dr. Guy L. Noyes has been made medical inspector of the public schools of Columbia.—Dr. Carlos C. English, Kansas City, has been appointed first assistant physician at the State Sanatorium for Tuberculosis, Mount Vernon, vice Dr. George W. Orrick, resigned.—Dr. and Mrs. Francis R. Anthony, Maryville, have located for the winter in Vienna, Austria.

St. Louis

Tuberculosis Research Society Organized.—A research society devoted to the investigation of tuberculosis and its complications has been organized in St. Louis with the object of investigating and reporting on the different phases of the

disease. Clinics and hospitals will be searched for material suitable for research work.

Personal.—Dr. Llewellyn P. Williamson has reentered the medical corps of the army and is stationed at Fort D. A. Russell, Wyo.—Dr. Leo Loeb has entered on his duties as director of the research department of the Barnard Free Skin and Cancer Hospital. He is aided by his two former assistants, Drs. Mayer L. Fleisher and O. Ishii.—Dr. Walter C. G. Kirchner has returned from Europe.

Hospital Staff Appointed.—The hospital board has selected the visiting staff for the public hospitals. The fitness of the applicants was based entirely on professional attainments and standing, political influence being absolutely ignored. No one could be considered who had been in practice less than five years. The appointments follow:

Medicine.—O. H. Brown, H. J. Cummings, George Dock, William P. Elmer, William Engelbach, L. S. Luton, George Richter, John Salter.

Surgery.—E. A. Babler, Willard Bartlett, Vilray P. Blair, Ernst Jonas, W. E. Leighton, Max W. Myer, Louis Rassieur, Francis Reeder.

Gynecology and Obstetrics.—H. S. Crossen, A. N. Curtis, Hugo Ehrenfest, George Gellhorn, Percy Swahlen, Fred J. Taussig.

Ear, Nose and Throat.—William D. Black, H. W. Loeb, C. F. Pängsten, Roy T. Scholz.

Eye.—John Green, Jr., J. Ellis Jennings, Clarence Loeb, Ernst Saxl, Nathaniel M. Semple.

Oral Surgeons.—J. P. Harper, D.D.S., Virgil Loeb.

Children's Diseases.—J. R. Clemens, Aaron Levy, Gustav Lippmann.

Genito-Urinary.—C. E. Burford, J. W. Marchildon, William M. Robertson, Henry J. Scherck.

Deformities (Orthopedics).—Nathaniel Allison.

Neurology.—M. A. Bliss, C. G. Chaddock, W. W. Graves, M. W. Hoge, Sidney I. Schwab.

Skin.—M. F. Engman, J. J. Houwink, W. H. Mook.

X-Ray.—R. D. Carman, Fred B. Hall.

In addition to the above appointments, the following members of the temporary staff will fill out their terms:

Medicine.—Elsworth S. Smith, Jr., Carl J. Luyties, G. C. Crandall.
Surgery.—M. G. Seelig, Willis Young.

NEBRASKA

Alumni Week.—The first celebration of alumni week of the College of Medicine of Nebraska University was held during the past week. An interesting program of medical papers and clinics at the hospitals and the college was carried out and the social features were not forgotten.

NEW YORK

Health Officers' Conference.—The conference of Sanitary Officers of the State of New York will be held at Buffalo, November 16-18.

Personal.—Dr. Robert T. Irvine, health physician of Ossining and physician to Sing Sing prison, was very seriously injured in an automobile accident, October 25.

Poliomyelitis.—According to the recent report of the State Department of Health, there have been 146 cases of infantile paralysis in this state since May 1. Thirty-one of these resulted fatally. During September ninety-two cases, with sixteen deaths were reported.

Typhoid Below the Average.—The report of typhoid conditions in New York state, which Governor White requested, has been submitted by Dr. Porter and shows that the mortality for the year 1910 is about 10 per cent, less than the previous normal rates. Yonkers and Niagara Falls have had an unusual number of cases.

The First District Branch Meets.—The fourth annual meeting of the First District Branch of the Medical Society of the State of New York was held in Newburgh, Thursday, October 27. The following officers were elected: president, Dr. W. Stanton Gleason, Newburgh; vice-president, Dr. H. D. Hardenbergh, Middletown; secretary, Dr. Charles Ellery Denison, New York City; treasurer, Dr. James E. Sadlier, Poughkeepsie. The 1911 meeting will be held at Tuxedo Park.

New York City

Harvey Society Lecture.—The second lecture of the Harvey Society course, delivered by Prof. W. E. Castle, Harvard University, November 5, is on the subject "Unit Characters in Heredity."

Another Case of Cholera.—The Italian liner Taormina from Genoa, which arrived at quarantine, October 21, was held over for several days because of a death during the voyage which the ship's doctor believed to be due to cholera.

Trains Must Not Pollute Water Supply.—The New York Central Railroad has been informed by the water pollution committee of the Merchant's Association that trains may be efficient carriers of typhoid and asks that the railroads close the toilets while trains are within the Croton Watershed.

To Enlarge Hospital.—The Manhattan Eye, Ear and Throat Hospital has secured a plot of ground at the southeast corner of Third Avenue and Sixty-Fourth Street where it is proposed to build an addition to the hospital.—Two extensions to the three-story hospital and school on Randall's Island are to be erected at a cost of \$40,000. These extensions are to be used as playrooms.

To Aid Health Department.—Health Commissioner Lederle has secured the assistance of three physicians and two college professors to act as an advisory board of statisticians to the Health Department. Their services are to be gratuitous. These assistants are Dr. Roger C. Tracey, formerly a registrar of the Health Department; Dr. William S. Guilfoyle, the present registrar; Dr. Cressy L. Wilbur, Professor C. E. A. Winslow, formerly of the Massachusetts Institute of Technology, and Professor Walter L. Wilcox, professor of economics at Cornell. This board plans for better computation of health and mortality statistics.

Buffalo

Personal.—Dr. James P. Barr was injured recently in a collision between his automobile and a trolley car.—Dr. Harvey R. Gaylord has returned from Europe.

Health Department to Supervise Insane.—Hereafter the Department of Health will have supervision of the detention of the insane instead of the police department. This means that the unfortunate insane will not be detained in police stations or regarded as criminals or indigents, but more humane and scientific treatment will be given them at first hand.

NORTH CAROLINA

Contributing Editors to Bulletin.—The Secretary of the North Carolina State Board of Health announces the following list of contributing editors to the *Bulletin*: Governor W. W. Kitchin, Raleigh; Hon. A. H. Eller, Winston-Salem; Hon. E. W. Sikes, Wake Forest; Hon. W. C. Dowd, Charlotte; Mr. Clarence Poe, Raleigh; Mr. Archibald Johnson, Thomasville; Rev. George W. Lay, Raleigh; Dr. Henry L. Smith, Davidson; Dr. Francis P. Venable, Chapel Hill; Dr. W. P. Few, Durham; Dr. William L. Potteat, Wake Forest; Prof. F. L. Stevens, Raleigh; Dr. Cyrus Thompson, Jacksonville; Dr. Charles O. H. Laughinghouse, Greenville; Dr. Lewis B. McBrayer, Asheville; Dr. Benjamin K. Hays, Oxford; Dr. Edward J. Wood, Wilmington; Dr. William DeB. MacNider, Chapel Hill; Dr. Hubert A. Royster, Raleigh, and Dr. James L. Nicholson, Richlands. The condition imposed is that the acceptance of the position of contributing editor shall be understood to mean that each individual so honored shall furnish at least one thousand words annually to the pages of the *Bulletin*.

PENNSYLVANIA

Money Collected for Tuberculosis Society.—The receipts of the house-to-house collection in Reading for the Berks County Tuberculosis Society aggregated \$9,524.

Infantile Paralysis in the State.—Since the first of July 1,018 cases of infantile paralysis have been reported to the authorities. However, there has been a marked decrease in the number of cases since the advent of cooler weather.

Sanatorium Burns.—The Inwood Sanatorium just outside the borough of West Conshohocken, in lower Merion, was destroyed by fire October 23. The loss will probably reach \$60,000. The seventy-five women under treatment in the institution escaped injury.

Philadelphia

Age of Dr. Shoemaker.—The age of the late Dr. John Veitch Shoemaker, noted in THE JOURNAL, October 22, page 1485, was 58 instead of 52.

Gift to Hospital.—The Frederick Douglas Memorial Hospital and Training School for Nurses, announced October 24, a gift of \$1,000 from Henry Phipps.

New State Laboratory.—The Department of Health of Pennsylvania has leased the entire building at 2000 Arch Street for use as a biologic laboratory.

Cholera Suspects Captured Elsewhere.—Cholera suspects, who landed in Philadelphia on the steamship Taormina, from Italian ports, and who escaped detention here, are held in Cincinnati, Youngstown, O., and Schenectady, N. Y.

Milk Commission Named.—Mayor Reyburn October 24 appointed the following commission to investigate the milk supply of the city: Dr. Charles Lincoln Furbush, chairman; Drs. Charles B. Penrose, Henry Leffman, Randle C. Rosenberger, Clarence J. Marshall, and Samuel M. Hamill.

Orthopedic Club Visits University.—The Inter-Urban Orthopedic Club of the United States visited the University of Pennsylvania on Saturday, November 5, as the guests of Dr. James K. Young. After the inspection of the orthopedic department, the x-ray laboratory and the new laboratory buildings of the medical school, they were taken by their host to the Widener Memorial Home, where they were entertained at luncheon by Dr. George D. Widener.

University Adds Course in Sanitary Engineering.—The new course in public health, which has been inaugurated at the University of Pennsylvania under the auspices of the engineering department and the laboratory of hygiene, is being developed rapidly. This course was begun as the result of the demand for the services of trained men as public health officers. It embraces sanitary engineering; public water supplies; the designing of hydraulic works; proper disposal of waste and sewage; the inspection of meat, milk and other animal products; personal and general hygiene, and lectures on sanitary legislation.

Exhibit on Infant Life.—Director Neff is having an exhibit on infant mortality and infantile paralysis prepared for display at the American Association for the Study and Prevention of Infantile Paralysis, to be held in Baltimore, November 9-11. A part of the exhibit will also be displayed at the conference of city officials on charities and corrections to be held in Altoona, November 16, and subsequently the whole display is to be exhibited in this city in a building which is to be loaned for the purpose by Felix Isman. The exhibit includes innumerable charts showing the bearing that humidity, temperature, housing conditions, congestion and numerous other phases of physical welfare may have in relation to infant growth and life.

Personal.—Dr. Ralph Butler has been appointed chief of the laryngologic and aural department of the German Hospital, succeeding the late Dr. Barton H. Potts.—Dr. James A. Babbitt has been appointed to the position in the dispensary left vacant by the promotion of Dr. Butler.—Dr. Alexander C. Abbott, professor of hygiene and bacteriology in the University of Pennsylvania, and director of the laboratory of hygiene, will deliver lectures at the University of Maryland, November 9 and 10.—Dr. Charles Hunsinger is seriously ill in Jefferson Hospital.—Dr. John A. McGinn has been elected clinical professor of obstetrics in the Medico-Chirurgical College.—Dr. Charles M. Burk was operated on in the German Hospital, October 26, for intestinal trouble and is in a serious condition.—Drs. James G. Mumford, of Boston, and Edward N. Brush, of Towson, Md., read papers at the stated meeting of the College of Physicians, November 2.

VERMONT

Physician Elected Governor.—Lieutenant-Governor John A. Mead, Rutland, a retired physician, was elected governor of the state on the republican ticket by a plurality of about 17,000.

Medical Club Elects.—At the annual meeting of the Rutland Medical and Surgical Reporting Club, September 20, Dr. Mark R. Crain was elected president; Dr. William W. Townsend, vice-president, and Dr. Ray E. Smith, secretary.

State Society Meeting.—The Vermont State Medical Society held its ninety-seventh annual meeting in St. Albans, October 13 and 14, and elected the following officers: president, Dr. Henry C. Tinkman, Burlington; vice-president, Dr. Stephen W. Paige, St. Albans; secretary, Dr. Clarence H. Beecher, Burlington (reelected); treasurer, Dr. Bingham H. Stone, Burlington (reelected); auditor, Dr. Anson M. Norton, Bristol (reelected); anniversary chairman, Dr. Schuyler W. Hammond, Rutland; and delegates to medical societies: American Medical Association, Dr. James N. Jenne, Burlington; to Connecticut River Valley Medical Association, Dr. William N. Bryant, Ludlow; to White Mountain Medical Association, Dr. Clinton J. Rumrill, Randolph; to White River Valley Medical Association, Dr. William Lindsay, Montpelier; to Maine State Medical Society, Dr. Mark P. Stanley, White River Junction; to New Hampshire Medical Society, Dr. Fred T. Kidder, Woodstock; to Massachusetts Medical Society, Dr. Edward M. Crane, Hardwick; to Connecticut Medical Society, Dr. Patrick E. McSweeney, Burlington; to Rhode Island Medical Society, Dr. Clayton W. Bartlett, Bennington;

to Medical Society of the State of New York, Dr. William W. Townsend, Rutland. The House of Delegates elected the following officers: president, Dr. John P. Gifford, Randolph; vice-presidents, Drs. William W. Townsend, Rutland, and T. Frank Gartland, White River Junction, and secretary, Dr. Lyman Allen, Burlington. The treasurer reported a gift of \$1,500, the income of which shall be paid annually in October to the treasurer of the society for the purpose of establishing a lectureship, and providing for a speaker to be appointed by the president, for each general meeting on either sanitary science or general medicine.

VIRGINIA

County Societies May Unite.—At the regular quarterly meeting of the Northampton County Medical Society, held in Cape Charles, October 6, the question of the merger of the Northampton and Accomac County societies was favorably considered, and Dr. John H. Ayers, Accomac, was elected temporary chairman of the organizing committee.

Personal.—Dr. C. C. Hudson, Richmond, has been elected medical examiner of the health department, vice Dr. W. Brownley Foster, resigned, to become chief health officer of Roanoke.—Dr. Roy K. Flanagan, Charlottesville, has been appointed director of inspection for the state health department.—Dr. Powhattan S. Schenck has been appointed health commissioner of Norfolk, vice Dr. Henry R. Dupuy.—Dr. Charles J. Andrews has been made assistant health commissioner in charge of the bacteriologic work of the department, vice Dr. Edward C. S. Taliaferro.—Dr. John A. Johnston, chief surgeon at the National Soldiers' Home, has resigned.—Dr. Elisha Barksdale, city physician of Lynchburg, underwent operation at the German Hospital, Philadelphia, recently for infected glands of the neck.

WISCONSIN

Gift to Hospital.—Miss Moyca Newell, New York City, has donated \$10,000 to the endowment fund of the Kenosha Hospital as a memorial to her parents, the late Mr. and Mrs. Frederick Newell, pioneer residents of Kenosha.

Personal.—Dr. Frederick A. Kraft, formerly a member of the fire and police court, has succeeded Dr. William Colby Rucker as health commissioner of Milwaukee.—Dr. Ben C. Britt, Green Bay, has been appointed surgeon at the Veteran's Home, Waupaca, vice Dr. Bartholomew Bantley, resigned.—Dr. William Lorenz, formerly of Kankakee (Ill.) State Hospital, has been appointed assistant superintendent of the Wisconsin State Hospital, Mendota.

GENERAL NEWS

Alumni Association to Meet.—The annual meeting of the Alumni Association of the Lying-in Hospital of the City of New York will be held November 9, at the Harvard Club. Dr. J. Whitridge Williams, Baltimore, will read a paper entitled "My Experience in Labor Complicated by Contracted Pelvis."

Army Examination.—Seventy-six physicians are wanted for the U. S. Army. Applicants must be citizens, between 22 and 30 years of age, graduates of reputable medical schools, and must have had one year's hospital training or its equivalent, in practice subsequent to graduation. Examinations will be held Jan. 15, 1911, at various points throughout the country, and full particulars may be obtained from the Surgeon General of the Army, Washington, D. C.

Meeting of Military Surgeons.—At the annual session of the American Association of Military Surgeons, which met in Richmond, Va., this week, the following officers were elected: president, Surgeon-General George H. Torney, of the Army; vice-presidents, Surgeon Charles P. Wertenbaker of the Marine Hospital Service, Surgeon William C. Braisted of the Navy, and Colonel Charles Adams, Chicago, Surgeon General of Illinois; treasurer, Major Herbert A. Arnold, N. G. Pa., Ardmore, reelected.

FOREIGN NEWS

The Recent International Gynecologic Congress.—The fifth international congress of obstetrics and gynecology convened at St. Petersburg, September 22, with 800 registered members. It was the first international special congress that has been held on Russian soil, and twice it had to be postponed on account of war, political unrest or epidemics. The German gynecologists took the leading part in the transactions, Martin Bumm, Döderlein, Winter and Sellheim reading addresses

and a number of others taking part in various ways. Italy was represented by Pestalozza, editor of *Ginecologia*, and Mangiagalli, Mexico by Barreiro and France by Jayle, Le Filliatre and Abadie, Great Britain by Simpson and others, with Fontoyant from Madagascar, van de Velde from Holland and the representatives from the United States. Austria was not officially represented, owing to the five-day quarantine now enforced on account of cholera. An interesting sketch of the meeting by W. Beckmann in the *St. Petersburg med. Wochenschrift* just received comments on the proceedings that they brought out nothing materially new, although they demonstrated much industry and research on the part of the participants. When the subject of "Cesarean Section" was placed on the order of the day it was still open to discussion, but experience has demonstrated that the newer extraperitoneal technics have not proved adapted for infected cases, as was hoped at first, and consequently they have become merely a modification of the technic of the classic section. The unanimity on this point was so complete as to be touching, he declares, and extremely monotonous. The discussion of "Non-Operative Treatment of Cancer of the Uterus" showed that no definite progress had been realized by the tentative work done on all sides, and that certain forms of serotherapy had done direct harm. The general impression from the discussion was an encouragement to try various measures, cauterization and excoelation more energetically, without giving up the hope of more radical measures if conditions can be improved to permit. Fulguration and electrocongelation received only tepid endorsement from the speakers. The third subject on the program, the "Vaginal Route in Accouchement and Gynecology," gave the president of the congress, Professor von Ott, an opportunity to display his brilliant mastery of the vaginal technic, as shown in his own work and that of his pupils who have compiled, analyzed and sifted his entire material. The demonstrations on patients and the long records of successes will certainly, Beckmann is convinced, tend to increase the interest in the vaginal route, which seems to have declined somewhat during the last few years. No one appeared at the congress to discuss the subject, "Influence of the Nervous System in the Origin and Control of Uterine Hemorrhage," which had been placed on the order of the day at the request of the British committee. The question of "Treatment of Displacements of the Uterus" elicited a lively discussion, as Sellheim and von Knorre deprecated operative measures, while Dützmann and others reported excellent results from them. Fränkel's communication on the functions of the corpus luteum, based on over 400 experiments, aroused much interest, as also Abadie's report of the successful formation of a vagina out of a loop of small intestine. Spinal anesthesia found an ardent advocate in Le Filliatre, who performs operations even on the jaws with this technic and does not use inhalation anesthesia at all any more. But Abadie denounced the spinal technic so savagely that it almost made his hearers resolve to refrain from this technic henceforth. The program listed seventy-one communications and twenty demonstrations, and the organization of the congress was acknowledged to be flawless, thanks to the efforts of Professor von Ott and the secretary, Professor Sadovski, to whom the rest of the committee of organization seem to have left all the work. Russian hospitality to invited guests is proverbial, and its reputation was sustained on this occasion. The special features of the congress were mentioned in these columns July 23, 1910, page 324.

Ehrlich's Arseno-Benzol (606) in Syphilis.—An entire session of the recent German Naturforscher Congress was devoted to this new remedy; Ehrlich's own report was summarized in the Berlin Letter on page 1483. Neisser said that the destructive action of the drug on the spirochetes not only shortened the treatment of syphilis but would certainly aid in restricting the spread of syphilis by promptly reducing the danger of contagion from the infected, although, he added, reinfections would be observed probably more frequently. He advised not to abandon the tried method of chronic treatment of the infection although presumably it will not be necessary to keep up the old technic of seven or eight courses in the 3 to 5 years after infection. The serologic test may reveal those who do not need continued treatment, but this is not always reliable as experience has shown that after numerous negative responses the reaction may become positive and symptoms may recur. Expectant waiting in these cases would lose the ground already won. The question now is whether the continued treatment, if deemed necessary, should be intermittent or continuous. The system may become accustomed to the drug and the spirochetes may become drug-proof.

while, on the other hand, with continuous treatment the special properties of the drug may display their best action. Early and energetic treatment with "606" in every case of syphilis he regards as a duty now, and he does not rely on a single injection but repeats the 0.6 gm. dose after 3 or 6 weeks, sometimes interposing mercurial treatment. Alt expressed the hope that the symposium would be followed by a period of silent and extremely careful study of the new remedy to prevent any possible bad harvest that might throw discredit on Ehrlich's precious seed. He said that 75 per cent. of the mishaps reported to date might have been avoided by more scrupulous heeding of the directions as to doses, solution and administration. He stated that the drug not only kills all the accessible, fully developed spirochetes but it loosens up and induces hyperemia, local leukocytosis and a kind of inflammation in the syphilitic tissues and accumulations. When this process occurs in an enclosed space, as in the skull, the changes may entail transient symptoms of irritation or even paralysis. With syphilitic and parasymphilitic brain affections, slight sensory and motor symptoms may thus occur but they generally prove transient. When paresis is so well developed that the untrained eye can recognize it, the affection has progressed beyond relief from any drug; benefit can be anticipated only during the "heat lightning symptoms" stage. Especially in incipient taboparalysis the prospects are good for treatment with "606." Cerebral syphilis, he continued, is a very convincing and grateful field for the new drug but large doses should be avoided and the patient should be treated with as much caution as an epileptic with impending status epilepticus. The early forms of tabes have been much benefited in his experience; some of his tabetic patients treated last February and March have been freed to date (September) from their former attacks of pains. The effect of mere suggestion would probably have worn off long ere this. One of his patients with pronounced ataxia last March took part in the recent parade of veterans, marching with the best of them. He warns that tabetics are often in the habit of taking sedatives of various kinds and these must be reckoned with or untoward complications may result which might erroneously be attributed to the "606." Wechselmann denounced the statement recently made that the "606" is equivalent to two doses of calomel, and reported a case in which the former apparently cured completely malignant syphilis which had resisted for 4 years numerous calomel and other mercurial and arsenical courses. The ulcerations on the penis had healed over only once and for a few days during the entire 4 years. After three injections of the "606" in the course of 4 months (0.25, 0.45 and 0.45 gm.) every process has healed and the patient's earning capacity has been entirely restored. He excludes from the treatment persons with flabby, weak myocardium, such as is often encountered in tabetics; fever and an eruption are liable to follow the injection of the new drug when the heart is weak from any cause, although this reaction always subsided harmlessly in 2 or 3 days in his cases. No injury of the optic nerve from the new drug has been observed to date, he stated. Local necrosis has developed more frequently in his later series of cases; it appeared after 2 or 3 weeks and proved extremely indolent. Some of the tissues are still capable of recuperating so that active measures are contraindicated in treatment. Ehrlich called attention to the local necrosis observed after injection of the remedy in the breast of fowls; certain tissues seem more susceptible. In conclusion Wechselmann declared that the efficacy of the new drug has been proved by the experiences to date while its dangers have proved less than had been anticipated at first. Orth reported similar experiences with local necrosis in the buttocks after injection of "606." In the first case death followed the 10th day after the injection but the tissues were bacteriologically sterile and there was no suppuration. In the second case the patient died from cancer in the throat 6 weeks after the injection; the necrotic patch still showed the yellow field around a hemorrhagic center characteristic of this necrosis. Mielley observed transient arsenic melanosis in an infant with inherited syphilis, but otherwise had no by-effects of consequence to relate from his 157 cases. Margulies reported extensive research with the new drug which has confirmed the fact that the principle of complete sterilization by a single large dose can be successfully applied in all the trypanosome affections studied. Further, the spirilla do not become accustomed to the drug so that equally effectual action may be anticipated with fractioned dosage in spirilla affections. The animals

did not show any increased sensitiveness to the drug under repeated doses. Stern discussed the cases refractory to "606," having encountered eight among his eighty patients thus treated. The patients would have responded equally well to ordinary mercurial treatment and two of them probably even better. Scholtz suggested that possibly the blood serum of syphilitics just treated with "606" might have a curative action, and reported encouraging experiences in this line. In two cases injection of the serum was followed by subsidence of the manifestations of syphilis as under mild mercurial treatment; in three other cases the benefit was less pronounced. Grünfeld obtained the best results from the "606" in tertiary and inherited syphilis and found it harmless. He added that armed with this new remedy flying squadrons might be organized and sent throughout the country to combat syphilis as effectually as the flying squadrons now handle eye diseases in Russia. Hitherto the tediousness of the treatment of syphilis has prevented the organization of flying syphilis squadrons. Dohi, of Tokio, presented photographs of two syphilitics whose specific lesions, he said, had vanished under the "606" like snowflakes in the sunshine. Grouven reported infiltration and painfulness at the site of the first injection after a second injection elsewhere, demonstrating irregular absorption of the drug, but otherwise had no special by-effects even with four repetitions of the injections—no signs of anaphylaxis or diminution of efficiency. He also reported the curative action on an infected rabbit of the blood serum from a patient treated with "606." Glück stated that he had observed no by-effects in 417 cases although he had injected up to 0.8 gm. in some cases. Friedländer advocated an injection of the new drug in every case of chancre without waiting for a certain diagnosis. He advises continuing treatment with "606" only when new symptoms develop. One great advantage of the new remedy, he remarks, will be that thousands will be saved by it from the clutches of unscrupulous quacks. Salmon reported from Paris that a prophylactic small dose of "606" had proved effectual in warding off infection in monkeys. He regards tuberculosis and lupus as contraindications, having observed hemoptysis after injection in one case and ulceration of a tuberculous skin lesion in another. Schindler remarked that in the rejoicing over "606" we must not forget to rejoice over our possession of mercury too. Nagelschmidt reported extensive experiences with "606" in cases of incipient tabes and advocated his technic which has given excellent results. He gives first a very small dose; this is often followed by exacerbation of symptoms, and he waits for this reaction to subside entirely, sometimes for one or several weeks, before he repeats the same or a little larger dose, continuing in this cautious way with suitable intervals until he has given up to 1.5 or 2 gm. of the "606." Piek commented on the varying intensity of the reaction in different persons, the hysterical, neurasthenic and those with lively reflex action displaying the severest reactions.

MANILA LETTER

(From Our Regular Correspondent)

MANILA, Sept. 20, 1910.

Opening of the New General Hospital

The new Philippine General Hospital has at last been opened to government employees and to the public. The Bureau of Health gave a reception to the public on the opening of the institution at which the U. S. Secretary of War, the Hon. Jacob M. Dickinson, Governor-General Forbes and other prominent government officials were present. There had been considerable delay in opening the new hospital, for which it seemed dillicult to place the blame, and it was only after an executive order setting the date for the opening of the institution that it began to appear that there was any hope of getting into the new quarters before Christmas. The civil hospital, the old institution for government employees, has been taken over by the Philippine General Hospital and constitutes at present the greatest function of the latter institution. Few charity patients have as yet been admitted, owing to lack of accommodation. The city wards of St. Paul's Hospital have not yet been transferred and few private patients have entered the new hospital. Work on equipment and arrangement is rapidly going forward, however. When everything is completed Manila promises to have the most complete and modern hospital in the entire Orient. The Philippine Medical School, located on the same campus as the hospital, also entered its new quarters last week, but with very little display. As has been previously noted, both

institutions are of the latest type of reinforced concrete structure, have an abundance of light and ventilation and are well suited to a tropical country.

Culture of the Leprosy Bacillus

Considerable interest attached to the recent work of M. T. Clegg of the Bureau of Science in the successful growth on artificial media of the leprosy bacillus. For several years attempts have been made at the Bureau of Science to grow this organism, but without definite success, until the recently successful efforts of Mr. Clegg. The value of the present work lies in the fact that it paves the way not only for further investigation into the nature of leprosy, its portals of entry into the system and its agents of transmission, but also for experiments of a therapeutic nature. Already the possibility of a specific serum therapy has suggested itself and some few preliminary steps have been taken in that direction. The following is the technic employed in the growth of the *Bacillus leproi*:

The organism in several cases was obtained from the spleen, taken out under aseptic conditions, of patients recently dead of leprosy. It was grown in symbiosis with the ameba and the cholera vibrio. "Ten tubes, each containing a 24-hour growth of the ameba and the cholera vibrio, were inoculated with the splenic pulp, as were also ten control tubes containing sterile agar. All the tubes were placed in the incubator and kept at a temperature of 37 C. for 7 days. At the end of this period smears from the tubes containing the mixed culture of ameba and cholera vibrio showed, when stained by the Ziehl-Neelson method, a change in the morphology and a multiplication of the leprosy bacilli, while smears made from the control tubes stained in a similar manner showed no evidence of a multiplication of the bacilli inoculated and no noticeable changes in morphology. Transplants of the mixed cultures of amebas and cholera vibrio and leprosy bacilli were made to fresh agar tubes and incubated at the same temperature. Smears from these tubes made 3 days later and stained as before showed a great increase in the number of the acid-fast bacilli and also a change in their morphology from the long, slender bacilli found in smears from leprosy lesions to short plump rods and occasionally coccus forms. This deviation in morphology is not constant, however, on continued cultivation: some cultures have resumed a more typical morphology. Transplants of the mixed cultures were then made once a week for 3 months. After having been on the artificial medium for this length of time, the cultures were placed at a temperature of 60 C. for 30 minutes. This temperature was sufficient to kill the amebas and the cholera vibrios, but not the acid-fast bacilli. Transplantations were made from the heated cultures to fresh tubes containing amebas and cholera vibrios and also to tubes containing plain, sterile agar. After 3 days' incubation, smears from the tubes containing the amebas and cholera vibrios showed a development of the acid-fast bacilli, and at the end of 6 days, small, brownish colonies with regular margins appeared on the surface of the tubes containing plain agar only. Smear preparations made from these colonies and stained by the Ziehl-Neelson method showed microscopically an acid-fast bacillus."

After being once isolated in pure culture the leprosy bacillus has been found to be easy of cultivation on artificial media, resembling somewhat the tubercle bacillus in this respect. It has not been found possible so far to produce the disease in monkeys with the pure culture of the bacillus. In guinea-pigs, however, after several weeks some lesions were produced which closely resemble macroscopically and microscopically those found in the human being, from which the acid-fast organism was again recovered. In none of the experimental animals did any tuberculous lesions develop. Thus the likelihood that the acid-fast organism is the tubercle bacillus is rendered very slight.

Leprosy in the Philippines

While leprosy is not a rare disease in the Philippines, one seldom has occasion to see a case except at the leper hospitals. Legal restrictions are very close and the Bureau of Health has always been very active in its campaign of segregation. Every health officer throughout the islands is required to keep a keen eye open for all new cases and escaped lepers, and to report them to the Director of Health. Arrangement is speedily made for the immediate transfer of all such patients either to the leper department of San Lazaro Hospital in Manila or to the Culion Leper Colony. In suspected cases the Bureau of Science is called upon to aid in the diagnosis by laboratory examinations.

The Culion Leper Colony is an interesting institution, not only from its medical aspects, but also from the civil standpoint. It is located on the small island of Culion, south of Luzon, and is the great detention camp for the lepers of the Philippine Islands. It has its own civil government, under the direction of the central government of course, elects its own administrative officials and perhaps resembles a small agricultural community as much as it does a large state charity hospital institution. The members of the colony are encouraged, and in a measure required, to engage in some agricultural or industrial activity. The former is preferable, as its environments are more healthful and the great majority of the Filipinos are better adapted to agriculture.

The occurrence of leprosy in the Philippine Islands may be judged from the *Quarterly Report of the Bureau of Health for the Philippine Islands* for the second quarter of 1910: In the Culion Colony there were remaining April 1, 1910, 1,579 cases; admitted since that date, 180; born, 3; discharged, 0; escaped, 3; died, 78; remaining, 1,681. At the San Lazaro Hospital: remaining April 1, 1910, 133; admitted, 55; discharged, 5; discharged, not leprosy, 5; escaped, 4; died, 6; remaining, 166. To these must be added 220 lepers in the Moro (Mohammedan) Province. In addition also the Bureau of Health estimates that there are 205 lepers not yet transferred to Culion. This makes the total 2,272 for the entire Philippine Islands with a population of 8,000,000. Of the total number of lepers 1,681 are Filipinos, 3 Europeans, 1 American and 1 Chinese.

LONDON LETTER

(From Our Regular Correspondent)

LONDON, Oct. 22, 1910.

Discovery of Radium in Cornwall

A discovery of radium has been made in Cornwall which must help the progress of radium therapy. The element is obtained from pitchblende. The amount actually produced to date is 5,500 milligrams of 10 per cent. radium, or 550 grams of pure radium. In addition, 8 tons of pitchblende concentrates have been stored which, according to Sir William Ramsay, will provide 550 grams more. Sir William Ramsay states that there are not more than 5,500 milligrams, apart from this supply, in the whole world. It is impossible to say what proportion of the radium in use at present is pure, but much of it does not exceed the 10 per cent. standard. Polonium also exists in the pitchblende concentrates which have been obtained from the Cornish mines, but to what extent is not yet known. The process of purification of the pitchblende ore is carried on in a factory in London. The ore is crushed by the ordinary processes and delivered in London in a concentrated form. The uranium and iron are first dissolved out, and the radium is then precipitated out of the clear liquid. The precipitate is converted into the bromid, which by rapid crystallization is separated in a state of purity. This is a new process which occupies only a couple of months, while the process employed on the continent of Europe has occupied 2 years and the latest process a year. From each ton of pitchblende 530 milligrams of radium are produced. The Cornish supply appears to be much richer than the Austrian, which has hitherto been supposed to be the best. At present, the medical demand for radium is very great, much greater than the supply. The price is from \$90 to \$100 per milligram. The greatest precautions are taken for the safety of the first stock of British radium: it is kept in a specially constructed safe lined with lead, the only metal through which the emanations do not escape.

Plague in London

In a recent letter I reported the occurrence of a case of plague in a native member of the crew of a vessel which had arrived at Bombay. Another case has been discovered on the river at Thames. The patient was a native steward of the *S. S. Himalaya*, which has also come from Bombay. He applied for treatment at the Branch Seamen's Hospital, saying that he had been ailing for some days. He was admitted and died suddenly on the following day. The necropsy showed appearances suggestive of plague and material was sent to the government bacteriologist, who confirmed the diagnosis.

British Medical Education

The problem of medical education in Great Britain is a difficult and very complex one. Though many and rapid changes in the methods have taken place they have not kept pace with the still more rapid advance of medicine and its ancillary sciences. The present system has roots some centuries old among people whose temperament is very conservative and who

adopt reforms only under compulsion. British medical education is conducted by a large number of very diverse bodies—17 universities, 7 royal corporations and 2 other diploma-granting bodies. These bodies are controlled by a coordinating authority, the General Council of Medical Education and Registration, which works under and is responsible to the government. This council is made up in the following way: Each educational body sends a representative, the government nominates 5 members and the physicians elect 6 from among themselves. The council regulates the standard of education to which the various bodies must conform and appoints visitors to report on the examinations conducted by these bodies. It insists on a certain minimum of training and the passing of specified examinations by medical students before they can become physicians. The scheme of medical education occupies a minimum of 5 years and more usually extends to 6 or 7 years. On entrance the student must pass an examination of a general educational character. He then devotes one year to elementary science—chemistry, botany, biology and physics; 2 years to scientific work of direct professional reference, that is, to anatomy and physiology; and 2 years to clinical work. At the end of each of these periods examinations have to be passed. Anatomy and physiology must be thoroughly mastered and many rejections occur and the students do not reach the last stage of their education until their fifth year. The enormous progress of medical science has rendered the last stage difficult and the 2 years allotted to it often prove insufficient. Six or 12 months above the allotted period may be spent in learning the practice of medicine, surgery and obstetrics, and in acquiring a familiarity which is no longer allowed to be slight, with ophthalmology and the administration of anesthetics, to mention only two special subjects. On the whole, the medical students are well-educated before they are permitted to practice, and although the standard of examination varies a good deal among the different educational bodies there is none which is not respectable or which is comparable with those bodies in the United States and Canada which have been censured in Mr. Flexner's recent report.

PARIS LETTER

(From Our Regular Correspondent)

PARIS, Oct. 21, 1910.

The Eleventh French Congress of Internal Medicine

The eleventh Congrès français de médecine interne met October 15 at Paris under the presidency of Professor Landouzy, dean of the Paris medical college. Among those attending were several foreign professors, especially Maragliano of Genoa, Henrijean of Liège, and Mayor of Geneva.

The general strike on the railroads, which had just been declared, hindered the success of the meeting very much; and besides the congress felt the disadvantage of those defects of organization which, unfortunately, are becoming too frequent in this kind of meetings. The papers were distributed to the members only at the session, which impeded the discussion very much. Moreover, for some time it has been the custom to appoint several essayists on each subject. This practice has some advantages, it is true, when the essayists divide the subject so that each undertakes the discussion of one side of the question, so that their work is mutually complementary. Otherwise the number of the papers leads to tiresome repetitions; and this was the case in this meeting. For example, the subject of bradycardias was treated in two papers, one by Drs. Vaquez and Esmein of Paris, and the other by Dr. Gallavardin of Lyons, each of whom covered the entire subject. An attempt was made to remedy the state of affairs by forming an association open to physicians of French-speaking countries, who, through a permanent commission, on which the various nationalities should be represented, would undertake the work of organizing the congress. Professor Bard of Geneva was commissioned to make a report on this subject at the next meeting, which will take place at Lyons, in 1911, under the presidency of Dr. J. Teissier, professor of the medical clinic at the Lyons college of medicine. It was otherwise in the case of the two questions of present-day importance, namely, the treatment of syphilis by Ehrlich's method and the value of tuberculin therapy; these aroused the most interesting discussions.

Treatment of Syphilis by "606"

Dr. Milian, physician of the hospitals of Paris, has treated 139 patients by "606." He recognizes that Ehrlich's preparation has the toxicity and may have the bad results peculiar to all arsenical derivatives, but, according to his own experience, accidents are very rare and he has never observed the least

visual trouble in any case. The only general trouble which has been observed has been occasional fever, which never exceeds 38 C. (100 F.). Local accidents, except pain, may be avoided in great measure if care is taken to make the injection into the muscular and not in the subcutaneous cellular tissues and to select the lumbar in preference to the gluteal region. The drug is of remarkable power, especially on the secondary manifestations of syphilis. Dr. Jeanselme, physician of the hospitals of Paris, and *agrégé* of the Paris medical college, in collaboration with Drs. Laignel-Lavastine and Touraine, has treated fifty syphilitics by "606" without ever having seen phenomena of intoxication or serious accidents. The injection into the gluteal region is accompanied by sharp pains which often radiate into the whole leg. For several days the buttock is tense and doughy, and walking is difficult. Morbilliform or urticarial erythemas are observed sometimes at the site of the injection, sometimes at a distance, and the temperature remains high for three or four days. The next day after the injection a turgescence of the chancre and the neighboring tissues and a papillous appearance of the roseola are observed at the same time, but these phenomena are ephemeral and soon regression of the syphilitis begins, the hypertrophied mucous plaques become effaced, dry up and in a few days epidermis forms over them. Papillous or acneiform syphilitis which resist mercury become absorbed in about 2 weeks. Headache disappears in from 1 to 4 days. Dr. Sieard and Dr. Netter, *agrégés* at the Paris medical college, likewise reported the success which they obtained with Ehrlich's preparation. The communication made by Dr. L. Jacquet, physician of the hospitals of Paris, was less favorable. Dr. Jacquet treated three patients in his service. The first had a sclerogummatus syphilitic of the tongue which rendered the movements of mastication and deglutition painful. Under the influence of "606," the pains diminished and the tongue became more mobile, but there was no objective modification of the lesion of the tongue. The second patient had a lingual ulceration with tertiary labial lesion. The latter improved rapidly, but the ulcer of the tongue persisted without change. It is probable, however, that it was a tuberculous ulceration. The history of the third patient is particularly interesting. He was a man of 53, with an ulcerated gumma of the right thigh and had already had several vomitings without blood, with painful gastric crises. An injection of 0.5 gm. of arsenobenzol was made. Seven days later when it appeared that the gumma was drying up and was manifestly undergoing epidermatization, abundant blackish vomiting occurred and the twelfth day after the injection the patient died. At the necropsy, a calloused ulcer of the stomach was found with gastric dilatation. Was "606" responsible for this death? Dr. Jacquet was compelled to believe it was. The patient had never before had hematemesis. He had entered the hospital not cachectic, in a fairly good general condition. He was kept quiet and on a milk diet and thus in the best possible condition to support the treatment. The violent vasodilating action exerted by arsenical compounds and the various hemorrhages which they provoke are well known. Therefore, Jacquet thinks that ulceration of the digestive tube should be added to the contra-indications mentioned by Ehrlich.

The Discussion on "606" in the Academy of Medicine

Aroused by Dr. Hallopeau's communication at a recent session of the Académie de médecine, which I mentioned in a previous letter (THE JOURNAL, October 8, p. 1483), Dr. Ehrlich has written a letter to Dr. Netter which the latter laid before the academy, at the session of October 11. Ehrlich declares that he knows of no case of amaurosis or of any ocular lesion due to "606." As for the known cases of death, which number no more than twelve, Ehrlich remarks that in the syphilitic services where he has made the greatest number of injections, and where at least 8,000 patients have been treated, there has been only one death, and that due to the injection having been made under unfavorable conditions. The other deaths were in insane asylums or in clinics of internal medicine. He says that injections in subjects of severe diseases of the nervous system have been made absolutely contrary to his unvariable instructions. The cases of death are to be explained: (1) by a local reaction of syphilitic infiltrates into nerves whose functions are essential to existence; (2) by a general hypersensitiveness of the organism to the toxic agent (for a long time similar sensitiveness of general paralytics toward mercury has been known); (3) by a defective technic (insufficient asepsis, abscess). One death by rupture of an aneurism has been recorded. Dr. Ehrlich has particularly discouraged injections in subjects of vascular lesions.

Surgeons and Physicians

The address of Dr. Delagenière, president of the twenty-third Congrès français de chirurgie, which I mentioned in a previous letter (October 7, p. 1483), which blamed physicians for sending the patients to surgeons too late, has called forth an editorial response. The *Semaine Médicale* remarks that, so far as the surgical treatment of exophthalmic goiter, for instance, is concerned, the essayists of the surgical association are not quite up to date, since, according to the recent studies of M. Stern, there is a symptom-complex called "basedowoid" which is entirely different from real Basedow's disease. While surgery of the thyroid gland and its vessels often benefits true exophthalmic goiter it is injurious to basedowoid.

According to M. Delagenière, surgery holds the "first scientific place among medical sciences." This is an exaggerated pretension, which cannot fail to hinder surgical progress. In a recent article in the *Revue Scientifique*, Dr. Forgue, professor of the surgical clinic at the Montpellier college of medicine, declares that while at present surgery has increased its therapeutic domain by invading the province of medicine, it is impossible to foresee what will happen next. Already in some points surgeons have beat a retreat. "If to-morrow, medicine should discover a serum treatment for tuberculosis and cancer, we should be thereby expelled from our greatest operative domain."

Compulsory Physical Education

The Congrès de la Ligue de l'enseignement has on the motion of Dr. Lachaud, deputy, unanimously adopted a resolution asking that the government make physical education compulsory.

BERLIN LETTER

(From Our Regular Correspondent)

BERLIN, Oct. 13, 1910.

Personal

Professor Sauerbruch, assistant of Professor Friedrich at Marburg and formerly for many years an assistant of Mikulicz, has been called to Zurich as director of the surgical clinic to succeed von Krönlein.

Imperial Scientific Society

On the occasion of his address delivered at the centennial of the Berlin university, the Kaiser announced the foundation, under his patronage, of a scientific society, the functions of which shall be the erection and maintenance of institutions for research. These institutions will differ from the universities, which serve not only for research but for instruction, in being devoted solely to study and will be modeled on the institutions established in America by millionaires. In Germany we have had for medical purposes only one example of this kind of institution, namely, the George Speyer House in Frankfurt a. M. at which Ehrlich has carried on for some years his chemical investigations which resulted in the epochal discovery of his remedy for syphilis. Up to the present about \$2,500,000 (10,000,000 marks) are available for the new imperial scientific society.

Coffee Substitutes Rejected

A manufacturer of cereal and malt coffee has proposed to the minister of justice to furnish his preparation as a substitute for coffee in the prisons. At the request of the minister of education the scientific deputation for medical affairs made the following report through Professors Rubner and Kraus: Coffee cannot be replaced by corn or malt. Such a substance at most serves no other purpose than the preparation of a dark coffee-like liquid or a slight addition of nutriment to the diet which could be accomplished quite as well and at less expense by a little bread. There is no equivalent for genuine coffee because in substitutes its stimulating action is lacking. For this reason comparisons of price are not to be considered. As the diet of prisoners affords very little condiments or invigorating elements, coffee should be retained. The substitutes are, to be sure, cheaper than coffee, but considering the cost of material and of preparation they are sold at an excessively high price. Consequently the refusal of the proposal is recommended.

VIENNA LETTER

(From Our Regular Correspondent)

VIENNA, Oct. 18, 1910.

Jubilee of Professors von Reuss and Urbantschitsch

A few days ago the twenty-fifth anniversary of their appointment as professors was celebrated by Dr. von Reuss, the well-known ophthalmologist, and Dr. Urbantschitsch, head

of the ear clinic in Vienna, the successor of Politzer. The two men are united by close friendship, and both can be regarded as typical representatives of the Vienna school. They have, during the quarter of a century, seen many pupils from all parts of the world. The ear department especially is still the Mecca of all surgeons who wish to become experts in this modern branch of medicine. The celebration of the day was witnessed by representatives of the French, English, American, Italian and Japanese doctors now studying in this city.

Unveiling of Commemorative Tablets for Nothnagel and Gussenbauer

In commemoration of two famous professors of the university who have put their mark on the progress of medicine, funds were collected for a few months among the friends of the deceased, with the result that a short time ago there was unveiled a monument, in bas-relief, of Professor Gussenbauer, the pupil and successor of Billroth, who has continued the world-famed methods of his teacher and friend. In accordance with the curt, positive ways of the scientist, the inscription says nothing but "Karl Gussenbauer, the Surgeon." The other monument is in honor of the beloved teacher and famous physician, Nothnagel. The life-sized tablet, on which is a speaking portrait, a speaking likeness, bears the motto of the professor, to which he always adhered: "Only a kind man can be a good physician." Naturally, the ceremony of unveiling was witnessed by a select group of personal friends and followers of the two men, besides official representatives of medical corporations.

Medical Men Successful with Sick Benefit Clubs

In various districts of the country the increased demands on living expenditures resulted in increased demands by the doctors on the managing board with sick clubs, with consequent conflicts. In all these instances the doctors carried their point, and have now a right to demand a fee of 4 kronen (about \$1) per head of the members of the club, minor surgery, midwifery and night work being paid for extra. This means an increase of about 40 to 50 per cent. on the present payment. Thus the value of organization was demonstrated to those outside of it, with the result that nearly all practitioners are members of the organization now.

Marriages

WALTER G. HARDER, M.D., to Miss Clara Campe, both of San Francisco, October 15.

ARTHUR W. THOMAS, M.D., to Miss Edith Jones, both of Springfield, Mo., October 19.

RICHARD A. ROACH, M.D., to Miss Anna Katherin Merle, both of Chicago, October 26.

GEORGE H. LAMLEY, M.D., to Miss Bertine Robinson, both of Blissfield, Mich., October 20.

EUGAR NELSON ZINN, M.D., to Miss Lizzie Hanson, both of Thompson, Iowa, October 12.

FREDERICK TIGHE, M.D., to Miss Amelia Hennessy, both of Newburyport, Mass., recently.

JOSÉ M. FERRER, M.D., to Miss Teresa R. O'Donohue, both of New York City, October 18.

HERMAN THEODORE RADIN, M.D., to Miss Pauline Loewy, both of New York City, October 27.

JAMES HARTZELL LANGSTAFFE, M.D., to Miss Aldine Merit, both of Fairbury, Ill., October 22.

FRANK H. REIHAN, M.D., Smith Center, Kan., to Miss Elizabeth Kieme of Seattle, October 8.

FRANK SHERWOOD MEADE, M.D., Madison, Wis., to Miss Lucy Wood of Bloomington, Ill., October 25.

HOBGLAND COOK DAVIS, M.D., Baltimore, to Mrs. Katharine Carroll Dowell, at Baltimore, October 19.

D. EMORY SHY, M.D., Knobnoster, Mo., to Miss Esther Rothwell of Rocky Ford, Colo., October 11.

HENRY GOLDFWART, M.D., to Miss Amanda Moore, both of Mobile, Ala., at New York City, October 22.

DARWIN WALTON HALL, M.D., Kansas City, Mo., to Miss Katherine Motter of St. Joseph, Mo., October 5.

HORACE G. MERRILL, M.D., Provo, Utah, to Miss Merl Miller of Murray, Utah, at Salt Lake City, October 20.

JOHN P. LONGWELL, M.D., and MATTIE LOUISA BERRY, M.D., both of Wellsboro, Pa., at Leona, Pa., October 12.

Deaths

Frederick Holme Wiggin, M.D. Bellevue Hospital Medical College, New York City, 1877; a prominent physician of New York City; died at Atlantic City, N. J., October 28, aged 56. Dr. Wiggin was a member of the American Medical Association; formerly secretary and later president of the New York State Medical Association; third vice-president of the American Medical Association in 1898 and formerly a member of the Judicial Council; fellow of the New York Academy of Medicine; a member of the Harvey Society, the New York Medico-Surgical Society, and the New York Academy of Sciences; president of the Alumni Society of Bellevue Hospital; honorary member of the Congress of German Surgeons at Berlin; from 1892 to 1908 visiting surgeon and gynecologist at the New York City Hospital, and adjunct visiting surgeon at Bellevue Hospital during 1897 and 1898.

William Canniff, M.D. New York University, New York City, 1854; University of Victoria College, Toronto, 1859; assistant surgeon in the Royal Artillery from December, 1855, until the close of the Crimean War; member of the Royal College of Surgeons, England, 1855; lecturer on general pathology in Victoria University, 1858; professor of surgery in 1859, and given the degree of M.D. from that institution in the same year; acting assistant surgeon U. S. Army, 1865; one of the founders, secretary in 1867, and vice-president in 1869 of the Canadian Medical Association; president of the Medical Section of the Canadian Institute, Toronto, 1870; a member of the board of examiners of the College of Physicians and Surgeons, 1883; for several years health officer of Toronto, and later a resident of Gravenhurst, Ont.; died in Belleville, Ont., October 18, aged 80.

James Baynes Walker, M.D. University of Pennsylvania, Philadelphia, 1872; a member of the American Medical Association, American Climatological Association, American Academy of Medicine, and president of the Medical Club of Philadelphia, and formerly president of the Northern Medical Association of Philadelphia and Philadelphia County Medical Society; a member of the State Board of Medical Examiners; professor of practice of medicine in the Woman's Medical College of Pennsylvania from 1879 to 1890; visiting physician to the Philadelphia and Woman's Hospitals, and consulting physician to the West Philadelphia Hospital for Women; died at his home in Philadelphia, October 19, from diabetes, aged 63.

William Franklin Hines, M.D. College of Physicians and Surgeons, Baltimore, 1877; formerly of Chestertown; a member of the Medical and Chirurgical Faculty of Maryland, and chief of the Bureau of Vital Statistics of the State Department of Health; for four years a member of the State Board of Medical Examiners, for ten years health officer of Kent County, and for two years superintendent of the State Bureau of Immigration; died at his home in Baltimore, October 17, from cirrhosis of the liver, aged 54.

George Whipple Porter, M.D. Harvard Medical School, 1874; a member of the Rhode Island Medical Society and the American Academy of Medicine; one of the founders of and surgeon to the department of gynecology of the Rhode Island Hospital; one of the founders of and consulting physician to the Providence Lying-in Hospital and St. Elizabeth's Home; for several years surgeon of the First Light Infantry, N. G. R. I.; died in Boston, October 15, from pneumonia, aged 63.

John Somers Buist, M.D. Medical College of the State of South Carolina, Charleston, 1861; emeritus professor of general surgery and surgical pathology in his alma mater; a member of the South Carolina Medical Association, and Southern Surgical and Gynecological Society; surgeon in the Confederate service during the Civil War; died at his home in Charleston, September 29, from cerebral hemorrhage, aged 70.

James Americus Reagan, M.D. Shelby Medical College, Nashville, 1859; Vanderbilt University, Nashville, Tenn., 1877; a pioneer clergyman and practitioner of north Buncombe County, N. C.; for several years mayor of Weaverville; a member of the Medical Society of the State of North Carolina; died at his home in Weaverville, October 24, aged 86.

Nathan G. Hardister, M.D. Vanderbilt University, Nashville, Tenn., 1879; Jefferson Medical College, 1880; formerly of Jacksonport, Ark., but recently of Hoxie, Ark.; whose body was found floating in White River September 13, is believed to have committed suicide while under the influence of drugs. He was a Confederate veteran and 63 years of age.

William S. Webster, M.D. College of Physicians and Surgeons, New York City, 1856; a surgeon in the Army during the Civil War; local surgeon in Liberty, N. Y., of the New

York, Ontario and Western Railroad, and a practitioner of Liberty for more than fifty years; died at his home, July 23, from cerebral hemorrhage, aged 77.

Edwin Augustus Knight, M.D. New York University, New York City, 1867; of Newton, Mass.; a veteran of the Civil War; visiting physician at Newton Hospital; died in Franklin, N. H., June 14, from the effects of prussic acid, self-administered it is believed with suicidal intent, aged 67.

Charles E. Hill, M.D. Syracuse, N. Y., Medical College (Eclectic), 1850; surgeon of the One Hundred and Eighty-Eighth Volunteer Infantry during the Civil War; up to 1880 a practitioner of Fabius, and thereafter of Syracuse; died in North Syracuse, October 11, from heart disease, aged 85.

Orville B. Blackman, M.D. Hahnemann Medical College, Chicago, 1873; a member of the Illinois State Medical Society, and of the staff of the Dixon Public Hospital; died at the home of his daughter in Malvern, Pa., October 15, from cerebral hemorrhage, aged 58.

William G. Nicholson, M.D. Rush Medical College, 1897; a member of the American Medical Association and the Fox River Valley Medical Society; surgeon to St. Mary's Hospital, Green Bay, Wis.; died at his home in that city, October 16, from pneumonia, aged 41.

James McClelland Duncan, M.D. Miami Medical College, Cincinnati, 1892; a member of the American Medical Association; president of the school board of Pawnee, Ill., and for four years president of the village; died at his home, October 16, from typhoid fever, aged 48.

William Green, M.D. College of Physicians and Surgeons, New York City, 1854; formerly a practitioner of Scranton, Pa., and of Virginia; and for the last twenty years a resident of Lincoln, Neb.; died at his home, October 20, from cerebral hemorrhage, aged 79.

Samuel Marion Carter, M.D. University of Nashville and Vanderbilt University, 1885; a member of the Knox County Medical Society, and for ten years physician of Knox County; died at his home in Knoxville, Tenn., October 11, from chronic nephritis, aged 62.

William Henry Fisher, M.D. Bellevue Hospital Medical College, 1876; coroner of Tioga County, N. Y., from 1880 to 1883; a member of the board of health and first president of the village of Spencer; died at his home in Elmira, October 18, aged 56.

Jean Philippe Rottot, M.D. Laval University. —; one of the founders of the Montreal branch of Laval University and dean for many years, retiring in 1907; a practitioner of Montreal for 63 years; died in that city, September 28, aged 85.

William L. Rouse, M.D. Medical College of Ohio, Cincinnati, 1875; a member of the American Medical Association; president of the Greene County Medical Society; died at his home in Painterville, Ohio, October 18, from cerebral hemorrhage, aged 60.

Ballery Wagner Hunter, M.D. Medical College of the State of South Carolina, Charleston, 1883; a member of the American Medical Association; died at his home in Charleston, August 13, from pachymeningitis, following septicemia, aged 46.

John A. Leavy, M.D. St. Louis Medical College, 1857; an honorary member of the St. Louis Medical Society; surgeon in the Confederate service during the Civil War; died at his home in St. Louis, October 24, from cerebral hemorrhage, aged 76.

Harvey C. Ensign (years of practice, Wayne County, Pa., 1895); justice of the peace of Waymart for twenty years; and for about forty years a practitioner of Waymart; died at his home, October 17, from cerebral hemorrhage, aged 65.

Francis Drayton Nabers, M.D. Tulane University, New Orleans, 1867; of Birmingham, Ala.; a Confederate veteran; died at the home of his son in Birmingham, September 28, from paralysis agitans, aged 65.

James Ross Bell, an eclectic practitioner of Ohio for 62 years; surgeon in the army during the Civil War; died in the Soldiers' Home Hospital, Dayton, Ohio, September 24, from senile debility, aged 85.

Richard Leuschner, M.D. Michigan College of Medicine and Surgery, Detroit, 1892; a member of the American Medical Association; died at his home in Mount Clemens, October 14, from pneumonia, aged 51.

Phineas H. Wheeler, M.D. Dartmouth Medical School, Hanover, N. H., 1865; surgeon in the army during the Civil War; died at his home in Alton, N. H., October 19, from cerebral hemorrhage, aged 70.

David Presbury Butler, Jr., M.D. Boston University, 1898; physician in charge of the Rutland (Mass.) Cottages; died at his home in Rutland, October 15, from endocarditis, aged 37.

James Lemon, M.D. Joplin (Mo.) College of Physicians and Surgeons, 1882; a veteran of the Civil War; died at his home in Erie, Kan., October 7, from chronic nervous disease, aged 69.

T. Newton Lewis, M.D. Pennsylvania Medical College, Gettysburg, 1861; formerly of Adrian, Mich.; died at his home in Mount Dora, Fla., January 7, from heart disease, aged 70.

Charles Francis Brem, M.D. New York University, New York City, 1867; a Confederate veteran; died at his home in Charlotte, N. C., October 10, from heart disease, aged 64.

Warren Decoto Osgood, M.D. Cooper Medical College, San Francisco, 1910; of Oakland, Cal.; died in the Alameda Sanitarium, October 14, from typhoid fever, aged 23.

Samuel L. Hargreaves, for many years a practitioner of Hebron, Neb., and prior to that time for twenty years in Missouri; died at his home, August 6, aged 75.

Peter Orrin Stonebraker, M.D. Rush Medical College, 1892; of Scotland, S. D.; died in St. Joseph's Hospital, Sioux City, Iowa, September 27, from pneumonia, aged 45.

Jesse Walter Evans, M.D. Rush Medical College, Chicago, 1873; a veteran of the Civil War; died at his home in Varna, Ill., October 14, from pneumonia, aged 73.

Daniel Archibald Sinclair, M.D. University of Toronto, 1903; formerly of Melbourne, Ont.; died at his home in Pasadena, Cal., October 1, from nephritis, aged 34.

Daniel Richardson Pool (license, Miss.); for many years a practitioner of Ellisville; died at his home, July 21, from senile debility, aged 84.

Benjamin James Zdzense, M.D. Rush Medical College, 1891; died at his home in Sparta, Mich., August 3, from valvular heart disease, aged 60.

Charles Stoddard Stroud, M.D. McGill University, Montreal, 1876; died at his home in Montreal, June 5, from cerebral hemorrhage, aged 66.

Alonzo Atwood (years of practice, Ohio, 1896); died at his home in Middlefield, April 9, from senile debility, aged 78.

Edmund Henry Dillabough (license, Ont., 1868); died at Hamilton, Ont., October 26, aged 76.

Pharmacology

TWO DANGEROUS HAIR DYES

"Eau Sublime" and "Mrs. Potter's Walnut Tint Hair Stain"

Inquiries were recently made regarding the composition of "Eau Sublime," a hair dye put on the market by Mrs. H. Guilford, New York. Our correspondent states that a patient using this preparation was suffering from "a marked lassitude and an obscure general eruption." Since many similar cases have been reported from the use of Mrs. Potter's Walnut Juice Hair Stain, now called "Mrs. Potter's Walnut Tint Hair Stain" which owes its poisonous properties to the presence of paraphenylen diamine, the presence of the latter in "Eau Sublime" was at once suspected. In view of the dangerous nature of this substance, it was considered of importance to make a chemical examination of "Eau Sublime" to determine whether or not paraphenylen diamine was responsible for the effects following its use. On request for a specimen of the preparation, the correspondent sent an original package, which was examined in the Association Laboratory. The following is a report of the examination:

"Eau Sublime," as received in the Association Laboratory, was contained in a carton sealed with a label bearing the name of the preparation, its manufacturer and its uses. The carton contained two one-ounce bottles, one marked "A" containing a brown liquid and the other marked "B" containing a colorless liquid. The cork in this bottle, which was wired down, was bleached where it was exposed to the liquid.

That one of the ingredients of "Eau Sublime" is paraphenylen diamine was shown by the response of the liquid in bottle "A" to the following tests, recommended for the detection of paraphenylen diamine: Some of the liquid was mixed with an equal volume of hydrogen peroxid solution and the mixture placed on paper or cotton, which became bluish-black on drying. A splinter of pine wood dipped into the liquid and then treated with dilute acetic acid became bright red. The diluted acidified liquid became violet on adding ferric chloride solution. A few drops of the liquid added to 4 or 5 c.c. of a 1 per cent. solution of potassium permanganate decolorized the latter, emitting at the same time a faint odor of ammonia. A drop of the liquid placed on a white surface and then treated with a drop of bromine water, became at first a bright green and then a dull violet color.

The identification of the contents of bottle "B" as hydrogen peroxid, suggested by the bleached condition of the cork and the pressure of the gas in the bottle, was verified by the following tests: Added to dilute, acidified potassium permanganate solution the latter was decolorized. A few drops added to 4 or 5 c.c. of an acidified solution of potassium dichromate and the mixture shaken with 5 c.c. ether, produced in the latter a blue color.

These tests show that "Eau Sublime" consists, essentially, of hydrogen peroxid and paraphenylen diamine. This emphasizes the need of cautioning the public against the indiscriminate use of hair dyes, particularly those containing paraphenylen diamine, which, although exploited as "harmless" preparations, are decidedly dangerous. The tests above mentioned could be carried out by a physician, and from the results of such tests he would be placed in a position to act as an adviser and to caution his patients.

"Eau Sublime" has been declared misbranded by the federal government and the case published in Notice of Judgment No. 434. While no mention is made in the government's report of the identity of the essential drug in the nostrum, the statement is made: "the use of said drug ["Eau Sublime"] would tend to produce an eczema of the scalp."

Between the dates of Feb. 13 and Oct. 22, 1909, there were reported to THE JOURNAL twenty-three cases of poisoning due to the use of Mrs. Potter's Walnut Juice Hair Stain. This hair dye was shown by analysis to depend for its action on the presence of paraphenylen diamine. The predominating symptom of the poisoning in each case was a dermatitis of varying degrees of intensity. We now have to report five more cases of poisoning from the use of the same dangerous dye.

Sept. 21, 1910, Dr. P. R. Straight, Bradford, Pa., one case.
Oct. 4, 1910, Dr. H. B. Ormsby, Cleveland, one case.
Oct. 17, 1910, Dr. H. K. Gaskill, Philadelphia, three cases.

CAMPHENOL

To the inquiry, "What is Camphenol?" the chemical laboratory reports:

Camphenol is made by Johnson & Johnson, New Brunswick, N. J. Under the name of the article on the carton appears the following formula: $C_{10}H_{16}O-C_6H_5(CH_3)OH=C_6H_5OH$. This formula consists of the chemical formulas for camphor, cresol and phenol, written one after another, and from this one would conclude that Camphenol is a compound of camphor, phenol and cresol in molecular proportions. Examination shows, however, that Camphenol is but a modification of the well-known camphorated phenol (the liquid produced when solid camphor and phenol are triturated together). In Camphenol a part of the phenol, in the camphorated phenol, has been replaced by cresol, and this liquid has been diluted and emulsified with gelatin or some similar substance and perfumed. In other words this preparation is an emulsion containing relatively small quantities of cresol, phenol and camphor and is another illustration of the attempts of would-be pharmaceutical houses to produce new synthetics in the simplest manner possible—that of writing the chemical formulas of the constituents of a remedy in a way to indicate a chemical combination.

Correspondence

Interstate Reciprocity in Licensing Physicians

To the Editor:—This subject is not receiving the attention it should receive by the medical profession in general. To be sure an occasional article appears from time to time in medical journals, but that is not enough. More action is needed. Something must be done for the future of the old practitioner—for the physician who is in good standing with his local and state societies and the American Medical Association, and who has been in active practice for the last ten or more years.

Suppose that for his own health, or that of some other member of his family, or for any other good reason, he wants to go into some other state. If the state in which he wishes to locate does not reciprocate with the state in which he has been practicing, he must then go before the board of medical examiners and pass an examination before he can get his license; an examination which probably three-fourths of the members of the board themselves could not pass; an examination meant for recent graduates. What chance does the old practitioner have of passing this examination?

To make it still worse, some states are about to require that no physician will be allowed to even take the state board examination unless he has studied a year or two in a college previous to taking his medical course. To make this apply to the old physician is a decided injustice. When he began his medical studies he was not obliged to have had any college training. He had all the necessary requirements at the time but since he graduated, the requirements have changed.

What is he going to do? Must he go back to the university and take a college course before he can get a license to practice medicine? Again I say is it just? And what is going to be done about it? Something must be done or else they will rise up in arms against the unjust way they are being treated. I am most heartily in favor of higher requirements for the coming physicians—but allowances must be made for the old practitioner who for good reasons wishes to change his location from one state to another. It seems to me a national license should be issued granting the privilege to practice anywhere in the United States to physicians who have been practicing ten or more years, and are in good standing in their local and state societies and the American Medical Association.

E. F. HAMLIN, M.D., Slatersville, R. I.

To the Editor:—In THE JOURNAL of October 15, p. 1397, is a communication headed, "Interstate Reciprocity in License to Practice," which is much overdrawn, although probably unintentionally. The writer appears to be much put out with present methods used in the examination and licensure of practitioners of 10 to 25 years' standing, and refers to this "tyranny against which the masses of the older practitioners should rise up." He also designates the trained modern graduate as one of "the inexperienced tyro and the compend brigade."

If the doctor really wishes to change his location without an examination, it would be well for him to get the "Laws (abstract) Regulating Practice . . ." from the American Medical Association, and he will find that many of the states make provision for the old practitioner by reciprocating on the basis of his diploma alone, without the examination. However, if an examination appears necessary, I would suggest that he consult the State Board number of THE JOURNAL, May 21, and observe the number of low-grade states in which practically everybody gets through; then ascertain with what other states they reciprocate on the basis of an examination. There are several low-grade states that reciprocate with others of much higher standard, and this, meanwhile, is one weak point in reciprocity. Now if the old practitioner will buy some modern "compend," and read systematically every day

a certain number of pages, he will before long have an up-to-date knowledge of the essentials requisite to pass examinations in any of those easy states referred to. Then he will not feel the burden of the job, but will grow into the knowledge, which he will find very helpful in other respects as well.

Any old practitioner of average ability who could not prepare himself in this manner must be sadly in need of renovation. The points that he learns will give him a renewed interest in the study, and get him up to date. The satisfaction also of earning a medical license by examination, which makes available a wider field of reciprocity, will pay for the moderate effort.

C. FRED CURTIS, M.D., Bath, Me.

The Electric Treatment of Poliomyelitis

To the Editor:—In the short paper on "The Treatment of Poliomyelitis from the Neurologist's Point of View" published in THE JOURNAL, October 22, Dr. B. Sachs says: "Muscular exercise is the chief aim in the treatment, and for that reason one must follow the simple rule that in treating the paralyzed muscles that form of current is to be used which gives the best contraction with currents of moderate strength."

I believe that all who have paid attention to this matter will agree with this statement of Dr. Sachs. But in many cases of poliomyelitis no contraction whatever can be produced by "currents of moderate strength." And indeed in many cases no contraction, or only a feeble one, can be produced by even painful currents. No good can be accomplished by using electricity unless the current produces muscular contraction. And in many cases muscular contraction can be produced only by currents which are painful. Such currents ought not to be used, at least on a child. Indeed many young children will not bear even a moderate amount of pain and soon come to dread the application of electricity.

I have often known a mild current to be used which produced no contraction of the muscles. These applications of electricity are useless. On the other hand, contractions of the muscles are sometimes brought out by the use of strong currents which produce crying spells and states of nervousness in the child. If the electric current produces no contraction of the muscles it is useless; if it produces pain, and nervousness, and outeries it is worse than useless; it is distinctly harmful. I speak now especially of young children. Of course older persons will stand a current much better than young children.

So I would quite agree with Dr. Sach's statement that electricity is of value in the treatment of poliomyelitis only if we can get "contractions with a current of moderate strength." But I have known of so much useless and harmful treatment by electricity that I have thought it worth while to write this brief note by way of protest against it.

I believe that the electric treatment of poliomyelitis must be considered as the least valuable measure that we have and of far less worth than massage, passive exercise and orthopedic measures which Dr. Sachs so well describes. I advise electricity in only a small number of cases of poliomyelitis.

THEODORE DILLER, Pittsburg.

Hexamethylenamin in Pellagra

To the Editor:—Two weeks ago I began to treat a patient with well-defined pellagra in the second stage, with 15 gr. of hexamethylenamin, three times a day, with what seem to be remarkable results. The second night after the patient began to take the medicine, she slept 3 hours; the third night she slept 6 hours, and now for a week, she has slept all night and several hours during the day. Before this, the insomnia had resisted all ordinary narcotics. Within 4 days after the patient began the treatment all vertigo disappeared; also the numbness, tingling and burning. All these symptoms

had been constant and very annoying for 5 months previously. The urine became clear and the stools normal in frequency, color and odor for the first time in 6 months. The patient's improvement in every way was so remarkable that I took her yesterday to Dr. Beverly R. Tucker, of Richmond, Va., who confirmed my diagnosis. He informed me at that time that he also had treated several patients with hexamethylenamin, but in smaller doses, with excellent results. Do you think that this rapid improvement is due to the time of the year or are there other instances in which a patient has improved so rapidly? Hexamethylenamin is known to be a systemic antiseptic; on this fact I based the treatment.

I hope that others may try this and obtain the same satisfactory results.

B. B. BAGBY, West Point, Va.

Queries and Minor Notes

ANONYMOUS COMMUNICATIONS will not be noticed. Every letter must contain the writer's name and address, but these will be omitted, on request.

LITERATURE ON TUBERCULIN

To the Editor:—Please furnish references to the most recent literature on tuberculin treatment. M. N. C., Alabama.

ANSWER.—As our readers are aware, we often, in answering correspondents, give in this department lists of articles and books on various subjects, when we think that such lists will be of general interest. In many cases, however, we receive questions similar to the above, which we do not feel justified in answering in THE JOURNAL because of the Index which we publish every six months, and which is intended to answer such questions. It includes the principal articles published during the previous six months and it is in constant use by physicians everywhere. Its completeness and accessibility make it unnecessary in most cases for us to publish new lists of references. New readers are apt, of course, to overlook this feature of THE JOURNAL, and we therefore take space here to call attention to it. The following titles are selected from a list of over seventy references in the Index to the last complete volume, January to June, 1910, and from others to be indexed in the current volume:

- Adfrecht, E.: Tuberculin in Diagnosis and Treatment of Pulmonary Tuberculosis. *Berl. klin. Wchnschr.*, March 14, 1910; abstr. in THE JOURNAL, April 30, 1910, p. 1485.
- Baldwin, E. R.: General Principles of Tuberculin Diagnosis and Treatment, THE JOURNAL, Jan. 22, 1910, p. 260.
- Crowe, H. W.: A New Method of Treating Acute Pulmonary Tuberculosis by the Alternate Use of Human and Bovine Tuberculin. *Lancet*, London, 1910; abstr. in THE JOURNAL, May 21, 1910, p. 1727.
- Escherich, T.: Indications for and Results of Tuberculin Treatment of Tuberculosis in Children. *Wien. klin. Wchnschr.*, May 13, 1910; abstr. in THE JOURNAL, July 2, 1910, p. 94.
- Griffin, W. A.: The Use of Tuberculin at the Sharon Sanatorium. *Boston Med. and Surg. Jour.*, July 28, 1910; abstr. in THE JOURNAL, Aug. 13, 1910, p. 621.
- Hartwell, H. F., and Streeter, E. C.: Therapeutic Administration of Tuberculin in Surgical Tuberculosis. *Boston Med. and Surg. Jour.*, Jan. 6, 1910; abstr. in THE JOURNAL, Jan. 22, 1910, p. 319.
- Hawes, J. B., and Floyd, C.: Tuberculin Treatment of Tuberculosis in Dispensary Patients. *Boston Med. and Surg. Jour.*, Jan. 6, 1910; abstr. in THE JOURNAL, Jan. 22, 1910, p. 319.
- Neumann, J.: Treatment of Tuberculosis with Large Doses of Tuberculin. *Lancet*, London, 1910; abstr. in THE JOURNAL, March 12, 1910, p. 917.
- Raw, N.: Treatment of the Surgical Forms of Tuberculosis by Tuberculin. *Lancet*, London, March 26, 1910; abstr. in THE JOURNAL, April 23, 1910, p. 1410.

HOW TO BECOME AN F.R.C.S.

To the Editor: Please give requirements for obtaining the diploma of F.R.C.S. in England or Scotland. C. N.

ANSWER.—The diploma of F.R.C.S. is granted by the Royal College of Surgeons of England to a few distinguished persons in an honorary capacity. Each year, two persons who have long held the diploma of member may be elected to the fellowship. But the majority of fellows obtain the diploma by passing an examination which consists of two parts, the first covering anatomy and phys-

iology, which may be taken after completing three years of medical work, and the second covering surgery, surgical anatomy and pathology, which may be taken after six years of professional study. These examinations are held in May and November of each year and are partly written and partly oral. The second includes also a number of practical tests, such as the examination of patients and the performance of operations on the cadaver. The candidate must be 25 years of age and a graduate in medicine of some university recognized by the college or hold a diploma from some other British licensing body. The fees for admission to the fellowship, including the fees for the examinations, are 30 guineas, or about \$150. For candidates who already hold the membership diploma of the college the fee is 20 guineas (about \$102). The Royal College of Surgeons of Edinburgh seldom grants its fellowship except on the passing of one examination, and the fee is £45 or about \$215, or £35 for candidates who are already licentiates of the college. We suggest that our correspondent address a letter to the secretary of the Royal College of Surgeons, London (or Edinburgh, or both), stating what medical qualifications he now holds, where and when obtained and after what period of study, and asking what steps in the circumstances it would be necessary for him to take to obtain the fellowship of the college.

TREATMENT OF MORPHIN POISONING

To the Editor:—Please give in your Queries and Minor Notes department the chemical antidote for morphin poisoning, and explain its action. H.

ANSWER.—The most effective chemical antidote for morphin poisoning is potassium permanganate, which is believed to act by oxidizing morphin to oxydimorphin, which is non-poisonous. It should be employed as a solution to wash out the stomach. This is applicable even in cases in which morphin has entered the system by other channels, since morphin is excreted into the stomach. Precipitants of alkaloids, such as tannic acid, may act as antidotes by rendering the morphin insoluble.

LOCOMOTOR ATAXIA

To the Editor:—If locomotor ataxia is sclerosis of the posterior columns of the spinal cord, which are sensory, then why does it affect motion mostly? W. P. H.

ANSWER.—In locomotor ataxia there is degeneration of sensory fibers, chiefly those coming from the deeper tissues, such as the muscles, tendons and joints. As these fibers supply the muscular sense, this sense is to a large extent lost in locomotor ataxia. Hence the ataxia patient cannot regulate his movements, although in the earlier stages of the disease there is no loss of muscular power.

BOOKS ON CANINE SURGERY

To the Editor:—Kindly give references to books or literature pertaining to surgery on dogs, as well as anatomy of the dog and cat. O. M. S.

ANSWER.—There is no book devoted to the subject of surgery on the dog, all the literature on this subject being contained in scattered original articles treating each of certain features. The recognized authority on the anatomy of the dog is "Anatomic des Hundes," by Ellenberger and Baum, Berlin, 1891, published by Paul Parey. Rigard and Jennings' "Anatomy of the Cat," published by Henry Holt & Co., New York, is an excellent work on this topic.

The Public Service

Medical Department, U. S. Army

Changes for the week ended Oct. 29, 1910.

De Loffre, S. M., capt., relieved from duty at Fort Bliss, Texas, in time to enable him to comply with this order and will proceed to San Francisco and take the transport to sail for the Philippine Islands about Jan. 5, 1911, for duty.

Manly, Clarence J., major, granted leave of absence for one month on surgeon's certificate of disability.

Phelan, Henry Du R., Med. Res. Corps, relieved from duty at Fort De Russy, Honolulu, H. T., and will take the transport leaving Manila April 15.

The following officers are relieved from duty in the Philippine Islands and will sail from Manila to the United States on the date named: Jan. 15, 1911: Mocerlet, W. H.; Huntington, P. H., and Powell, W. A., captains, and Daywalt, George W., Med. Res. Corps, Feb. 15, 1911: Bloombergh, H. D., and Purnell, H. S., captains; Worthington, J. A., 1st lieutenant, and Le Hardy, J. C., and Lincoln, H. F., Med. Res. Corps, March 15, 1911: Davis, William B., colonel, April 15, 1911: Snyder, H. M., 1st lieutenant, and Bagby, E. W., and Ballard, J. C., Med. Res. Corps.

Hogan, David D., Med. Res. Corps, granted leave of absence for one month on his relief from duty at Fort Schuyler, N. Y.

Tetrault, C. A., Med. Res. Corps, at expiration of his present leave of absence ordered to Fort Micbie, N. Y., for duty.

Medical Corps, U. S. Navy

Changes for the week ended Oct. 29, 1910.

Brownell, C. D., surgeon, detached from the *North Dakota* and ordered to await orders.

Pleadwell, F. L., surgeon, detached from the bureau of medicine and surgery, Navy Department, and ordered to the *North Dakota*.

Shook, F. M., passed asst.-surgeon, granted sick leave for one month when discharged from treatment at the Naval Medical School Hospital, Washington, D. C.

McDowell, R. W., asst.-surgeon, granted sick leave for two months when discharged from treatment at the Naval Medical School Hospital, Washington, D. C.

Cather, D. C., passed asst.-surgeon, detached from the *Iowa* and ordered to the *Delaware*.

Whitmore, G. E., asst.-surgeon, detached from the *Delaware* and ordered to the *Connecticut*.

McDowell, R. W., asst.-surgeon, detached from the *Connecticut*.

Brownell, C. D., surgeon, ordered to duty at the naval hospital, Los Angeles, Oct. 26.

Kelley, H. L., passed asst.-surgeon, commissioned passed asst.-surgeon from June 6, 1910.

Lawrence, H. F., passed asst.-surgeon, commissioned passed asst.-surgeon from Sept. 21, 1910.

U. S. Public Health and Marine-Hospital Service

Changes for the seven days ended Oct. 26, 1910.

Trask, J. W., asst.-surgeon-general, granted 2 days' leave of absence from Oct. 24, 1910.

Carmichael, D. A., surgeon, granted 19 days' leave of absence from Nov. 15, 1910.

McIntosh, W. P., surgeon, granted 21 days' leave of absence from Nov. 11, 1910.

Wertenbaker, C. P., surgeon, leave of absence for 4 days, from Oct. 20, 1910, amended to read 2 days.

Young, G. B., and Wertenbaker, C. P., surgeons, detailed to represent the service at the annual meeting of the Association of Military Surgeons, to be held in Richmond, Va., Nov. 1-4, 1910.

Stimpson, W. G., surgeon, directed to proceed to Delaware Break-water (quarantine), Delaware, on special temporary duty.

Lavinder, C. H., passed asst.-surgeon, directed to proceed to Columbia, S. C., on special temporary duty.

Rucker, W. C., passed asst.-surgeon, directed to proceed to New York, Boston, Philadelphia and Baltimore on special temporary duty.

Frost, W. H., passed asst.-surgeon, granted 7 days' leave of absence from Oct. 18, 1910, under paragraph 191 of the Service Regulations. Granted 7 days' leave of absence from Oct. 25, 1910.

Ridlon, J. R., asst.-surgeon, relieved from duty on United States Revenue Cutter *Manning* and directed to proceed to Washington, D. C., and report to the Director of the Hygienic Laboratory for duty.

Marsh, W. H., acting asst.-surgeon, granted 11 days' leave of absence from Oct. 29, 1910.

Tappan, J. W., acting asst.-surgeon, detailed to represent the service at the meeting of the International Medical Association to be held in El Paso, Texas, Oct. 27-29, 1910.

Wakefield, H. C., acting asst.-surgeon, leave of absence for 14 days from Oct. 10, 1910, revoked. Granted 7 days' leave of absence from Oct. 18, 1910, under paragraph 210 of the Service Regulations.

Wilson, J. G., acting asst.-surgeon, granted 21 days' leave of absence from Nov. 4, 1910.

Medical Economics

THIS DEPARTMENT EMBODIES THE SUBJECTS OF ORGANIZATION, POSTGRADUATE WORK, CONTRACT PRACTICE, INSURANCE FEES, LEGISLATION, ETC.

LODGE PRACTICE IN NEW YORK CITY

Lodge practice, with its evils and dangers, is a prominent factor in the practice of medicine in other countries, notably England. Its growth and possible influence on physicians in this country has been much discussed. Frequent instances of disputes between local lodges and local medical societies, in the past few years, abundantly prove that this evil is increasing. This is strikingly illustrated in an article by Dr. Morris J. Clurman, of New York City, in the *Medical Record* (Oct. 22, 1910, p. 717).

Dr. Clurman states that, in the lower East Side of New York City, there are at present between 1,500 and 2,000 lodges consisting of societies and benevolent associations, founded mainly by the poorer class of working men, for the double purpose of social intercourse and mutual aid. Each of these societies elects some physician to take care of the local society members. As Dr. Clurman says, such an arrangement would

seem, at first sight, to be "reasonable, practical and eminently satisfactory." but, like Captain Cuttle's celebrated aphorism, "The value of the observation lies in the application of it." Dr. Clurman points out that the test of the value of such an arrangement is the practical manner in which its medical benevolences are administered. He gives a graphic picture of the experience of the lodge doctor 20 years ago and to-day:

"Twenty years ago, when lodge practice was in its infancy, societies would send humble delegates to some physician and ask him to accept the office of lodge doctor for a fair and reasonable consideration. In most cases, the physician thus approached would think twice before entering into such an agreement since, very naturally, routine family practice with its direct returns for every call seemed more remunerative than cheap contract practice. However, young and ambitious medical tyros naturally sought some means of getting patients to come to them and this seemed an easy way to help make both ends meet and also to obtain what seemed to be a legitimate and ethical way of advertising oneself.

"Tis true that for some years all physicians who undertook such lodge practice found in it a wonderful stepping-stone toward obtaining a medical reputation. The lodge doctor found that he came in contact at the sick bed with a large class of patients who would not have patronized him in any other way. In time, however, the lodge physician, after establishing a reputation as a busy practitioner—and perhaps as a good one—became more or less independent. He discovered that it now paid him to disentangle himself from the onerous duties of the lodge doctor and once more to resume straightforward family practice. What with the advertisement he had received, the numerous families who had employed him in the capacity of lodge doctor and the normal growth of his regular practice, he now found that financial affairs went smilingly with him even after giving up these societies. Very naturally such shining examples of medical success and pseudo-prominence came to be regarded with envy by others in the East Side profession and more especially those of the younger element.

"Hand in hand with the increased number of physicians on the East Side a keen competition now arose among them to be elected as lodge physician in as many societies as possible. . . . But now the quilt had been reversed. It was the doctors who sought after the societies and not vice versa, as formerly. The societies found that, inasmuch as physicians were so anxious to be their lodge doctors, they could well afford to discriminate and choose from the numerous candidates.

"At first the chief qualification for a physician who wished to be a lodge doctor were his medical skill and knowledge, but . . . it was not long before the physician with the best business instincts 'crawled and intruded' into the occupancy of these positions. The physician who knew how to ingratiate himself into the good-will of some of the individual leaders or more active members of these societies were almost invariably elected. At first, he simply had to be a 'good fellow' with them to become the holder of the coveted positions. In time, even that was not enough. He had to hold out more inducements, and these inducements naturally varied with the caliber of the men with whom he was dealing. Sometimes the judicious distribution of a few 'shekels' among the most influential of the society leaders brought the physician the necessary votes to elect him. Sometimes it was the unwritten promise of a bounteous blow-out to the members if he were elected. . . . It often happened that a worthy medical candidate would be defeated by his more Philistine colleague. It is easy to see what a deplorable state of affairs such an unequal competition has naturally and inevitably brought about."

The above might well be headed "The Evolution of the Lodge Doctor." The introduction of contract methods, competitive bidding, unprofessional and undignified competition and the giving of unlimited services for limited and inadequate compensation must inevitably result in degeneration of professional standards and services. The picture presented is commended to the careful consideration of all physicians who contemplate engaging in lodge practice, in the belief that it will serve as a stepping-stone to something better. In the great majority of cases, the steps lead down and not up.

After an equally vivid description of a society election, at which three or four physicians are rival candidates, and an account of an actual instance in the practice of an East Side

lodge doctor, as illustrating the contempt in which the contract physician is held by his patients, Dr. Churman continues:

"To-day there is scarcely an East Side working man who is not a member of some association which has a physician to take charge of its members. . . . With few exceptions the market price 'per head' is as follows: One dollar a year for the unmarried member and \$3 a year for every married member, including his family. Let us not forget that the East Side working man, when married, does not believe in race suicide. For these terms he [the physician] is supposed to make as many professional visits in time of sickness as he is called on to do. Very often he may be called on forty or even fifty times a year by one family. Time and again he is called for the most trivial of complaints since his presence is so easily obtained."

Dr. Churman is equally graphic in describing the effect of such a system on the young physician.

"Let us consider what little chance a young graduate now has on the East Side. If he happens to be a well-trained man from a good medical school, a hospital man and perhaps with a good preliminary medical education, it is all the worse for him. He will not be given a chance to practice medicine legitimately. A fair competition would be conducive to his medical progress, but when he discovers that commercialism has become the prime factor, it is not long before his lofty ideals are dragged and sullied in the dust. Especially is this true of the able but needy young practitioner. He soon discovers that the only way he can build up a practice is by getting lodges. Instead of devoting his spare time to perfecting himself in his medical knowledge he is compelled to devise ways and means for obtaining societies. The iron heel of necessity compels him to become proficient in the invidious art of winning out at society elections. His medical mind becomes warped, and instead of progressing ethically he gradually retrogrades into a proselyte of commercialism and a mere huckster of medical advice."

Dr. Churman's description of the degeneration of the young and enthusiastic medical graduate to the "commercial huckster" who has not time to keep abreast of the advances in medical knowledge is perfectly in harmony with the facts and emphasizes the frequently reiterated statement that the commercial and ignorant physician is not only a menace to the profession but a positive danger to the community.

After describing a routine day's work of a lodge physician with eight or ten lodges to look after and arriving at the very natural conclusion that as a result of lodge practice "the lodge doctor becomes careless and slipshod in his medical ways," Dr. Churman concludes:

"We are in too enlightened an age not to be able to remedy or at least to make lighter most evils, and the evil of lodge practice is one that can be solved and eradicated. To do this, vigorous and strenuous action must be taken by the East Side physicians. In the main it is only by a return to their medical ideals and by grappling these ideals to their souls with hooks of steel that they can solve this problem."

The only possible solution of the evils of lodge practice lies in the unanimous refusal of all competent and self-respecting physicians to engage in such work. County and local medical societies should discuss this question frequently and, above all, dispassionately and impersonally. Senior medical students should be told that such methods as a stepping-stone to independence and a competency are disappointing and lead, in the end, only to degeneration and ultimate degradation. Leaders of lodges and fraternal societies should be shown that competitive methods in the selection of professional men can lead only to securing the cheapest and poorest professional services and that the lodge that pays a pittance for its medical service can expect to secure only services commensurate in value to the compensation given.

Above all, the public should be informed that the lodge doctor is not a safe man to employ, since the large demands on his time and the number of calls required of him effectually prevent him from keeping abreast of medical progress and cause him to degenerate into a distributor of pills and draughts, careless in his methods of examination and hasty and often inaccurate in his diagnosis. When these facts are known election as a lodge physician will no longer be

regarded as a desirable step to an independent practice and the incentive for such ruinous and unprofessional competition will disappear.

POSTGRADUATE COURSE FOR COUNTY SOCIETIES

DR. JOHN H. BLACKBURN, DIRECTOR
BOWLING GREEN, KENTUCKY

[The Director will be glad to furnish further information and literature to any county society desiring to take up the course.]

Third Month—Fourth Weekly Meeting

NEPHROLITHIASIS

ETIOLOGY AND PATHOLOGY: Age, sex, water, diet, habits. Changes in kidney structure.

CHEMICAL VARIETIES: (1) Uric acid and urates, (2) oxalate of lime, (3) triple phosphates. Shape, size and number of calculi. Uric-acid, sodium-urate, and lime infarcts.

SYMPTOMS: 1. Aseptic cases. Pain, colic, urine. 2. Septic cases. Urine, chills, fever, sweats. Physical examination.

DIAGNOSIS: Value of x-ray, of wax-tipped ureteral catheter, exploratory operation. Differentiation.

TUMORS OF THE KIDNEY

VARIETIES: Benign, adenoma, fibroma, lipoma. Malignant, hypernephroma, sarcoma, carcinoma. Cysts of kidney, simple, retention cysts, and polycystic disease.

SYMPTOMS OF TUMOR: Hematuria, pain, tumor.

OPERATIONS ON THE KIDNEY

NEPHROPEXY: Indications. Incision, sutures, Brödel's suture. DECAPITATION OF KIDNEY FOR CHRONIC NEPHRITIS: History, indications, technic. (Edebohl's: Surgical Treatment of Bright's Disease.)

NEPHROTOMY: Indications; technic in detail.

NEPHROTRESIS.

NEPHROLITHOTOMY: Indications; technic.

NEPHRECTOMY: Total or partial, pericapsular or subcapsular, lumbar or abdominal. Technic in detail.

Monthly Meeting

The Significance of Hematuria, of Pyuria.

Indications for Nephrectomy; Technic of Operation.

Diagnosis for Treatment of Calculus in the Kidney; in the Ureter.

State Boards of Registration

COMING EXAMINATIONS

ARKANSAS: Regular, Little Rock, November 8-9. Sec., Dr. F. T. Murphy, Brinkley; Homeopathic, Little Rock, November 11. Sec., Dr. P. C. Williams, Texarkana; Eclectic, Little Rock, November 8-9. Sec., Dr. G. A. Hinton, Hot Springs.

CONNECTICUT: Regular, City Hall, New Haven, November 8-9. Sec., Dr. Charles A. Tuttle; Homeopathic, Grace Hospital, New Haven, November 8. Sec., Dr. Edwin C. M. Hall, 82 Grand Ave.; Eclectic, Hotel Garde, New Haven, November 8. Sec., Dr. Thomas S. Hodge, 19 Main St., Torrington.

FLORIDA: Palatka, November 9-10. Sec., Dr. J. D. Fernandez, Jacksonville.

LOUISIANA: Homeopathic, New Orleans, November 7. Sec., Dr. John T. Crebbin, 1207 Maison Blanche Building.

MAINE: City Council Rooms, Portland, November 8-9. Sec., Dr. Frank W. Searle, 806 Congress Street.

MASSACHUSETTS: State House, Boston, November 8-9. Sec., Dr. Edwin B. Harvey.

NEBRASKA: State Capitol, Lincoln, November 9-10. Sec., Dr. E. Arthur Cuff, 141 S. Twelfth Street.

NEVADA: Carson City, November 7-9. Sec., Dr. S. L. Lee.

TEXAS: Palestine, November 22-24. Sec., Dr. R. H. McLeod.

WEST VIRGINIA: Morgantown, November 14-16. Sec., Dr. H. A. Barbee, Point Pleasant.

Maryland June Report

Dr. J. McPherson Scott, secretary of the Board of Medical Examiners of Maryland, reports the written examination held at Baltimore, June 21-24, 1910. The number of subjects examined in was 9; total number of questions asked, 90; percent

age required to pass, 75. The total number of candidates examined was 117, of whom 95 passed and 22 failed. The following colleges were represented:

College	PASSED	Year Grad.	Per Cent.
George Washington University	(1907) 75	(1910)	79
College of Physicians and Surgeons, Chicago	(1908)		76
Johns Hopkins University	(1910) 78, 80, 81, 82, 82, 83, 84, 84, 85, 85, 86, 86, 88, 89		
University of Maryland (1909)	75	(1910) 75, 75, 75, 75, 76, 78, 79, 80, 80, 80, 81, 82, 82, 83, 83, 83, 84, 84, 85, 85, 86, 86, 87, 89, 89, 89	
Baltimore Medical College (1909)	75, 77	(1910) 75, 75, 76, 78, 80, 81, 81, 81, 82, 82, 83, 84, 85, 85, 86, 87, 88	
College of Physicians and Surgeons, Baltimore	(1907) 82; (1909) 81; (1910) 77, 82, 83, 84, 85, 86, 87, 88		
Maryland Medical College	(1908) 76	(1910) 75, 79, 90	
Woman's Medical College of Baltimore	(1910)		79
Harvard Medical School	(1910)		82
Jefferson Medical College	(1910)		80, 91
University of Pennsylvania (1910)	75, 75, 78, 79, 81, 83, 83, 86, 87		
University of the South	(1908)		75
Queen's University, Kingston, Ontario	(1888)		86
University of Dublin, Ireland	(1877)		79

FAILED

Howard University, Washington, D. C.	(1908)	72
Louisville and Hospital Medical College	(1908)	64
University of Maryland (1903)	56; (1909) 61, 66; (1910) 61, 66, 71, 72, 72, 73, 73	
Baltimore Medical College	(1901) 48; (1904) 67; (1910) 67, 68	
Maryland Medical College (1907)	65; (1909) 65; (1910) 53, 65, 70	
University College of Medicine, Richmond	(1908)	55

The following questions were asked:

ANATOMY

1. Give a general classification of bones and name a bone in each class. 2. Name structures transmitted through any four of these six foramina: foramen magnum, jugular foramen, sphenoidal fissure, foramen ovale, foramen rotundum, optic foramen. 3. What bones enter into formation of the nasal fossae? 4. Name cavities of the heart and describe the valves. 5. Locate the imaginary lines dividing the abdominal cavity into regions. Name regions and state contents of lower central region. 6. Describe the lachrymal apparatus. 7. Through what arteries is the collateral circulation carried on after ligation of subclavian artery (lower third)? 8. Locate and describe Peyer's patches. 9. What nerves supply the tongue? 10. Give origin, insertion, action and nerve-supply of the latissimus dorsi and biceps femoris muscles.

MATERIA MEDICA

1. What are alkaloids? What is an infusion? What is a decoction? Define fixed and volatile or essential oils. 2. Give two remedies of the following classes and the doses of each: galactagogues, sialagogues, emetics, antiseptics, anthelmintics, diuretics, antipyretics. 3. Give six official preparations of iron used internally, and give dose of each. 4. Cinchona: Mention the most important preparations and their doses. 5. Arsenic: Mention the official preparations and average dose of each. Give the official antidote for arsenical poisoning and how prepared. 6. Name five official acids used internally and give dose of each. 7. Name three preparations obtained from the animal kingdom and give source of each. 8. Give six official preparations of mercury used internally and dose of each. 9. Name five official powders, composition and dose of each. 10. Write a prescription using official terms containing compound tincture of gentian, tincture of nuxvomica and bicarbonate of soda. Write one containing reduced iron, arsenious acid, sulphate of strychnin and sulphate of quinin. One containing digitalis, nitrate of potassium and extract of buchu. One containing pepsin, subnitrate of bismuth and paregoric.

OBSTETRICS

1. Give general directions and preparation of the patient for labor and delivery. 2. What anesthetic should be used in labor, and the indications for use of each? 3. What conditions demand the emptying of the uterus prior to quickening, and what is the technic of the procedure? 4. What indications require the use of forceps, give the method of using them and the dangers of their use to mother and child. 5. What is the mechanism of labor in a breech presentation? 6. Describe Credé's method of expressing the placenta. 7. What are the common causes of hemorrhage during and after labor? 8. Give indications for and method of amputation of the cervix uteri. 9. Give causes and treatment of pelvic peritonitis. 10. What are the dangers to be avoided in performing a dilatation of the cervix and curetting of the uterus?

SURGERY

1. What are the signs of intestinal perforation in typhoid fever, and what is the surgical treatment? 2. Describe what is generally known as the radical operation for the cure of cancer of the breast. 3. Describe intubation of the larynx, laryngotomy and laryngotracheotomy. Give indications for each. 4. Give symptoms and treatment of acute catarrhal conjunctivitis. 5. Describe phimosi, paraphimosi, hypospadi, epispadi. 6. Describe two operations for cancer of the stomach. 7. Define the following operations: (a) enterotomy; (b) enterostomy; (c) entero-anastomosis; (d) enterectomy. 8. Define and describe the following diseases of the hip: (a) coxitis; (b) coxitis tuberculosa; (c) coxa vara. 9. Describe ectropion of the bladder, cause and treatment; (a) palliative; (b) operative. 10. Describe mastoiditis, acute and chronic, causes and treatment of each.

CHEMISTRY

1. Define (a) chemistry, (b) chemical compound, (c) chemical affinity and (d) chemical reagents. 2. What does the presence of an abnormal quantity of chlorin in drinking water indicate? Give

tests to determine its presence. 3. State the names and the general chemical and physical properties of the "halogens." 4. State of the two chlorids of mercury: (a) their names, (b) chemical formulas, (c) composition, (d) solubility, (e) color and other properties. 5. What are normal and decinormal solutions and how are they made? 6. Complete the following equations:

7. (a) State the specific gravity of normal urine, (b) causes of deviations in the specific gravity of urine, and (c) What is the reaction of urine during the formation of phosphatic calculus? 8. Give a chemical test for each of the following: (a) proteids, (b) phenol, (c) lactic acid, (d) amyllum, (e) croceate. 9. State of silver nitrate: its composition, properties and names by which it is known. 10. (a) Give tests and antidotes for nitric acid, (b) What are amalgams? (c) What are "indicators"? (d) Give a brief outline of the differences between "leucomaines" and "ptomaines." (e) What kinds of blood are distinguished and give the differences between them?

PRACTICE

1. Define (a) enteroptosis, (b) Ludwig's angina, (c) purpura, (d) myxedema, (e) angina pectoris. 2. Define (a) rabies, (b) ascaris lumbricoides, (c) empyema, (d) chololithiasis, (e) dysphagia, and give some of the causes. 3. Give differential diagnosis between measles and scarlet fever. 4. Give differential diagnosis between serofibrinous pleurisy and pneumonia. 5. Give differential diagnosis between hysteria and epilepsy. 6. Give treatment of a case of typhoid fever and the most frequent complications. 7. Give treatment of early pulmonary tuberculosis and state in detail what methods should be employed to prevent contagion from such a case. 8. Name types of chronic nephritis and symptoms of each type. 9. What diseases are likely to occur in the right inguinal region? 10. Give symptoms and treatment of gastric ulcer.

THERAPEUTICS

1. Name five antispasmodics and the general indications for their use. 2. Write two prescriptions in Latin, each containing four ingredients, one in dry, the other in liquid form, with directions for administration, and state the condition for which they are to be used. 3. What is an antitoxic serum? Name disease most amenable to serum therapy; give source of serum and describe method of administration. 4. What are the therapeutic uses of opium? Strvehin? Describe symptoms of poisoning by each. 5. Give the indications for venesection and describe the operation. 6. Give the physiologic action and therapeutic uses of colchicum. 7. Give the physiologic action, therapeutic use and effect of overdose and constant use of digitalis. 8. Describe purpose and method of introduction of vaccine lymph into human system and physiologic manifestations. 9. Give mode of action of cardiac sedatives, cardiac stimulants, cardiac tonics; name three of each. 10. What is meant by the terms "antagonists," "antidotes?" Describe uses and mode of action.

PATHOLOGY

1. State the method you would use in preparing a specimen of fresh kidney tissue for microscopical examination. 2. State the general principles of the methods used in isolating and identifying bacteria. 3. How would you prepare a specimen of sputum in order to demonstrate the presence or absence of tubercle bacilli? 4. Give the life history of the *Trichina spiralis*, and the pathology of a case of human trichinosis. 5. If you were given two specimens of serum and told that one was human and the other bovine, how would you proceed to differentiate them? Or, what is anaphylaxis, and what alarming symptoms are sometimes due to this phenomenon? (Answer either one of the above, but not both.) 6. What would you expect to be the macroscopic appearances of the abdominal viscera in a patient with typhoid fever dying of hemorrhage in the third week of the disease? 7. State in the order in which they occur the changes which lead from healthy lung tissue to a healed tuberculous cavity. 8. What changes, not local, may be noted during the course of, and what sequelae may follow, an attack of diphtheria? What is the best way to prevent these changes, and why? 9. What is arteriosclerosis? What are the common causes leading to this condition? Mention its effect on the heart and kidneys. 10. What changes in the brain may lead to, occur in, and follow a stroke of apoplexy, the effect of which is paralysis of the right side?

PHYSIOLOGY

1. (a) What is meant by muscular contraction? (b) What effect has temperature or veratrin on muscular contraction? (c) What is the difference between simple and compound or tetanic contraction, and what are the chemical changes in the muscle during contraction and rigor? 2. State briefly the general physiology of the nerve-cell and what is meant by the neuron doctrine? 3. (a) What is meant by the knee-jerk? (b) What use are the knee-jerk and spinal reflexes as diagnostic signs? 4. What changes take place during sleep, and what are the neuron and an-mia theories of sleep? 5. Give the composition of the blood, its reaction, specific gravity, temperature, difference between arterial and venous, the amount in the body and the time required for a complete circulation. 6. What is meant by blood-pressure and how determined? (b) What effect has menstruation on blood-pressure? (c) What effect has the blood-pressure in the arteries on the pulse rate? 7. Give the difference in each ingredient, between inspired and expired air, (b) the effect of work on the respiratory movement, (c) the cause of the first respiratory movement. 8. Give composition and specific gravity of the saliva and the gastric juice, and the composition and physiologic action of the pancreatic secretion; (b) which is the only secretion in the body containing a free acid, and what is the acid? 9. State the general physiologic importance of bile, and what would be the effect of complete occlusion of the bile duct. 10. Name the nerves of the submaxillary gland, and state in full the effect of stimulating each. (b) What is meant by the paralytic "secretion"?

Book Notices

LIPPINCOTT'S NEW MEDICAL DICTIONARY. A Vocabulary of the Terms Used in Medicine and the Allied Sciences, with their Pronunciation, Etymology, and Signification, Including Much Collateral Information of a Descriptive and Encyclopedic Character. By Henry W. Cattell, M.D., Editor of "International Clinics." Flexible Leather. Price, \$5. Pp. 1,198, with illustrations in the text. Philadelphia: J. B. Lippincott Co., 1910.

This dictionary possesses a number of excellent features, some of which are innovations, and a few less excellent. It appears to offer copious information, well arranged, and made more accessible by a good system of cross-references. The practice of referring to current literature and to other works of reference is a commendable one. Another satisfactory feature is the arrangement of such terms as "Krause's corpuscles," "van't Hoff's law," "Noguchi's method" under "Krause," "van't Hoff," and "Noguchi" instead of under the generic portion of the term. Since the proper name is constant and the generic word often variable (for instance, one person will speak of the "Wassermann method," another of the "Wassermann test," and a third of the "Wassermann reaction"), arrangement under the generic word is apt to be unsatisfactory. Preference is given throughout to arrangement under specific instead of general heads. In some instances this results in making information somewhat less readily accessible; for example, there are no tables of muscles, nerves, etc., from which each one can be picked out at a glance. Some items of information appear to be lost entirely in the shuffle; for example, we are unable to find Mallory's and Van Gieson's stains, either under "stain" or under "Mallory" and "Van Gieson." The definitions of proprietary substances are, as a rule, good.

A blemish which is not peculiar to this work is the insertion at separate points in the vocabulary of two forms of the same word, as, for instance, "gastrenteralgia" and "gastroenteralgia," without cross-reference from one to the other or any indication of preference.

It is difficult to understand the principle which guided the selection of illustrations; for instance, portraits, however eminent the subjects, seem out of place in a work which makes no pretense of occupying the place of a biographical dictionary; and it seems equally unsuitable to fill space in a medical dictionary with illustrations showing elementary botanical facts.

The work is made a guide to capitalization by confining the use of capitals to words which are always capitalized, such as proper nouns. This is a very useful feature. It is a pity that this dictionary could not also have distinguished abbreviations from symbols and uncontracted words in the vocabulary by omitting periods after the unabbreviated expressions. Phonetic pronunciation is not given, but division of words into syllables is indicated. The spelling "anæsthesia," "œsophagus," etc., are preferred to "ane-sthesia," "esophagus," which is to be deplored as a step backward.

On the whole, however, the book is a very creditable and useful piece of lexicography.

THE DIAGNOSIS OF SMALLPOX. By T. F. Ricketts, M.D., Medical Superintendent of the Smallpox Hospitals and of the River Ambulance Service of the Metropolitan Asylums Board. Illustrated from Photographs by J. B. Byles, F.R.C.S., Senior Assistant Medical Officer at the Smallpox Hospitals of the Metropolitan Asylums Board. Cloth. Price, \$6 net. Pp. 154, with 136 illustrations. New York: Funk & Wagnalls Co., 1910.

The authors of this book have seen small-pox and write from knowledge gained through personal experience with the disease. This fact gives confidence and assurance of safe guidance to the inexperienced when struggling to make a diagnosis with information derived from books alone. The book, though not free from serious faults, is a painstaking and valuable presentation of the diagnosis of small-pox. The authors have especially emphasized the value of the distribution of the small-pox lesions as an aid to diagnosis. The distribution of the eruptions in small-pox has always been of much value in making a diagnosis, and we should never neglect to scrutinize closely the location of the lesions and give due weight to the findings, but the authors have laid greater stress on the distribution of the lesions as a guide to diag-

nosis than is generally given to this feature of the disease. They really overestimate this factor in diagnosis, but it is gratifying to see this feature of small-pox so thoroughly presented. An experienced diagnostician will not depend on this sign with as much confidence as the authors would have him, and the inexperienced who rely on it to the extent advised will certainly come to grief. It is but fair to say, however, that the authors, after discussing distribution, call attention to the numerous exceptions to the rule which they make so prominent.

The illustrations are good and give as perfect a picture of the skin lesions as the photographic art can make. For the most part, they are in duplicate; that is, two pictures of the same subject are placed side by side on the same page, to be viewed through a stereoscope. They are perfect enough for diagnostic purposes when viewed by the unaided eye, but seen through a stereoscope the picture is almost as satisfactory as that seen when looking at the living subject.

There is, however, a very serious fault in presenting all these fine photographs, and no doubt the authors have discovered it before this. Certainly they will see the fault as soon as their attention is called to it. In order to make a diagnosis in small-pox it is of the greatest importance that we know the life history of a lesion; that is, how many days old the lesion is. A photograph of a case of chicken-pox on the fifth day of the eruption may look to the eye identical with a photograph of a case of small-pox on the twelfth day of the eruption. For example, Plate XIV is said to be from a photograph of a case of small-pox; but no one could make the diagnosis of small-pox from the picture without knowing the number of days these lesions have existed. If it is small-pox, it is the twelfth or thirteenth day of the eruption. If the case looks like this on the fifth day it would certainly be chicken-pox. And distribution in this very picture would not save the diagnostician from error if he knew not the day of the eruption. Plate CIX shows chicken-pox; and the lesions must be not more than five days old. Hundreds of cases of small-pox look like this when photographed on the twelfth or thirteenth day. An experienced diagnostician could make the diagnosis in these cases, perhaps, without knowing how old the lesions are; but in this book photographs are used to teach the inexperienced; and this cannot be done if the day of the eruption is not known. This is a defect that can easily be remedied in a second edition. The day of the eruption should be noted below all the photographs.

The colored plates are valuable to those who are not familiar with the natural color of the eruptions of the various diseases presented. These are taken by the Sanger-Shepherd process and give the natural color of the skin lesions.

The chapter on vaccination is sound and can be safely followed. The publishers have done their work well, not forgetting to name a high price for the book—six dollars.

AIDS TO MICROSCOPIC DIAGNOSIS (BACTERIAL AND PARASITIC DISEASES). By Ernest B. Knox, M.D., Diplomat in Public Health (Honors), Royal Colleges of Physicians and Surgeons, Ireland. Cloth. Price, \$1 net. Pp. 156. New York: William Wood & Co., 1910.

This is practically an epitome, and is intended to serve the purpose of a review of the subject only. The title is misleading, because the book contains much that is entirely foreign to microscopic diagnosis, such as prophylaxis and treatment, and inasmuch as other works cover the same ground to better advantage, there really does not seem to be any *raison d'être* for this book.

AMERICAN RED CROSS ABRIDGED TEXT-BOOK ON FIRST AID: A Manual of Instruction. Industrial Edition. By Major Charles Lynch, Medical Corps, United States Army and First Lieutenant M. J. Shields, Medical Reserve Corps, United States Army. Prepared for and endorsed by the American Red Cross. Paper. Price, 30 cents net. Pp. 175, with 49 illustrations. Philadelphia: P. Blakiston's Son & Co., 1910.

This book is a manual of instructions for workers in the industrial field with especial reference to mine workers, abridged with great care from the "American National Red Cross Text-Book on First Aid and Relief Columns," by the same author, prepared for, and endorsed by, the American National Red Cross.

Medicolegal

Constitutionality of Order of School Board Requiring Vaccination

The Court of Civil Appeals of Texas says, that it was contended in the case of *McSween vs. Board of School Trustees of the City of Fort Worth* (129 S. W. R. 206), that an order of the school board, requiring the vaccination of pupils as a condition precedent to attendance in the public free schools of the city, was in contravention of the provision of the state constitution, that "the legislature may pass laws prescribing the qualifications of practitioners of medicine in this state and to punish persons for malpractice, but no preference shall be given by law to any school of medicine." But the court does not agree with the contention, because, as shown by the language quoted, it is evident that the restriction therein imposed was intended to apply to legislation only which might be enacted prescribing the qualifications of practitioners of medicine.

Furthermore, the order adopted by the school board, excluding from the schools all pupils who should refuse to be vaccinated unless successfully vaccinated already, merely prescribed a condition on which the right of pupils to attend the schools should depend. It gave the pupils who had not been successfully vaccinated the choice to be vaccinated and attend school, or to refuse to be vaccinated and remain out of school until the danger of small-pox had passed. It did not compel vaccination, and, therefore, was not in violation of the provision of the state constitution that "the people shall be secure in their persons, houses, papers and possessions from all unreasonable seizures or searches.

Nor does the court agree with the contention that the power vested in the board of city commissioners, by the city charter, to enact laws, rules and regulations for the promotion of health and the suppression of disease, left the school board without authority to adopt the order complained of. The provisions in the city charter that the board of school trustees should adopt such rules, regulations and by-laws as they might deem proper, and that the free schools of the city should be under the control and supervision of such board, which should have the power to control, manage and govern said schools in all things and matters, etc., were sufficiently comprehensive to include the delegation to the school board of authority to pass the order. In case of an epidemic of small-pox, unquestionably it could have closed the schools temporarily, if the trustees should be convinced that to continue them would result disastrously to the health of the pupils. Such an order would have excluded all pupils, and it would have been valid even though the purpose of its adoption were to protect the health of the pupils. It cannot be said that in the adoption of the city charter the legislature intended to deny the school board power to adopt sanitary regulations for the schools. Indeed, the court thinks a contrary intention was apparent from the provisions of the charter with reference to the powers of the school board. If correct in this, the board was authorized to adopt any reasonable regulation to effect the purpose sought to be accomplished.

The order in question was the exercise of police power for the protection of the pupils of the public schools, and, therefore, was not unconstitutional as depriving of liberty without due process of law.

Legal Insanity and Epilepsy

The Supreme Court of Wisconsin says, in *Oborn vs. State* (126 N. W. R. 737), that the term "insanity," as used in the special plea in a criminal case, means such abnormal mental condition, from any cause, as to render the accused at the time of committing the alleged criminal act incapable of distinguishing between right and wrong, and so unconscious at the time of the nature of the act which he is committing, and that commission of it will subject him to punishment. True, there are things in some of the cases liable to lead to the belief that legal insanity may exist if, though the person

be fully conscious of the wrong and its punishable character, he because of a perverted mind, is moved by an uncontrollable impulse.

This court, however, is not committed to the doctrine that one can successfully claim immunity from punishment for his wrongful act, consciously committed with consciousness of its wrongful character, on the ground that, through an abnormal mental condition, he did the act under an uncontrollable impulse rendering him legally insane. One, at his peril of punishment, commits an act while capable of distinguishing between right and wrong, and conscious of the nature of his act. He is legally bound, in such circumstances, to exercise such self-control as to preclude his escaping altogether from the consequences of his act on the plea of insanity, though his condition may affect the grade of the offense. Thus far the charity of the law goes and no farther.

Nor does proof of epilepsy necessarily directly establish insanity, as epilepsy is not, as a matter of fact or law, insanity, though evidence of an epileptic condition may bear, circumstantially, on the mental condition of the afflicted person to the extent of establishing insanity. As the court reads the cases cited to it, they are to the effect that a person may be an epileptic and be perfectly responsible for his actions, except when suffering from an epileptic disturbance, called a fit; that epilepsy may cause insanity, but does not constitute it, and the two should not be confounded. That a person afflicted with insanity may yet have capacity to distinguish between right and wrong, and if so he is legally sane. That it is not sufficient to establish irresponsibility to show epileptic affliction, but it must be shown by evidence as a fact that epilepsy is a disease which affects the mind, or produces insanity, and that there was legal insanity in the given instance.

Therefore, whether the accused, in any given case, was afflicted with epilepsy, and if so whether the affliction was a mental disease or had impaired his mind, and if so whether sufficiently to render him unable to appreciate between right and wrong, are matters of fact to be established by evidence.

Pregnancy, Childbirth, Sound Health and Insurance

The Supreme Court of Idaho holds, in *Rasicot vs. Royal Neighbors of America* (108 Pac. R. 1048) that an agreement or stipulation in a contract of insurance made with a married woman that the policy shall not go into effect unless it is delivered to her "while in sound health" is not violated by reason of the applicant being pregnant at the time of the delivery of the policy.

Pregnancy, the court says, is not *per se* a condition of "unsound" health, nor is it a "disease" or "ailment" within the meaning of those terms used in this application and policy. The term "sound health" has been frequently defined by the courts, and, so far as the court is advised, it has never been held that this term used in an insurance policy or certificate covered every slight ailment or indisposition of health of a temporary character which does not tend directly to shorten the life or undermine the constitution of the insured. So far as the court is informed, this term of itself and standing alone has never been held to cover or include a case of pregnancy.

So, also, a statement made by a married woman who applies for insurance in a fraternal benefit society that she has not consulted with a physician "in regard to a personal ailment" within the last seven years does not cover a single attendance by a physician on the applicant some three years prior thereto when she was confined and gave birth to a child. Confinement in childbirth is not a "personal ailment" within the meaning of such a provision in the contract. Childbirth is a physiologic fact which occurs in the regular course of Nature, and neither signifies nor entails disease or ailment in the usual and ordinary use of those terms.

But, besides all this, the court holds that where a fraternal benefit society received an application from a woman for insurance which warranted the literal truth of the answers given by her, and she represented, and at the time honestly believed, that she was not pregnant, when in fact and truth she was, and the contract provided that the society would

not become liable in such a case and that it would not consider such an application until at least two months after confinement, and the society collected and received dues, assessments and premiums from the insured for a period of nearly five years thereafter, during which time the applicant was in good health, the insurance society will be held to have waived the right to insist on a breach of the contract for the falsity of the answer.

INDIANA STATE MEDICAL ASSOCIATION

Annual Meeting, held at Fort Wayne, Sept. 28-30, 1910

The President, DR. T. C. KENNEDY, Shelbyville, in the Chair

Officers Elected

A list of the officers elected was published in THE JOURNAL, Oct. 8, 1910, p. 1293.

The Wassermann Reaction and Its Value to the Physician

DR. W. T. MEFFORD, Chicago, besides giving the general principles in regard to the uses of the Wassermann test, reported his experience in this work. The value of the test was shown particularly in cases of obscure diagnosis in which the reaction proved positive, and in which the patient then being put on mercurial treatment, rapidly improved.

Serodiagnosis of Syphilis

DR. J. P. SIMONDS, Indianapolis: The phenomenon of bacteriolysis, first demonstrated by Pfeiffer in 1894, gave to the study of immunity an importance it had not before possessed. It has been shown that:

1. There is in the blood serum of a syphilitic patient an antibody which, in the presence of extract or syphilitic liver or solution of lecithin, has the power of binding or absorbing complement, and thus of preventing hemolysis when red-blood corpuscles and hemolytic amoebocytes are added.

2. This principle has been utilized in a test which is highly specific for syphilis, so that we are probably justified in saying that any patient whose serum gives a positive reaction still harbors the syphilitic virus.

3. This test is of unquestionable value to the practitioner in differential diagnosis, in solving the difficult problem of when a syphilitic may safely marry, and, if not in actually controlling, at least in directing the treatment of the patient.

Discussion on Serodiagnosis of Syphilis

DR. C. G. BEALL, Fort Wayne: Following the Wassermann announcement of this test for syphilis, many attempts have been made to determine the presence of syphilitic virus by simpler methods. Principal among these was an attempt to get a precipitate in the serum of luetic individuals by means of a solution of liver salts. The consensus of opinion now is that the precipitate test was practically worthless. A more simple recent test is that of Nicolas, Favre and Gautier, by the introduction beneath the skin of a preparation called syphiline, which is a syphilitic extract. Like tuberculin, it is used on and beneath the skin. Results have been reported in fifty cases, and in 42 per cent. they agreed with the Wassermann reaction. Another test for the same purpose has been the cobra-venom test. However, this has the same objections that the Wassermann has or the Noguchi modification, because of the experience that is necessary to obtain reliable results. Recently it has been found that the reaction occurs frequently after ether narcosis. I have made about forty tests, and they agreed fairly well with the clinical diagnosis, yet my results are not to be relied on, because of the extreme technical skill required in making the test, and the

number of errors that are apt to appear. Kaplan made 300 tests before he felt competent to draw any conclusions. Naturally, this puts the test beyond the ordinary man's power.

DR. C. F. NEU, Indianapolis: It is unfortunate that in a test that is apparently so valuable there are so many difficulties in the application. When one takes into consideration the details that have to be watched, and the minutiae so necessary to carry out the operation, one can readily understand that it is not practical for the ordinary practitioner. It can be carried out only by one who devotes his time and attention to laboratory methods.

It should be borne in mind that the tests are negative in from 8 to 10 per cent. of cases in which there is positive evidence of syphilis, and the positive reaction is given in other conditions besides syphilis. The Wassermann reaction has been reported positive in cases of scarlet fever, tuberculosis, leprosy, meningitis and malignant growths. It is true that there might have been some syphilitic conditions present, but the mere facts that in from 8 to 10 per cent. of syphilitic cases the Wassermann reaction was negative, and that a positive reaction is obtained in other conditions besides syphilis, makes it very important that these points be kept in mind.

DR. W. R. DAVIDSON, Evansville: The consensus of opinion seems to be that the test should be limited only to expert laboratory workers, and yet almost in the same breath the recommendation is made that everybody who treats lues should make this test. If the work is good, certainly it should be carried out more extensively; but in the nature of things it would be impossible for me, for instance, to make this test every day. Would it be advisable for me to go on and work with it?

DR. H. R. ALBURGER, Bloomington: I think that the wisest plan for the man doing ordinary clinical diagnosis, if he does want this test, is to put it in the hands of a man who is specializing on it. I believe it is only a question of a short time until this test will be put on a practical basis for general use, but the general practitioner must as yet depend on the men in the laboratories to do that sort of work for him. I believe that the reason we get positive results in cases that are negatively syphilitic is that we have all inherited some immunity to syphilis.

DR. JOHN A. MACDONALD, Indianapolis: Dr. Alburger has perhaps unintentionally sounded a note of warning. By the very nature of the work it must be in the hands of men who are prepared to do it. There are few men in any community who are prepared to do this work correctly. If we overload them with work we shall get unsatisfactory or delayed results. This, however, does not impair the value of the reaction; it should only produce an economy in its use. If we limit its use to decisions of the possibility of marriage in certain forms of syphilis or to those cases in which doubt arises, and to conditions of the central nervous system, then we have done quite enough at the present time.

There are two diseases which are very similar in our hands—syphilis and malaria. If an error of 8 per cent. in the Wassermann reaction be admitted, we must go right back to the therapeutic test. Consequently, we give a man quinin and iron and the usual treatment for malaria, and with the patient with suspected syphilis we go ahead and give him mercury, and he recovers or improves if he has syphilis.

DR. THEODORE POTTER, Indianapolis: Dr. Davidson's question remains unanswered. The most important feature of this question, I think, is to get the mass of the profession to understand what a test of this sort is and what a laboratory method is, and to use it rationally and operate with the laboratory men. We have the idea that laboratory tests are perfect and infallible, and we misjudge the reports of the laboratory men and do harm to the whole cause. It was so with the examination for tubercle bacteria. It is so still in many instances; if the patient's sputum is examined for tubercle bacilli with negative results, the physician often and the patient generally conclude that the latter is not tuberculous. We are to blame for such misinterpretation. We should join with the laboratory men in working the matter out, but we should not make the mistake of thinking that the reports are all infallible, or that the test is always absolutely final.

I like Dr. McDonald's suggestion that, so far as possible, we reserve the application for the test to cases in which it is really needed, and not call on the laboratory men to make the Wassermann test in a perfectly plain case of syphilis.

DR. W. T. MEFFORD, Chicago: All laboratory men and men who have written on the technic make it seem extremely difficult. They frighten people from attempting to learn it. It is a very simple matter. There is not a man or woman here whom I cannot teach to do this test in two days. The materials are standardized and prepared all ready for use, and anyone can take the serum and do the work, after one or two days' experience. The best laboratory worker we ever had was a young woman 18 years old, and it was not two weeks until she was doing the work as perfectly as I could. One afternoon I taught another to do laboratory work for Dr. Butler, who is an expert in the Wassermann test, and he told me that she was as good a worker as he ever saw. In my opinion we all ought to learn to do this test. The materials necessary are: an incubator (\$35), a centrifuge (\$30) and a few test-tubes. Langstein introduced the drop method of doing this work. I use it and find it absolutely correct. As to the absolute necessity of having all the materials exact, it is necessary to have exact only the luetic liver, the serum, the complement and the amboceptor. Ten drops of the salt solution can be put in a test-tube and it works just as well as another amount. Some corpuscles give off more serum than others, so one will not have the exact number of corpuscles anyway.

DR. J. P. SIMONDS, Indianapolis: My experience has convinced me that the serum test for syphilis is by no means a simple one; that it is exceedingly delicate and useful; but that if improperly done it may lead to great confusion in diagnosis. The mere mechanical manipulation of reagents and apparatus necessary to making the test is comparatively simple. But in all work in hemolysis the opportunity for error is very great and often comes from sources entirely unexpected. Hence I do not believe that the work of a man who knows only the mechanical side of the test without a thorough knowledge of the underlying principles can be relied on. Unless one has accurate amounts of amboceptor one is likely to get either a positive or a negative reaction where one should not. The only way to determine the amount which is accurate is to restandardize very often. This applies to the antigen, which must be restandardized occasionally. In order to restandardize reagents one must understand the principles of hemolysis. Mere mechanical skill is not sufficient. It is often stated that reagents dried on filter-paper will keep almost indefinitely. At the Indiana State Laboratory we had one test-tube of the fluid serum and a lot of the dried filter-paper slips. For some reason, to our great surprise, the serum that was dried on the filter-paper deteriorated first. That is entirely contrary to the teachings of the text-books. Our fluid serum has lost very little of its original potency, but had to be restandardized. This experience is an illustration of the unexpected things that may happen.

As a further illustration of the ease with which a mistake may occur, it has been found that a very slight variation in the acidity of the reagents may entirely change the results of the test. Sachs and Altman tested serum with reference to the influence of alkalinity on the reaction, and found that if 1/800 to 1/3,200 normal sodium hydroxid solution were added, the syphilitic reaction with known positive serums could be abolished. But if to this alkaline serum enough hydrochloric acid was added to bring it back to the proper reaction, a positive result would be obtained. Not infrequently, an exceedingly slight variation in the alkalinity or acidity of a serum, such as might be produced by unclean test-tubes, may entirely vitiate the result. I must say, however, that Sachs and Altman found that varying the reaction in non-syphilitic serums would never make them react positively. I believe that the test done by the average busy practitioner would give results more confusing than enlightening, and that it should, therefore, be done only by regular laboratory workers who are well equipped with all necessary apparatus and who thoroughly understand the principles of hemolysis.

(To be continued)

MEDICAL SOCIETY OF THE STATE OF PENNSYLVANIA

Sixtieth Annual Meeting, held at Pittsburg, Oct. 3-6, 1910

(Continued from page 1582)

Treatment of Croupous Pneumonia

DR. G. W. NORRIS, Philadelphia: The most important therapeutic indication in pneumonia is to prevent toxemia. Many of the drugs employed are worse than useless. Serotherapy has proved of no value, as also that with leukocytic extracts. It is still too early to be dogmatic concerning the efficacy of vaccine therapy, although the results so far have been somewhat promising. Death in pneumonia is generally the result of toxemia, and, to a considerable extent, is independent of the amount of pulmonary involvement. In its production vasomotor failure plays a much more prominent part than heart failure. This fact is still not sufficiently appreciated, and hence treatment is often misdirected and inefficient. All drugs and methods of treatment which tend to lower blood pressure are therefore contraindicated.

Public and Private Aspects of the Pneumonia Question

DR. W. C. WHITE, Pittsburg: I here suggest two plans for a systematic crusade against pneumonia: (1) the discovery of a specific cure; (2) the inauguration of a popular campaign of education and instruction in the laws governing the prevention and cure of pneumonia similar to, and involving the same scope as the plan already utilized for the reduction of the mortality from tuberculosis.

Effect on the Different Forms of the Leukocytes in Cases of Tuberculosis Produced by Some Therapeutic Measures

DRS. SOLIS-COHEN AND STRICKLER, Philadelphia: One hundred and thirty-five leukocytic counts were made on 25 patients with pulmonary tuberculosis. Bier's suction hyperemia in cases suitable for this treatment causes an increase in the proportion of lymphocytes and of polymuclear cells with one and two nuclei. Application of fly blisters every five days and the absorption of the serum cause an increase in the proportion of polymuclear cells with one and two nuclei, and, in most instances, an increase in the proportion of lymphocytes. Iodin in the form of iodoform, administered by mouth, causes an increase in the proportion of polymuclear cells with one and two nuclei. Creosote given in the form of the carbonate, as a rule, causes an increase in the proportion of the lymphocytes and of polymuclear cells with one and two nuclei. Nuclein seems to cause an increase in the proportion of polymorphonuclear neutrophils. The effect produced in the blood by many therapeutic measures is not, as a rule, maintained indefinitely, but only for a variable period, averaging about a month.

Enuresis from Thyroid Insufficiency

DR. E. BOSWORTH MCCREADY, Pittsburg, read this paper, in which he formulated the following conclusions: 1. There is a large class of individuals which includes many of those who, as children, show various developmental defects, whose condition may be traced to a primary defect in the ovum, resulting from disease in the progenitors. 2. The resulting cell hypoplasia involves the structural elements of the ductless glands. 3. Enuresis is a very common symptom of hypoplasia. 4. The administration of thyroid extract will not only relieve the enuresis, but will also cause a marked improvement in the general physical and mental condition.

Mental Disturbance Following Traumatism. Medicolegal Considerations

DR. ALFRED GORDON, Philadelphia: I have studied thirty-seven cases during a period of 8 years, and have formulated the following conclusion: Trauma may be a determining cause of abnormal psychic manifestations, following immediately, or sometime later. Their appearance weeks after the shock excites the suspicion of their existence in a mild form immediately following the accident. Confusional states and delirium are the most frequent forms of insanity following traumatism.

Dementia may be the ultimate result of persistent confusional and delirious states. Traumatic psychoses do not present a strictly defined morbid picture, but present a great variety of psychic manifestations.

Present Status of Psychotherapy

DR. E. E. MAYER, Pittsburg: Physicians should well understand what they mean by the term psychoneurosis. We are apt to speak of neurosis when we do not mean neurosis. For example, we refer to gastroneurosis, when we know there is no underlying physical defect, but a mental factor at play and, therefore, that the condition is not a gastric condition, but a psychic state. That which should be done is to get at the patient's mental state, ascertain what things are troubling him mentally. The treatment of these conditions has a technic just as important and just as complex as that of any physical disease.

Traumatic Neurosis

DR. J. L. SALINGER, Philadelphia: The existence of traumatic neurosis as a nosologic entity is still denied by some of the most prominent neurologists. The causative factor is trauma, but there are many predisposing conditions. The litigation which frequently ensues after accidents is a large etiologic factor. The symptomatology consists largely of mental phenomena. If proper and speedy adjustment of the patient's claims is impossible the neurosis is apt to be prolonged. Litigation hysteria and traumatic hysteria must be strictly differentiated. Following an accident only when the presence of symptoms that were not previously present are demonstrated, can a causal connection between trauma and disease be regarded as probable.

Discussion on Neurosis

DR. T. DILLER, Pittsburg: While the claims of the subjects of traumatic neurosis are still unsettled there is practically no treatment for these patients. I should hesitate to attempt an analysis of the mental troubles of patients as suggested by Dr. Mayer. I have practiced the old-fashioned psychotherapy, that of ordinary sympathy, re-education, suggestion, and that sort of thing, but I should feel that we were getting into pretty deep water to follow Dr. Mayer's plan.

DR. T. A. WILLIAMS, Washington, D. C.: The general practitioner should disabuse his mind of the idea of there being special difficulty or complexity in psychotherapy. Psychoanalysis is no more difficult or impossible than chemical analysis. However, it requires a technic of its own and a thorough knowledge of the subject. This knowledge may be acquired by any one willing to take the trouble.

DR. A. GORDON, Philadelphia: There is no rule in regard to recovery in cases of litigation following traumatic neurosis. I have had cases in which the neurosis persisted in spite of satisfactory settlement of litigation.

DR. E. E. MAYER, Pittsburg: It is the physician's duty to find the cause of the trouble, be it physical or mental. I do not doubt that Dr. Diller really practices psychotherapy, though he may not dignify it by the name.

DR. J. L. SALINGER, Pittsburg: I should regard the cases mentioned by Dr. Gordon as persisting in spite of receiving indemnity as not cases of neurosis, but of organic disease.

Treatment of Acne Vulgaris

DR. JOHN G. BURKE, Pittsburg: The usual constitutional measures against constipation, anemia and sluggish circulation must be carried out. Additional constitutional agents are the bacteria, though the results cannot be relied on to the exclusion of other remedies. Stock vaccines have been of little service, the best results having been obtained with a mixture of the acne bacilli and *Staphylococcus aureus*. A preparation containing beta naphthol, 5 per cent.; precipitated sulphur, 20 per cent.; green soap, 35 per cent., and wool fat, 35 per cent., has been of service. The x-ray will cure acne, but the tendency to produce atrophy of the skin with the resulting telangiectasis should make one hesitate to use it, as we may replace a curable disease with an incurable one.

Diagnosis of Hay-Fever in Children

DR. W. C. HOLLOPETER, Philadelphia: Hay-fever is essentially a disorder of early life. It is the sequel of hay-fever, annually repeated, that we find eventually seriously handicapping mature life in the form of asthma, emphysema, and cardiac and renal troubles. It is because hay-fever may be called anything rather than what it really is, especially in children, that so much uncertainty is caused in its early diagnosis. Hay-fever, like diphtheria, is a local expression of a systemic toxemia, and for its relief often calls for the making-over of the child physically as well as mentally.

Subacromial Bursitis: Etiology, Anatomy and Pathology

DR. A. R. ALLEN, Carlisle: Sepsis, traumatism and non-use are the causes of subacromial bursitis. The abnormal conditions found in these cases are thickening of the bursal walls, adhesions and adhesive bands. In some cases cheesy deposits occur.

Treatment of Subdeltoid Bursitis

DR. J. T. RUGH, Philadelphia: Inasmuch as the seat of the trouble is in close relation to the shoulder-joint, the restoration of function will be accompanied by pain. The fact that treatment will extend over a prolonged period of time must be impressed on the patient and his will power and fortitude must be developed to secure and maintain the thorough cooperation so essential to success. Many of these patients unfortunately are of the nervous, shrinking and pessimistic type, a fact which renders the labor and efforts of the surgeon doubly hard, as he must overcome their tendency to give up after a week or two of painful experience. A necessary adjunct to be constantly held out to the patient is the fact that the condition is curable, no matter what the character of the lesion in the bursa.

Discussion on Bursitis

DR. D. SILVER, Pittsburg: I find in these, as well as in post-operative cases, that it is much better to put them up to the full limit of motion once a day, then let them alone. I have not found it necessary to use a splint, but keep the arm in a sling and use manipulation. Put these patients through the whole range of motion and they come out very nicely. I think we are in error in diagnosing these cases as rheumatic instead of trying to find out what the real condition is.

DR. W. H. CAMERON, Pittsburg: I deal almost entirely with subacute and chronic cases and some patients with supposed rheumatism come to my office, and I seldom find that they have been examined.

DR. T. T. THOMAS, Philadelphia: Besides clinical observations, I have been making some studies on the cadaver in the last year in connection with these cases. I know that the bursitis theory is being rapidly and generally accepted in this country and is gaining ground abroad, still I do not believe that the cause of the trouble in these cases is in the bursa. I believe the condition is due to a peri-arthritis, but not to one localized to the bursa.

DR. G. G. DAVIS, Philadelphia: I believe that there is such a thing as a bursitis which is induced by disease in the same way that a person can get housemaid's knee in rheumatoid cases; also, I think that bursitis, subacromial or subdeltoid, can be due to an injury. When the joint is moved it moves to a certain extent, and then it is stopped by the ligaments. It is not stopped by the bursa. The bursa have nothing to do with the strength of the joint.

Traumatic Lesions of the Brachial Plexus and its Component Roots

DR. C. K. MILLS, Philadelphia: Lesions of the brachial plexus and its component roots are usually of traumatic origin. The few cases not instances of traumatism being examples of a neuritis, due to infection or toxemia, and rare cases of neuro-mata and of hemorrhage into the plexus or its roots. The diagnostic points of most value in distinguishing this condition from hysteria are the absence of atrophy, electrical changes in the nerves and muscles, and also the retention of the deep and superficial reflexes in the hysterical case. The sensory changes, if carefully studied, have a different topog-

raphy, those of hysteria being glove-like, or assuming some other form not related to the nerve supply; those of root and plexus lesions following the peripheral or root distribution of the sensory nerves. Emotional crises may be present in the hysterical and organic cases. Surgical procedures are important in traumatic cases. Now and then much can be accomplished by dissection of the plexus from the inflammatory tissues in which it has been embedded, but usually such an operation is of little permanent result. When pain is intense and persistent, it is desirable to have a unilateral laminectomy performed and the sensory roots cut. The good accomplished in such cases is not always immediate, as memorial pain may remain for some time, but usually the result will eventually be good. Conditions in the shoulder-joint should always be carefully attended to, as the pain present may be due in part to local conditions which can be relieved by opening and treating the parts within it. Even in cases in which paralysis and atrophy are permanent, it is usually best not to resort to amputation, as often, even after this operation, painful neural responses remain.

DISCUSSION

DR. C. H. FRAZIER, Philadelphia. We have two groups of cases: those in which we do operation and find the plexus embedded in a mass of cicatricial tissue, and in which, after the removal of the cicatricial mass and careful, well-planned nerve anastomosis, the results of the operation are very unsatisfactory; and a second group in which at the operation no gross macroscopic lesion is demonstrable even though patients may have been subjected to the same character of injury. The operation of laminectomy for relief of traumatic neuritis, brachial neuralgia, the tabetic crises, and excessive pain for inoperable tumor of the cord, should be resorted to much more frequently than it is. It is not nearly so formidable an operation now as in the past.

DR. T. TURNER THOMAS, Philadelphia: The extravasation of blood around the nerve due to injury produces a condition which probably explains a good many of the so-called traumatic conditions in which the plexus itself is supposed to be injured.

DR. E. E. MAYER, Pittsburg: In my opinion, the first practical question in reference to paralysis of the brachial plexus is the question of operative procedure or not, and my opinion is practically that expressed by Dr. Frazier.

(To be continued)

MICHIGAN STATE MEDICAL SOCIETY

Forty-Fifth Annual Meeting, held at Bay City, Sept. 28-29, 1910

(Concluded from page 1587)

Stomach Disorders Requiring Surgical Intervention from the Viewpoint of an Internist

DR. C. D. AARON, Detroit: The simplest operation on the stomach is gastrostomy. It is indicated in impermeable strictures of the esophagus, for the removal of foreign bodies situated so low down in the esophagus as to make their removal from above impossible, and for the removal of foreign bodies in the stomach. In carcinomatous strictures of the esophagus or of the cardia gastrostomy is a thankless operation and should be undertaken only when the stenosed part is impassable for fluids. A simple, uncomplicated gastric ulcer does not demand surgical intervention. Only in the event of complications and of the ulcer defying thorough internal treatment, and impairing nutrition by interference with motility, should there be any question of surgical intervention. So far as surgery is available, no procedure but the removal of the ulcer by excision or gastro-enterostomy is to be considered. One of the most frequent complications of gastric ulcer is hemorrhage. The surgically most important complication of gastric ulcer is benign pyloric stenosis with subsequent dilatation of the stomach. Hypertrophic stenosis of the pylorus has been successfully operated on in very young children. In hour-glass stomach gastro-anastomosis is the procedure to be recommended. The diagnosis of this condition is now easily made by the use of bismuth with the x-ray.

DISCUSSION

DR. C. B. BURR, Flint: The neurotic patient is often submitted to an operation which might have been avoided, in all probability, and the operative furor is by no means confined to the surgeon. The patient has often acquired an appetite for an operation, which, if fed by the physicians, leads to bad consequences. In cases of feeble mobility, deficient innervation, or the direct consequences of depression, there is oftentimes this disposition on the part of both physician and patient to adopt surgical measures for the relief of what seems to be symptoms that demand that sort of interference.

DR. H. M. RICH, Detroit: There are two kinds of congenital pyloric stenosis in small children, one of which is a true hypertrophy, while the other is a spastic condition. It is always important that a diagnosis be made as early as possible, because in the treatment of hypertrophied stenosis an operation seems to be the only thing that will cure those patients, and it has been very successful when undertaken early.

DR. B. A. SHEPARD, Plainwell: In a case of gastric ulcer, when we figure out the condition of the patient, he is in an anemic condition, and yet without hemorrhage. Ulcer is a result in such cases more than it is a cause, and yet we often look to the ulcer as the cause of the condition. In conditions of that kind a surgical procedure will aggravate it. Instead of following surgical means we should push nutrition. We cannot always do it by feeding everything, but by a rational course of nutrition the patient can be brought up above the standard where we can supply the "antipepsin," if that is what we want to call it.

DR. WILLIAM E. BLODGETT, Detroit: In regard to the relation of posture to gastric dilatation and the retention of food, and morbid decomposition and absorption, Dr. Patterson, of Ann Arbor, reports the case of a woman physician who had had chronic arthritis for a number of years, and on whom he operated for a chronic condition which had no relation to the joint stiffness. There were no considerable adhesions of the joints, but it was a remarkable condition to find a patient who had previously been stiff-kneed, generally limber and without pain. In a few days the condition returned. A number of cases have been reported. I think we might suppose that care of the stomach may improve some joint conditions when the origin is not the tonsils, or any other definite and discoverable source.

DR. C. W. HITCHCOCK, Detroit: Frequently mental states may have an influence on the digestive functions. Unnatural attacks of depression and persistent attacks of excitement will produce in themselves the most profound alterations in the digestive functions, and these sometimes the surgeon will overlook. I have had patients complain more acutely of the digestive derangement than of the mental state, when it has been proved that it was the mental depression itself which produced the profound alterations of the digestive functions to which the patient's attention was chiefly attracted.

DR. J. E. DAVIS, Detroit: The point should be emphasized that it is in the class of functional diseases that the greatest care should be exercised in referring patients for surgical treatment. Probably 70 per cent. of stomach diseases are functional in character, and these would not be helped by surgical treatment. We should take the firm position that when we have a distinctly functional case, it should not be referred for surgical treatment.

DR. J. FLINTERMAN, Detroit: I remember the case of a man of 63 who had all the symptoms of stenosis caused by carcinoma. The stomach was dilated, but a peculiar feature was that the man had erratic chills, followed by a very high temperature, and by symptoms of mental excitement; in the attacks he became unmanageable, and could not be kept in bed, but as soon as the temperature dropped these symptoms stopped. Careful examination showed that the man was subject to endocarditis, and for some reasons an operation was declined, although the patient insisted on it. He had not had any chill for several weeks. The heart did not make

any serious trouble, and finally operation was decided on. Stenosis of the pylorus was found. Immediately after the operation the man had serious chills again, and died under acute symptoms of pulmonary edema. Necropsy showed that the patient had endocarditis. On one of the mitral valves was a distinct polypus, but the condition was not due to a malignant tumor; it was found to be of a benign nature. In this case operation was out of place, but the wishes of the patient were carried out.

The Future of Psychotherapy

DR. T. KLINGMAN, Ann Arbor: The contentions of many physicians that psychotherapy is unscientific and unworthy of the interests of a natural philosopher were until recently, perhaps, not without foundation, but since the works of Freud and Jung have placed this method of treatment on a sound scientific basis, we must regard this verdict as unjust and erroneous. We no longer limit the application to our usual consolation to our patients through which we place them in a state of credulous expectation, nor do we regard the treatment of psychoneuroses by suggestion a scientific procedure, as we know that the suggestion technic does not concern itself with the origin and significance of the morbid symptom, but suppresses it and prevents the pathogenic idea from manifestation. Suggestion increases the resistance which we must overcome before we are able to bring the malady to a favorable termination. It cannot therefore be regarded as either sound medicine or sound psychology. I have long since rejected hypnosis and find a more satisfactory means in gaining access to the subconscious through the analysis of dreams in the application of the psychoanalytic method of treatment which is the method which has placed psychotherapy on a sound scientific basis, and has opened a wide field for a new line of research.

Differential Diagnosis of Organic and Functional Diseases of the Stomach

DR. J. E. DAVIS, Detroit: The chief graphic signs should be as well known as their names. Functional signs will be most frequently used in eliminating the less important. The patient's history should be carefully obtained; data should be critically compared, and indecision should hark one back to the original history.

DISCUSSION

DR. B. A. SHEPARD, Plainwell: I think that we often find people who are afflicted with gastric disturbances of nervous origin, among those who are doing intellectual work, especially school children, and those who follow the higher intellectual pursuits.

DR. J. T. WATKINS, Detroit: Functional diseases of the stomach are being gradually lessened in number. In the last two years a great many obscure diseases of the stomach have been cleared up by the finding of gall-stones or chronic appendicitis, or perhaps a chronic cholecystitis, and in those cases it hardly seems to me that we can attribute the stomach symptoms to the nervous system.

DR. J. G. MANWARING, Flint: The statement has been made, and not approved, that the hypersecretion of hydrochloric acid is evidence of ulcer. I think with a little moderation that is true. Recurring attacks are practically due to ulcer. A malignant development of ulcer on the duodenum is a great rarity. The development of a malignant condition in ulcer of the stomach is not so rare. One can thoroughly diagnose ulcer of the duodenum, and assure the patient that the probabilities are that he will never have cancer there. We cannot so assure him if it is in front of the pylorus.

Inoculations of Bacterial Vaccines in Rheumatic Arthritis

DR. G. A. PETERSON, Mount Clemens: So far as treatment is concerned, the cases may be divided into three groups. Patients in the first received the salicylate treatment and mineral baths; those in the second received mineral baths only; those in the third received inoculations of bacterial vaccines and mineral baths. One hundred and sixty-two rheumatic patients were treated with bacterial vaccines from June

1, 1906, to Oct. 1, 1909. On March 1, 1910, the records show recurrences in 54 patients; during the same period 48 patients were treated with salicylates and mineral baths, 26 of whom had recurrences.

DISCUSSION

DR. ANDREW P. BIDDLE, Detroit: From personal experience as a patient, I desire to express my positive conviction that the vast majority of rheumatic conditions are septic in character. The majority of the patients who go to the so-called resorts are not treated in a scientific manner. Very little distinction is made in many instances between a case truly rheumatic, and one due to some other condition. I believe that most so-called rheumatic conditions are due to bacterial infection.

Symposium on Obstetric Anesthesia

DR. W. H. MORLEY, Detroit, discussed scopolamin and morphin.

DR. J. B. WHITNEY, Grand Rapids, described the technic of anesthesia in obstetrics.

DR. JOHN BELL, Detroit, spoke of anesthesia in its relation to post-partum hemorrhage.

DR. N. N. WOOD, Ann Arbor, discussed chloroform and ether, stating that chloroform is not the ideal anesthetic for obstetrical use. He pointed out its disadvantages, and said that it was not so free from danger as was commonly believed or as the text-books usually stated. The element of danger was distinctly increased when chloroform anesthesia was used for obstetric operations. Ether might be used as a routine anesthetic in obstetric work. He described the method of administration as practiced at the University Hospital Maternity, and the results obtained.

DISCUSSION

DR. R. R. SMITH, Grand Rapids: I do not think the use of morphin-scopolamin in obstetrics will ever be very popular. I have used it as an adjunct in between 400 and 500 surgical cases and am fairly well acquainted with its action. It is rather uncertain, and tends to reduce the strength of the pains, modify the natural course of the labor, and would require perhaps more constant attention on the part of the obstetrician than is often practical to give in the average case.

DR. C. E. BOYS, Kalamazoo: I desire to emphasize the point of decomposition of chloroform when used in the presence of an open light. In one instance during a high forceps operation I almost collapsed because of the accumulation of gas in the room. I have in mind also another instance in which three physicians and two nurses were in attendance on an operation, when three out of the five were overcome and had to retire to another room, thus leaving the patient in charge of only two. This constitutes one of the objections to chloroform.

DR. J. H. CARSTENS, Detroit: Having been an obstetrician myself once, and having used chloroform thousands of times in obstetrics, I must say I cannot feel that there is any particular danger in its use. I have never had any trouble with it. When operating on a pregnant woman I never hesitate to use chloroform. As to the danger of postpartum hemorrhage, I have been in the habit of giving a hypodermic injection of ergot or a good dose of it before giving the chloroform, and then when nearly finished I would stop the chloroform, so that by the time the forceps were applied and the child delivered or version performed the patient would be almost out from under the influence of the anesthetic, after which I would watch the uterus well to see that thorough contraction took place.

DR. REUBEN PETERSON, Ann Arbor: My opinion has always been similar to that expressed by Dr. Carstens. Perhaps it is imagination that has led me to believe that some peculiar reason exists whereby the obstetric patient does not run the same risk or danger in the taking of chloroform as do other patients. Still I cannot but feel that possibly our observations have been a little incomplete, and certain recent reports have shown that there is considerable danger in the administration of chloroform to the pregnant woman. In the Univer-

sity Hospital we try to teach a method that can be readily employed by the practitioner, and we have not taken up the use of scopolamin. A little nitrous-oxid gas has been used, but we have confined ourselves to the administration of ether almost entirely for the purpose of teaching the student to use one anesthetic.

DR. H. W. YATES, Detroit: With Dr. Carstens and others we must agree that in the case of a normal patient, one who needs the anesthetic for but a short time, chloroform is the easiest means of anesthesia and fairly safe.

DR. JAMES P. LETTS, Romeo: Chloroform should not be indiscriminately used in obstetrics. As country physicians we find times when it is impossible to use anything except chloroform because we are alone, and the only help we have is that of a servant or neighbor. Under these circumstances I have found that chloroform is about the only anesthetic we have.

DR. E. T. ABRAMS, Dollar Bay: In my own practice I do not believe I have ever used ether in an obstetric case. The great danger from the use of chloroform comes from its indiscriminate and careless use. There is no question but that anesthesia is a predisposing factor to post-partum hemorrhage in any case and in all cases.

DR. STEVENS, Detroit: I have never seen any danger from the use of chloroform in obstetrics.

DR. H. W. LONGYEAR, Detroit: I have never been afraid to give chloroform in obstetric cases. In surgical work I rarely use it—never unless anesthesia by gas and ether is contraindicated.

DR. B. R. SCHENCK, Detroit: In a normal case, I believe chloroform is the proper anesthetic to use, providing one can give it at the beginning of pains and take it away so that it is not continuous. If one has an operative case in which the patient must be completely under the influence of the anesthetic and relaxed, I think ether should be employed. In giving a mixed anesthetic, such as morphin and scopolamin, the danger is that before the advent of anesthesia the patient does not show the line of resistance she would show previous to the administration of ether. A skilled anesthetist is necessary.

DR. B. A. SHEPARD, Plainwell: In pregnancy, the kidney is doing an unusual amount of functioning which tends to raise the blood pressure, and labor also tends to raise blood pressure. Ether, if it has any effect, also tends to raise blood pressure. Hence we have in the administration of ether in these cases an agent which will make a bad matter worse, in that we are liable to have excessively high blood pressure at the time of labor. Chloroform, on the other hand, is a drug which lowers blood pressure, and by giving it in labor we offset that tendency.

Pelvic Infections, Based on the Study of One Hundred Consecutive Operations

DR. B. R. SCHENCK, Detroit: I criticize the method employed by most text-book writers in considering this subject, in that so much stress is laid on the different pathologic lesions that the student loses sight of the subject in its broader aspects, and the physician attempts to diagnosticate and treat a particular lesion rather than attempt to aid Nature to take care of an infection. The subject is the most important one in gynecology, because the commonest, and the most difficult because of the low average of the patients requires the utmost conservation of organs. The average age of my patients, 100 in number, was 29; 40 patients were under 25 years. The proportion of lesions in the 100 cases was: adherent appendages in 31; pyosalpinx and ovarian abscess, 36; pelvic abscess, 14; salpingitis, 8; hydrosalpinx, 5; pelvic peritonitis with localized effusion, 6, and associated appendicitis in 12 cases. It is more important to recognize the type of the infection than the exact pathologic condition. Of gonorrhoeal infection there were 43 cases; of puerperal infection 21, and of tuberculosis, 14. Tuberculosis is more frequent than is generally supposed. Many cases are missed unless the specimen is examined microscopically. There are no hard and fast rules of treatment. In general, except for the evacuation of the abscess vaginally, gonorrhoeal infection should be treated without operation. When chronic, with acute exacerbations,

hysterectomy should be done, although conservative work is often justifiable. Streptococcus infection should be treated by the opsonic method. Great caution is required in doing abdominal operations, even in chronic cases. In one of my patients culture showed streptococci two years after infection. From 60 to 70 per cent. of the cases of peritoneal tuberculosis in women show primary foci in the tubes. A radical operation should be done. The operations done in these 100 cases were: hysterectomy, 37; conservative abdominal operation, 41; vaginal puncture, 17; incision and drainage above Poupert's ligament, 5. There were two deaths, both cases being instances of streptococcus infection.

Value of Vaginal Incision in Acute Pelvic Infections

DR. REUBEN PETERSON, Ann Arbor: It is inadvisable to operate from above in acute pelvic infections because, first, such septic patients do not stand prolonged abdominal operations well; second, contamination of the peritoneal cavity by the contents of pus tubes will result in death from peritonitis in a certain percentage of cases on account of mixed infection being present. A better plan is to open through the vagina and establish good drainage. Later, when pulse and temperature are normal, if the patient still has pelvic symptoms, a laparotomy can be safely performed, and all or part of the internal genitalia removed.

Discussion on Pelvic Infections

DR. J. H. CARSTENS, Detroit: We recognize two distinct pathologic conditions in the pelvis: the one is infection of the uterus going up into the tubes, producing an inflammation of the pelvic peritoneum with pus in the tubes, surrounding the tubes, and in the adhesions. Another kind of pelvic inflammation involves the pelvic cellular tissue, and has nothing whatever to do with the peritoneum except that the inflammation extends from within the loose cellular tissue to the peritoneum, when we have there a kind of peritonitis which will cause adhesions. When we open up an abdomen like that we find that the tubes are intact, the pelvis is free from pus, there is nothing the matter with the uterus and tubes, but the infection has traveled by the lymph channels through a tear in the uterus or the vagina and has involved the lymphatics and the cellular tissue of the pelvis. These conditions are generally of puerperal origin. In these cases the pelvis should be opened and drained. We can operate in the chronic cases by abdominal section, but in the acute cases drainage should be instituted.

DR. T. A. MCGRAW, Detroit: The extension of gonorrhoea into the tubes may be prevented by vigorous and correct treatment of the acute condition. Acute pelvic infections in many cases follow urethritis or acute gonorrhoeal infection of the gland of Bartholin or its duct. Those patients do not come to us in the primary stage. In a great many cases the physician himself unwittingly and carelessly assists in the extension of the infection from the gland of Bartholin, or from the lower urinary tract to the tubes by unwarranted manipulations. If physicians would understand that the cervix or vagina is not affected, but simply the lower part of the generative tract, and keep out of the upper part, I think that in a great many cases extension might be prevented. There are generally two or three abscesses present; therefore, when we open up that is not enough, for we can find that there are other abscesses by good bimanual examination, palpating with one finger in the opening and the other in the abdomen. A drainage tube is better than gauze. I always use it and never have trouble. We must not use too stiff a tube because it might ulcerate the bowel.

DR. R. R. SMITH, Grand Rapids: In treatment of tubal infections, a great many different factors must be considered, and among them the duration, the nature, and the extent of the lesion. The younger the woman the more reason there is for conservatism; and the older the woman the more reason for radicalism. There are no minor arguments. We must consider all factors and resort to a variety of procedures in handling of these cases.

DR. H. W. YATES, Detroit: In the acute stages of gonorrhoeal infection operation should almost always be deferred,

If it is necessary to do anything at this time it should be simply drainage. Cases of acute puerperal origin are of a different type. The late Dr. Pryor called attention to the good results which he obtained from making a wide opening in the posterior cul-de-sac and the free use of gauze. To him we owe much in the treatment of acute cases of puerperal fever.

DR. F. W. ROBBINS, Detroit: In the treatment of conditions of the uterus we should ask ourselves: What would I advise if this patient were my mother or sister?

DR. L. W. TOLES, Lansing: In spite of the best drainage, many of these patients will need care in the future, and they should be warned of that possibility and told that they may avail themselves of the chance of a permanent cure in the future.

DR. A. S. WHELOCK, Goodrich: In many cases that seem just as severe as any that we have drained and thought necessary to drain, operation being refused, the destruction has proved not so serious as we had believed it to be. Many of these patients have gone on to perfect recovery and subsequent pregnancy, and in after years absolutely no trace of former trouble could be found.

DR. R. J. HUTCHINSON, Grand Rapids: Every surgeon seems to have trouble with the openings closing before the diseased tissues in the pelvis have become repaired. The transverse incision is the correct one to make, but in making that incision and taking measures to prevent its closing we must bear in mind that the healthy vaginal mucous membrane and tissues immediately underneath it are the ones that close over and keep in the septic material. By making a T-shaped incision, getting the finger in the cavity and making one incision at right angles to the other, we prevent the two edges coming together. It is almost impossible for the center of that incision to heal before drainage is established.

Immediate vs. Deferred Operation for Hemorrhage Due to Tubal Pregnancy

DR. H. H. HEWITT, Detroit: In about 95 per cent. of cases there is little difference whether the operation is immediate or deferred. In the remaining 5 per cent., or in patients in profound shock from hemorrhage, there is opportunity for argument as to the time for operation.

DISCUSSION

DR. R. R. SMITH, Grand Rapids: The question really restricts itself to the patients who present marked shock at the time they are seen. All other cases are acknowledged to be operable surgical cases, and should be so treated.

DR. J. BELL, Detroit: It must not be forgotten that in waiting, or not operating, which some men advocate, there is always the possibility of pus being in the pelvis, a lot of blood is poured out there, and there is liable to be sepsis which will develop into abscesses or possibly peritonitis. I favor operating always and never trusting to Nature to repair the condition.

Local Anesthesia for Radical Cure of Inguinal and Femoral Herniæ

DR. J. A. MACMILLAN, Detroit: The surgical anatomy of these regions favors the successful employment of local anesthesia. Nerve blocking is not applicable in operation for femoral hernia. There are advantages in local over general anesthesia for these operations; but modifications of the operative technique are required.

DISCUSSION

DR. J. REYCROFT, Potoskey: People are afraid and unwilling to be operated on under a local anesthetic, and physicians would be unwilling to operate if they were compelled to do so under local anesthesia.

DR. L. J. HIRSCHMAN, Detroit: It is much easier for the surgeon to put a patient under a general anesthetic, but it is not easier for the patient. Many patients have been operated on for so-called trivial troubles under local anesthesia where we would often have deaths from postoperative pro-

cedures. There has been a demand for local anesthesia so that we can still further reduce the mortality of surgical operations.

DR. W. H. BELKNAP, Greenville: I think that in certain cases local anesthesia has a decided advantage. A woman of 34 on whom I operated for a strangulated hernia was not in condition to take a general anesthetic. I used a 0.5 per cent. solution of adrenalin by skin infiltration, did a radical operation, and she had practically no pain. Anesthesia was complete, and healing was perfect.

The Radiograph as an Aid in Diagnosis of Suppurations in the Mastoid and Accessory Sinuses

DR. E. J. BERNSTEIN, Kalamazoo: The careful clinician is being convinced that many hitherto obscure ailments owe their origin to diseases of the accessory sinuses of the nose, and that often serious trouble may exist there without demonstrable pus in the nose. The radiograph gives a graphic picture not only of the presence or absence of pus, but also of the kind, whether diploic, cellular or pneumatic, and the size of the mastoid. This enables the surgeon to avoid wounding structures.

DISCUSSION

DR. A. W. CRANE, Kalamazoo: It is only by the skiagraphy of the great number of cases, and many of them not in acute stages, that such a diagnosis or anything like a working knowledge of plates can be obtained.

MEDICAL ASSOCIATION OF THE SOUTHWEST

Fifth Annual Meeting, held at Wichita, Kan., Oct. 11-12, 1910

(Concluded from page 1588)

Officers Elected

The following officers were elected: president, Dr. Middleton L. Perry, Parsons, Kan.; vice-presidents, Drs. J. M. Griffin, Sulphur Springs, Kan., William H. Stauffer, St. Louis, and Wilmer L. Allison, Fort Worth, Texas; and secretary-treasurer, Dr. Fred H. Clark, El Reno, Okla. (reelected).

Resolutions were adopted endorsing the use of antiseptics in the preservation of food products, and favoring the establishment of a national department of public health.

The next meeting is to be held in Oklahoma City.

Treatment of Patients Desperately Ill in Consequence of Accident

DR. CHARLES E. BOWERS, Wichita, Kan.: Many of these patients seem to be beyond hope; others recover notwithstanding shock, hemorrhage, or infection, which may be present. In such cases it becomes necessary to do what we can to save lives that are thus jeopardized, and prompt and efficient intervention is demanded. In treating shock the first therapeutic agent indicated is something that will raise the body temperature, and the best heat is dry or moist. Perhaps a hot bath will do most. The second thing to do is to lower the head in order to improve the circulation of the brain, which has much to do with shock; with better brain circulation the patient will soon recover from shock. The third thing to do is to re-establish the normal specific gravity of the blood, and that can be done by saline solutions subcutaneously or by the rectum, or by the transfusion of blood.

DISCUSSION

DR. HOWARD HILL, Kansas City, Mo.: The various manifestations of lowered blood-pressure, such as anemia, can best be met by the use of normal saline solution; the application of heat externally, and the internal administration of salines constitute practically all that has to be done. Morphine is beneficial in many cases of shock. It cuts off the afferent impulses.

DR. JOHN PUNTON, Kansas City, Mo.: From whatever the shock may come, to whatever the injury may be due, the prognosis is always as important as the treatment itself. Shock spends its force on the vital organs, hence we have a disturb-

ance of the pulse, the temperature and respiration. I have found that shock is attended with more or less loss of consciousness, and the question of prognosis in the presence of loss of consciousness is often a very perplexing one to the surgeon as well as to the internist. There is no surgical rule that enables the surgeon to tell positively whether the prognosis is favorable or not, but I have found that a good rule to adopt in such cases is not to lengthen the time the loss of consciousness is present. The generally accepted view is that the longer the duration of the loss of consciousness the less chance there is for recovery. As a general rule that is true, but it is subject to so many exceptions that it is worth while for us to remember that in the presence of shock, and in the presence of loss of consciousness due thereto, the respiratory center plays a more important rôle in the prognosis than does the temperature or the increased pulse when there is a question as to prognosis; therefore, it is wise to remember that the increased respiration is a very much more unfavorable sign than either the raised temperature or the accelerated pulse, and if the surgeons will adopt that rule, they will give a favorable prognosis when they might otherwise be led in the loss of consciousness to give an unfavorable one.

DR. GEORGE A. BOYLE, Enid, Okla.: I think the personal element enters into every case of shock. There are individual characteristics. Phlegmatic persons will stand more injury with greater shock and recover than others who are highly organized, nervous individuals. After twenty-five years' experience I am unable to determine just what the prognosis in a given case of shock is going to be.

DR. D. A. MYERS, Lawton, Okla.: In cases of infection in which the pulse and temperature are divergent, by giving a bad prognosis one will be on the safe side. But as soon as the pulse and temperature begin to harmonize, it is safe to encourage the patient. The outlook is more favorable.

Postoperative Thrombosis

DR. ST. CLOUD COOPER, Fort Smith, Ark., read a paper in which he reported a case of postoperative thrombosis complicated with neuritis.

DISCUSSION

DR. J. D. GRIFFITH, Kansas City, Mo.: I have encountered postoperative thrombosis of the lower extremities in six cases. Two such cases I have had within the last two or three weeks, and in five of these cases the thrombosis has occurred on the left side, and one on the right side.

DR. EDWARD H. OCHSNER, Chicago: So far as I know, no one has been able to throw any light on the cause or causes of postoperative thrombosis, or why it occurs more frequently on the left than on the right side. Thrombosis occurs after simple cases of appendectomy, and it takes place in a larger percentage of cases on the left side than on the right after operations for appendicitis.

DR. J. E. GILCHRIST, Greenville, Tex.: We know very little about the cause or causes of postoperative thrombosis. It not only occurs following simple surgical operations, but sometimes follows fevers and other conditions. I have seen severe thrombosis following typhoid; the patient's limb would be greatly swollen and blistered, the condition being attended with great pain and all the symptoms of surgical thrombosis. The treatment outlined by Dr. Cooper is rational, and in the cases I have had I have employed the same method of treatment.

DR. CHARLES H. CARGILE, Bentonville, Ark.: I recall a case of thrombosis following exploration of the region of the kidney for obstinate pain. The pain was relieved by operation. In this case the thrombosis occurred on the left side.

DR. HOWARD HILL, Kansas City, Mo.: Several years ago, Franklin P. Mall of Johns Hopkins Hospital conducted an investigation on cadavers, in which, in a number of cases, he found a constriction ring in the common iliac vein before it joins with its fellow of the opposite side. This constriction ring leads to slowing of the current in the vein in the region below. If these observations could be confirmed by some other anatomist, it would be a clue to the reason why thrombosis occurs on the left side. I do not know the reason

DR. ST. C. COOPER, Fort Smith, Ark.: I do not think the blisters I spoke of were caused by poor circulation; they were probably due to some trophic disturbance such as we have in Raynaud's disease.

President's Address: Fatigue

DR. G. H. MOODY, San Antonio, Tex.: Fatigue is relative in degree and follows prolonged and excessive activity. The degree of fatigue which may follow a given amount of activity or strain will depend on the nervous integrity and the healthfulness of the individual. Also, the amount of fatigue which an individual may be able to overcome promptly by rest and sleep is likewise dependent on the recuperative capacity of the individual, and on his opportunity and inclination for adequate rest and recuperation. The more normal and robust the individual, the more easily, naturally and irresistibly will sleep and rest follow and continue until the fatigue is fully overcome. On the other hand, the more delicate or neuropathic the individual, either from bad heredity, disease, or prolonged strain, or other cause, the less will be the capacity for rest and pleasurable repose, and the fatigue of each day's activities may not be fully restored from day to day, and there will result, finally, a chronic irritability and restlessness which renders impossible adequate recuperation voluntarily. This tends to produce a condition simulating brilliancy, in which greater efforts are encouraged in the young, until there ensues an acute breakdown or chronic exhaustion. The forms in which these results of prolonged fatigue and exhaustion generally appear are indigestion, malnutrition, the various fatigue neuroses, known as the occupation neuroses, insomnia, neurasthenia, psychasthenia, hysteria, the acute insanities, in which the strain of the climacteric plays a part, and dementia and paranoia, which are generally misfortunes of the developmental period of life. There also occur drug and alcohol addictions, the majority of which are developed as the result of a conscientious effort to bear the burdens of life by means of stimulating, anesthetizing, or narcotizing overfatigued feelings, in order to make life bearable for awhile, with the hope that a change in conditions may perchance finally come.

Locomotor ataxia and pareses may occur when continued strain and fatigue play an important part together, generally with a syphilitic diathesis and a neuropathic constitution. In fact, while the best authorities maintain that there is a specific constitutional basis in these cases, they seem never to develop without the long-continued fatigue and the neuropathic constitution in which adequate rest is difficult through life. Formerly, patients with tabes or paresis degenerated rapidly, and dementia and death came early. In the light of recent investigations, it is found that the decline could be brought to a standstill in most of these cases, and that the tabetics, especially, should be able to have a comfortable and fairly useful life, not shortened materially by reason of the disease, and that the paretics should become able to live at home comfortably for many years, their degree of comfort depending on the time and the course of the disease when the diagnosis is made and proper treatment instituted. It is hoped that in these parasymphilitic conditions the "606" of Ehrlich will prove of great value. Much is being done by proper administration of mercury and arsenic preparations, preferably hypodermically in both instances, the arsenical preparation found efficacious being sodium cacodylate. These patients should not be given the iodids. They degenerate the patient rapidly and do no good. From whatever standpoint these cases are considered, the important elements of fatigue must be kept always in mind.

In such purely physical disorders as gastro-enteroptosis, and other conditions of similar origin, we more readily take into account the general condition of fatigue and the diminished general muscular tonicity of the patient, and reckon with it in whatever other medical or surgical procedure thought to be indicated.

It is to be hoped that in time there will be a universal attempt on the part of the public to make a scientific estimate of the individual capacities and limitations of each child. With this estimate correctly made or even approximately so,

individuals will pass through the educational and developmental stages of life into maturity without so much uncertainty concerning their future.

Oration on Surgery: The Prevention and Treatment of Septic Infections of the Extremities

DR. EDWARD H. OCHSNER, Chicago: The severer wounds that naturally come to the physician from the very first we must divide into two classes: the more superficial wounds, that are likely to be infected with ordinary pyogenic microorganisms only, and those which are likely to be infected with the tetanus bacillus in addition. In the latter the same method of disinfection is used as in the former, but in addition I always give a prophylactic dose of antitetanus serum, and, if the wound is deep or likely to contain foreign material, I lay it wide open, remove the foreign material and leave the wound gaping and to heal by granulation subsequently. All fresh wounds are treated in the following manner when they first come in: If the laceration is extensive, the patient is given a general anesthetic; if less severe, the extremity is immersed in a 2 per cent. phenol solution in tepid water for from 5 to 10 minutes. This is an excellent local anesthetic, and makes it possible to scrub the parts without causing undue pain. The extremity is cleansed thoroughly with soap and sterile water by the aid of a brush or pieces of sterile gauze; then washed off with ether, scrubbed well with turpentine, swabbed with tincture of iodine, rinsed with alcohol, and finally a sterile dressing is put on. If in spite of these precautions, or because of their neglect, septic infection does develop, by instituting and rigidly adhering to a definite rational plan of treatment we can secure healing with practically no mortality, rarely, if ever, lose a member, and usually without permanent impairment of function. A patient with septic infection with pyrexia, be it ever so slight, should be kept in bed with the extremity elevated in a comfortable relaxed position. This last point is of considerable importance. If the muscles are not relaxed they make pressure on the lymphatics and veins and hinder return circulation, and the tenseness of the muscles tires the patient unnecessarily and reduces his resistance. The two factors which lower resistance almost more than any other two are pain and fatigue, and by observing the rules here laid down these can be reduced to the minimum. By the proper combination and judicious application of phenol, boric acid, alcohol, and tincture of iodine, one can practically always destroy the bacteria or decrease their virulence. Ninety-five per cent. phenol is a powerful germicide, and can be safely applied with a cotton swab over the reddened, inflamed area, until it turns white; the phenol is then quickly washed off with strong alcohol. Inflamed skin will tolerate an amount of 95 per cent. phenol that would destroy normal healthy skin. After this preliminary application, the extremity is encased in a large hygroscopic elastic wet dressing. For wet dressing I use a saturated solution of boric acid in water, to which from 1/6 to 1/2 of 95 per cent. alcohol is added. Saturated solution of boric acid is, in my opinion, the best non-toxic antiseptic we have, and alcohol is a powerful dehydrant, and in addition keeps the part warm and comfortable, preventing that cold, clammy feeling which a wet dressing is so apt to cause. In the majority of cases, the veins and lymphatics can be drained by simply elevating the affected extremity, and this can be done so effectually that incision rarely becomes necessary. This drainage by elevation is assisted by the dehydrating power of the alcohol.

In conclusion, permit me briefly to recapitulate: Insist on absolute rest and proper elevation of the affected extremity, with the patient recumbent in bed if there is the slightest pyrexia. Do not incise until there is unmistakable evidence of pus, and do not remove the lymph glands unless they are necrotic and suppurating. If incision becomes necessary, it should be within the line of demarcation and, if possible, distal to it and to an Esmarch constrictor. The incision should be swabbed with tincture of iodine, the constrictor being released so as to close the cut veins and lymphatics. The inflamed part should be manipulated, kneaded and squeezed as little as possible. General hygiene and elimination must be attended to. If very red and inflamed, the skin may be

painted with 95 per cent. phenol until it turns white, when it is washed off with strong alcohol, and a copious wet dressing applied, consisting of from one to five parts of saturated solution of boric acid and one part of 96 per cent. alcohol.

If these directions are carefully followed, healing can be secured in a relatively short time, with almost no morbidity and practically no mortality.

Colitis

DR. W. H. STAUFFER, St. Louis: Errors of digestion as a cause of colitis have been much exaggerated, though as causes of gastritis and enteritis they easily take first rank. In most cases of colitis the important factors are how, when and where we eat rather than what we eat. Syphilis, tuberculosis and impairment of the nervous system are responsible for at least 50 per cent. of all the cases that have come under my observation. Most children, and not a few adults, respond to the call of Nature only when compelled to do so, with the inevitable result that what in health is a not unpleasant duty is soon transformed into a painful pathologic process. The most valuable diagnostic aid is the proper use of the sigmoidoscope, an instrument which has not been sufficiently used by the general practitioner. Dr. Hanes of Louisville has suggested the inverted position in examining and treating patients with colitis. The treatment of colitis until recently has been very unsatisfactory. Tuberculous ulceration may be primary and entirely local, and as such will respond to local antiseptics and nourishing food. So-called membranous colitis is generally organized retained mucus, and may be treated effectively by rest and drainage. When possible, direct application to the diseased part should be made through the sigmoidoscope, or a Wall's bougie placed in position under direct observation. Jacobi, Tuttle and Soper have demonstrated the impossibility of passing a rectal tube into the colon unless there is some abnormality of the sigmoid. The medication depends on the pathology, and every indication must be met as it arises. Ichthyol and argyrol in various percentages are of signal service. Oil of eucalyptus or thyme in olive oil has given me excellent results. Appendicostomy or cecostomy should always be employed in amebic dysentery. Experience has shown that there should be no haste in closing the fistulas.

DISCUSSION

DR. L. P. WARREN, Wichita, Kan.: It is the consensus of opinion among expert proctologists that it is practically impossible to pass a tube into the descending colon. The sigmoid itself and rectum may be inspected, but it is not possible to pass the proctoscope far enough to see into the descending colon.

DR. S. N. MAYBERRY, Enid, Okla.: The general practitioner is not always able to interpret correctly what he sees. What is the clinical appearance of early tuberculosis of the anus before the patient complains of any symptoms to speak of? After introducing the sigmoidoscope, I am unable to tell in some cases whether there is a tuberculous condition or not. I have had two cases of rectal disease in which I could not make a satisfactory diagnosis.

DR. W. H. STAUFFER, St. Louis: It is not possible to pass a tube in all cases into the colon, but it can be done in 50 per cent. It takes great care and a great deal of cooperation on part of the patient. It cannot always be done the first time, any more than the practitioner can pass a stomach tube the first time he tries to do so.

As to the clinical appearance of disease about the anus, the best comparison we can make of ulceration or of the various pathologic conditions in this region is that they resemble conditions of the throat. In 50 per cent. of the cases, if one should find a syphilitic ulcer in the rectum, he could probably find a similar condition in the patient's throat. Edges and everything would compare with the one seen in the rectum.

Pyloric Obstruction Due to Extrinsic Causes

DR. G. A. BEENLE, Kansas City, Mo.: One patient, very fat, and slightly jaundiced, with temperature of 102 F., complained of cutting pains throughout the right hypochondrium and

epigastrium extending through to the back or right side, opposite the lower thoracic vertebra. The tongue was coated, and there were nausea and vomiting. The stomach was distended. No peristaltic wave could be elicited by massage. Extension upward and backward of the left arm caused an increase of pain, and tenderness was diffused over the epigastrium. A diagnosis of gall-stones complicated with adhesions involving the stomach was made, and operation advised. Incision revealed a mass at the site of the gall-bladder which proved to be a reflected portion of omentum containing a hard caseous mass of tubercular deposit, wedged down on the gall-bladder, and adherent in every direction. Careful exsection revealed the pyloric half of the stomach drawn down and firmly anchored. There was a slight amount of fluid in the cavity, and a few scattered tubercles could be felt on the peritoneum. The gall-bladder, although slightly dilated and full, appeared normal and was not opened. This patient recovered with complete freedom from the previous symptoms, and was in good health six months after operation. In this case, had a stomach analysis been made, the findings no doubt would have strongly indicated obstruction with dilatation and motor insufficiency, but decision as to the actual cause could be made positive only through incision.

Diagnosis and Treatment of Psoriasis

DR. W. FRICK, Kansas City, Mo.: There are no specifics in the treatment of this disease. Patients must be studied as well as the disease, and cannot all be treated successfully in the same manner or with the same drug. Many patients with psoriasis appear to be perfectly healthy in every other way. In these cases we will find sometimes deficient elimination, imperfect assimilation, or some other imperfection in metabolic processes of which the patients are not aware. When these defects are discovered and corrected the patients are treated with better results. Of recent years it is remarkable to see the rapid improvement under a few treatments with the *x*-ray. This improvement is not permanent, however, and must necessarily be supplemented by other methods of treatment. External treatment is resorted to in nearly all cases, and relief is obtained more quickly by this means than by internal treatment. Various drugs are used in treating this disease; the essential thing to do for patients is to cure the existing disease and teach them how to avoid the causes, if possible, or how to check a beginning attack.

2. **General Paresis.**—The bacteriologic studies on which this preliminary report is based were carried out in twenty-nine cases, which included general paresis of the insane, and other forms of insanity as controls, in which the authors secured a growth of their organism in nine. The description of the organism isolated is as follows: A short bacillus, from 2 to 3 microns in length, from 0.3 to 0.5 microns in thickness, arranged singly and in pairs (end to end) and in groups; sporiferous; Gram positive; actively motile. Bouillon: turbid; no pellicle. Gelatin stab: growth follows the puncture, whitish in color; and no liquefaction of medium; no gas production. Agar slant: growth moist, grayish white, filmlike, abundant in from 48 to 72 hours. Potato: no visible growth up to 10 days. Litmus milk: turned acid in 3 days, followed by coagulation in from 5 to 7 days. Blood serum: filmlike, and whitish in color; no liquefaction. Microscopic agglutination tests, using 1 to 20 and 1 to 40 dilution, were positive in general paresis and negative in a few controls, using blood for the latter tests from apparently normal individuals and from cases of dementia praecox. As to identification of this organism, comparative studies fail to show any organism that has the same cultural peculiarities.

4. **Paratyphoid Fever.**—This paper is based on six cases of paratyphoid fever occurring in the author's practice. Five of these occurred within a week, and apprehension as to an impending epidemic was excited, but no more developed. The mode of transmission was never discovered, neither was the focus of origin located. Some of the patients used ice, others did not; the homes were widely separated; the milk supply was not common; the drinking water was found to be free from all contamination; and the failure of further development of the disease excluded the water as the source of disease. It is Paul's opinion that many cases of this disease are diagnosed and treated as typhoid.

6. **Hexamethylenamin in Meningitis.**—In this case, clearly one of meningococcus meningitis, hexamethylenamin was prescribed, 10 grains on the evening of November 18, and 15 grains four times daily afterward. Two days later the test for hexamethylenamin in the cerebrospinal fluid was positive. The cells in the fluid were diminished from 18,360 before hexamethylenamin was administered to 3,030 to each c.mm.; meningococci were present in smears and cultures before, absent after. November 29, there having been no disturbance from hexamethylenamin, it was increased to 20 grains, four times daily (80 grains daily). The patient's condition was growing worse, and he died December 8.

Necropsy: Purulent cerebrospinal meningitis with Gram-negative intracellular and extracellular diplococci in the exudate; purulent sphenoid sinusitis and purulent otitis media of the right ear with Gram-negative diplococci; catarrhal inflammation of the left ear and antrum; early bronchopneumonia; calcified tubercles in lung; fibrous pleuritis.

The apparent effect of the drug on the organisms of the spinal fluid, the comparatively long duration of an apparently very acute infection treated with hexamethylenamin, together with its demonstrated presence in the spinal fluid in strengths of from 1 in 50,000 to 1 in 200,000, Brem believes, indicate that the drug might be useful as an adjunct in the treatment of meningitis cases or as a substitute for Flexner's serum in meningococcus meningitis should the serum not be obtainable.

9. **Doses for Infants.**—Fried's formula is as follows: "Make the age in months numerator, and 150 denominator of the fraction." Thus, for a baby 2 months old, 2/150; 3 months, 3/150; 4 months, 4/150, etc. This simplifies the computation. The resultant fraction will be very near or the same as when arrived at by Young's rule. For those who for some reason or other would prefer to retain the classic rule of Young, Fried has somewhat modified or rather added to the rule, which will facilitate considerably the computation of doses for children below one year. Young's rule as modified now reads as follows: For children below 12 years and above 1 year, add 12 to the age and divide the age by the number

thus obtained. For infants below 1 year, add 144 to the year in months and divide the age in months by the number thus obtained: Thus, for a baby 8 months old, $\frac{8}{8+144} = \frac{8}{152}$ of adult dose; for a baby 1 month old, $\frac{1}{1+144} = \frac{1}{145}$ of adult dose.

23. **Analysis of Wound Infection.**—The series of 1,000 cases reported on by Graves comprises 574 laparotomies, of which 235 were combined with plastic vaginal operations; 376 uncombined plastic operations, 55 breast operations and 11 miscellaneous. In the list of laparotomies are included inguinal hernias and operations on kidneys. Cases of chronic pelvic inflammatory disease are included as clean cases if the patients were not running a high temperature at the time of the operation. Some of these having sterile pus in the pelvis were temporarily drained through the vagina. Radical operations for cancer of the cervix uteri are also included as clean cases, although operation was done in the presence of an ulcerated surface. Complete lacerations of the perineum are also regarded as clean cases, although the field of operation is exposed to the mucous membrane of the rectum. Out of the 1,000 operative cases, 51 patients had some form of wound infection which in all but one case was of a mild form, the organism being a staphylococcus in all instances. Twenty-eight of these infected cases were laparotomy wounds in which the infection consisted mostly (19 cases) of slight sepsis of a buried catgut knot, the wound closing immediately after extraction of the knot. The other 9 laparotomy wounds were septic to a greater or less extent throughout the wound. Of these 9 cases of general sepsis in the laparotomy wound, 7 occurred in extensive abdominal hernia wounds and 2 occurred in inguinal hernia wounds. In other words, all the cases of general sepsis in the list of laparotomies occurred in hernia wounds. Nine of the breast wounds were more or less septic, the sepsis of 2 of them, however, being confined to a small area where the angle of a too tightly drawn plastic flap necrosed. Ten of the perineum wounds had stitch abscesses, though none was completely septic. Three of these cases were operations for complete lacerations; 4 were cases of very large thin-walled rectoceles. Of the trachelorrhaphies, one wound failed to unite; of the anterior colporrhaphies, one went septic; of the miscellaneous cases, a plastic on the urethra and an operation on the cervix for antelexion failed to unite by first intention. The total mortality from all causes in the 1,000 cases was 3. One patient died from shock following a radical operation for cancer of the cervix. The second patient with a pre-existing heart lesion died of cerebral embolism following an operation for chronic

appendicitis. The third patient was operated on for an enormous postoperative ventral hernia. The lower end of the wound became septic. Five weeks after the operation and after the wound had healed, the patient died of sudden acute endocarditis, which was probably in some way the result of the wound sepsis. This case is, therefore, recorded as one of death from sepsis.

29 and 31. Abstracted in THE JOURNAL, July 9, 1910, pp. 155, 156.

30. **Autopsychology of the Manic-Depressive.**—Reid says that although insight is generally given as one of the diagnostic features of manic-depressive insanity, a careful study of the question would indicate that it is not as constant as is generally supposed. The following figures are based on a series of 100 cases of manic-depressive insanity treated in the Government Hospital for the Insane during the past two years. These patients have been discharged recovered, or have recovered and remain in the hospital, owing to their short periods of lucidity: Insight complete, 39 per cent.; insight partial, 33 per cent.; insight lacking, 28 per cent. The majority of these are cases in which there was no doubt as to the diagnosis, inasmuch as they have had one, and in some cases many previous attacks. In compiling the above figures it was noted that all those cases manifesting complete insight into their condition were persons of average or superior intelligence, and that there were no colored persons in this group. Of the 28 individuals completely lacking in insight, 6 were colored and 22 were white. Only 5 of the 28 were persons of education. Reid is, therefore, led to believe that insight is, to a large extent, dependent on the intelligence of the individual. The records of this hospital fail to show that insight is ever complete in the colored race.

38. **One Thousand Cases of Obstetrics.**—Of the whole number of cases included in Moore's list there have been 16 deaths, a mortality of 1.6 per cent. The causes of death have been: Sepsis 7, eclampsia 5, tuberculosis (last stage) 2, pneumonia 1, typhoid 1. In the last 450 cases there has been but one death from septic infection. There were 12 cases of eclampsia; 4 cases of placenta prævia, all marginal except one, in which the os was entirely covered. Hematoma occurred once. In this instance the tumor of the vulva was as large as a fetal head. It occurred postpartum and did not, therefore, interfere with delivery. Rupture of the lower uterine segment occurred twice, in both instances extending above the

vaginal junction. Prolapse of the funis occurred 5 times with the loss of 2 children. Moore had 3 cases of fibroma interfering with delivery. In 1 case a low attached pedunculated tumor was detached and brought away before the advancing head in the grasp of the forceps. In the other 2 cases the tumors were intramural and so obstructed the passage as to render delivery difficult. This was accomplished, however, without further interference than the use of forceps.

In Moore's series there have been 4 cases of twins. There have been 17 still-born children from the following causes: prolapsed funis, 2; trauma from difficult deliveries, including 1 craniotomy, 5; breech deliveries with retained head, 2; children of eclamptic women, 2; placenta prævia, 2; causes unknown, 4. The sexes were divided very evenly, 517 girls and 483 boys. A somewhat remarkable fact in connection with these cases is that fully 50 per cent. of the mothers have been primiparæ. When it is considered that not 20 per cent. of women in the childbearing period are recent brides, what, asks Moore, is the inference in a record like this? Simply, American women who are at all engaged in the perpetuation of the race have one child and quit.

49. **Heart Muscle in Typhoid.**—In a study of forty-three hearts from patients dying of typhoid, Hamman was able to find some changes in practically all, although in most the lesions were not extensive enough to allow one to assume with certainty that the efficiency of the heart muscle was compromised. In at least six of the cases both the fiber and interstitial lesions were so intense that he could hardly associate their presence with complete efficiency of the organ. He does not find any evidence of widespread change in the smaller branches of the coronary arteries, but frequently periarteritis and endarteritis in the large and medium-sized branches. No doubt these lesions must interfere in some degree with the nutrition of the heart and are of importance both for the immediate efficiency of the organ and its future integrity.

There are certain symptoms during the course of an acute infectious disease which point directly to the presence of some cardiac lesion and often to cardiac insufficiency, notably irregularities of rhythm, and the physical signs of beginning dilatation. Certain sudden deaths can be satisfactorily explained only on the assumption of abrupt cardiac failure. It is during convalescence particularly that the symptoms of a damaged myocardium stand out most clearly. Such symptoms are not nearly so common after typhoid as after other infections, notably diphtheria, but they occur frequently enough to indicate the significance of the damage the heart has sustained. Undoubtedly these lesions of the myocardium and of the arteries are of the greatest importance for the future health of the individual. Typhoid has not in this regard the same importance as rheumatism, syphilis, or diphtheria, but on account of its prevalence is a factor seriously to be reckoned with. The prevention of infectious diseases will proba-

bly prove one of the strongest prophylactic measures against the degenerative lesions of the circulatory system.

51. **Pharmacology of Ergot.**—The important facts brought out by Wood and Hofer are to the effect that ergot is a stimulant to all the unstriated muscle tissue of the body. As a part of this general action there is a stimulant effect on the arterial muscles and probably also on the heart. The action on the blood-vessels occurs after destruction of the vasomotor center and, therefore, must be the result of an effect on some portion of the peripheral vasomotor mechanism. The degree of elevation of blood-pressure affords an accurate criterion of the activity of ergot and is, in their opinion, the most available method for the biologic assay of the drug. The active principle of ergot is an alkaloidal substance which occurs in the drug probably in chemical union with a resinous body. For the combination they suggest the retention of the name suggested by Jacobi—sphaecelotoxin—and for the alkaloidal substance the term applied by Kraft—hydro-ergotinin. The percentage of sphaecelotoxin varies accurately with the physiologic activity of different specimens of ergot. The percentage of sphaecelotoxin in a fluid extract may easily be estimated by precipitating with water and extracting with benzol. A fluid extract of ergot exposed to the air deteriorates extremely rapidly. The deterioration of fluid extract of ergot may be much retarded by protecting it against contact with the air, but under the most favorable conditions there is a loss of strength approximating 10 per cent. a month.

52. **Utilization of Milk-Fat.**—This paper furnishes a comparison of the results obtained from three observations made on an atrophic infant in which the absorption of fat was determined. Each observation lasted for 3 days, during which time the fat in the food and feces was determined. For 12 days immediately preceding the first observation the infant was fed exclusively on human milk and the first observation succeeded this preliminary period without interruption. There was an interval of 4 days between the first and second observations and an interval of 3 days between the second and third observations. During the first observation the infant was given 840 c.c. of breast-milk daily. During the second observation he was given 840 c.c. daily of a mixture of cow's milk containing approximately 3 per cent. of fat, 6 per cent. of milk-sugar and 1 per cent. of protein. During the third observation the infant was given 840 c.c. daily of a mixture of cow's milk prepared with rennet, in which the percentages of fat, sugar and protein were approximately the same as during the second observation. In the interval between the first and second observations the infant was fed on breast-milk. In the interval between the second and third observations he was given the same preparation of cow's milk treated with rennet that he received during the third observation. Carmin was given at the beginning and end of each observation.

The dried feces from the breast-milk period contained 33.4 per cent of fat; from the cow's-milk period 54.4 per cent. and from the second cow's-milk period 52.75 per cent. The difference between the breast and cow's-milk periods is offset to a great extent when the total percentage of excreted fat is estimated. Assuming that the fat in the feces represents fat that has been ingested, then 10.6 per cent of the ingested fat was excreted in the feces during the breast-milk period against 11.5 per cent. during each of the cow's-milk periods. Wentworth has little doubt that the absorption of fat during the breast-milk period was disturbed by the excessive quantity of fat ingested the first day, and that these percentages do not afford an accurate basis for comparison of the three periods. During the breast-milk period the infant ingested 11 gm. and absorbed 10.35 gm. more fat than during either of the cow's-milk periods. In other words, he absorbed 16 per cent. more fat during the breast-milk period than during either of the cow's-milk periods.

54. **Constriction of the Splanchnic Arteries.**—Sudden occlusions of the superior mesenteric artery in dogs results in hemorrhagic infarction of the intestines. Permanent constriction of the superior mesenteric artery and celiac axis, as well as gradual occlusion of one or both of these vessels, may be present in dogs for at least 5 months, without

giving rise to a definite and constant elevation of blood-pressure or to hypertrophy of the heart. At necropsy, no definite association can be found in man between sclerosis of the abdominal aorta and great splanchnic vessels and cardiac hypertrophy.

55. **Quantitative Index to Tuberculin Dosage.**—The authors maintain that it is just as possible to obtain a constitutional reaction from tuberculin placed on the skin as from tuberculin introduced beneath the skin. Tuberculin reactions, whether local, focal or constitutional, must be looked on as varying grades of the same response of the body to a varying quantity of tuberculin used. In the body in which tuberculosis has developed, the degree of the reaction of the surface cells to the poison contained in the different tuberculins depends on (a) depth of scarification; (b) point of application; (c) distribution of lymphatics; (d) readiness of absorption; (e) exact amount of tuberculin used. At times the serum of individual patients contains a substance which is capable of producing a cutaneous tuberculin reaction in individuals who are very susceptible to tuberculin. The interval of dosage varies for the result desired, less than 7 days for tolerance, and 14 or more for retention of the reaction power of the cells. In the majority of patients, if the interval of doses be 2 weeks or more, the amount of local reaction from the same dose of tuberculin does not change in a period of many months. It is possible by determining the minimal cutaneous reaction to 0.01 c.c. of varying solutions of tuberculin, to state the exact amount of tuberculin which will produce a certain grade of reaction when introduced beneath the skin.

64. **Digestibility of Bleached Flour.**—The experiments of Rockwood tend to show that the gluten of bleached flour, both cooked and uncooked, digests somewhat more readily than that of unbleached flour. Bread made with yeast from bleached flour did not differ in digestibility from that made from unbleached flour. The nitrite reacting material largely or altogether disappears before the bread is removed from the oven. Boiled starch prepared from bleached and unbleached flour forms, by the action of pancreatin, reducing sugar at equal speeds. Tested with iodine there is no difference in the rapidity of starch digestion, either by pancreatin or by the salivary ferment. Diastase gives the same results.

77. Abstracted in THE JOURNAL, May 21, 1910, p. 1714.

78. **Postoperative Neuroses of Pelvic Origin.**—Crouse advises that we should be extremely careful to weigh the nerve features of our patients, together with the pathologic state of the female genitalia, before promising prompt relief after operations. A gynecologic examination is not complete without a careful examination of the sacral plexus, which is best located through the rectum. A sensitive state of this plexus, or other intrapelvic nerves, prohibits a promise that the irritating symptoms will promptly disappear after operation—the symptoms which frequently induce a woman to submit to the trying ordeal of a severe operation. Time, tonics, eliminatives, rest, and an assurance of ultimate success on the part of the surgeon, are the remedies needed.

79. **Twisted Pedicles.**—A series of interesting cases is reported by Ward. Briefly, they are as follows: Case 1. Acute torsion of an enormous hydrosalpinx of the right side simulating acute appendicitis, complicated by a 4 months' pregnancy; operation; recovery. Case 2. Twisted pedicle of a left hydrosalpinx; acute strangulation, followed by diffuse peritonitis; operation; recovery. Case 3. Twisted pedicle of a dermoid cyst of the right side with recurrent attacks of partial strangulation and peritonitis. Diagnosed as appendicitis by several physicians. The case was complicated by a dermoid of the left ovary; operation; recovery. Case 4. Parovarian cyst with twisted pedicle firmly bound down to uterus and accompanied by a peritonitis and persistent hemorrhage; operation; recovery. Case 5. Left parovarian cyst with a number of attacks of partial strangulation; no peritonitis; operation; recovery. Case 6. Left parovarian cyst with twisted pedicle; very severe dysmenorrhea; no adhesions; operation; recovery.

Ward says that the lesions most closely simulating acute torsion of a pelvic tumor, be it hydrosalpinx, parovarian or ovarian, are: acute appendicitis, ruptured tubal pregnancy, intestinal perforation, and acute intestinal obstruction. In all these lesions, the onset is inaugurated by localized sharp acute pain, accompanied by symptoms of shock, followed by those of peritonitis. In a case of twisted pedicle, the pain of the acute strangulation persists, to a greater degree, is more acute, agonizing, paroxysmal and cramp-like than the pain of a diffuse peritonitis unaccompanied by a strangulation. In ruptured tubal pregnancy or intestinal perforation, shock and collapse are more acute and profound. In intestinal perforation there is the history of the ulcer, and in the ruptured tubal pregnancy the menstrual history and the pelvic signs. In acute intestinal obstruction there is the inability to secure a bowel movement or the passage of gas. In all these lesions the treatment must be the same if the patient's life is to be saved, i. e., prompt surgical interference. In acute strangulation, the earlier the operation is undertaken, the less severe is the peritonitis with its accompanying adhe-

sions, the simpler is the operation, and the milder is the post-operative reaction.

84. Suspending the Uterus by Round Ligaments.—The operation referred to by Branch is done as follows: A small median abdominal or Pfannenstiel incision is made exposing the pelvic organs. A silk traction suture is passed through each round ligament about 3 cm. from the uterus. A purse-string suture of catgut is placed on each side beginning in the parietal peritoneum near the internal abdominal ring, including the portion of round ligament extending from the internal abdominal ring to the silk traction suture previously taken. This suture is tied later and closes up an open space through which a loop of bowel has been known to enter and became strangulated. A sharp Halsted clamp is pushed through the rectus muscle, its posterior fascia, and peritoneum, grasping the traction suture, and by drawing it the round ligament is brought out and readily sutured to the under surface of the outer portion of the fascia of the rectus. Fine silk is generally used for this purpose, care being taken not to stragulate the ligaments by too sharp a kink. The ligaments are usually not crossed over to the opposite side, but sutured to the fascia on its own side. The catgut purse-string sutures previously placed are now tied and the incision closed in layers throughout.

Branch emphasizes the importance first, of the purse-string catgut suture, and second, of the suturing of the round ligaments to the under surface of the rectus sheath, thus shutting off the peritoneal cavity from the exterior by strong fascial layers. In some cases the vaginal outlet was relaxed and perineorrhaphy was also done. Of the patients who came to be relieved of retroflexion, a large majority were nulliparous white women; 66 per cent. of these are cured absolutely of their symptoms; 75 per cent. of subsequent pregnancies have been normal; 10 per cent. of the women suffer recurrence of symptoms after labor. The operation described is only fairly satisfactory, in that it falls short of fulfilling the requirements imposed on it.

95. Studies on Infant Mortality.—The death-rate among Filipinos (47.65 per cent.) in Manila, as shown by McLaughlin and Andrews, is excessive compared with that of other nationalities: Spaniards, 12.05 per cent.; Americans, 13.27 per cent.; other Occidentals, 14.32 per cent.; Chinese, 16.64 per cent. This enormous death-rate is due to the high mortality of children. Of 9,307 deaths among the Filipino population, 6,041 or 64.9 per cent. were of children under the age of 5, and 4,542, or 48.8 per cent. were of infants under 1 year of age. According to the United States census of the year 1900, the deaths of children under 1 year constitute 18.28 per cent. of the total mortality; in France, from 1896 to 1900, the

infant mortality constituted 20 per cent. of the total, but in Manila the deaths of infants under 1 year aggregate 48.8 per cent. of the total number.

Beriberi is the largest factor in the infant mortality of Manila. The deaths of breast-fed children constitute 73.74 per cent. of the total infant mortality; furthermore, 87 per cent. of infants dying of beriberi and convulsions in Manila are breast-fed. The average Filipino mothers are in poor physical condition, many of them are beriberic and subsist on a diet favorable to beriberi. It seems that there is an intimate relation between beriberi of infants and a mother's milk poor in quality and lacking certain necessary elements which are not included in the mother's dietary. At first glance it might seem advisable to supplant breast feeding by artificial, but under existing conditions this would be a blunder. The children saved from beriberi would be sacrificed to enteric diseases. That small part of the population which is artificially fed furnishes 65 per cent. of the deaths from enteric diseases, and the breast-fed, much the larger part of the population, furnishes but 35 per cent. of the infant mortality from this cause; so that even in Manila, breast-feeding of infants exerts a deterrent influence on the mortality from gastrointestinal diseases. A possible solution of the problem lies in improving the quality of the mother's milk and encouraging the continuance of the custom of breast-feeding so general among the Filipino poor.

101. Tropical Bronchomycosis.—Castellani says that a type of bronchomycosis in which oidium-like and saccharomyces-like fungi are found is not rare in Ceylon. The condition might be called broncho-oidiomycosis, or more briefly broncho-oidiosis. Two types of the condition may be clinically distinguished, a mild and a severe one, the latter closely resembles phthisis. The mild type is apparently amenable to treatment with potassium iodid.

The strains of oidia found in Castellani's cases are different from the ordinary *Oidium albicans* and *Oidium lactis*, as they do not affect milk. All the strains found by Castellani are identical in all respects, except that some produce gas in galactose and others do not. For the oidium which produces gas in galactose he proposes the name *Oidium tropicale*; for the saccharomyces he suggests the name *Saccharomyces krusci*. The diagnosis of broncho-oidiosis can be made only by bacteriologic methods. It is differentiated from phthisis by the absence of tubercle bacilli and the negative animal inoculation; from bronchial spirochetosis by the absence of spirochetes; and from endemic hemoptysis by the absence of the ova of the trematode. Care should be taken before making the diagnosis of bronchomycosis that the sputum is collected in sterile vessels and examined as soon as possible, because sputum left exposed to the air frequently becomes contaminated in the tropics with various species of non-pathogenic saccharomyces and oidia. Primary bronchomycosis should be also differentiated from those cases of chronic debilitating disease in which *Oidium albicans* spreads from the mouth to the bronchi.

Castellani has recently encountered two cases of a peculiar type of acute, fatal enterocolitis showing intermediate symptoms between dysentery and cholera. Some of the stools were serous and cholera-like; others consisted practically of mucus only. There was no blood. Both patients died within 48 hours. The stools, collected in sterile Petri dishes, were examined for *Vibrio cholerae*, with negative results. On the other hand, 85 per cent. of the colonies which developed on bile-salt agar and ordinary agar were of a peculiar spirillum; the others resembled organisms of the colon group. The cultural characteristics show the spirillum most probably to be a new species, for which Castellani proposes the name of *Spirillum ceylanicum*.

102. An Intestinal Flagellate in Man.—In the stools of patients in Ceylon suffering from ankylostomiasis, Castellani and Chalmers have observed a flagellate which is pear-shaped or rounded, measuring from 8 to 20 microns in diameter, possessing two flagella and an undulating membrane, and being capable of ameboid movements. It is easily cultivated together with bacteria on several media, the best of which is apparently nutrose-agar or nutrose-broth. The developmental

stages and the methods of reproduction have not as yet been studied and therefore the exact zoologic position of the parasite can not be defined. They propose to classify it provisionally under the genus *Bodo* and to name it *Bodo asiaticus*.

104. **Amebic Abscess of the Liver.**—Rogers attributes not a little of the recent improvement in the results of the treatment of liver abscess in the Calcutta hospitals to the adoption of a routine course of ipecacuanha in the after-treatment of liver abscesses, however they may be dealt with.

105. **Intestinal Amebiasis without Diarrhea.**—The purpose of this paper is to show that the prevalence of amebic infection of the colon without diarrhea is of sufficiently frequent occurrence to deserve careful consideration by clinicians and to make evident the necessity of altering our conception of the disease to conform with the acceptance of such observations. In selecting the fifty cases for this report, only those in which the clinical observations were of sufficient accuracy for publication and in which the diagnosis was confirmed by necropsy have been used. Of the fifty patients, eight were foreigners and forty-two natives of the Philippine Islands, forty-seven were males and three females. The causes of death were as follows: From peritonitis following perforation of the appendix, 3—2 of these were produced by amebic ulceration, the other by an unknown cause, not amebic; from liver abscesses, 4—in 1 perforating into the right pleura, 1 into the abdominal cavity, and 2 were without perforation; from acute pericarditis, 1; from pulmonary tuberculosis, 8—and in 3 of these abdominal tuberculosis was also present; from chronic æstivo-autumnal fever, 2; from perforation of amebic ulcers in the large intestines, 5—4 times in the cecum and ascending colon and once in the transverse colon; from acute beriberi, 7; from lobar pneumonia, 20. Characteristic amebic lesions were present at necropsy in all of the fifty cases. These lesions varied in type from those which were just beginning to those showing ulcers having the characteristic extensive destruction of the mucous membrane of the bowel so often seen in cases of amebiasis of long standing. Other parasites, such as monads, trichuris, hookworms and ascaris were present in several of these patients.

106. **Differential Blood Counts.**—By employing the ordinary technic for making a count of the white blood-cells, with the exception that he uses a diluting fluid made by adding five drops of Giemsa's stain to five cubic centimeters of 2 per cent. formalin, Stitt also is able quickly and accurately to make a polymorphonuclear percentage count, or a complete differential count in addition to that of the leukocytes. Another advantage is that blood-parasites are also perfectly stained, are shown distinctly, and by reason of the larger amount of blood visible in each field, the finding of them is far less tedious than where a stained, dry film is used. The usual technic in making the hemocytometer preparation is employed, Türk ruling being used. Stitt counts the leukocytes in the three upper or lower square millimeters, divides by three to obtain an average per square millimeter, multiplies by ten for the content of a cubic millimeter and then by twenty for the dilution (blood to 0.5, diluent to 11). Having counted the leukocytes he again goes over the same portion of the ruled surface and determines the polymorphonuclears and estimates the percentage of these to the total leukocytes. The red cells are practically diaphanous and not disintegrated as they are when acetic acid is used as a diluent; consequently it is easy to distinguish the particulars concerning the size, etc., of a particular red cell containing a malarial parasite.

118. **Blood Transfusion in Hemophilia.**—In the case reported by Goodman, the patient was only 2½ years old. The donor was a young man, aged 19. The transfusion was continued for one hour and a half and was successful, checking all nozing.

119. **Graft of the Vena Cava on the Abdominal Aorta.**—The operation consisted of transplanting between the cut ends of the abdominal aorta a segment of vena cava. Its purpose was to study the details of the technic of the graft of a large vein on the aortic trunk and its remote results. Three experiments were performed on two cats and one dog. The three animals which underwent the transplantation of the vena cava on the abdominal aorta were in normal condition a few hours after the operation and recovered without any complication. The causes, which after several months brought about, directly or indirectly, the death of the animals are completely independent of the operations. Three months, ten months, and fourteen months after the operation the abdominal aorta of the animals and its venous segment were extirpated for the study of the anastomosis and of the venous wall. It was found that the venous wall reacts against the arterial blood-pressure by thickening its wall. The condition of the venous wall and of the anastomoses examined fourteen months after the operation shows that, for a long time, a segment of vena cava can functionate as a part of the abdominal aorta. It is probable that in the treatment of aneurysm, rupture of large arteries, embolus, and localized arteritis, the transplantation of venous segments can be used safely, but it must be emphasized that without a proper technic, the results of the operation will be disastrous.

120. **Treatment of Air Embolism.**—Cats and dogs were used by Blair and McGuigan. The animals were prepared for blood-pressure tracings. A cannula was inserted in the right external jugular close to its innominate junction, for the injection of air and adrenalin and salt solution. A continuous blood pressure measurement was taken during the experiment, and is recorded in millimeters of mercury. A measured volume of air was injected in each case, when the quantity was small, injection was made with an air-tight syringe; when over 10 c.c. it was pressed in by a siphon. They found that injection of air into the heart, no matter how small the quantity, produces a disturbance of the circulation that can be readily

seen in the blood-pressure record; there are fall of pressure, dyspneic symptoms, and restlessness. If the volume of air injected be small, the changes are usually temporary; if large, a sudden fall of pressure to almost the base line occurs, great dyspnea and labored breathing, and a fluttering heart. The respiration always stops before the heart, but the ineffectiveness of the heart-beat is the cause of the respiratory failure. In other words, the practically valveless right heart cannot supply blood to be pumped to the respiratory center and the center fails while the heart continues to beat ineffectively, the blood-pressure being almost zero.

While the heart is in this condition, the injection of adrenalin is effective in restoring the normal pressure in some cases; in others it is worthless; whether or not it is of value seemed to depend largely on the character of the heart-beat at the time the injection was made and the length of time that had elapsed since respiration ceased. Except when air or fluid is rushed into the heart under considerable pressure, the heart-beat does not cease for some time, but becomes less and less strong. When at necropsy, after rushing air and fluid into the heart, no beat was seen, the beat always recurred on opening the heart and removing the internal pressure. In all cases in which at necropsy air was found in quantity in the left heart, adrenalin was ineffective. The action of adrenalin can also be most clearly seen if it is injected with the air, or closely following.

During these experiments the authors observed nothing that would verify the conclusions that the depression accompanying air embolism is due to blocking the pulmonary vessels with air, but the rarity with which traces of air were found on the left side of the heart or were seen in the carotid cannula, even after large quantities of air, 10 c.c. or more, had been rapidly disposed of, leads them to the tentative conclusion that at least a part of the air was either eliminated or absorbed while passing through the pulmonary circulation. Based on the observations made during these experiments, they believe that death from air embolism is clinically a rare occurrence, but should grave depression follow the aspiration of air into a vein, the treatment they propose is the introduction of adrenalin chlorid in a fairly concentrated solution, 1:10,000 to 1:1,000, directly into the right ventricle and that this be accompanied by a small amount of normal saline solution. In their experiments they always used 40 c.c. or more of saline solution, but in most cases a large quantity of air had been put in under pressure and it required a pressure of 60 cm. of water to force the fluid into the vein. They suggested that for clinical application a fine hypodermic needle could be pushed through the chest wall directly into the right heart, which could be done by inserting the needle through the chest wall and lung at the anterior extremity of the third or fourth right intercostal spaces. They observed no evil effects in dogs from perforating the heart wall with a fine needle, but to attempt to do it through the chest wall would be a very uncertain procedure.

126. Function of the Appendix.—Corner claims that: (a) Lymphoid tissue is the characteristic feature of the cecal apex. The vermiform appendix of man is represented in the vertebrate kingdom by a mass of lymphoid tissue, situated most frequently at the cecal apex. (b) As the vertebrate scale is ascended, this lymphoid tissue tends to be collected together into a specially differentiated portion of the intestinal canal, the vermiform appendix. (c) The vermiform appendix of man is not, therefore, solely a vestigial structure, though it undoubtedly represents the terminal part of the cecum. On the contrary, it is a specialized part of the alimentary canal. Nature having made use of a disappearing structure and endowed it with a secondary function by giving it lymphoid tissue to protect the body against the micro-organisms in the ileocecal region. The comparative absence of lymphoid tissue in the rest of the large intestine is inexplicable, as it is in the cecum that the feces have been brought up to the proper consistence to allow of their passage along the colon, and in consequence there are no more prolonged periods of "rest" in the presence of moisture, the feces becoming dryer and harder; consequently there will be less fermentative action.

127. Suturing Hollow Viscera.—Since it has been abundantly proved that perforating stitches are harmful in theory only, Bartlett asks why not carry all gut needles into the lumen and thus be sure to get the firmest sort of a hold. That is what he does.

128. Rectosigmoidal Arterial Anastomosis.—Davis examined twenty-one subjects. The rectosigmoidal loop was present in nineteen cases; superior hemorrhoidal artery bifurcated before junction with loop, seven cases; loop anastomosed with lower division, two cases. The lowest loop was found in one subject with the critical point almost in the bottom of the cul-de-sac of Douglas. In the vast majority of other cases it was found about 1.5 cm. beneath the promontory of the sacrum. Davis suggests, therefore, that following high resection of the rectum, gangrene of the stump can be avoided by ligation of the superior hemorrhoidal artery proximal to the point of entrance of the anastomotic loop from the sigmoidal artery. When high resection of the rectum is to be done by the sacral route, a preliminary abdominal incision is of value to determine the presence and location of the critical point, the relations of the superior hemorrhoidal artery, and permits of a definite placing of ligatures to check hemorrhage. The anastomotic loop is not present in some cases. High resection of the rectum for carcinoma in these cases should be terminated with a permanent colostomy.

131. Wright's Solution for Drainage.—This solution is composed of sodium chlorid 4 per cent. and sodium citrate 1 per cent. in water. Sodium citrate (1 per cent.) in the solution causes a precipitation of calcium salts in the lymph, removing thereby that which is essential to coagulation. The presence, then, of the sodium citrate in the wound cavity ensures a comparatively free exit of the lymph discharge. The sodium chlorid, in hypertonic solution (4 per cent.), by osmosis brings about a flow of lymph through the walls of the cavity, the sodium citrate having dissolved clot and prevented further coagulation. Thus there is brought about a continuous pouring forth of lymph of high antitrophic power from the blood stream and lymph spaces, through the walls of the abscess cavity and out through the wound. The 4 per cent. solution is in itself antiseptic since bacteria will not grow in it. The abscess is opened by a wound as small as will allow the cavity to be wiped out, or thoroughly emptied by expression. The skin round the wound is thoroughly cleaned with 70 per cent. alcohol.

The skin in this region, up to the very mouth of the wound, is smeared with boric acid or eucalyptus vaselin. If the skin tension closes the lips of the wound a bit of rubber dam may be put in. The wound is covered with a voluminous pad of gauze or of absorbent cotton covered with gauze, dripping wet with hot salt and sodium citrate solution. A many-tailed bandage or some other application holds the poultice in position and the part is put at rest. Outside the dressing may be applied a hot flaxseed poultice or a hot-water bottle. In any case, as often as the dressing gets cold more of the hot solution is poured over the whole dressing to wet and warm it again, or the dressing is removed and the whole part is soaked, if possible, or bathed with the same solution. The amount of sodium chlorid in this solution is such that it will irritate the skin and lead to pustulation in a few days. Hence the frequent application of protective vaselin to the unbroken surrounding skin. This solution is contraindicated if there is a tendency to persistent oozing of blood from the wound. It is also contraindicated when the formation of protective adhesions is desirable, as in certain abdominal wounds just after operation. The solution should be used only for the first 36 to 72 hours after operation, during the acute stage of the inflammation. If used longer it leads to maceration and indolence in healing.

1. **Hereditary Aspects of Nervous Disease.**—Mott feels convinced from his own observation and experience that Gowers is correct when he asserts that there are few diseases in the production of which inheritance has a more marked influence than in epilepsy, and the traceable influence is always far less than that which exists. Moreover, he has observed that a similar heredity occurs in a considerable number of cases of insane epileptics. Mott has endeavored to ascertain the proportion of insane, feeble-minded and epileptic members occurring in the pedigrees of his hospital patients. In thirty-two pedigrees, which would include about 1,000 living representatives and 250 dead individuals, there were eight who had been in asylums, and in eight others fits were chronicled. In no case was either parent of the patient insane or epileptic. Two of the pedigrees furnished most of the cases. One was that of a patient suffering from neurasthenia, in which there were, besides insanity and epilepsy, migraine, hysteria, deaf-mutism, and imbecility. The other was the pedigree of a patient with exophthalmic goiter with several neuropathic members in the stock.

Two years ago Mott undertook to study the convolutional pattern of the brains of relatives dying in the asylums, with a view of seeing whether there is a similarity in the convolutional pattern in the members of the same family, just as there is a similarity of the physiognomy. An inquiry was initiated concerning relatives at the various asylums, and a request was made that brains of relatives should be kept for examination after the necropsies had been made. Isolated instances of two or more members of the same family were known to exist by Mott in the various asylums; but it soon became evident that a properly coordinated card system would reveal the fact that a very large number of parents and offspring and brothers and sisters, besides collateral relatives, were resident in the London County Asylums, or had been recently. In June the numbers had risen from a few hundred known instances to 1,834, made up from 854 families. Of 752 instances of two of a family, making in all 1,504 cases, the vast majority are directly and not collaterally related.

Another fact stands out prominently in an analysis of the 752 instances of two of a family, and that is, the much greater incidence of transmission from parents to offspring through the female side. The mother transmits to the offspring in the proportion of 60.7 per cent., the father 39.3 per cent. This is not accounted for wholly by the fact that there are more females in the asylums insane than males, for the ratio of females to males in the asylums is rather less than 11 to 9. When pairs of offspring of the two sexes are

affected, the proportion of males to females is 43.9 per cent. to 56.1 per cent., a difference of 12.2 per cent. But the percentage in which the mother transmits insanity to the offspring as compared with the father is as 67.7 per cent. to 39.3 per cent., a difference of 28.4 per cent., and this increase of 14.2 per cent. is mainly due to the fact that she transmits to the daughter nearly twice as often as the father does. It may well be asked whether this may not partly be due to the fact that the daughter, at the time of life when insanity is manifested, is more at home than the son, and therefore has more to do with her insane mother. Grandparents' heredity undoubtedly is very much below the proper ratio; it is due to the fact that there is far more difficulty in obtaining records. The hereditary transmission from females, however, markedly preponderates. In collateral insanity there is a more marked preponderance of females affected than males than in direct heredity, but the numbers are too few to draw any very decided conclusions, except the fact that the females with aunt affected are as numerous as all the rest combined. Of an average insane population of approximately 20,000, 717 cases are thus related, representing 342 families.

Mott says that every insane person should be considered as a biologic study. To say, merely, that one of his ancestors was insane, and therefore he has a bad heredity, and to label him thus, as is the common custom, is absurd. What we wish to know is what he was born with, and what has happened to him since birth. Consanguinity does not appear to produce insanity or nervous disease, provided both stocks are free from taint; but if there is insanity or epilepsy (not necessarily in the first ascendants, but even in the collaterals), then intermarriage of first cousins from these two stocks with collateral insanity will tend to insanity or epilepsy in some cases in the offspring of the two sane related parents. Mott has observed in many of these pedigrees, that maniac-depressive insanity in a stock is frequently associated with suicide in the members so affected, and even in others not affected. The tendency to suicide often runs in families, and some remarkable pedigrees have been published in which members of families in successive generations have taken their lives in a particular way, and sometimes even at a particular age; there is a suicidal obsession. Mott would explain this by initiative suggestion acting on a neuropathic stock. The transmission of an acquired character, such as the desire for alcohol, is contrary to the doctrine of heredity. That the desire for alcohol is transmitted from parent to offspring, in the form of like begetting like, instead of like begetting a tendency to like, Mott claims to be without foundation. What may be transmitted, he says, is the temperament that induces alcoholism, namely, a lack of will power and moral sense.

8. **Aneurysm of the Aorta.**—The patient in this case was a man, aged 49, who had previously been in the army for fifteen years. There was no history of previous illnesses, but he had probably had syphilis. On July 30, 1908, he drove into the country, and after returning stabled his horse and ate his supper. About 9 p. m. he felt a sudden feeling of suffocation, as if his throat was swollen. He was admitted that night into the hospital by the house physician, who noted that he was very short of breath, that there was some swelling of the neck, and that a loud systolic murmur was audible over the chest. He complained of no pain, but much distress. The next morning the patient was sitting up in bed with evident dyspnea, the eyeballs were staring; there was extreme cyanosis of the face and ears, and the neck looked thick and swollen; there was some swelling of the right arm and the right side of the chest, and the right hand was cold. The right pupil was larger than the left, the pulses were equal, and the pulse rate 100. On examination of the chest, the apex beat was in the fifth interspace, $\frac{1}{4}$ inch external to the nipple line, and there was visible pulsation over the second, third and fourth right intercostal spaces; over this area there was dulness to percussion, and a systolic thrill could be felt. On auscultation there was a systolic murmur at the apex, and over the pulsating area at the aortic base there was a loud continuous murmur of a whizzing character with marked systolic intensification; the murmur could also be heard behind over the spines of the dorsal vertebrae; the

second sound could be heard feebly. The lungs were emphysematous.

After a few days the more urgent symptoms were relieved, but there was still marked cyanosis of the face, and there was some edema of the right side of the chest and right arm. The superficial veins were becoming visible over the chest, and the external jugular veins, especially the right, were prominent. At first there appeared to be some slight systolic pulsation in this vein, which soon ceased. During the next few weeks the patient's condition gradually improved, so that by September 28 he was able to be up and about, and was discharged from the hospital. The physical signs then showed that the pulsation to the right of the sternum was less marked, and the continuous murmur had much diminished in intensity; the edema was also passing off, but the superficial veins were becoming more visible.

He was readmitted the following November for an attack of bronchitis following a chill, and it was then noted that the cardiac signs were much the same, except that the thrill and murmur had much diminished in intensity, but that the collateral circulation in the veins had visibly increased. These latter consisted of three large channels on each side of the abdomen, passing up from below from the iliac veins, four on the front of the abdomen, and one situated laterally on each side; the lateral veins passed up to the axilla and veins of the arms, the two in front joined the epigastric and intercostal mammary veins on the front of the chest wall; there were also some large channels from the thyroid veins. All these large veins were tortuous, and the current of blood was shown, on exercising pressure, to be traveling from above downward.

The patient left the hospital again and enjoyed fairly good health for the next twelve months; he could walk about with comfort, but was not capable of exertion or active exercise. In November, 1909, he began to be troubled with cough and dyspnea, and was readmitted to the hospital. There was then increasing cyanosis and edema of the right arm, neck and chest, and the lower part of the abdomen was also swollen, but not the legs. The veins were all more distended and loaded, and the intercostal veins were very prominent, but no pulsation could be seen or felt in the external jugulars. The heart was noticed to be markedly displaced downward; the apex beat was in the sixth intercostal space. He complained of pain around the left side of the chest and under the scapula. He became rapidly worse, and signs of hydrothorax supervened. He died on Jan. 13, 1910, having lived only one month on eighteen months from the time the aneurysm ruptured into the vein.

A necropsy was performed. At the upper part of the right side of the thorax there was a mass consisting of the aneurysm, distended superior vena cava, right auricle, lung and pleura, intimately adherent together; the heart was greatly displaced downward and was placed somewhat transversely, so that the upper border of the right auricle was at the level of the fourth interspace. All the external veins were greatly dilated, and the *venæ azygos*, major and minor, were also much dilated. The heart was slightly enlarged. The aorta was dilated and very atheromatous, and from the right and posterior part of the first part of the arch an aneurysm of the size of a Tangerine orange protruded toward the right side, pressing on and partly enveloping the superior vena cava; above, this vein was greatly dilated. The aortic valves were competent. There was a second aneurysmal dilatation at the junction of the second and third parts of the aorta. The other organs were healthy.

17. Meaning of Audible Signs in Mitral Stenosis.—The case reported by Morison exemplifies a common clinical experience, namely, that of the existence of unsuspected valvular

disease. A well-made man, unemployed but employable, is exhausted, and doubtless depressed, by a long and fruitless search for work, takes insufficient food for a fatiguing journey, develops a suppurative tonsillitis, and when apparently convalescent suddenly finds himself overwhelmed by cardiac palpitation. After recovery a short recurrence of tonsillitis with some rise of temperature induces an arrhythmic action, which suddenly blazes into a short and sharp tachycardia, which subsides as suddenly as it arose. Morison maintains that these disturbances of cardiac motion are originated in the nervous, not in the muscular system of the heart, and that they may be induced by any exertion, emotion, enfeeblement, or reflex irritation, which tends, under certain circumstances, by accelerating the action of the heart or otherwise, to cause the muscular factor in this or that part of the organ to escape from the control of the nervous system.

The physical signs on which Morison dwells more particularly are the absence of bruit in the tachycardiac heart; the triple rhythm audible at the apex; the so-called crescendo murmur so characteristic of this lesion in many cases; and the arrhythmia. In the case related there were four phases as regards the audible signs:

1. A period of accelerated regular action, in which the first and second sounds resembled one another in duration and character, a "tic-tac" rhythm, as it has been called, in which no adventitious bruit was audible.

2. A period of slow action, in which there were triple rhythm at the apex and reduplication of the second sound at the base, when bruit was likewise absent, except in so far it was represented by a bruit-like admixture or modification of the last of the sounds at the apex.

3. A period somewhat suddenly inaugurated by the complete presence of a characteristic and loud crescendo murmur at the apex, accentuated first sound, and disappearance of the triple rhythm, while the reduplication of the second sound persisted—the time interval or duration of this reduplication at the base being the same, so far as the ear could determine, as when the triple rhythm with slow rate was present.

4. A period just prior to the relapse of this case into the second tachycardia, when the heart was arrhythmic, moderately accelerated (114), and still presented the presystolic crescendo bruit, which was abolished by the succeeding regular tachycardia, the latter being suddenly followed by triple rhythm, slow rate, and a bruit noted as diastolic; this, again, yielding to the characteristic presystolic crescendo murmur with restored cardiac force, with which the patient left the hospital.

18. Active Lobar Collapse of the Lung.—The cases described by Pasteur prove, he says, as conclusively as clinical evidence can prove, that sudden deflation of large tracts of lung may occur after certain surgical operations with a fairly well-defined train of attendant symptoms and physical signs.

Case 1.—Radical cure of hernia; active collapse of the right lower lobe 24 hours after operation; recovery.

Case 2.—Abscess in the right side of the abdomen following operation for right inguinal hernia; incision and drainage; active collapse of the right lower lobe on the fourth day; recovery.

Case 3.—Left salpingectomy for pyosalpinx; active collapse of the left lower lobe on the third day; recovery.

Case 4.—Cholecystitis; cholecystectomy; massive collapse of the right, middle and lower lobes early on the fourth day; recovery.

Case 5.—Gall-stone colic; cholecystotomy; active collapse of the right lower lobe on the second day, with recurrent attacks of heart failure; recovery.

Pasteur looks on these five cases as clear examples of active lobar collapse from reflex inhibition of the diaphragm, occurring most probably in otherwise fairly healthy lungs, and in the absence of inflammatory lesions of the diaphragmatic pleura or peritoneum, such as are almost invariably found in fatal instances of the condition after surgical operations on the abdomen. As to the cause of active lobar collapse in these cases, Pasteur says the following points are to be noted:

1. The cases of diphtheritic paralysis quoted above prove beyond question that arrest of diaphragmatic movement does cause massive lobar collapse of the lung.

2. The entire series of fatal cases (other than those due to paralysis) have, without exception, this feature in common, namely, the existence of a powerful source of irritation in the neighborhood of the diaphragm within the area supplied by the vagus—that is to say, a condition of things in which reflex inhibition of that muscle might very readily be set up.

3. In four out of five cases the lung affected is on the same side as the operation wound.

4. The disappearance of apex beat and heart sounds from the normal position and their displacement toward the affected side.

5. The sudden overdilatation of the unaffected lung.

6. The almost complete silence over the affected lobe.

In the face of this evidence, Pasteur continues, it is difficult to resist the conclusion that arrest of diaphragmatic movement is the cause of massive lobar collapse in these cases; indeed, it seems almost impossible to account for the facts observed on any other hypothesis.

26. **Problems in Infant Feeding.**—During the past few months Findlay has gathered some information regarding weaning of babies. He quotes statistics relating to 200 cases. Of the mothers, 95.5 per cent. had milk at the beginning; 91.5 per cent. had sufficient milk for the first month; 69.5 per cent. suckled their children for at least six months; and 29 per cent. for twelve months or longer. Of the 58 children weaned before six months, 32 were taken off the breast during the first month; 14 during the second month; 8 during the third month; 3 during the fourth month; 1 during the fifth month. Of those weaned during the first month the causes were: disappearance of milk, 9 cases; abscess of the breast, 4 cases; puerperal fever, 3 cases; menstruation, 1 case; child being sent out to nurse, 3 cases; child not having the strength to suck, 2 cases; mother having rheumatism, 1 case; mother going out to work, 1 case; unknown, 7 cases. Weaning during the second month was occasioned by illness of mother in 2 cases; illness of child in 1 case; child being sent to hospital in 1 case; mother going out to work in 1 case; milk disappearing in 3 cases; milk not being considered good in 1 case; inflamed breasts in 1 case; child refusing to suck in 1 case; causes unknown in 3 cases. In the third month no cause was given in 3 cases; the milk disappeared in 3 cases; in 1 case the medical adviser considered the mother too weak to suckle; and in another case the child did not seem to be thriving. The child being sent to hospital with bronchitis, the mother developing mastitis, and the milk disappearing were the causes of weaning the three children during the fourth month. No cause was given for the case weaned during the fifth month.

The chief point of interest in the above statistics is the large proportion of children weaned during the first month, and it would thus seem, says Findlay, that if a mother can manage to suckle her child for the first month there is great probability that she will be able to continue breast-feeding for at least six months. In only 8 per cent. of all cases was the cause of weaning before six months really due to want of milk.

29. **Double Central Blindness.**—Buchanan's case is interesting, especially in view of the fact that, as a result of a fall on the street and striking the back of his head on the causeway stones, the man lost the power of central vision of both eyes while peripheral vision remained but little altered. Vision of each eye was very markedly reduced, being only 2/60 in the right eye and 1/60 in the left. Perimetric examination revealed the fact that there was but little contraction of the peripheral parts, but that there was a distinct central scotoma, of small size only, in each eye.

55. **Floating Capsule Test of Stomach Functioning.**—Cohn gives the patient a capsule containing 1 gram of bi-muth and in a few minutes it can be seen at the lowest part of the stomach. The test meal is then taken, and another capsule with half a gram of bi-muth is then swallowed. This floats on the surface of the stomach content until it finally lands beside the first capsule. With a test cauliflower meal the capsule sinks through the fluid portion of the stomach content and floats on the more solid stratum, while with a meat test meal there is no such stratification of the stomach content and the capsule floats on the top of the stomach content. He explains this by the stimulation of gastric secretion by the meat; this digests and renders the mass more homogeneous. It is thus possible to detect gastric achylia by this means, having the two capsules swallowed together. If there is no gastric secretion both capsules float side by side on the stomach content until it is all evacuated, while with gastric secretion and consequent digestion, the heavier capsule sinks downward earlier. Cohn was able to see by the moving shadow of the floating capsule the pulsation of the left ventricle in a case of aortic insufficiency. The capsule had been swallowed after a glass of milk. It is even possible in this way to distinguish the single phases of the systole and diastole.

57. **Constitutional Pathologic Tendencies in Children.**—Heim remarks that a bird's-eye view of the history of medicine in the last hundred years shows a periodical prevalence and recurrence of medical conceptions which he explains as a result of a periodical prevalence and recurrence of certain constitutional tendencies. They are not passing fashions thought but the logical outcome of the conditions that confront practitioners in different decades. The vogue of venesection two generations ago is a typical instance of this; people were shorter, stockier, and more plethoric, and venesection then was urgently indicated. Now the predominance of the thin, the nervous and the anemic forbids venesection for the majority of patients although its importance under proper indications is recognized. Not only the conditions of life and hygiene, but also the character of the pathogenic microbes are constantly varying. Children used to thrive on milk, eggs, meat and butter, and some do so still; but, he declares, if we attempt to push such a diet for the children of the present day, fully 70 per cent. will grow thin and pale and lose their appetite. Any attempt to feed such infants with fat, especially the fat of milk, or any overfeeding is liable to be followed by the development of eczema, milk crust, urticaria, prurigo, recurring pharyngitis or coryza, bronchitis, adenoid vegetations, mucous stools, etc. With restriction of the ingestion of fat, the symptoms subside. Finkelstein ascribes this to exudative diathesis to defective metabolism, but it is not necessary to go back of the simple fact that these symptoms are elicited by fat in the diet and tend to subside when the intake of fat is reduced. It is remarkable, Heim continues, that it is the fat of cow's milk which is most injurious; the infants can frequently bear pig fat or cod liver oil much better. He has seen eczema heal under a course of cod liver oil. There is nothing in these children to reveal the tendency to this diathesis until the manifestations develop. In children with the exudative diathesis the reaction to tuberculous infection assumes the familiar picture of scrofula. The larger part of the clinical picture of scrofula is an artificial product, the result of forced feeding with milk, eggs and butter or overfeeding of any kind, and this part of the clinical picture may be eradicated by dieting, while a course of tuberculin may modify for the better the tuberculous element in the syndrome. Scrofula is the exudative diathesis plus tuberculosis. This diathesis modifies likewise the reaction to all other infections. It is an everyday experience that such children take vaccination very hard and that they are particularly susceptible to "children's diseases," especially scarlet fever. This disease is less common than measles as many children seem to be immune to it, and since Czerny's views in regard to the proper diet and treatment of children with the exudative diathesis have been practically applied to the children in Breslau by himself and physicians trained in his service, the number of cases of scarlet fever in the town has fallen off to a remarkable extent. Heim goes still further and asserts that the severer form of scarlet fever, fatal in three or four days, occurs only in children with the exudative diathesis plus a neuropathic constitutional tendency. Malignant scarlet fever is analogous to the "fatal driving-in of eczema" which we now know to be the toxic sepsis of infants with the exudative plus the neuropathic tendency. The latter tendency, he continues, may be recognized by the floating tenth rib and flabby muscles, the general nervousness and unstable temperature. With this tendency alone a change from breast to cow's milk is often beneficial. The change to artificial feeding should generally be reserved for the pure neuropathic constitution. The latter is usually associated with the exudative diathesis, and in this event any fat in the artificial diet will do harm. In these cases the superposed injurious influence of both diatheses is apparent; no change of diet seems to benefit and some intercurrent infection is liable to carry off the infant. The indications in these cases are for exclusive or mixed whey or buttermilk diet. Prurigo is a symptom of the exudative diathesis, he says, but the itching reveals the neuropathic tendency, as also the croup and asthma in the laryngitis and bronchitis due to the exudative diathesis. Further research on prevailing constitutional tendencies viewed from a broad outlook will certainly, Heim

declares, open new horizons for successfully influencing the health of the rising generation.

65. **Influence of Ehrlich's "606" on Inherited Syphilis.**—Herxheimer and Reinke examined post mortem the organs of two infants, about two months old, who had been given "606" two and four days before death, the condition being practically hopeless at the time. No normal spirochetes could be discovered in any of the organs and all the organs were free from them except the lungs; here spirochetes were found but all were agglutinated or degenerated or nearly or quite destroyed. These findings were remarkable in comparison with the large numbers of spirochetes found so constantly in the organs of children with such serious signs of inherited syphilis as these infants presented. The restriction of the spirochetes to the lungs may be due to a possibly longer survival in the presence of oxygen.

69. **Lumbar Puncture.**—In this address delivered at the annual meeting of the Mittelrheinischer Aerzte, Curschmann pleads for the more general adoption of lumbar puncture both for diagnosis and as a curative measure, extolling its value and insisting on its comparative harmlessness. He regards it as far more important for the early diagnosis of tabes or paresis than the Wassermann reaction in the blood serum. Only the cytologic and chemical examination of the cerebrospinal fluid gives decisive findings in these cases, disclosing or excluding these diseases by the local findings. In all forms of meningitis, he declares, lumbar puncture is of the greatest symptomatic and very frequently of direct curative importance, and should be the first thing done in every form of meningitis. Among the cases he cites to illustrate this is one of metastatic suppurative meningitis after erysipelas, a typical instance of a post-traumatic infection of the meninges after a fall on the back of the neck and head. The severe streptococcus meningitis rapidly healed after a single lumbar puncture releasing about 30 c.c. of fluid under a pressure of over 300 mm. He has also witnessed similar benefit in fibrinous-suppurative meningitis following pneumonia or influenza, and also prompt symptomatic relief when convulsions and other symptoms indicated merely increased pressure of the spinal fluid without inflammation. In the tuberculous form the outlook is less promising, but Stark and others have reported recoveries under systematic lumbar puncture, and Curschmann has encountered three cases of tuberculous meningitis in which the disease progressed with long remissions and necropsy revealed old and recent lesions in the meninges. The spontaneous improvement observed in these cases, although transient, suggests the necessity for more active measures in treatment of tuberculous meningitis, especially repeated lumbar puncture. Likewise in hemorrhagic internal pachymeningitis lumbar puncture may cure; this happened in two out of three cases of this variety, the recovery persisting to date, two and three years later, and the other patient was materially improved for several months. Neisser and Pollack have reported cures from puncture of the brain in such cases, but lumbar puncture should be given a trial first. The diagnostic importance and therapeutic efficiency of lumbar puncture for symptoms following trauma of the skull are demonstrated in other cases cited. The headache and vertigo subsided in some cases after the puncture even when the

fluid seemed to be normal, as in the case of one patient not punctured until five weeks after the accident. A traumatic neurosis had seemed inevitable in this case but the patient recovered completely after the puncture. He insists that if lumbar puncture were applied as a routine measure after every accident to the head, the present conception of the purely functional nature of the disturbances observed would often have to be revised. In his seven years' extensive experience with lumbar puncture he has observed only one threatening collapse and that was in an obese patient with syphilitic spastic paralysis who required camphor injections to combat the collapse that followed the puncture. Curschmann punctures with the patient reclining on his side and advises this position, at least for the very impressionable, for arteriosclerosis and patients with weak hearts. He had one tragic mishap; suppurative meningitis developed 4 days after a diagnostic lumbar puncture in a woman of 58 suspected of progressive paresis. The most serious contraindication for lumbar puncture, he continues, is the presence of a tumor or of accumulated blood in the posterior cranial fossa, especially in the cerebellum. But even with a tumor, lumbar puncture may give great relief and ward off choked disc and blindness. Oppenheim and others have reported fatalities from this cause and Curschmann had one similar experience, the lowering of the pressure in the spinal canal causing a small tumor protruding into the fourth ventricle to be sucked against the foramen magnum. It is possible, he adds, that if a sterile fluid had been injected under pressure into the spinal canal when alarming symptoms developed, the counter-pressure might have opened up the foramen again. In a certain proportion of cases, however, the supposed tumor proves to be merely a serous meningitis or hydrocephalus and lumbar puncture is directly curative. In one such case recently the suspicion of a tumor in the cerebellum prevented the proposed lumbar puncture but necropsy revealed nothing to explain the symptoms but internal hydrocephalus; the fluid might possibly have been easily drained away.

- 89 *Sign of Twin Pregnancy. (Neues Zeichen für die Diagnose der Zwillingschwangerschaft.) C. J. Gauss.
- 90 Medicolegal Estimate of Duration of Pregnancy. (Schwangerschaftsdauer vor Gericht.) W. Poten.

89. Sign of Twin Pregnancy.—Gauss calls attention to the frequent oblique anterior parietal presentation of the head of the first twin. The sagittal suture lies oblique and so close to the sacrum that the entire anterior parietal bone can be easily palpated. He describes three typical cases with illustrations; the pressure from the second fetus twists the head, already in the pelvis, of the first twin into an extreme Nägele oblique presentation. He states that there were 58 twin

births in 4,014 deliveries at the Freiburg clinic and he found this sign in 54.5 per cent. of the 11 cases in which the head of the first twin presented. It can scarcely be recognized except by examination through the vagina. It does not occur with every twin vertex presentation as the first head may be twisted around as under normal conditions, but when it is present it may be accepted as a certain sign of twins.

September 27, XXXI, No. 116, pp. 1225-1232

- 91 *Prophylaxis of Echinococcus Disease. P. Barabasci.

91. Prophylaxis against Echinococcus Disease.—Barabasci suggests immunizing dogs against the echinococcus and thus breaking the chain of this pathologic cycle. His experiment gave promising results, the antibodies generated in the females being transmitted to their puppies. He injected the animals for months with fluid from echinococcus cysts and then fed them with large amounts of tapeworm heads. They seemed to tolerate and expel the tapeworms without injury, no parasites being discovered in the animals when they were killed over 2 months later.
